INTRODUCTION

The Antarctic is unique: geographically, politically, and scientifically. It is the most remote, hostile, and naturally dangerous continent, while at the same time it is the most pristine and least developed. Antarctica is the only major part of the Earth's landmass not directly governed by one nation; rather, it exists under the control of a carefully developed, although still evolving, treaty, which has a multitude of acceding nations. It is the only place in the world in which claims of ownership have been set aside. International agreements that ban nuclear testing contain damage to the environment under specific regulations and replace international competition with scientific investigations and organizations link nations in sustained, peaceful joint efforts.

Despite its isolation and harsh environment, the Antarctic is home to, or major feeding grounds for, large populations of wildlife. The largest living animals on the Earth, blue whales, can be found there, as can a wide variety of other whales, seals, and many more species of marine life. Some of the world's largest flying birds—wandering albatrosses with wing spans of 3 m and southern giant petrels—can be found in the region, as can a number of different species of penguins, including the emperor, which can weigh up to 35 kg. At the other end of the size spectrum, the terrestrial Antarctic hosts population densities of tardigrades between ten and one thousand times greater than those of temperate or tropical zones. There are also particularly abundant groups of microorganisms, many considered extremophilic, living under extreme conditions that they not only tolerate, but also need in order to exist.

Another Antarctic visitor, in relatively modern times, has been humans. In the nineteenth century, the Southern Ocean surrounding the Antarctic continent was prized as a source of wealth in the form of whale and seal oil and blubber. Around a century ago, the mainland itself became the focus of geographical exploration and the compilation of scientific data. In more recent decades, particularly since the International Geophysical Year of 1957–1958, the major human emphasis placed on the terrestrial, ice, marine, and atmospheric aspects of the southern polar region has been on scientific investigation and increasing our knowledge of the Earth and beyond. In this way, the Antarctic has been shown to be much closer to the rest of the planet than had earlier been thought, because it is a key component of many global systems, including climate, weather, oceanographic circulation patterns, complex interactions in ecosystems, and the influence of the stratosphere (including the ozone layer) in the reception of solar radiation planetwide.

Intriguingly, for an area of such importance, there is not a single, universally accepted definition for what the Antarctic is, because the region has variously defined boundaries for different purposes. Some consider it to be the continent itself, and there is debate as to whether the floating ice shelves that are seaward extensions of the continental ice sheet form an integral part of the "land" surface of the continent. There is also a question of whether this definition includes the islands immediately adjacent to the continent, many of which are attached to the continent by ice shelves. Along and above the Antarctic Peninsula, the off-lying islands are also sometimes regarded as part of the continent.

A purely geographical definition of Antarctica is the area south of the Antarctic Circle (at 66°33′39″ S), below the latitude at which the sun does not rise on Midwinter Day and does not set on Midsummer Day. A political boundary is the area south of 60° S latitude, the northern limit of jurisdiction for the Antarctic Treaty, which became effective in 1961 with twelve original signatories and now has been acceded to by forty-five countries.

Perhaps the consensus of Antarctic scholars is that the best boundary is the Polar Front (formerly known as the Antarctic Convergence), an irregular belt in the Southern Ocean some 20 miles wide occurring between 48° S and 61° S. This is where the cold, dense waters of the Southern Ocean sink beneath the warmer surface waters of the southern Atlantic, Pacific, and Indian oceans, marking a distinct change in the surface temperature and chemical composition, which in turn affects the creatures living on either side of it. This is both an ecosystem boundary for many marine species and an administrative boundary; it was chosen by the Convention for the Conservation of Antarctic Marine Living Resources for the extent of its jurisdiction. It is also the boundary adopted by the Scientific Committee on Antarctic Research because it is defined by natural features, including the northern limit of the Antarctic Circumpolar Current.

Many, but not all, of the sub-Antarctic islands and island groups are within the Polar Front. Those islands and island groups lying south of the Polar Front, but not forming part of the Antarctic continent, include Bouvetøya, Heard Island, the MacDonald Islands, the Balleny Islands, Scott Island, Peter I Øy, South Georgia, the South Orkney Islands, and the South Sandwich Islands.

All these definitions and aspects of the Antarctic are only small parts of the diverse, multifaceted, and hugely significant area of the world introduced, explained, and covered in detail in the *Encyclopedia of the Antarctic*. The two volumes of this work comprise overviews and in-depth discussions of people, historical events, places, wildlife, scientific research, our place in and use of the environment, technological developments, and geopolitics. They also explain the host of scientific studies for which the Antarctic has become an international center, including geophysics, glaciology, atmosphere and climate, solar-terrestrial physics, astronomy, human impacts, oceanography, terrestrial and marine biology, geology, botany, and sea ice. These volumes are the result of the combined efforts of more than three hundred international scholars and experts in many fields, most of whom have dedicated their lives to the study, understanding, and preservation of the Antarctic.

All of this makes the *Encyclopedia of the Antarctic* a unique resource and tool for a wide readership of students, researchers, scholars, and anyone with a general interest in the region of the Antarctic, sub-Antarctic, and Southern Ocean. It both examines the broad, complex theoretical context and fills in the specific details of the existing knowledge about the Antarctic—its history, life forms, and influence on the rest of the Earth, as well as its place in our scientific understanding of the world.

The goal of this project was to produce a comprehensive, multivolume work that would cover the entire scope of Antarctic knowledge. Of course, even in two volumes this is impossible, but the *Encyclopedia of the Antarctic* is larger, more thorough, and more inclusive than any previous work of its kind. The encyclopedia took shape through the contributions of many people, most importantly an advisory board consisting of internationally distinguished scholars who drew up lists of topics in their fields, determined suitable lengths for the entries, and suggested appropriate authors. This all reflected a degree of subjectivity, of course, which was tempered by the process of the advisors, each helping to refine the subsequent overall list of topics, and by the countless suggestions for improving the content that were received from scholars throughout the world. Several authors who were given assignments believed that other topics were of such importance that they voluntarily wrote and submitted extra entries, which were in turn assessed for their viability as part of the encyclopedia. Input from the advisors, authors, and other scholars around the world continued throughout the development and writing of the encyclopedia, and the list of entries was revised virtually until the volumes went to production, allowing it to provide a reliable, up-to-date view of the current state of scholarship about the Antarctic.

The *Encyclopedia of the Antarctic* comprises 495 free-standing, alphabetically ordered entries of 500 to 6000 words in length. These range from factual, data-driven entries, such as biographies, wildlife details, and statements about national Antarctic programmes, to longer overviews on major themes and analytical discussions of issues that are of significant interest to both scientific researchers and the general public, such as climate change, conservation, geopolitics, biogeography, and pollution.

How to Use This Book

Although each entry is self-contained, the links between the entries can be explored in a variety of ways. The **Thematic List of Entries** in the front matter of each volume groups the entries within broad categories and provides a useful summary. Cross-references **(See also)** given at the end of almost all entries refer the reader to other related topics within the encyclopedia. Each entry also contains a list of **References and Further Reading,** including sources used by the writer as well as additional items that may be of interest to and expand the knowledge of the reader. Seven **Appendices,** including the text of the Antarctic Treaty, and sixteen **Maps** further guide the reader in exploring the features of this vast region. A thorough, analytical **Index** provides a detailed listing of topics that help the reader navigate through the wealth of information provided within the entries.

Acknowledgments

Numerous people contributed to making this encyclopedia possible. I would like to express my thanks to the members of the advisory board, all of whom have extensive knowledge of and experience in the Antarctic, for

their general guidance and advice, their valuable input in their fields of expertise, and their writing and editorial contributions. In particular, the efforts and support of David W. H. Walton and Associate Editor Liz Cruwys have been crucial to the success of this vast project.

It has also been a pleasure to work with the authors of the entries in these volumes, many of whom assisted in a variety of ways above and beyond writing the articles that bear their names. I would particularly like to thank Robert Burton, Peter Clarkson, Ann Savours, Martin Siegert, and Ian R. Stone for such help. I would also like to give special mention to G. E. "Tony" Fogg, John Heap, Malcolm Kirton, and Irynej Skira, all of whom have passed away since contributing very valuable entries to this encyclopedia.

I am enormously grateful to Gillian Lindsey, under whose supervision this project was initiated and a pattern for its ultimate completion was laid out. Without her contributions, this encyclopedia would never have begun. At Routledge, special thanks go to Development Editor Susan Cronin, who kept track of the progress of 311 contributors and oversaw the organisation of all of the materials that compose this work. A team of production assistants, copyeditors, and designers at Taylor and Francis/Routledge also deserve thanks for putting together the final product. I am also most appreciative of input from Mark Nuttall, the editor of the *Encyclopedia of the Arctic*.

I would like to express my gratitude to Julian Dowdeswell, the Director of the Scott Polar Research Institute, where I was employed throughout the assignment and editing stages of the encyclopedia. He gave his unstinting support while these efforts were being carried out. Finally, I would like to thank Liz, my wife, and Ralph and Angelyn, my parents, for their patience, encouragement, and support throughout all of the stages of this enormous project.

A

ADAPTATION AND EVOLUTION

The term *evolution* can be used with different interpretations, dependent on the context. Two broad generalisations are useful to recognise. First, in everyday use across many disciplines and subject areas within and outside science, "evolution" is often used simply to describe processes of change or development. Second, within evolutionary biology, its use is associated with very precise definitions. Here, it is used in the context of the fundamental processes by which biological change occurs, developing from concepts originally proposed in the nineteenth century and made famous by the mechanism of natural selection independently proposed by Charles Darwin and Alfred Russell Wallace. These recognise that the characteristics of living organisms are not simply determined by the environment around them, but also by features passed on or inherited from their parent(s). It is in the latter sense that the concept of evolution will be examined here in the context of Antarctic biology.

It was many years after the lives of Darwin and Wallace before the mechanism of inheritance was discovered, through Crick and Watson's pioneering work on the structure of the nucleic acid DNA (deoxyribonucleic acid). Nucleic acids such as DNA are very long polymer molecules, made up of chains of nucleotide subunits, and these chains provide the genetic code for all the proteins that, ultimately, contribute to all of an organism's activities, from intracellular biochemical processes to their morphology and behaviour, and the interactions that are seen. This code is carried in the form of *genes,* which are specific sequences of nucleotides coding for a particular protein. All living organisms contain their own unique genetic "blueprint," and it is this that is passed on to future generations in the various processes of reproduction that exist. During all forms of reproduction, these chains are copied to give rise to new individual organisms. However, the process is not perfect, and "copying errors" can occur, introducing variation. Furthermore, in sexual reproduction the DNA of the two parents is "mixed," giving rise to new combinations of genes. This results in offspring that differ in (often minute) detail from their parents, and thus have different abilities to function effectively in their environment. Therefore, some are inevitably more successful than others and, importantly, can then contribute relatively more offspring of their own into the next generation. These offspring, or at least some of them, will carry the successful characteristic in their own DNA, providing a new starting point from which the process of change can continue.

The process by which the influence of environmental characteristics on organisms leads to differential success is known as *natural* selection. Over time, the consequence that is seen (of gradual and, occasionally, rapid change) is described as *evolution by natural selection*. The related term *adaptation* is used to describe the features that have progressively developed in response to selection, and allowed some organisms greater success during the evolutionary process, while the term *fitness* is used to describe the relative success of an organism in passing on its genetic material to future generations. It is important to note that, in terms of strict definition, this terminology can be applied only in circumstances where the biological features of concern are controlled in some part through heritable variations in genetic material (*genotypic* variation), and do not apply in circumstances where there is no heritable component and all variation encountered is only in direct response to the environment (purely *phenotypic* variation).

Evolutionary processes ultimately underlie the patterns of diversity that are seen now (and also at any other time in the history of life), as progressive accretion of evolutionary changes may eventually lead to reproductive isolation and speciation. Here, the contrast between Antarctic terrestrial and marine environments provides a striking illustration. On land, diversity is low in all groups of biota, while on the marine continental shelf it is very high. Both these features are driven by the history of Antarctic glaciation over geological and evolutionary time. Even today, terrestrial habitats comprise a small proportion of continental surface area, and are generally individually of limited extent and often very isolated, while the marine continental shelf is extensive. At periods of peak glaciation and ice sheet extent, both would have been drastically impacted. On land this has resulted in considerable extinction, whereby many contemporary habitats were obliterated, and the severe environmental stresses permitted the survival of only a tiny proportion of the preglaciation fauna and flora. By contrast, in the sea, while it is now known that much larger ice shelves extended widely to the point of continental shelf drop-off, patterns of diversity present today indicate that this resulted in extensive fragmentation of marine habitats, rather than outright destruction. This fragmentation provides a classic mechanism that drives the generation of diversity through allopatric speciation—the independent evolution over time of isolated populations of an ancestral line. Although the overall difference between the terrestrial and marine environments is striking, it should be noted that the remnant terrestrial biota, often overlooked as insignificant, does show evidence of analogous radiation processes within the few groups that have persisted.

Few would query the simple statement that Antarctica is an extreme environment, and it is easy to generate physical environmental statistics in support. This leads automatically to the view that Antarctica is stressful. However, it is prudent to avoid anthropomorphism—while conditions are genuinely stressful for humans, they may not be for an organism that has become adapted over evolutionary time to the conditions experienced there. Indeed, such an organism may rapidly experience rising stress levels as conditions move away from those typical of its "extreme" environment towards a state that humans would regard as far more comfortable. Thus Adélie penguins *(Pygoscelis adeliae),* with a circumpolar distribution that is one of the most southerly of all the penguins, show clear indications of heat stress even in the maritime Antarctic at the northern edge of their current range (between the northern Antarctic Peninsula and the South Sandwich Islands). Recent population decreases near the northern edge of this species range may indeed indicate range contraction in part linked with regional climate warming, demonstrating the importance of selection in defining geographical distribution. Over evolutionary time, responses to selection imposed by the Antarctic environment (particularly the abiotic stresses of temperature, extreme seasonality in radiation levels and, on land, low water availability and freeze-thaw cycles) have generated striking examples of the development of evolutionary adaptations. While biotic stresses (largely through competition for resources, or predation) are currently thought to be insignificant and outweighed by abiotic stresses on land (although based on limited data), this is not the case in the much more complex marine communities. Space does not permit an exhaustive survey of relevant studies; rather, a series of illustrations from very different Antarctic biota, environments, and physiological or biochemical processes is considered here.

The challenges of life at low temperature provide clear examples of evolutionary adaptation in the terrestrial realm. Across the continent and the Antarctic Peninsula, virtually all habitats experience the twin challenges of short, cold summers and extended periods of winter freezing. Indeed, some habitats on inland continental nunataks may experience conditions suitable for biological activity for only a few days each year, and not at all in some summers. Studies of Antarctic terrestrial arthropods have revealed two basic adaptive strategies, those of freeze intolerance and freezing tolerance. The former strategy is utilised by the two most common groups of Antarctic terrestrial arthropods, the Acari (mites) and Collembola (springtails). Although the ability is not restricted to Antarctic members of these groups, it is very well developed in these and there is very little evidence of significant cost ("chilling injury") or mortality being experienced before the freezing point is reached, as is the norm in temperate or tropical species. Freezing-tolerant invertebrates are represented in the Antarctic by some higher insects (Diptera, Coleoptera), as well as microscopic invertebrates such as nematode worms. In some freezing-tolerant invertebrates there is also evidence for the use of antifreeze or thermal hysteresis proteins, analogous but with a different evolutionary origin to those found in teleost fish, in stabilising the frozen state.

Water stress, or desiccation, is at least as important as temperature in the biology of most Antarctic terrestrial biota. Desiccation tolerance is of great importance in terrestrial habitats worldwide, and has received considerable attention. The biochemical responses involve the same groups of chemicals as found in freezing tolerance and avoidance, leading to the proposal that desiccation tolerance is likely to have been an evolutionary precursor for cold tolerance in these invertebrates. While cold and desiccation tolerance features are not uniquely associated with Antarctic environments and species, their possession and evolutionary development has clearly been an important factor in the success of the major groups of biota now found in Antarctic terrestrial habitats.

A linked consequence of short, cold, and unpredictable active seasons for terrestrial biota is that it is not normally possible to complete the life cycle within a single season, or even rely on development to a single specific overwintering or resistant stage. Thus, life history features such as obligate diapause and temporally synchronised development, familiar amongst invertebrates of lower latitudes (and even of the milder Arctic terrestrial habitats), are rare or nonexistent. Instead, life cycles often appear to be "free running," and the switch between active and inactive states governed directly by local environmental conditions. This can be seen as Antarctic organisms gaining an evolutionary fitness advantage through the loss of ancestral features. However, extended life cycles per se are not seen as an evolutionary response to the stresses of the Antarctic environment, rather being the result of direct thermodynamic constraints. Indeed, within studies of biochemistry and ecophysiology, there is evidence of evolutionary developments to maximise the rates of biological processes during the short environmental windows that are available for growth and development.

Extended life cycles and slow growth are also typical of Antarctic marine invertebrates and fish. However, endothermic marine vertebrates (birds and mammals) appear to show no such limitation. Considerable populations of birds, seals, and whales are present throughout the Southern Ocean, from the sub-Antarctic islands to the continental coast. While some, notably the great whales and seabirds such as skuas and gulls, migrate to and from the Antarctic annually and thus rely on the region's marine resources only during the austral summer, others are present year-round. The Antarctic coast and pack ice are home to several species of seal (notably, leopard, Ross, and crabeater seals, the latter being one of the most abundant mammals on Earth, in terms of biomass), and virtually unstudied species of the smaller whales. Two penguins (Adélie, emperor) breed around the continental Antarctic coastline, with emperor penguin colonies being virtually restricted to sea ice in this region. Whales, seals, and penguins display clear morphological and physiological adaptations to life in these frigid waters, in terms of particularly effective insulation (blubber, fur, feathers) and control of circulation to surface areas and limbs.

Behavioural and life history adaptations are also present to maximise the chance of breeding success in the short window of opportunity provided during the Antarctic summer. Thus, Adélie penguins commence nesting earlier than any of the other Antarctic penguin species, even at locations where other species breed. Among the mammals, southern elephant and Weddell seals produce some of the richest milk known, and their young show some of the most rapid rates of growth and weaning seen in seals. Perhaps the most spectacular illustration of a life history adaptation driven by Antarctic environmental conditions is that of the life cycle of the emperor penguin. This species, the largest of the penguins living today, is the only vertebrate to spend the Antarctic winter on the continent, or at least the fast ice surrounding it. The short summer is insufficient to permit pairing, incubation, and development and fledging of chicks within a single season. Therefore, egg-laying takes place late in the austral summer, with the egg being incubated on the male bird's feet and protected under a special flap of skin. The female returns to sea after egg-laying and spends the winter foraging. However, the male must remain in the colony, relying on resources of body fat stored during the previous summer. During the most extreme conditions of winter, the incubating male birds obtain some protection from the environment by huddling together in a tightly packed group, with constant movement of individuals away from the windward side, in order to maximise individual survival chances. This is possibly the only example of the complete breakdown of breeding and nesting territoriality known amongst birds. Finally, when the chick hatches later in winter, it is still several weeks before female birds can return with a fresh food supply, and the male provides sustenance in the form of a secretion from its crop. Even then, the timing of the female's return is crucial as, by the end of winter, the male has used such a large proportion of his body's resources that he must also return to the sea to feed. There is a narrow window within which the female must return if the chick is not to be abandoned.

Low temperature presents very different challenges to life in the sea to that on land. The seas around

Antarctica are uniformly cold and, of most biological significance, thermally very stable. Around much of the continent annual variation in sea temperature is less than 2°C–3°C, and, in areas under permanent sea ice or ice shelves, it may be only fractions of a degree. Such stability over geological and evolutionary timescales has allowed biological processes to become tightly matched to their thermal environment, to the extent that any movement away from these stable conditions rapidly exceeds the tolerance limits of the biota. Thus, many Antarctic marine biota exhibit strong stenothermy, with little or no ability to tolerate thermal conditions outside a very narrow band. Such biota are obviously vulnerable to any large-scale process leading to rapid thermal change.

Ice formation is a highly visible seasonal feature of the Antarctic marine environment, with the formation of surface sea ice roughly doubling the apparent area of the continent. However, this represents little threat to biota, unless they become entrapped within it. The formation of anchor ice on substrata in the shallow subtidal environment provides a more direct threat, and is often advanced as an explanation for the apparently low diversity or biomass present in this zone. Antarctic marine invertebrates have body fluids that are isosmotic with seawater (that is, they have the same chemical concentration) and, thus, are not threatened with ice formation unless their medium freezes. This is not, however, the case with fish. Their body fluids are less concentrated than seawater, and therefore in the absence of a protective mechanism would freeze before the freezing point of seawater (~–1.8°C) is reached. Yet fish body fluids are forced to make intimate contact with seawater during passage through the gills, while fish bodies are not insulated from their surrounding medium. This threat has led to the evolution, in Antarctic notothenioid fish, of an antifreeze protein that reduces the freezing point of their body fluids to that of seawater, allowing them to survive by supercooling. Detailed genetic and molecular biological studies have identified the precursor gene for this antifreeze protein, and followed its subsequent modification during the radiation of the notothenioids. Analogous antifreeze proteins are now known from some Arctic fish, with completely different precursors, illustrating the fundamental importance of this adaptation for the existence of teleost fish in polar marine waters.

One group of notothenioid fish, the "icefish," illustrates a further evolutionary adaptation that is unique amongst the vertebrates. These fish have lost the ability to synthesise the oxygen carrying pigment haemoglobin, otherwise ubiquitous across all vertebrates, and their blood contains no functional erythrocytes. That they can do so is a consequence of their cold, stable thermal environment. Oxygen solubility in water is inversely proportional to temperature, and is maximal near to freezing point. However, biological maintenance costs ("standard metabolism") simply increase with temperature, meaning that the cost of staying alive is minimum in seawater near to freezing. Thus, the balance between high oxygen content of Antarctic seawater and low maintenance costs has allowed icefish to dispense with the use of haemoglobin altogether, presumably also generating a significant saving in the costs of protein synthesis.

The high oxygen content of cold seawater has also been proposed to underlie a completely separate evolutionary feature demonstrated repeatedly amongst a range of groups of Antarctic marine invertebrates—that of *gigantism*. Here, high oxygen content of Antarctic seawater represents one extreme of a continuum of availability levels throughout the Earth's oceans (and freshwaters), with levels elsewhere along the continuum generating greater constraints on growth and development.

Finally, it is clear that, as the environmental stresses experienced in Antarctica became more extreme following isolation from the other elements of the Gondwanan supercontinent, they exceeded the thresholds (biochemical, physiological, ecological) beyond which certain parts of the biota (species, higher groups, communities) could no longer persist. This is most striking in the terrestrial environment, where the vast majority of life found is limited to "lower" taxonomic groupings, and most of the "higher" and familiar groups from lower latitudes are simply no longer present. Thus, other than on the Antarctic Peninsula where two flowering plants and two dipteran insects (flies) are found, there are no higher plants (flowering and woody plants), higher insects, nonmarine mammals, or birds, and important ecological functional groups (e.g., obligate grazing animals, predators) are also absent or of little significance. In the sea, diversity patterns also illustrate that environmental conditions have led to reduced overall diversity or loss of some major familiar groups (e.g., reptant decapods—familiar as crabs at lower latitudes—and teleost fish), while others show considerably greater radiation than seen elsewhere (e.g., pycnogonids—sea spiders—and some molluscs). Whether the latter is an evolutionary consequence of reduced competition or the freeing of ecological space by the loss of the former remains debatable. However, a particularly interesting evolutionary example is provided by the remaining representatives of a group that is generally poorly represented—the teleost fish. One group of teleosts, the notothenioids, have survived in southern polar waters, and their subsequent evolution, now confirmed through molecular phylogenetic approaches, provides a particularly clear example of the development of a "species cloud." This example also provides a good example of the importance of the evolution of a novel physiological adaptation (antifreeze protein) at the base of the group's evolutionary radiation.

ADÉLIE PENGUIN

Adélie penguin (*Pygoscelis adeliae,* Hombron & Jacquinot 1841) was named after a portion of the East Antarctic coast, Adélie Land, the first known visit to which was made in 1840 by the French expedition led by Jules-Sébastien-César Durmont d'Urville; the region was named after Durmont D'Urville's wife, Adéle. The first specimens of this species were collected there, at Point Géologie, by the two naturalists/surgeons of the expedition, who subsequently described the species. It is one of three species subsequently included in the genus *Pygoscelis,* meaning "rump-legged," in reference to the penguins' upright, bipedal means of walking. The "pygoscelids" are among the few penguins that actually have prominent tail feathers, with the Adélie having the longest, thus earning the alternative name, no longer used, of "long-tailed penguin."

General Characteristics

The Adélie penguin is very much a marine organism, spending about 90% of its life at sea in the waters that encircle the Antarctic continent, not just those lying south of the Polar Front but also those that contain sea ice for at least several months of the year. In the latter, the species differs markedly from its two congeners, the Chinstrap *(Pygoscelis antarctica)* and Gentoo *(Pygoscelis papua)* penguins, which tend to avoid contact with sea ice as much as possible (they breed farther north and nest later in the summer). The Adélie penguin at sea occurs in small flocks, generally five to ten individuals; flock sizes are much larger near to colonies during the breeding season. Throughout the larger part of the year, fall to early spring, these groups spend most of the day resting on ice floes; individuals forage for only a few hours per day. Before spring migration, individuals begin to forage much more in order to build up the fat reserves needed for breeding. Later, in the autumn, at sea, they will forage intensively just prior to their annual moult.

The Adélie is about the same size as the majority of penguin species, about 60–70 cm tall and weighing about 3.2–3.5 kg on average, depending on sex, in its leanest state. However, this species has the important ability to gain body mass by accumulating subcutaneous fat so that at times of the year, just before breeding and just before the annual moult, it reaches a mass of 7 kg among males and 6.5 kg among females. Males are slightly larger than females, perhaps most noticeable in the beak and with greater certainty when the two members of a pair are compared directly with one another. The back and head of the adult in fresh plumage are bluish-black, including the backs of the flippers; its stomach, breast, throat, and flipper undersides are white. The black color quickly loses its sheen, turning to jet-black. By the end of the summer, and just before the annual moult, the plumage has faded noticeably, with tips of feathers then appearing white to brownish. The fledgling and yearling are similar in color pattern, the fledgling of a bluish hue where the yearling is black; both have a white chin, which is lost during the first moult at about 14 months of age. Seemingly, the characteristic long tail of this species is used to increase maneuverability while moving through water usually congested with ice floes and brash.

Populations

Total world population, as of the mid-1990s, is about 2,445,000 pairs, distributed among approximately 161 colonies located on continental headlands and offshore islands. Colony sites are characterized by ice-free terrain, easy access from the sea (not cliffs), lack of persistent fast ice (continuous sea ice locked in place by an irregular shoreline or grounded icebergs), and plenty of small pebbles, which are used as nesting material. Colonies range in size from a few dozen to approximately 200,000 breeding pairs; only six colonies exceed 100,000 pairs. Colony populations are actually about 30%–40% larger than what is represented by breeders, owing to numbers of nonbreeders that spend much time at the colony, generally younger birds gaining initial experience in the breeding process.

In recent decades, breeding colonies throughout most of Antarctica have been increasing in size in response to increasing divergence of sea ice and the size of polynyas, which are areas of minimal ice resulting most often from strong currents or winds. The majority of Adélie penguin colonies occur adjacent to a polynya. More divergent sea ice, perhaps a result of global warming, increases this species' access to the sea and to food. In the very northernmost part of its range, on the northwest coast of the Antarctic Peninsula, sea ice is disappearing and this species is being replaced by its less "pagophilic" congeners. Increasing temperatures may also be providing additional nesting habitat for this species, as coastal glaciers and ice shelves retreat in the north leaving coastal land that was formerly ice covered. The history of this species since the last Ice Age glacial maximum (19,000 years ago) has been one of colonizing sites as ice sheets retreated or as areas of fast ice became less persistent on an annual basis. The portion of the Antarctic Peninsula where the species is now retreating has been occupied only with the lower temperatures and more northerly sea ice that came with the Little Ice Age, which lasted from about 800 years before present until recent years.

Genetically, there are just two forms of this species, one residing in the Ross Sea and the other occurring everywhere else. Although the species exhibits a high degree of philopatry (returning to breed at the place of hatching) under stable and unchallenging conditions, a phenomenon that encourages genetic differentiation, philopatry disappears when heavy sea-ice conditions make it a challenge to return to natal colonies. Such conditions occur sporadically but often enough in local areas that the world population, genetically, is relatively well mixed compared with seabird species elsewhere.

Breeding Biology

Adélie penguins arrive at their colonies to breed beginning in late September at low latitudes (60° S) and by mid-October at high latitudes (78° S). The breeding process then requires about 125 days to complete, with the window of time allowed being slightly longer at lower latitudes. At high latitudes, it is much more critical for penguins to arrive as early as possible. Older birds, particularly males, arrive first. Any bird that arrives at the colony after about mid-November will not breed. Age of first breeding averages about 4.5 years of age (range 3–7) in females and 5.5 years (range 4–8) in males. The proportion of birds that attempt to breed increases with age, reaching maximum, 80%–90%, by age 6 in females and 7 in males. In almost all cases, an individual visits the colony at least 1 year previously before breeding. During that visit, much-needed experience in the breeding process is acquired.

Nests are built of small stones, required to keep eggs above any meltwaters. Nests are grouped into subcolonies that occur on hummocks or ridges, again to avoid meltwater from snow fields or glaciers. Egg laying begins on about 1 November in colonies at low latitude and on 6 or 7 November farther south. Laying is then highly synchronous, with the large majority of eggs laid during a 10-day period. Few eggs are laid in the last week of November. Two eggs are laid in the vast majority of nests, although one egg is common among the very latest layers. As females age, they lay their eggs earlier in the season. Incubation averages about 35 days and involves trade-offs of incubation duties between members of the pair, with males spending slightly more days in that activity. Once the chicks hatch, members of the pair share equally in provisioning chicks.

The newly hatched chick is completely covered in down and weighs on average about 85 g. Parents will guard their chicks, with just one parent foraging at any given time, for the first 22 or so days. The chick then begins to demand additional food, thus driving both parents away. Chicks left alone bunch together in the vicinity of their subcolony in groups called crèches. When parents return with food, giving a loud call upon reaching the nest, chicks will recognize the vocalization and go running to the nest. At 40–45 days, the chick reaches maximum mass, weighing 3.1–3.3 kg, and begins to lose its down to show real feathers. It will fledge, losing about 15% of its mass and becoming independent of its parents, at around 50–55 days of age. Even though the vast majority of females lay two eggs, the average breeding success is about 0.9 chicks fledged per pair that attempt breeding. This figure varies depending on the severity of environmental conditions experienced by the parents.

Following the breeding season, adults undergo a moult of their feathers. The process takes about 2–3 weeks during which they do not enter the water. Thus, they must gorge themselves in the few weeks before moulting, to build up large subcutaneous fat deposits. Most Adélie penguins moult while positioned on large ice floes, but in the northern part of the species' range, where sea ice is not always available, individuals often return to their colonies to moult.

Foraging Behavior

Adélie penguins employ several modes of travel. Over long distances, they swim at about 7–8 km per hour, although in bursts they can swim two to three times faster, being able to dart about almost like fish. Where there is extensive sea ice they walk at about 3 km per hour; pauses in long-range walks translate to a net speed of about 1–2 km per hour. Thus, individuals travel much more efficiently by swimming. This they do, using their flippers for propulsion, by passing underwater, 3–5 m deep, for a couple hundred meters, rising at intervals for a breath "on the fly"; such a behavior is similar to the movement of porpoises and so this mode of travel is called porpoising. When about to make landfall, the frequency of surfacing, actually as they look for places to land, becomes much higher. They also "toboggan" on their bellies over ice, pushing along using their feet; when a stiff breeze is blowing at an angle to their direction of travel (they are virtually "sailing"), they attain speeds faster than walking. When leaving the water to reach the land or ice floes, they accelerate rapidly and are capable of attaining ledges of 2 m above the water surface. Where there are beaches, they walk or scramble ashore.

As a colonially breeding species, Adélie penguins must radiate outward from the colony at sea in search of food. This scenario is known as "central place foraging," and with it the problems of prey depletion or interference competition are important and vary directly with colony size. Therefore, at small colonies, foraging trips may take birds only 10–12 km away, compared with trips on the order of 100 km for birds residing at large colonies or those foraging where food availability is a challenge. Food may become depleted near large colonies.

Throughout most of its range, during the breeding season, the species feeds principally on crystal krill *(Euphausia superba)* and Antarctic silverfish *(Pleuragramma antarcticum)*. In the few areas *(e.g., Antarctic Peninsula)* where continental shelves are narrow and the distance from colonies to the continental slope is near (tens of km), the summer diet is dominated by Antarctic krill *(E. superba)*. Thus, composition of the diet changes depending on the degree to which the penguins are foraging in neritic versus pelagic waters. During winter, individuals dwell away from waters of the shelf at the outer edge of the large-scale ice pack, north of the Antarctic Circle. Here there is an ample period of light each day allowing Adélie penguins to have a diverse diet composed of Antarctic krill, deep-water lantern fish (myctophids, especially *Electrona antarctica*), and squid (especially *Psychroteuthis glacialis*).

In penguins, the duration and depth of diving is directly related to body size. This species is a highly capable diver, being able to hold its breath longer relative to its size than its congeners and most other penguin species, perhaps an adaptation allowing it to forage under vast ice floes where breath holding is an advantage in the search for prey. Foraging dives average 115–230 seconds, with the longest recorded being 350 seconds. Adélie penguins usually feed at 30–60 m depth but have been recorded to 170 m. When foraging during summer to feed themselves and at the same time provisioning chicks, Adélie penguins often dive continuously in bouts lasting 2–4 hours; several bouts often occur sequentially with periods of rest in between before returning with up to 1 kg of food for chicks.

Predators

At sea, Adélie penguins are preyed upon heavily by leopard seals *(Hydrurga leptonyx),* which catch them mainly by stealth, as the penguins are generally capable of eluding the seals in the open water. The seals wait by the edges of ice floes in areas where there are many penguins, or along beaches or benches of beach ice at colonies. They then grab the penguins as they swim by, or as they fall back into the water after failing to attain a high ledge. The seals also smash through thin ice to capture penguins walking overhead. For these reasons, Adélie penguins pause for long periods when they meet an ice crack or lead while walking, or when they are thinking about diving into the water, in order to be confident that there are no seals lurking in the vicinity.

At colonies, skuas (*Catharacta* spp.) act mainly as scavengers, taking eggs and small chicks that are deserted or poorly defended by parents. Once penguin chicks enter into crèches, the skuas are able to kill the smaller and weaker chicks, especially when they become isolated from the crèches or subcolonies. Adult penguins will drive skuas away, not so much in an act of altruism, but in defense of their own chicks or in exercise of a general distaste for the close approach of these birds.

ADVENTURERS, MODERN

Adventure Tourism

The term *adventure tourism* defines those activities conducted by nongovernment parties operating in Antarctica—either commercially or noncommercially—for the purposes of physical recreation, exploration, competition, private scientific research, or a combination of any of these. The most common examples from recent times are mountaineering and South Pole ski traverses.

Adventurer Numbers, Locations, and Access

Very few people undertake these activities. For example, in the 2004–2005 season, of 30,232 tourists only 221 were transported inland for the more "adventurous" streams of tourism such as mountaineering and polar ski traverses (IAATO 2005). An even smaller number of climbers and skiers visit the Antarctic Peninsula aboard yachts. Other activities undertaken in recent years include running marathons, sea kayaking, scuba diving, and ballooning.

The principal gateways for Antarctic adventure tourism are Ushuaia in Argentina, Punta Arenas in Chile, and Cape Town, South Africa. The majority of yachts leave from Ushuaia and the majority of tourist flights, either to the Antarctic Peninsula or inland, leave from Punta Arenas. Most of the yachts travel a certain distance down the peninsula, undertaking climbing, skiing, kayaking, wildlife watching, photography, diving, or any combination of these, their itineraries largely defined by time available and sea-ice conditions. Flights from Punta Arenas go to either King George Island or a summer-only base at Patriot Hills in the southern Ellsworth Mountains. From Patriot Hills expeditioners are flown either to Vinson Massif and environs for climbing, or to various starting points for South Pole ski traverses.

History of Adventure Tourism

The first major modern private expedition—and still perhaps the most serious in its technical preparations and scientific contributions—was the Transglobe Expedition led by Sir Ranulph Fiennes from 1979 to 1982, the goal of which was to circumnavigate the

Earth in a north–south direction while passing over both Poles. For the Antarctic section, a party of four wintered in Dronning Maud Land, not far from South Africa's SANAE base, following which—from October 1980 to January 1981—Fiennes, Charlie Burton, and Oliver Shepard crossed the continent using snow scooters with air support, travelling some 2,800 miles. During this time Ginny Fiennes ran the base camp and conducted very-low-frequency radio research.

The longest Antarctic traverse of any kind was the 1989–1990 International Trans-Antarctic Expedition in which six members, including Will Steger (US), Jean-Louis Etienne (France), and Geoff Somers (UK), journeyed by dogsled, with resupply by air, from the northern tip of the Antarctic Peninsula to the then-Soviet base Mirny on the coast of East Antarctica—3,741 miles in 222 days.

The longest full ski traverse was undertaken in 2000–2001 by Norwegians Rolf Bae and Erik Sonneland, who traveled 2,350 miles from the Norwegian base Troll to Ross Island via the South Pole in 107 days, before leaving the continent by ship. Other notable efforts through the recent decades included the "Footsteps of Scott" expedition led by Robert Swan and Roger Mear in 1985–1987, the unsupported journey of Fiennes and Michael Stroud in 1992–1993, and the ski and sail traverse by Alain Hubert and Dixie Dansercoer in 1997–1998.

Commercial ascents of Vinson Massif began in 1985–1986, and by the end of the 2004–2005 season around 970 individuals had climbed to the summit. The main factor for Vinson's increasing popularity is its status as one of the "Seven Summits"—the highest peak on each continent. The success rate for climbers has usually been around 95%, owing to the straightforward nature of the climbing and the generally reliable weather in the area. The first ski descent from the summit of Vinson Massif was made by Martyn Williams (UK) and Pat Morrow (Canada) in 1985, the first snowboard descent by Stephen Koch (US) in 1999, and the first parapente descent by Vernon Tejas (US) in 1988 (Gildea 1998).

On the Antarctic Peninsula and adjacent islands many of the significant peaks were first ascended by personnel from government programs. The area has, however, proved popular with adventure tourists since the 1980s, mainly due to its relative low cost and accessibility for an Antarctic destination. Most of these have traveled by yacht, many undertaking mountaineering and skiing, particularly in areas close to the coast, for reasons of logistics and weather. In recent years the area and peaks around Wiencke Island, Port Lockroy, Paradise Harbor, and the Lemaire Channel have been particularly heavily visited.

Since the early 1990s some significant climbing has been done in the various massifs of the Sor Rondane and Muhlig-Hoffman Mountains in Dronning Maud Land, usually accessed by flights from Cape Town to a blue-ice runway within sight of the mountains. Many of the expedition objectives here are extremely steep rock peaks that have produced the hardest technical climbing yet done in Antarctica.

The other main adventure activity in Antarctica is skiing to the South Pole from one of a number of different starting points, usually close to a coastline, either inside or outside an ice shelf, with the merits of various parameters and styles a highly contentious topic within the adventure community. Expeditioners haul sleds containing their food, fuel, and equipment, sometimes resupplied at one or more points during their journey.

Solo Adventuring

Perhaps the most significant feat of solo adventuring to date has been the Norwegian Borge Ousland's continental crossing, when he traveled 1,760 miles in 64 days without resupply, from Berkner Island to Ross Island, obtaining great benefit from the use of sails, covering 140 miles in one 24-hour period. In the 1992–1993 season his fellow Norwegian Erling Kagge became the first to ski solo to the Pole, a feat that has since been repeated numerous times from various starting points. The current fastest time for a non-kiting traverse from any coast to the Pole was achieved in the 2003–2004 season when Briton Fiona Thornewill traveled unsupported from Hercules Inlet to the Pole in 42 days.

Several significant solo climbs have been achieved, particularly in the Sentinel Range. The most noted of these were the American Terrence "Mugs" Stump's climbs of the southwest face of Mount Gardner (4587 m) and the more difficult west face of Mount Tyree (4852 m) in November 1989. The only major Antarctic peak to have received a winter ascent is Mount Erebus, climbed solo by British alpinist Roger Mear on June 7, 1985.

Regulation

There is currently no legal framework to enforce liability for costs incurred by national Antarctic programs in emergency rescues of private adventurers, a potential problem that has long been a prime concern for governments. To date there have been few such incidents, but all have had some impact on official programs.

All adventurers are strongly advised to take out suitable insurance policies to cover rescues and emergencies, but there is no legal framework in any country to realistically enforce this other than by withholding of permits or prosecution of those who flout the law. In reality enforcement currently relies on cooperation by those operators, particularly those who are members of the International Association of Antarctic Tour Operators, who transport the expeditioners to the continent. Such tourist operators are bound by the 2005 Liability Annex to the Antarctic Treaty to hold suitable insurance to cover liability in the event of causing environmental damage in the course of their activities.

Those adventurers not operating primarily within one of the regular programs of such operators, and whose nations are members of the Antarctic Treaty, are bound by the relevant domestic legislation of their country to give advance notice of their activities, submit an Initial Environmental Evaluation, show significant self-rescue or appropriate third-party search-and-rescue arrangements including insurance, and obtain permits for waste management and import of certain materials.

AEROBIOLOGY

Aerobiology is the study of finely divided suspensions of particles of biological origin, or activity, in air. The passively airborne materials, which constitute bioaerosols, include microorganisms, pollen, spores, and fragments, or products of larger organisms. They occupy the size range circa 0.5–100 microns (aerodynamic diameter) and are collectively termed the air-spora. Aerobiology encompasses study of the physical, chemical, and biological properties of the air-spora, including the identity, source, movements, survival, infectivity, toxicity, and allergenicity of particles.

The Antarctic air-spora is characterized by low particle abundance and diversity, with a virtual absence of pollen. The density of the Antarctic air-spora (usually <1 particle m^{-3}) is tens or hundreds of thousands times lower than in temperate regions. Numbers of airborne particles are lower during winter than in summer, because of reduced biological activity at this time and the covering of sources by snow and ice. Abundance and diversity of the air-spora is higher in the maritime Antarctic (Antarctic Peninsula, South Shetland Islands, and South Orkney Islands) than in ice-free coastal regions of continental Antarctica, reflecting regional differences in biodiversity. Common particles include lichen soredia (vegetative propagules), feather fragments, and diatoms. Absolute peaks in abundance and diversity occur when air from South America passes over the Antarctic Peninsula and Scotia Arc region. On these rare occasions, the air-spora is more typical in composition to that of temperate regions, having a high content of spores of decomposer fungi and pollen, although abundance remains low in comparison.

The term *aerobiology* was coined in the 1930s by Fred C. Meier, whose work on long-distance spore dispersal included trans-Atlantic and Arctic flights by Charles Lindbergh. However, aerobiological research predates this time, and the first Antarctic studies were conducted by scientists on national expeditions early in the twentieth century: Erik Ekelöf on the Swedish South Polar Expedition, 1901–1904; Hans Gazert on the German South Polar Expedition, 1901–1903; and J. H. Harvey Pirie on the Scottish National Antarctic Expedition, 1902–1904. These workers simply exposed petri plates to the atmosphere, most of which produced no cultures. Similar microbiological studies were conducted by Edward Atkinson on Robert Falcon Scott's last expedition (1910–1913), Archibald McLean on Douglas Mawson's Australasian Antarctic Expedition (1911–1914), and Paul Siple on Richard Byrd's 1933–1935 expedition.

Since the 1960s, aerobiology has been applied to ecological problems and used as a method for monitoring human impacts in Antarctica. Monitoring was initiated in tandem with the Dry Valleys Drilling Project and other US field activities, including testing for biological exploration on Mars and associated quarantine measures. Ecological questions approached using aerobiology concern the dispersal of organisms into and around Antarctica, with particular respect to their colonization of new habitat. This is based on the premise that much of the diversity seen in Antarctic terrestrial and freshwater habitats in present times has arrived in Antarctica since the end of the last major glacial advance. Many of these organisms have small propagules easily carried by the strong winds found in Antarctica. Wind provides one of the few means available for transport of organisms to new habitat, exposed or formed as a result of changes in climate.

AIR-BORNE ICE

Ice forms in the atmosphere when water vapour freezes. Air temperatures generally fall with increasing altitude in the lower atmosphere. The air temperature is 0°C at an altitude of about 2300 m and falls to –56°C at an altitude of 11 km. This means that water vapour should freeze throughout much of the lower atmosphere, and ice crystals should be anticipated at altitudes above approximately 2300 m. Clouds at midaltitudes (3–7 km) contain significant quantities of ice crystals and variable amounts of water vapour, whereas clouds at high altitudes (7–11 km) are entirely composed of ice crystals. Rising air masses expand and cool, and produce clouds of water droplets at higher levels. Water droplets form around the many hundreds of small particles, or aerosols, that are found in air. These particles have diameters that are usually between 0.01 and1 μm. Water droplets in the atmosphere do not readily freeze, and temperatures usually need to fall at least to –5°C to –10°C, and often below –20°C, before ice crystals form. Freezing is brought about when the water droplets come into contact with certain types of aerosol rock particles and organic matter that have the right surface characteristics for water to freeze onto. These types of aerosol are only a small percentage of the total aerosol. Temperatures need to reach approximately –40°C before ice crystals can form directly from water vapour in very clean, or aerosol-deficient, air masses. Once the ice crystal forms, it can grow rapidly from other supercooled water droplets or water vapour. They stop growing when they become so big that they start to fall out of the atmosphere. For example, an ice crystal with a diameter of 75 μm drops at a rate of 5 cm/s, and so can continue to grow for some time before it sinks to a lower, warmer altitude.

Ice crystals come in many shapes and sizes depending on temperature and the amount of water vapour or supercooled droplets in the vicinity of the growing crystal. Ice crystals are usually shaped like columns or plates. Columnar crystals, such as needles, usually form at temperatures between –4°C and –10°C. Plates form between –10°C and –20°C. Plates are flat, thin slivers of ice that fall to earth in a wide variety of shapes. They are typically 5 mm or more in diameter, but they are less than 0.1 mm thick. Columnar crystals form again at lower temperatures, between –20°C and –35°C. Columnar crystals fall with their long axes nearly vertical, whereas plate crystals fall with their flat faces almost horizontal.

Ice crystals in the atmosphere reflect and bend, or refract, sunlight, creating optical effects in the sky, which include solar haloes and sun dogs. Halos are rings of light surrounding the sun. Most halos are bright white rings, but some are coloured because the ice crystals act as prisms, splitting white light into its different colours. Halos are produced by ice crystals in cirrus clouds at altitudes between 5 and 10 km. Halos are often produced by columnar crystals, which fall in a predominantly vertical orientation. Light enters one side of the columnar ice crystal and exits through another side. The light is refracted both when it enters and again when it leaves the ice crystal. The two refractions bend the light by 22° from its original direction. Someone looking at the sun through a cirrus cloud will see a ring of light from the sun or moon. This so-called 22° halo is the most common type of solar halo observed, and can also be seen around the moon for the same reason. Halos also form by crystals that form in very cold weather (below –40°C) at ground level, called diamond dust, and when the sun is close to the horizon.

A rarer observation is a tangent arc, which is a patch of bright light observed along a halo. This occurs when sunlight is refracted by columnar ice crystals whose long axes are oriented horizontally.

Sun dogs are also seen frequently in Antarctica, particularly on cold sunny mornings or evenings. Then, the sun is near the horizon, on the same horizontal plane as the observer, and the air is loaded with ice crystals. Sun dogs, also known as mock suns or parhelia, are brightly coloured spots on each side of the sun. They are seen when platelike ice crystals fall with their flat faces horizontal. Haloes are observed if the plate crystals are randomly oriented, and sun columns are observed if the horizontal crystals gently rock during their fall.

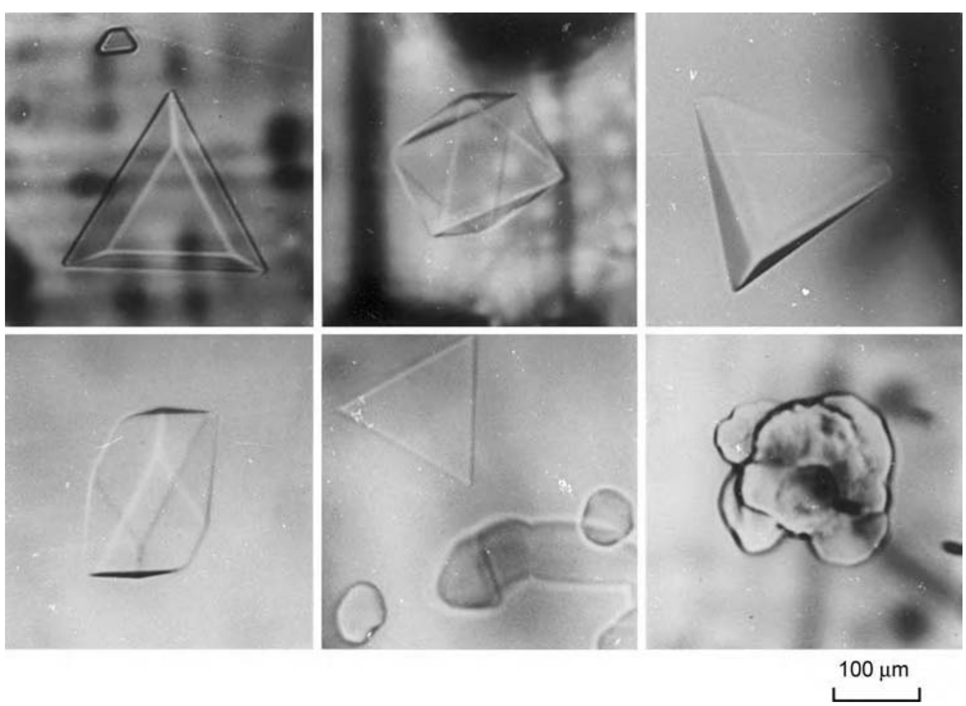
AIR HYDRATES IN ICE

An air hydrate is a transparent crystal in which air constituent gas molecules are trapped in polyhedral cages formed by hydrogen-bonded water molecules.



Air hydrates in ice.

This cage structure is called a clathrate and air hydrates are sometimes called clathrate hydrates. However, such terminology and explanations are misleading because the gas composition of atmospheric air is not preserved in air hydrates found in ice cores recovered from the Antarctic or Greenland ice sheets. Air hydrates found in ice cores contain a large variety of gas composition. An air hydrate might be defined more rigorously as a gas hydrate produced by the reaction of atmospheric air with ice (or water).

The history of natural air clathrate hydrates occurring in polar ice sheets started in the first deep core drilled through the ice sheet to bedrock at Byrd Station, Antarctica (Gow and others 1968). It was revealed that air bubbles completely disappeared below 1200 m depth, raising a puzzle on the existence of air constituent gasses in deep ice sheets. Miller (1969) explained this fact theoretically as a transformation of the air bubbles into air hydrates under high pressures that exceeded the air hydrate dissociation pressure at the *in situ* temperatures. Air hydrate inclusions were first observed by Shoji and Langway (1982) in deep ice samples recovered at Dye-3, Greenland. Further optical microscope examinations of available deep ice cores from Antarctica and Greenland supported Miller's predictions, but revealed an anomalously long transition zone, in which air bubbles and air hydrates coexisted much deeper than Miller's theory suggested. The transition zone in Antarctica is roughly from 500 m to 1200 m. The transition time in Antarctica is several tens of thousands of years. This very long transition is attributed to a very low nucleation rate of air hydrate in ice sheets.

In the transition zone, extremely high levels of gas fractionation were found (Ikeda et al. 1999). Air hydrates in the transition zone have gas compositions enriched by O_2 while N_2 is enriched in air bubbles in the zone. This phenomenon is explained by a faster diffusion (through the ice crystal lattice) of O_2 than N_2 in diffusive mass fluxes from air bubbles to air hydrates in the zone. Careful attention is therefore required in the interpretation of gas composition data obtained from high resolution gas analyses of ice cores.

After recovery of ice cores from deep ice sheets, air hydrates gradually dissociate to air bubbles during cold room storage of ice cores. The dissociation rate strongly depends on storage temperature (50% dissociation after about 4 years at –20°C, yet only 1% dissociation after about 6 years at –50°C).

AIRCRAFT RUNWAYS

There are no conventional runways on the mainland of Antarctica, and only three on offshore islands. The reason is that less than 0.4% of the total area of Antarctica consists of bare ground (Fox and Cooper 1994). The rest is ice and snow. However, vast areas of the ice sheet are usable by ski-equipped aircraft, and about 1% consists of bare ice that may in places be good for landing unmodified wheeled aircraft. In a few places, seasonal fast ice (sea ice attached to the coast) can be used by even large wheeled aircraft, if the ice is thick enough and snow is cleared from the runway.

Active Runways on Bare Ground

These are made of compacted gravel or crushed rock. Even the longest is too short for large jet aircraft. There are three:

1. Teniente Rodolfo Marsh Martín on King George Island (62°11′ S, 58°59′ W). Length 1292 m. Operated by Chile.
2. Vicecomodoro Marambio on Seymour Island (64°14′ S, 56°37′ W). Length 1250 m. Operated by Argentina.
3. Rothera on Adelaide Island (67°34′ S, 68°08′ W). Length 900 m. Operated by the United Kingdom.

Possible Runways on Bare Ground

There are places on the continent where hard runways suitable for intercontinental aircraft could be built, but high projected costs and environmental considerations have deterred serious interest. Examples are:

1. Marble Point in McMurdo Sound (77°25′ S, 163°42′ E). A 520 m gravel runway was built in 1957 but is no longer usable. A 3000 m runway could be constructed (Mellor 1988).
2. Davis on Vestfold Hills (68°33′ S, 78°01′ E). A 2000 m runway could be constructed (Shevlin and Johnson 1999).
3. Maitri on Vassfjellet (70°46′ S, 11°44′ E). A 3000 m runway could be constructed.
4. Deception Island (62°59′ S, 60°35′ W) was the site of the first powered flight in Antarctica (November 16, 1928). The runway was bisected by a volcanic eruption in 1969. A 1000 m runway could be constructed.
5. James Ross Island (63°52′ S, 57°55′ W). A 3000 m runway could be constructed.
6. Dundee Island (63°29′ S, 56°14′ W). Light aircraft have landed on raised beach gravel. A 1500 m runway could be constructed.

Runways on Sea Ice

Few are in use because the ice commonly breaks up and drifts out to sea in late spring. Snow is removed by a snow plough or snowblower.

1. McMurdo (77°52′ S, 166°29′ E) has two sea-ice runways intersecting at an angle of 80°. Length 3000 m. Operated by the United States. Aircraft weighing up to 300 tonnes have landed on these runways with ice thicknesses of 2.5 m. Prolonged parking of heavy aircraft in one place can lead to ice failure.
2. Terra Nova Bay (74°41′ S, 164°10′ E). Length 2740 m. Operated by Italy and used for C-130 aircraft on wheels weighing up to 80 tonnes.

Runways on the Ice Sheet

There are three kinds of runways on the ice sheet: blue-ice runways, white-ice runways, and skiways.

Blue-ice runways are naturally occurring, snow-free areas that offer the best hope for landing unmodified wheeled aircraft in Antarctica (Mellor and Swithinbank 1989). Blue-ice runways are in use by heavy jet transport aircraft, and in many places there is no practical weight limit. Using satellite images and aerial photographs, Swithinbank (1991) identified many possible sites. Some would prove suitable for wheeled operations by aircraft up to and including Boeing 747. Which sites these are can be determined only by ground surveys that have not yet been done. Large areas of the continent have not even been reconnoitered. The attraction of a well-chosen blue-ice runway is that construction and maintenance costs are almost nil. There are ice fields with clear approaches and potentially long runways facing into the prevailing wind, while others are dogged by turbulent crosswinds from nearby mountains. In practice the choice of an airfield site involves a compromise between the aviator's ideal and its distance from his intended destination. At one extreme, a near-perfect site may prove attractive for intercontinental operations even if it is 1000 km from the ultimate destination in Antarctica. At the other extreme, a relatively poor site may be attractive because of its proximity to the intended destination.

Unprepared blue-ice runways suitable for heavy wheeled aircraft include:

1. Patriot Hills (80°18′ S , 81°21′ W). Length 3000 m. This is in regular use by an Ilyushin-76TD jet transport weighing up to 170 tonnes.
2. Henriksen Nunataks Blue One (71°31′ S, 08°47′ E). Length 2750 m. This is in occasional use by an Ilyushin-76TD jet transport weighing up to 170 tonnes.
3. Austhamaren Peak (71°41′ S, 26°50′ E). Length 2400 m. Two runways intersect at 60°. Unproven.
4. Queen Fabiola Mountains (71°21′ S, 35°20′ E). Length 2500 m. Unproven.
5. Mill Glacier (85°06′ S, 149°50′ W). Length 3000 m. This is occasionally used by C-130 aircraft on wheels.
6. Odell Glacier (76°39′ S, 159°58′ E). Length 2000 m. This has been used by C-130 aircraft on wheels.

Whereas blue-ice runways are unprepared, white-ice runways suitable for wheeled aircraft range from graded bare ice to compacted snow. These include:

1. Pegasus (77°58′ S, 166°32′ E). Length 3000 m. Operated by the United States. This is in regular use by wheeled aircraft weighing up to 300 tonnes (Lockheed C5B).
2. Novolazarevskaya (70°51′ S, 11°36′ E). Length 2760 m. Operated by Russia. This is in occasional use by an Ilyushin-76TD jet transport weighing up to 170 tonnes.

3. Molodezhnaya (67°41′ S, 46°08′ E). Length 2500 m. Operated by Russia. This compacted snow runway has been used by Ilyushin-76TD aircraft weighing up to 170 tonnes.

Ski-equipped aircraft can land almost anywhere on the ice sheet where the surface is level and where sastrugi (wind-formed irregularities on the snow surface) are no more than about 0.2 m high. Skiways in regular use are groomed by grading (planing) or any other means available; methods range from dragging telegraph poles or anchor chains to running heavy tracked vehicles over the surface. Even manual labor with shovels has been used to prepare skiways for light aircraft. The most-used skiways are:

1. Williams Field (77°52′ S, 167°05′ E). Two 3000 m. skiways intersect at an angle of 80°. Operated by the United States. Used for LC-130 aircraft weighing up to 80 tonnes.
2. Amundsen-Scott South Pole Station (90°00′ S). Length 3000 m. Operated by the United States. Used for LC-130R aircraft weighing up to 80 tonnes.
3. Mirniy (66°33′ S, 93°00′ E). Length 3000 m. Operated by Russia. Used by Ilyushin-14 aircraft weighing up to 20 tonnes.
4. Vostok (78°28′ S, 106°48′ E). Length 3900 m. Operated by Russia. Used by Ilyushin-14 weighing up to 20 tonnes and LC-130 aircraft weighing up to 80 tonnes.

ALBATROSS AND PETRELS, AGREEMENT FOR THE CONSERVATION OF

The Agreement on the Conservation of Albatrosses and Petrels (ACAP) is an implementing agreement of the 1979 Convention on the Conservation of Migratory Species of Wild Animals (CMS). CMS is an international agreement that aims to conserve terrestrial, marine, and avian migratory species throughout their ranges. CMS entered into force on 1 November 1983, and as of August 2005 had ninety-one Contracting Parties. Under CMS, parties have an obligation to cooperate and develop agreements for species with an unfavourable conservation status as listed in Appendix II (Article IV).

ACAP aims "to achieve and maintain a favourable conservation status for albatrosses and petrels" (Article II.1). Parties agree to take measures to achieve this objective (Article II.2) and apply the precautionary approach (Article II.3). ACAP also aims to improve the understanding of the conservation status of albatrosses and petrels—including their susceptibility to threats at sea and on land and effective mitigation of those threats.

Conservation of albatrosses and petrels is critical since they are long-lived, mate for life, may fledge a chick only once every 2 years, and have low recruitment rates. They are particularly susceptible to longlining, and by-catch of birds has been a major issue. The Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) has been addressing the issue of long-lining and is now involved with ACAP to address these threats.

ACAP applies to the twenty-one recognised albatross species and seven petrel species occurring in the Southern Hemisphere. ACAP is open for signature to all twenty-five Range States (including non-CMS signatories) and regional economic integration organisations (Article XV). ACAP was finalised in Cape Town between 29 January and 02 February 2001 and entered into force on 01 February 2004. Eight of the eleven signatories have ratified ACAP, and all signatories are also Antarctic Treaty Consultative Parties (except the Republic of South Africa) as of August 2005.

The Action Plan forms an integral part of ACAP, and outlines measures necessary for meeting the objectives of the Agreement (Annex 2). These

ACAP-Listed Albatross and Petrel Species

Listed species (old taxonomy)*	New taxonomy†	Common name
Albatrosses		
Diomedea exulans	*Diomedea exulans*	Wandering Albatross
	Diomedea dabbenena	Tristran Albatross
	Diomedea antipodensis	Antipodean Albatross
	Diomedea gibsoni‡	Gibson's Albatross
Diomedea amsterdamensis	*Diomedea amsterdamensis*	Amsterdam Albatross
Diomedea epomophora	*Diomedea epomophora*	Southern Royal Albatross
	Diomedea sanfordi	Northern Royal Albatross
Diomedea irrorata	*Phoebastria irrorata*	Waved Albatross
Diomedea cauta	*Thalassarche cauta*	Shy Albatross
	Thalassarche steadi‡	White-capped Albatross
	Thalassarche salvini	Salvin's Albatross
	Thalassarche eremita	Chatham Albatross
Diomedea bulleri	*Thalassarche bulleri*	Buller's Albatross
	Thalassarche nov. sp. (platei)‡	Pacific Albatross
Diomedea chrysostoma	*Thalassarche chrysostoma*	Grey-headed Albatross
Diomedea melanophris	*Thalassarche melanophris*	Black-browed Albatross
	Thalassarche impavida	Campbell Albatross
Diomedea chlororhynchos	*Thalassarche carteri*	Indian Yellow-nosed Albatross
	Thalassarche chlororhynchos	Atlantic Yellow-nosed Albatross

measures address (a) species conservation; (b) habitat conservation and restoration; (c) management of human activities; (d) research and monitoring; (e) collation of information; (f) education and public awareness; and (g) implementation (see Article VI; Annex 2).

ACAP is in the early states of its development, hence its conservation outcomes are yet to be fully realised. Australia, the Secretariat, has been a key player in the prompt adoption of ACAP, and hosted the first Conference of Parties (COP 1) in 2004 which was attended by five parties, three signatories, and three Range States. Several observers were present at COP 1 including CCAMLR, the Antarctic Treaty Secretariat, Antarctic and Southern Ocean Coalition (ASOC), and the Scientific Committee on Antarctic

Research (SCAR). At COP 1, ACAP Parties adopted Resolution 1.4, *Criteria to define emergency situations and assign responsibility for action for the Agreement on the Conservation of Albatrosses and Petrels*.

Antarctic Treaty Consultative Parties that are Range States have been encouraged to become signatories to ACAP (ATCM XXVII / IP088 2004). Effective implementation of ACAP still requires the signature of more Range States and their cooperation in the implementation of conservation measures outlined in ACAP and developed at the regular COP.

ALBATROSSES: OVERVIEW

Albatrosses belong to the avian order Procellariiformes and the family Diomedeidae. They are a distinctive group of oceanic birds, characterised by their large size, long wings, and strong, powerful bills. Indeed albatrosses are among the largest flying birds, with wingspans exceeding 3 metres in some species. Large body mass and long, stiff wings combine to make these birds unsuitable for powered and flapping flight. Instead, albatrosses glide and soar upon the winds of the world's oceans.

Generally, albatrosses occur in the cooler oceanic regions of both hemispheres, principally between the latitudes of 30° and 55°. These areas are notable for their high winds, and it is wind, and the effect of winds upon the ocean, that most influences the distribution of albatrosses. Albatrosses originated in the Southern Hemisphere some 50 Ma, before spreading to the North Pacific Ocean. Despite a strong fossil record in the Northern Hemisphere, the Southern Ocean is today the stronghold of these birds, with most species confined to southern latitudes.

The name "albatross" is thought to have derived from the Arabic word *al-qadus,* after the Greek word *kados* (meaning scoop or bucket) that was originally applied to pelicans and later extended to other birds. Spanish and Portuguese seafarers later applied the name *alcatraz* to albatrosses and other large seabirds. Albatrosses have held a long fascination for mariners, typified in Samuel Taylor Coleridge's *The Rime of the Ancient Mariner,* perhaps the most familiar depiction of the albatross in Western literature. The albatross slain by the Ancient Mariner is thought to be one of the dark-plumaged and relatively small sooty albatrosses, one of the most diminutive members of the albatross family.

The exact number of extant albatross species is widely debated, as the taxonomic history of albatrosses is both complex and controversial. A revision of albatross systematics in the 1990s based on molecular studies elevated the number of species of albatrosses from fourteen to twenty-four. The acceptance of this revision has been equivocal with some authorities adopting the full twenty-four species, and others advocating a more conservative twenty-one species. The scientific nomenclature used here follows that endorsed BirdLife International, a group that recognises the suite of twenty-one species separated into four genera in the albatross family.

The status and trends of albatross populations are well documented. These assessments have highlighted the globally threatened status of this group of iconic birds, with nineteen of the twenty-one species listed as globally Threatened and the remainder Near Threatened. The precarious survival prospects for albatrosses places them as the avian family most threatened with extinction.

Species Characteristics and Status

The great albatrosses have among the largest wingspans of any flying bird and form the genus *Diomedea,* comprising six species of these massive and spectacular birds. The wandering albatrosses *(D. exulans)* have a wing span of over 3 metres, with body masses exceeding 10 kg. These spectacular birds have a circumpolar foraging distribution and breed at six main island groups in the Southern Ocean. Typically these majestic birds have plumage of variable colour that whitens with age.

The plumage of the Endangered Tristan albatross *(D. dabbenena)* is similar to that of wandering albatrosses, but Tristan albatrosses are much more restricted in their range, with the breeding population essentially restricted to Gough Island (Tristan da Cunha) and birds foraging mainly in South Atlantic waters. The Antipodean albatross *(D. antipodensis),* is endemic to New Zealand, and is listed as Vulnerable as it is restricted to three small islands for breeding. At sea, these birds disperse across the Tasman Sea and South Pacific Ocean, including areas of the Southern Ocean. Whilst smaller than wandering albatrosses, both species have a similar juvenile plumage, with Antipodean albatrosses retaining a darker adult plumage. This character is more similar to the Amsterdam albatross *(D. amsterdamensis),* which also retains a darker adult plumage. Amsterdam albatrosses are classified as Critically Endangered as the species comprises only an extremely small population (estimated at eighty mature individuals) confined to a single breeding island. Little is known about the foraging distribution of these imperilled birds, although breeding birds are known to forage over 2000 km from their breeding site of Amsterdam Island in the Indian Ocean.

The remaining two species of *Diomedea* albatrosses are the Southern Royal *(D. epomophora)* and Northern Royal *(D. sanfordi)* albatrosses. These species have broadly similar plumage patterns, although they differ with respect to underwing patterns and extent of white on their backs. Both species are listed as Threatened as a result of their restricted breeding ranges, the Northern Royal albatrosses being more acutely threatened (listed as Endangered) as a result of poor breeding success that is likely to sustain significant population decreases in the future.

The most numerous and frequently observed albatrosses in the Southern Oceans are members of the nine species that comprise the genus *Thalassarche*. Collectively these smaller albatrosses were known as mollymawks, from the Dutch word *mallemok,* which literally means "foolish gull." These birds are smaller than the great albatrosses, with wingspans of about 2 metres and average body masses of 2–4 kg. The plumage patterns of this group of albatrosses are broadly similar with light underparts, dark upperwings and grey or white heads.

The black-browed albatross *(Thalassarche melanophris)* is the most numerous of all albatross species and breeds at twelve sites around the Southern Hemisphere. Despite a current population of 680,000 pairs, as a result of documented population decreases this species is listed as Endangered, as it is inferred that the population decreases will continue to diminish the population. The morphologically similar Campbell albatross *(T. impavida),* distinguished from black-browed albatrosses by its pale iris, is globally listed as Vulnerable as the species is effectively restricted to a single New Zealand sub-Antarctic island.

The grey-headed *(T. chrysostoma)* and Buller's *(T. bulleri)* albatrosses are generally similar in their plumage with grey on their heads and necks; their bills are black with striking yellow to red stripes. Both species are listed as Vulnerable, Buller's albatrosses because of their restricted New Zealand breeding distribution and grey-headed albatrosses because of population decreases that, if they persist, will result in the Threatened status being upgraded to Endangered.

The Indian yellow-nosed albatross *(T. carteri)* and Atlantic yellow-nosed albatross *(T. chlororhynchos)* also have the striking beak colouration, but have paler heads than the grey-headed and Buller's albatrosses. Both species are listed as Endangered as a result of observed population decreases, although the Atlantic yellow-nosed albatross may require reclassification to Critically Endangered if threats do not abate.

The largest of the *Thalassarche* albatrosses are the shy *(T. cauta),* Salvin's *(T. salvini),* and Chatham *(T. eremita)* albatrosses, characterised by their deeper, yellow to grey bills, their predominantly pale underwings, and their relatively larger size. A white forehead and crown bordered by a dark eyebrow common to this group of birds presents them as looking rather stern! The Threatened status of these birds, which all breed exclusively in Australia and/or New Zealand, varies, the shy albatross listed as Near Threatened, Salvin's albatross as Vulnerable, and the Chatham albatross as Critically Endangered. Recent molecular and morphological information suggests that the Australian and New Zealand populations of shy albatrosses are distinct, and could represent separate species.

The remaining two species of albatross that traverse the Southern Ocean are the small and dark *Phoebetria* species, the sooty *(Phoebetria fusca)* and the light-mantled sooty albatross *(Phoebetria palpebrata).* The distribution of these two species differs, with sooty albatrosses being more restricted and also less numerous than the light-mantled sooty albatross, which has a circumpolar breeding distribution. As a result of available information on population trends, the light-mantled sooty albatross is listed as Near Threatened, while the sooty albatross is listed as Endangered. However, less is known about these species, compared with other albatrosses, and more contemporary population data may result in revision of their conservation status.

The remaining four species of albatross in the family Diomedeidae belong to the genus *Phoebastria.* The waved *(P. irrorata),* short-tailed *(P. albatrus),* Laysan *(P. immutabilis),* and black-footed albatross *(P. nigripes)* differ markedly in many elements of their appearance, biology, and behaviour. The waved albatross breeds only in the Galapagos Islands, whilst the Laysan and black-footed albatrosses are typically birds of the North Pacific Ocean, breeding on islands of the Hawaiian Leeward Archipelago and Japan. The short-tailed albatross is the biggest of the North Pacific species and is restricted to breeding on small isolated islands in Japan, principally the volcanic island of Torishima.

Distribution and Habitat Use

Albatrosses are among the most oceanic of all seabirds and, except whilst breeding, rarely approach land. Knowledge of the oceanic distribution of these birds has been derived in the past from at-sea surveys and returns of banding records. In more recent years, the ability to track albatrosses by satellite and archival geolocation tags has revolutionised our understanding of the incredible journeys that these birds undertake. Many species travel thousands of kilometres on trips between incubation shifts, or between feeding chicks. During the nonbreeding season, some species undertake complete circumnavigations of the Southern Ocean, one grey-headed albatross recently achieving this feat in just 46 days. While the high seas are the realm of many of these birds, they are consistently attracted to areas of the ocean that combine bathymetric and hydrographic features that provide important feeding areas. Some species show a propensity for aggregating in areas coinciding with frontal systems and mesoscale oceanographic features, whereas others, such as the shy albatross, forage preferentially in continental shelf and slope waters.

The diversity in foraging distributions of albatrosses is only recently becoming apparent as studies are able to compare not only different species during different phases of the breeding cycle, but also different sex and age classes and birds from different colonies. Understanding the oceanic distribution of these birds remains of considerable importance not only for identifying areas of overlap with environmental features but also with respect to elucidating overlap and interactions with fishing operations, and the recognition of areas can be incorporated in the identification of marine protected areas.

In the Southern Hemisphere, albatross breeding colonies are almost exclusively located on remote and windswept offshore islands between 37° and 57° S. The nesting habitats of these birds vary, with the larger great albatrosses nesting in dispersed groups on flat or gently sloping ground. The smaller *Thalassarche* albatrosses have a more varied nesting habitat that includes bare exposed rock flats and slopes, tussock slopes, or ledges on cliffs or steep slopes. Reflecting the variety of terrestrial habitats that these birds occupy, some species such as Buller's albatross nest in areas as diverse as meadows, tussock-covered slopes and cliffs, and under the canopy of forests. The two *Phoebetria* species nest on precarious ledges of steep cliffs, this habit perhaps explaining our relatively poor understanding of the life history of these species.

Life History

Albatrosses are characterised as having long life spans, low rates of natural mortality, high recruitment rates, and low productivity. Indeed it is their extreme life history traits that make them so vulnerable to influences that increase their natural levels of mortality. The breeding cycle of some of the great albatrosses is extremely long, extending over 12 months from nesting to chick fledgling, resulting in a biennial breeding pattern where breeding, if successful, can be attempted only every 2 years. Other smaller albatross species, such as shy and black-browed albatrosses, are able to breed in successive years, allowing an annual cycle. However, the *Phoebetria* species and some *Thalassarche* albatrosses are able to breed within a 12-month period yet breed only every 2 years.

All albatrosses lay a single egg, with southerly species constructing a large bowl-shaped nest and more tropical species laying in a simple scrape. The egg is incubated by both parents in alternating shifts for 6–12 weeks, after which the chick takes 3–9 months to fledge, depending on the species. Following fledging, albatrosses remain at sea for 3–5 years before returning to their natal island to breed. Albatrosses begin to breed at about 6–12 years of age, and generally retain the same partner between breeding attempts. Albatrosses are long lived, and have been known to breed when approaching 60 years of age. Life history models suggest that a few birds may live in excess of 80 years.

Diet and Trophic Interactions

Albatrosses are included among the oceans' top predators and scavengers. As with other Procellariiformes, albatrosses are characterised by having external tubular nostrils on the upper bill, these generally being associated with well-developed olfactory systems. An acute sense of smell is used by albatrosses to detect food, in addition to visual cues to detect prey and other predators. Most albatrosses are predominantly diurnal feeders, although some smaller species are also active at night, especially during periods of full moon. The larger albatross species are typically surface feeders, but the smaller species are able to dive several metres and actively propel themselves underwater. Albatrosses are generally described as being opportunistic feeders, their prey including squid, fish, and crustaceans. They are both active foragers, catching live prey, and also scavengers, taking advantage of dead prey and fishery offal, discards, and baits. Though albatrosses are generally solitary while searching for prey, when a rich food source is detected, multispecies flocks of hundreds of birds will congregate in efforts to obtain food.

It is this propensity to scavenge and congregate behind fishing vessels that threatens the survival of many albatross species today. The catastrophic population decreases recorded for albatross populations recently are mainly a consequence of incidental mortality in longline and trawl fisheries. More than 300,000 seabirds, including an estimated 100,000 albatrosses, are believed to be killed on longlines each year. Of the twenty-six species of seabird in danger of extinction because of the deaths caused by long-lining, seventeen species are albatrosses. Concerted and coordinated actions at both local and international levels are required to reverse the decrease and potential demise of these magnificent seabirds.

ALFRED WEGENER INSTITUTE FOR POLAR AND MARINE RESEARCH, GERMANY

The Alfred Wegener Institute for Polar and Marine Research (AWI) was established as a public foundation in 1980. It is a member of the Helmholtz Association of German Research Centers (HGF).

AWI is the national coordinator of German polar research activities. As an interdisciplinary scientific institution, AWI performs top-rate polar and marine research in strategic programmers of great complexity with large-scale facilities and infrastructure including the operation of mobile and stationary research platforms in the Arctic and Antarctic. It provides advice to the German government in Antarctic-related affairs.

Within the international organizations on polar and marine research, AWI represents the interests of German research institutions and the Federal Republic of Germany. It provides members for the international committees and organizations of the Antarctic Treaty System such as the Scientific Committee on Antarctic Research (SCAR), the Council of Managers of National Antarctic Programs (COMNAP), and others. Jörn Thiede, director of AWI, was elected as the president of SCAR for 2002–2006. AWI also holds membership in the European Polar Board (EPB), an associate committee of the European Science Foundation (ESF), the International Arctic Science Committee (IASC), the UN Intergovernmental Panel on Climate Change (IPCC), and other relevant organizations on Arctic research (AWI 2002; AWI 2004).

Several AWI scientists have had leading roles in past and present activities of international cooperative programs, including European Project on Ice Coring in Antarctica (EPICA), Climate Variability and Predictability (CLIVAR), Global Ocean Ecosystem Dynamics (GLOBEC), Joint Global Ocean Flux Studies (JGOFS), and others.

Since 1980, the main headquarters of AWI has been located in Bremerhaven. After the unification of Germany a newly established research facility in Potsdam became part of the institute in 1992. The Potsdam facility is primarily concerned with geoscientific studies in periglacial regions and with the investigation of atmospheric processes and climate in the polar regions. In 1998, AWI was enhanced by the integration of the Biologische Anstalt Helgoland

The major tool for AWI's marine research, the high-class ice-breaking research and supply vessel "RV Polarstern," commissioned in 1982. It calls the Atka Bay regularly to supply the German Antarctic research station "Neumayer." (Reference: AWI archive 2004)

(BAH), which included merging of the island facilities on Helgoland and on Sylt (Wadden Sea Station). Hence, research on the development and succession of living communities of coastal regions and the investigation of natural secondary products of marine organisms and of inputs of chemicals into the system form an additional focus at AWI.

As of 2005, AWI has 788 employees in Bremerhaven, Potsdam, and on the islands of Helgoland and Sylt. It operates on a budget of approximately 100 million euros and is funded jointly by the German Federal Ministry of Education and Research (90%), by the state of Bremen (8%), and by the states of Brandenburg and Schleswig-Holstein (1% each). External funds are applied for from the Deutsche Forschungsgemeinschaft (DFG), the framework programs of the European Union (EU), and other agencies.

AWI is an interdisciplinary scientific research institution with four departments: geosciences, biosciences, climate sciences, and new technologies. The research covers important components of the Earth system to investigate the oceans' role in global climate and to assess the role of polar regions within the Earth system. Observation and modeling focus on understanding naturally and anthropogenically driven processes of interaction between different compartments of the Earth system and their relevance in global processes with the aim to reduce present uncertainties in assessing future developments of global environmental changes induced by natural causes and human interference.

In this context, the fundamental database is composed of results from scientific investigations on recent variability of oceanographic and climatic processes, assessment of their changeableness in recent geological history, and the reconstruction of the long-term climatic history, which led to the formation of inland ice masses in previously comparatively warm polar regions of the Antarctic and Greenland. The wide spectrum of methods applied to pursue these research goals include modern satellite-based remote sensing as well as deep sea drilling and ice coring. AWI places particular emphasis on investigations of polar seas and their living biota. It undertakes terrestrial polar research and contributes significantly to atmospheric science, and to the paleoclimatic history of subpolar regions with permafrost.

Substantial services and infrastructures have been established such as logistic management of mobile and stationary research platforms, expedition store, laboratories, ice-core storage, aquarium, compute centre and databases networks, and library and electronic Publication Information Centre, as well as public relations department.

The high-class icebreaking research and supply vessel RV *Polarstern* is AWI's most powerful tool in all fields of marine research. Since 1982, it has been one of the most valuable polar research ships in the world. It traveled more than one million nautical miles and completed twenty-three Antarctic and twenty-one Arctic expeditions prior to 2006. Two aircraft Dornier 228-101 are used for scientific and logistic missions in the Arctic and Antarctic. Measurement techniques have been developed for glaciological, geophysical, and meteorological air-borne surveys. The permanently occupied stations in the Antarctic (Neumayer Station) and in the Arctic on Svalbard (Koldewey Station) are designed for long-term running of observatories. Summer-only stations are the Kohnen Station on the inland ice plateau of Dronning Maud Land and the Dallmann Laboratory on King George Island in the Antarctic and the Samoylov hut located in the Lena river delta in Siberia. The fleet of research vessels is completed by RV *Heincke,* facilitating marine investigations in regions from subpolar to tropical latitudes and by four small ships assigned to the island stations on Helgoland and Sylt.

The computer centre provides compute capacity for numerical models, integrated information systems including data storage, and retrieval systems for long-term archives of scientific data from expeditions and laboratories. As of 2006, 20 years of meteorological data from weather observations, radiosonde launches, and solar radiation measurements of the research ships and polar stations were available. Likewise, oceanographic data from flow meters and profile probes can be accessed. Aside from the data holdings of participating institutions there are additional data from over twenty-five national, European, and international projects available on a long-term basis. The Publishing Network for Geoscientific & Environmental Data (PANGAEA) is the platform for one of the few ICSU-approved World Data Centers (PANGAEA 2005). The Polarstern Data Acquisition System (PODAS) archives data collected during the RV *Polarstern* expeditions (PODAS 2005). To date the electronic Publication Information Centre (ePIC) of AWI has 10,700 records with some 7,100 AWI publications and 3,600 others such as posters, patents, and non-AWI publications (ePIC 2005). Any publication search at www.awi-bremerhaven.de will be processed by ePIC even providing the primary data and expeditions, which have been the basis to get the scientific results. State-of-the-art geographical information systems allow the production of charts and maps and the interpretation of geo-referenced data.

Currently, AWI has contractual agreements for scientific cooperation with scientific institution in twenty-three countries. Formal bilateral collaboration agreements for polar and marine research exist with sixty individual foreign research institutions.

On July 15, 1980, AWI was inaugurated and named after Alfred Wegener, an early prominent German polar researcher. He was an experienced explorer and died during his fourth Greenland expedition in 1930. Wegener was a geophysicist, meteorologist, and glaciologist and, in those capacities, not only a great research traveller and observer but also a distinguished theoretician. He developed the first in-depth ideas about the drifting of continents. Because his hypotheses appeared far-fetched at that time, his colleagues met him with hostility. It was not until the 1970s that Wegener's hypotheses were proven correct. In his capacity as expedition leader, Wegener was very highly respected as a person. He was the most appropriate candidate after whom to name Germany's largest polar research institution.

ALGAE

Algae are the most widespread and diverse photosynthetic organisms in the Antarctic terrestrial ecosystem. Currently, the term *algae* is often applied only to eukaryotic forms, that is, those with membrane-enclosed nuclei, chloroplasts, and mitochondria, to distinguish these from prokaryotic cyanobacteria (commonly known as "blue-green algae" or "blue-greens"), which have a much simpler cell structure. In this account both are regarded as algae as they share possession of chlorophyll and production of oxygen as a by-product of photosynthesis. Moreover, both have a major ecological role as primary producers. There are few habitats receiving light and having a sufficient supply of water and nutrient mineral salts in which the two forms do not co-occur. Algae are remarkably diverse and are the product of about nine distinct major evolutionary lineages. Fungi, plants, and animals have, by contrast, each emerged from a single lineage.

Algae grow in aquatic and nonaquatic habitats. The former includes lakes, ponds, and streams while the latter includes soils and rocks. In nonaquatic habitats, algae become more prominent in the vegetation as the environment becomes more challenging (e.g., with progression south from sub-Antarctic islands to continental Antarctica). However, in aquatic habitats, it is algae that usually dominate the biomass at all latitudes. While this account is about free-living forms, algae are also photosynthetic partners of fungi in the mutually beneficial symbiosis known as lichen in which they extend their range to habitats where otherwise they would be unsuccessful. For instance, only lichens grow on many exposed rock surfaces from sub- to continental Antarctica.

It is impossible to accurately estimate total species numbers of algae in Antarctica because there are few detailed studies of all habitats at localities covering the full latitudinal range. Many identifications are dubious and most have been made using floras produced for temperate regions. Algal taxonomy is undergoing considerable revision from the level of species to class, with increasing application of molecular genetics. An estimate of 700–1000 species in maritime and continental Antarctica might be reasonable while undoubtedly many more occur in sub-Antarctica. The following account focuses on the former regions.

In terms of biomass, blue-greens are dominant, especially at higher latitudes and in more extreme environments. Chlorophyta (green algae) can also be prominent. Among the Heterokontophyta, Bacillariophyceae (diatoms) are important especially in aquatic habitats while Xanthophyceae (yellow-green algae) are frequent in nonaquatic communities. Dinophyta (dinoflagellates), Cryptophyta (cryptophytes), Euglenophyta (euglenoids), and Chrysophyceae (golden algae) are of lower diversity, mostly as phytoplankton.

Algae in Aquatic Habitats

Communities vary greatly in species structure depending on prevailing physicochemical conditions. Lakes are waterbodies in which water is present all year, while ponds either freeze completely in winter or evaporate dry in summer. Streams flow for up to a few months over summer, then melt ceases and algae in stream beds become freeze-dried. The extreme high-amplitude fluctuations in pond and stream environments constrain species diversity compared with that in lakes. Chemical factors of importance in all habitats are availability of nutrients and concentrations of nonnutrient salts. In lakes, light is a significant influence. Light of different intensity and quality penetrates the water column depending on persistence and thickness of surface ice.

Aquatic communities are either periphyton or phytoplankton. The former attach to sediments, rocks, and aquatic vegetation while the latter are suspended in the water of lakes and ponds.

Mats of filamentous blue-greens are almost ubiquitous as periphyton in all aquatic habitats. Simple unbranched filaments of *Phormidium* spp. and *Leptolyngbya* spp. (order Oscillatoriales) are usually dominant while colonial unicells of *Aphanocapsa* sp. and filamentous *Nostoc* sp. can also be abundant. The latter is one of several Antarctic genera of blue-greens able to use elemental nitrogen as a nutrient by nitrogen-fixation in specialised cells termed heterocysts. Mats have varying abundance and diversity of associated diatoms, and unicellular and filamentous green and yellow-green algae.

Diatoms can be particularly diverse. For instance, 234 species have been recorded from freshwater lakes of the South Orkney and South Shetland Islands. However, in the closest known ponds to the South Pole, at La Gorce Mountains (86°30′ S), just one species, *Luticola muticopsis,* was found associated with thin mats dominated by one species of blue-green. Diatoms recovered from lake sediment cores are being used in palaeoecological studies (e.g., Roberts & McMinn 1997).

In streams, coherent mats usually cover much of the bed. However, where stones protrude through the mat, they are coated by black crusts of other blue-greens (e.g., unicellular, colonial *Gloeocapsa* spp. and filamentous *Schizothrix* sp. and *Calothrix* sp.). Unbranched filaments of green algae (e.g., *Binuclearia tectorum*), and yellow-green *Tribonema* sp. can be found trailing downstream from stones to which they are attached. Particularly in maritime Antarctica, stream beds can become covered by green filaments such as *Zygnema* sp. and *Mougeotia* sp. By contrast, in the dry valleys of southern Victoria Land, short narrow ribbons of the dominant green algae, *Prasiola calophylla,* verdantly encrust undersurfaces of stones where they are shaded from intense insolation. At the source of these streams, on meltwater irrigated terminal walls of glaciers, *P. calophylla* can be found caught around irregular protrusions of ice.

Phytoplankton communities are dominated by the smallest unicellular, colonial, and filamentous algae. Small size, ability to move using whiplike flagella, and nonspherical shapes all aid in keeping the organisms in suspension, especially in calm environments such as permanently ice-covered lakes (e.g., Lakes Fryxell and Vanda in southern Victoria Land). Species range from unicellular blue-green *Synechocystis* (1 μm diameter), through diverse unicellular phytoflagellates (e.g., the cryptophyte *Chroomonas lacustris,* the green *Pyramimonas* sp., and the chrysophycean *Ochromonas* sp.) and nonflagellate unicells (e.g., the green *Monoraphidium* and *Ankyra* sp.), to small colonial forms (e.g., the greens *Ankistrodesmus* sp. and *Scenedesmus* sp., which are a few tens of micrometres in diameter).

Certain lakes have particularly notable phytoplankton communities. Deep Lake at the Vestfold Hills never freezes due to its hypersaline waters. The sole phytoplankton is the green flagellate unicell *Dunaliella* sp. This swims even at a frigid winter temperature of –14°C. By contrast, different phytoplankton occupy different positions in the strongly vertically stratified waters of the permanently ice-covered lakes of southern Victoria Land. In Lake Fryxell, *Ochromonas* sp. inhabits cold, fresh, nutrient-poor but well-illuminated water just below the ice while *Chroomonas lacustris* and *Pyramimonas* sp. occur in deep, warmer, saline, nutrient-enriched but poorly illuminated conditions just above anoxic bottom waters. One study records twenty-eight species in the phytoplankton community (McKnight et al. 2000).

Various phytoflagellates (e.g., *Pyramimonas gelidicola, Ochromonas* sp., and *Cryptomonas* sp.) are able to supplement their nutrient and energy supplies by ingestion of particles of organic detritus, bacteria, and the smallest phytoplankton. This ability, in combination with photosynthesis, is termed mixotrophy. In Antarctica, this is beneficial in lakes where mineral nutrients are in low supply and when light is very dim or absent (e.g., in winter, when an alternative supply of organic carbon is needed to replace photosynthesis) (Laybourn-Parry et al. 2000).

Ponds are widespread, numerous, and highly diverse and almost all contain algae. Cryoconite ponds on melting surfaces of glaciers contain windblown mineral particles at the base of cylindrical melt-filled holes in the ice. They can be dominated by colonies of *Nostoc* sp. or contain a diversity of blue-greens and unicellular greens resembling communities in nearby soils. Ponds can cover extensive areas of ice shelves, for instance they extend over 1200 km^2 of the McMurdo Ice Shelf. Mat communities in these are dominated by nine species of blue-greens, six species of diatoms, and unidentified green unicells (Howard-Williams et al., 1990). Ponds in depressions in rocks and mineral soils usually contain mats similar to those on wet soils and close to lake shorelines. In and around penguin colonies, the highly nutrient-enriched waters often support dense populations of phytoplankton such as *Chlamydomonas* spp. and cryptophytes.

Algae in Nonaquatic Habitats

Mineral soils are widespread over ice-free regions. Extensive surface crusts and mats occur where there is a persistent melt-water supply in summer. Filamentous blue-greens *Phormidium* spp. and *Leptolyngbya* spp. are usually dominant. Mucilaginous colonies of *Nostoc commune* are also common. Within the mats are microscopic populations of green algae (e.g., unicellular *Chlorococcum* spp.), diatoms (e.g., *Luticola muticopsis* and *Hantzschia amphioxys*), and yellow-green algae (e.g., filamentous *Xanthonema* spp. and *Heterococcus* spp.).

Even at far south, high-latitude locations in La Gorce Mountains (86°30′ S, 148°00′ W, c. 2000 m altitude) bright green patches of the microscopic filamentous chlorophyte *Desmococcus* cf. *olivaceus* are visible at the interface between glacial ice and an overlying layer of fine-grained morainic detritus where this is just a few millimetres thick. Moisture to support growth is supplied by ice melt when the overlying dark mineral material is warmed by the sun to temperatures up to 7°C. Ambient summer air temperatures here are about –14°C. This is an example of the more general importance of solar heating in provision of a favourable microclimate.

Where water supply is even more restricted, algae are present as microscopic populations. An example is the soil in furrows around ice polygons in southern Victoria Land dry valleys. Here, microscopic populations of unicellular *Botrydiopsis* sp. persist in soil that is moistened by snowmelt, the snow having drifted into the depressions during rare summer snowfall. Even the most arid soils contain algae, which probably have little opportunity for growth but survive for long periods in a desiccated condition.

In the vicinity of bird and seal colonies the composition of soil algal communities reflects the greatly increased input of nitrogenous and phosphatic nutrients derived from the waste products of these marine animals. Luxuriantly green, sheetlike growths of the chlorophyte *Prasiola crispa* cover wet ground where it is not too disturbed by trampling. Although this marine influence occurs predominantly at coastal sites, for instance around penguin colonies, inland nunataks with nesting sites of petrels have the same algal communities. For instance, *P. crispa* is the most prominent alga at Robertskollen (Dronning Maud Land, 71°28′ S, 3°15′ W) despite it being about 130 km from the open sea.

Geothermal soils heated by volcanic activity are of very limited extent in Antarctica, being found close to the summits of three volcanoes in the Ross Sea region, on Deception Island in the South Shetland Islands, and on the South Sandwich Islands. They occur at altitudes up to 3700 m on Mount Erebus, Ross Island. At soil surface temperatures in excess of 35°C a thermophilic cyanobacterium, *Mastigocladus laminosus,* forms dark blue-green crusts. This species is a cosmopolitan thermophile and has probably been dispersed by wind to its isolated Antarctic habitats. At cooler temperatures species of unicellular green algae (*Chlorella* spp., *Coccomyxa* spp., *Bracteacoccus* sp.) dominate.

Soil algae have undoubtedly been transported to Antarctica by humans but whether they have colonised outside research stations is unknown (Broady & Smith 1994).

The living surfaces of bryophytes invariably support epiphytic populations of microscopic algae and small colonies of *Nostoc*. Black, green, and orange crusts of algae often develop over dead moss. Algae communities differ between moss communities. For instance, in the South Orkney Islands, moss turf supports a high abundance of the green unicell *Pseudococcomyxa simplex* while wetter moss carpets support a species rich community of blue-greens, diatoms, and green algae. Moss cushions provide a habitat for a limited flora of large unicellular green algae called desmids, with *Actinotaenium cucurbita* being the only species existing at 77° S in the southern Victoria Land dry valleys.

Algae are often associated with rock and stone surfaces. In moist conditions encrusting growths are visible (i.e., the communities are epilithic). In relatively humid maritime Antarctica crusts of cubical cell clusters of the green alga *Prasiococcus calcarius* form on sheltered faces of coastal rocks. In continental Antarctica, epilithic growths occur only where meltwater percolates over rock surfaces. Here, black crusts are dominated by unicellular, colonial blue-greens such as *Gloeocapsa* spp. The darkly pigmented mucilage coating the cells provides protection from intense insolation in summer and prolongs the period of cell hydration when the water supply ceases.

Where water supply is greatly restricted, algae retreat to hidden, so-called cryptic habitats, where traces of water can be retained. Although biomass is very low, algae in such niches dominate vegetation in the extensive cold deserts, as found in the dry valleys of southern Victoria Land and at the Vestfold Hills. It has been suggested that extraterrestrial life could be discovered in habitats similar to these.

The hypolithic habitat is provided by the undersurfaces of translucent stones, such as quartz. Where stones lie on top of the soil, light can penetrate to moist soil below, even if adjacent surface soil is extremely dry. Vivid crusts of green (e.g., *Desmococcus* spp. and *Prasiococcus calcarius*) and blue-green algae (e.g., *Leptolyngbya* sp. and unicellular *Chroococcidiopsis* sp.) coat the undersurfaces.

Algae and lichens can also exist within translucent rocks. Either they are chasmoendolithic, i.e. in narrow cracks penetrating the rock surface, or they are cryptoendolithic, i.e. in minute pores between rock crystals without obvious connection to the outside environment. Light penetrates a few millimetres and traces of moisture are held within the rock matrix. The algae are revealed only when thin flakes of rock are removed. At high altitude sites such as Linnaeus Terrace (1650 m), southern Victoria Land, the turnover time for cryptoendolithic biomass has been estimated to be about 10,000 years. Coastal communities tend to be dominated by the green alga *Desmococcus olivaceus* and *Prasiococcus calcarius* although also common are the blue-greens *Leptolyngbya* sp. and *Chroococcidiopsis* sp. At Linnaeus Terrace, lichen-dominated communities are most common but others are dominated by algae. The green unicellular *Hemichloris antarctica* occurs below overhanging rocks at intensities less than 0.01% of incident light. This is one of very few Antarctic endemic algae. Unicellular, colonial blue-green *Gloeocapsa* spp. grow in close proximity to the lichen-dominated community while *Chroococcidiopsis* sp. is rarely found in especially cold and dry habitats.

Snow algae occupy a very different habitat of ice crystals irrigated by meltwater. Microenvironmental temperatures do not, or barely, exceed 0°C. A small range of psychrophilic algae are able to grow vigorously enough to tint the snow a pinkish-red, green, yellow, or grey. Snow algae are most prominent in coastal regions of maritime Antarctica and the fringing lower latitudes of continental Antarctica. Their furthest south is at Ross Island (76°43′ S). They are absent from the vast majority of snow surfaces in Antarctica. Although most often sighted in the vicinity of nesting birds, snow distant from such nutrient sources can also contain visible populations. For instance, extensive grey snow at Windmill Islands is

ALGAL MATS

Algal mats are perhaps the most widespread microbial communities in Antarctica. They consist basically of a mesh of microscopic algal filaments embedded in their own mucilaginous sheaths, which in turn trap and bind sediment particles, providing shelter as well as nutrients to other algae, bacteria, heterotrophic microorganisms (flagellates, rhizopods, ciliates), and even metazoan (rotifers, tardigrades, and nematodes). Because of this structural complexity they are also referred to as *microbial mats*.

Many scientists use the term *cyanobacterial mats* on account of the almost invariably dominance of filamentous cyanobacteria ("blue-green algae"), most of which belong to the order Oscillatoriales (genera *Phormidium, Oscillatoria,* and *Leptolyngbya* among others). Commonly, nitrogen-fixing genera such as *Nostoc, Anabaena,* and *Nodularia* are also frequent. Diatoms, mainly represented by *Navicula muticopsis* and *Pinnularia borealis* can surpass cyanobacteria in species richness, but not in biomass. Green algae do not contribute substantially to algal mats except for a few nitrophilous species and the green mats dominated by macroscopic *Prasiola crispa.* Growth and development of algal mats also involves seasonal changes in species composition.

Algal mats thrive in a wide range of environments, from wet soils or constantly flushed ones, to the bottom of temporary pools and ephemeral runnels, to the channels of permanent rivers, to the edges and bottom of cryoconite holes and deep, permanently frozen lakes. In response to this wide spectrum of ecological conditions, they vary in thickness (from less than 4 mm to more than 3 cm), species composition, and colour. Differently coloured mats in one same area can represent distinct species compositions.

Well-lit algal mats from soils and shallow water bodies have a layered structure, with reddish upper layers formed by dead filaments or by a dense mesh of actively moving Oscillatoriales. These layers are rich in mucilage, sheath pigments, and carotenoids that provide the whole community with protection against desiccation and high irradiances. Lower layers are typically dark green and host a higher number of species, which includes cyanobacteria as well as diatoms and few green algae. They have high chlorophyll-*a* concentrations and generally display a higher photosynthetic activity. Algal mats from the dimly lit bottom of lakes have a photosynthetically active upper layer and an anoxic, heterotrophic low layer.

Resistance to desiccation and to high irradiance facilitates the colonization of suitable environments by algal mats. Often, the same species composition can be found in algal mats of lakes and the surrounding terrestrial areas, and between those mats covering the bottom of deep lakes and small cryoconite holes in the same area.

Daily mat production can be as high as 1 to 38 mg $C.m^{-2}.day^{-1}$, widely surpassing that of phytoplankton in the same lake. Moreover, algal mats can cover extensive areas of flushed soils at sites in continental Antarctica. On account of this, they are the main source of carbon fixation in a vast region of Antarctica. Therefore, algal mats can be regarded as very successful communities playing a key role in Antarctic ecosystems, and deserve close attention within the context of a changing environment.

AMSTERDAM ALBATROSS

The Amsterdam albatross *(Diomedea [exulans] amsterdamensis),* a member of the great albatrosses family Diomedeidae, is the rarest albatross of the Southern Hemisphere, breeding exclusively on Amsterdam Island (southern Indian Ocean, 37°50′ S, 77°32′ E). These birds were first mentioned in 1951, some 255 years after the island's discovery. The birds were described as a new species in 1983, but the taxonomy remains controversial. For example, some researchers suggest that Amsterdam albatrosses are a subspecies of the Wandering albatross *(D. exulans).*

Nevertheless, the great albatrosses evolved from a pelagic seabird species that originated in the Northern Tethys Sea approximately 54–38 Ma. These albatrosses then colonized the Southern Ocean, where several populations became isolated during the Pleistocene glaciations.

Adults (4.8–8 kg, males slightly larger than females) have an overall dark brown body and tail, with a lighter belly and white face and throat. Wings are brown on the dorsal side and white on the ventral side with black tips and trailing edges. The light pink bill has a black cutting edge to the upper mandible and a dusky tip. Plumage characteristics lighten with age, but juveniles and adults can be confused with certain populations of *D. exulans* (e.g., those from New Zealand).

Amsterdam albatrosses feed exclusively at sea upon fish and squids but their exact diet is unknown. During incubation, adults travel 200–1400 km per day (maximum distance of 2200 km from colony) making loops in a mostly northeast direction.

Males arrive on the Plateau des Tourbières (the only breeding ground, a peat bog of ~170 ha) in late January and build a conic nest using vegetal materials. When females arrive, partners exhibit spectacular displays including rare flight displays with vocalizations. Pairs bond for life. A single egg is laid in late February and both parents alternate incubation shifts (~7.5 days) before hatching occurs after 79 days, and brooding shifts (~2.5 days) until the chick becomes thermally independent (~28 days). The chick is then left alone and fed by both parents for another 7 months. Chicks depart alone in January–February and remain at sea for 4–8 years before returning to breed.

Breeding is biennial unless breeding failure occurs early. This strategy is associated with long life expectancy (at least 30–40 years), delayed first reproduction (7–10 years), high breeding success (71%–73%), and high adult survival (~96%).

Only 5–10 pairs bred each year in the 1980s and 15–20 during the late 1990s. The total population in 2005 totaled 120 to 150 birds. Prior breeding range and demographic simulations suggest that the population decreased before 1980, with the probable cause being mortality at sea resulting from bycatch in longlining fisheries. Breeding habitat was also threatened by introduced cattle until the French administration initiated efforts to protect it. Over the past 20 years, the population has increased by about 70%, suggesting that it may still be viable. However, recent discovery of avian cholera in the sympatric yellow-nosed albatross *(Thallassarche chlororynchos carteri)* represents a serious threat, as infection is already suspected. Amsterdam albatrosses are considered critically endangered by IUCN, with a high risk of extinction, based on their low population size and being a single-island endemic species.

AMSTERDAM ISLAND (ÎLE AMSTERDAM)

Amsterdam Island, in the southern Indian Ocean (37°50′ S, 77°32′ E), is one of the most isolated islands in the world. It is roughly oval in shape and covers 55 km^2. It is entirely volcanic in origin and numerous cones have been created during the last century. Steep cliffs (30–60 m) skirt most of the coastline, those at the west being up to 700 m high. The eastern part of the island slopes gently up from the sea to the central plateau (an old caldera) where it rises to 881 m (Mont de la Dives). Another small volcanic island, St. Paul Island (38°43′ S, 77°30′ E), 8 km^2 in area, lies 89 km to the south.

The location of Amsterdam Island, north of the subtropical convergence, strongly influences its climate: Mean annual air temperature is 13.8°C (11.2°C in August, 17.0°C in February), and annual rainfall is about 1127 mm per year, according to Météo-France records for 1951–1996. This oceanic and mild climate at the sea level changes in higher altitudes where the conditions are similar to those observed in the sub-Antarctic islands. There is no river or lake, only small ponds in the mires on the high plateau. The lowland remains very dry, especially during summer, and several fires occurred in the past.

Lowland slopes to 250 m are dominated by meadows of tussock grass *Poa novarae*. Dense grasslands of sedges *Scirpus nodosus* and *Spartina arundinacea* occur to about 600 m. At higher altitude, vegetation comprises feldmark of dwarf shrub *(Acaena magellanica),* sphagnum bogs, and mosses. Near the coast, the vegetation has been deeply modified by cattle *(Bos taurus),* introduced on the island in 1871. Introduced plant species have been favoured by grazing, and the formerly widespread tree *Phylica nitida,* up to 7 m high, and ferns, were recently restricted to few sheltered areas.

Moseley's rockhopper penguin *(Eudyptes chrysocome moseleyi),* yellow-nosed albatross (*Diomedea chlororhynchos bassi,* 37,000 pairs, 80% of the world population), sooty albatross *(Phoebetria fusca),* and the rare endemic Amsterdam albatross (*Diomedea amsterdamensis,* less than fifty breeding pairs) are the main breeding bird species. Amsterdam Island fur seal *(Arctocephalus tropicalis)* breed on the island (population of about 35,000 adults), and southern elephant seal *(Mirounga leonina)* occurs as nonbreeder. Introduced mammals are widespread: cattle, Norwegian rats, mice, and cats.

In 1988, a management plan was developed to reduce the effect of grazing on soil erosion, plant disturbance, and threats to birds, namely to the Amsterdam albatross. Fences have been erected and cattle from the southern part of the island were removed. In addition, more than 7,000 *Phylica nitida* have been planted. Whereas restoration processes are slow in the most eroded areas, vegetation close to the original one, without alien species, is now established at the south of the island.

Amsterdam Island was discovered by Sebastian del Cano (on one of Magellan's ships) in 1522, but was not landed on until 1696 by Van Vlaming. It was claimed by France in July 1843. The permanent scientific and meteorological station Martin de Viviès has been continuously operated by the Terres Australes et Antarctiques Françaises since 1951. It hosts about twenty people in winter and forty in summer. The crayfish industry operates around Amsterdam and St. Paul Islands.

AMUNDSEN, ROALD

Roald Engelbregt Gravning Amundsen was born in Hvidsten, southeast Norway, July 16, 1872, and he died June 18, 1928, when his plane disappeared into the sea off Bjørnøya, Svalbard. He made his career and his name within polar exploration and logistics, and he is assessed today as one of the most successful of polar travellers.

Amundsen stated that he decided to become a polar explorer when reading Sir John Franklin's books at the age of 15. At 17 he was in the crowd that turned out to honour Fridtjof Nansen on his return from the first crossing of Greenland, and this experience sharpened his resolve. His mother wanted him to become a doctor, and it was only after her death in 1893 that he could devote his time to his own choice of career.

In addition to the hard physical training in which he had already engaged, including skiing and swimming, he worked on an Arctic sealer in 1894. Expeditions to the Arctic or Antarctic at that time usually included a voyage by ship, and Amundsen read enough reports to understand that there could be problems when the expedition leader had to relate to a ship's captain. He therefore took his first mate's and captain's certificates in order to secure full control of his future expeditions.

In the summer of 1896, he was chosen as an unpaid able seaman and ski expert for the Belgian Antarctic Expedition on the *Belgica*. Appropriate participants were not easy to find, and Amundsen was promoted to second mate before departure. During the expedition he gained his first significant experience in the polar regions, with expedition doctor Frederick Cook as his mentor. They tested various types of equipment, such as sleeping bags, tents, and sledges, and they proved the effect of seals and penguins as a protection and cure for scurvy. Amundsen learned about survival techniques and leadership, and took his first ski trip on the Antarctic continent.

Amundsen was no scientist; he sought geographical conquests. However, he understood that sponsors and the public wanted scientific façades for expeditions, and he therefore equipped his own first expedition to determine the current position of the North Magnetic Pole. However, the real goal was the first complete navigation of the Northwest Passage, which was accomplished 1903–1906 on the *Gjøa*. During the expedition's almost two-year stay on King William Island, Amundsen learned from the Inuit many details with regard to successful polar travel, including dogsled driving, clothing, food, and igloo-building techniques.

The North Pole was Amundsen's next great polar goal, and he declared his second expedition to be a repeat and extension of Nansen's drift over the Arctic Basin in the *Fram*. News that both Frederick Cook and Robert E. Peary claimed to have reached the North Pole took away Amundsen's inducement to go north, and his attention turned to another great goal—the South Pole. He kept his change of plans secret until the last moment, thereby committing himself, his reputation, and his future career to getting there first. He believed that failure in any way, including arriving second to Robert Falcon Scott, would leave him as a cad who had unsuccessfully tried to perform a dirty trick. Accusations and hurt feelings, on the other hand, would drown under the acclamation of a tremendous feat.

Amundsen's 1910–1912 Antarctic expedition was a model of polar logistics and planning. He and four companions reached the South Pole on December 14, 1911, a month before Scott, and returned to his base camp at the Bay of Whales with scarcely any problems to report.

On the personal side Amundsen was less successful. He needed to be the absolute leader, and could not tolerate real or imagined criticism from his men. When Nansen's companion from the Arctic, Hjalmar Johansen, challenged his leadership, Amundsen removed Johansen from the Pole group and assured that he arrived back in Norway in disgrace. During the *Belgica* expedition's forced wintering in Antarctica, Amundsen had removed himself from the expedition over a slight he felt he had received from the leader. However, he informed expedition leader Adrein de Gerlache that he would stay with the group until they reached civilisation again!

World War I represented a time change in many ways, not least concerning transport methods, and Amundsen was quick to see that aircraft could revolutionise polar exploration. He bought one of the first planes to reach Norway, and he took the country's first civil pilot's licence, in September 1915. The plane, however, was quickly donated to the military. Amundsen's expedition on the *Maud,* 1918–1925, was to be the North Pole expedition to which he had previously committed himself. It was successful in obtaining important scientific results, but Amundsen left it in 1922 when it became obvious that ships were no longer the right transport method for his ambitions. He had on the way completed a navigation of the Northeast Passage, the third in history, thus making him the first to circumnavigate the Arctic.

Amundsen's last expeditions were all with aircraft in the Arctic. In 1923, on the Alaskan coast, his plane was damaged before a planned flight over the Arctic Ocean was realised. In 1925, he flew with Lincoln Ellsworth, Hjalmar Riiser-Larsen, and three others from Svalbard to 87°43′ N in two aircraft, *N24* and *N25*. The following year the Amundsen-Ellsworth-Nobile Transpolar Flight in the dirigible *Norge* flew over the North Pole while travelling from Svalbard to Alaska. Amundsen thus became the first person to have been at both Poles.

Amundsen was now 55 years old, unmarried, with constant financial problems and with a bitter tendency to fall out with his nearest associates. He had been almost unsurpassed as a polar explorer and expedition leader with the traditional methods of skis and dogsleds, but the modern means of transport made him more of a passenger than a dynamic leader. When Umberto Nobile crashed on the ice with his dirigible *Italia* in 1928, Amundsen rose to the occasion and set out to look for him in a French aircraft with five others. They disappeared into the Arctic, and only two pieces of the plane were ever found.

Amundsen was decorated by many countries for his feats as a polar explorer, and numerous book and films have been produced about his life.

AMUNDSEN-SCOTT STATION

Amundsen-Scott Station is the year-round United States research facility at the geographic South Pole. The station has been operated and occupied continuously since 1956.

When a US Navy ski-equipped R4D airplane landed at the site on October 31, 1956, to begin construction, it brought the only humans to have reached the surface there since Norwegian and UK parties led by Roald Amundsen and Robert F. Scott first attained the Pole in 1911 and 1912. (Richard E. Byrd of the United States flew over the South Pole, but did not land, on November 29, 1929.)

The 1956 arrival—a flight from McMurdo Station, on the Antarctic coast—marked the start of building a research station for the 1957–1958 International Geophysical Year. The first winter of occupation, 1957, nine support personnel and nine scientists conducted meteorology, seismology, glaciology, and ionospheric and auroral studies.

The IGY station, most of it beneath the surface of the snow, was operated until 1975, when new structures sheltered under a geodesic dome on the surface replaced it. The dome facility was designed to last about 25 years. Construction of yet a third central station facility—this one on stilts to prevent buildup of drifted snow—began in the 1990s with completion scheduled for 2007.

The 2005 winter population was 86, and the 2004–2005 summer season population peaked at more than 220. Some of these occupants were building the new station, which, when completed, is intended to accommodate 50 in winter and 150 in summer. As at other US facilities in Antarctica, most residents were Americans with grants for research or employed by US contractors for science support or construction. But a substantial number were scientists from other Antarctic Treaty nations working with US counterparts on cooperative research projects.

The Antarctic Plateau is a uniquely valuable location for astrophysics, climatology, glaciology, seismology, and other sciences. The extremely cold and dry atmosphere is transparent and dark throughout the infrared and millimeter wavelengths, making the South Pole one of the world's best places for telescope observing in those spectra. The station's location at the Earth's axis of rotation enables continuous observation of celestial bodies for weeks at a time, unaffected by the 24-hour rise-and-set interruptions of lower latitudes.

The air at the South Pole is some of the cleanest air on Earth, and yet daily sampling of it since 1957 has recorded, in trace amounts, the gradual global buildup of chlorinated fluorocarbons, lead from leaded gasoline, and other anthropogenic chemicals. This monitoring has helped scientists build the baseline against which to understand atmospheric trends in temperate latitudes nearer the sources of these substances.

The ice sheet itself is used as a detector of neutrinos. Originating in some of the farthest reaches of space and thus recording some of the earliest moments of the universe, these high-energy particles nearly always pass through substances unimpeded and unnoticed. On rare occasion, however, neutrinos interact with water or ice molecules. Scientists have buried photomultiplier tubes deep in the ice beneath the station to detect these interactions. An initial group of detectors proved the concept in the 1990s; starting in 2000, an additional array of detecting tubes was being designed and installed to instrument an entire cubic kilometer of ice with 4,800 photomultipliers. The project, called IceCube, was the largest research project at the South Pole and projected to cost nearly $300 million over its first 13 years of construction and operation. The project was expected to open unexplored bands of the electromagnetic spectrum for astronomy.

Other new facilities for astronomy and astrophysics include a 10-meter telescope being built in the 2000s to investigate properties of the dark energy that pervades the universe and accelerates its expansion, to constrain the mass of the neutrino, to search for the signature of primordial gravitational waves, and to test models of the origin of the universe.

Other research at Amundsen-Scott has included seismology to detect and characterize earthquakes worldwide, climate monitoring, ozone-hole studies, glaciology including ice core drilling for study of past climates, detection of microscopic life in the ice, and medical and psychological study of the human response to the cold, the high altitude, the long absence of sunlight in winter, and the annual 8½-month isolation in a remote yet confined environment.

To optimize the science, Amundsen-Scott South Pole Station and its surroundings are divided into sectors, each having an environment best for specific activities. The operations sector houses the main station and general operations. The clean air sector is upwind of the station for sampling pristine air and snow for climate research. The quiet sector limits noise and use of equipment to enable seismology and other vibration-sensitive pursuits. The radio frequency sector is reserved for communications equipment. The downwind sector, free from obstructions, is for balloon launches and aircraft operations. The dark sector is for astrophysics and is free of light pollution and electromagnetic noise.

The station is on the central Antarctic Plateau at an elevation of 2935 meters, which happens to be about the same thickness as the snow, firn, and ice on which it rests, making the nearest land almost 2 miles away—straight down. The ice is moving in the general direction of South America at about 10 meters a year; an annual ceremony is the setting of a new marker on the snow surface showing the exact location of the geographic South Pole—90°00′00″ S latitude. The extreme cold suppresses the atmospheric pressure, sometimes making the elevation seem like as much as 4000 meters. The ice plateau is featureless except for sastrugi to the horizon. Winter low temperature has reached –82.8°C, and the record high in summer was –13.6°C. Unlike Antarctica's coasts, the station does not get strong breezes; the wind averages 5.5 meters per second and has never exceeded 24 meters per second.

The South Pole is supplied entirely from the coastal station McMurdo during the 100 or so days of summer when outdoor operations are practical. Ever since the South Pole station was opened in 1956, airlift has been the sole method of transporting people and supplies over the 838 miles of ice and mountains. In the early 2000s, oversnow traverse equipment was being tested to carry cargo and fuel and perhaps relieve some of the demand on airlift.

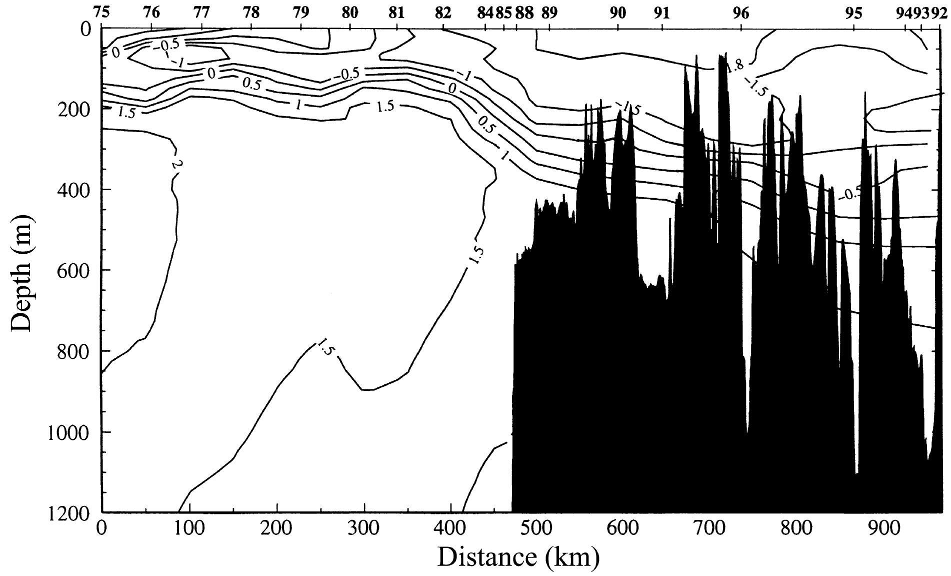
AMUNDSEN SEA, OCEANOGRAPHY OF

The Amundsen Sea lies off the coast of Marie Byrd Land between Cape Dart on Siple Island (126°09′ W) and Cape Flying Fish on Thurston Island (102°29′ W). Its northern limit is undefined, and in some studies its western boundary is extended toward the Ross Sea at Cape Colbeck (157°54′ W). Named for Roald Amundsen, who almost reached it while drifting westward on the *Belgica* in March 1899, the region was first visited by the *Resolution,* on which Captain Cook achieved his highest southern latitude, at 71°10′ S, 106°54′ W. On January 30, 1774, he wrote: "The outer or Northern edge of this immense ice field was composed of loose or broken ice so closely packed together that nothing could enter it; about a Mile in began the firm ice, in one compact solid body, and seemed to increase in height as you traced it to the South; In this field we counted Ninety Seven Ice Hills or Mountains, many of them vastly large.... We could not proceed one inch farther South...." The Amundsen Sea has since been visited by US expeditions in 1839, 1939–1941, 1946–1947, 1961, and several times during the 1985–2000 period, and by Norwegian, German, and British expeditions in 1929, 1994, and 2003.

Nearly perennial sea ice, often held fast by numerous grounded icebergs, continues to complicate travel and research in the Amundsen Sea. The extent and concentration of the sea ice cover has been monitored by satellites since the early 1970s, and the state of its ice shelves since the 1990s. Its sea-floor characteristics and ocean and sea-ice properties are slowly being revealed by work from research icebreakers that began in the 1990s. Biological observations indicate patchy areas of high productivity at all trophic levels. Regional applications of a circumpolar ocean model,



A vertical temperature section in the eastern Amundsen Sea extending from ~66.5° S (left) to ~74.5° S (right) between 101.3° W and 103.5° W. South of ocean station 89, this traverse encountered the rugged bottom topography of the eastern and southern continental shelf in Pine Island Bay. The waters warmer than 0°C that blanket the deep floor of the shelf here are common throughout the Southeast Pacific sector, unlike the colder waters that characterize shelf regions from the Ross westward through the Weddell Sea. (Modified from a figure by Hellmer et al. in Antarctic Research Series Vol 75, 1998.)

driven by realistic atmospheric forcing, are broadly consistent with ocean measurements. Refinements await more accurate bathymetry, more *in situ* meteorological data, and higher model resolution.

The Amundsen Sea continental shelf broadens westward, from approximately 200 km around Thurston Island and under the Abbot Ice Shelf to more than 500 km along 104° W past the King and Canisteo peninsulas and under the Pine Island Glacier. It then narrows to approximately 200 km near 120° W around Carney Island and to close to 100 km near 135° W, beyond the western end of the Getz Ice Shelf. Minimal bottom relief occurs at its 400–700 m deep outer limits, but broad sills deepen southward into very rough troughs, some exceeding 1500 m depths near ice shelf calving fronts. These troughs were cut by grounded glaciers during past ice ages and contain a variety of geomorphological features ranging from subtle lineations to hundred-meter scale topography. Large islands appear to anchor the northern edges of the lengthy Abbot and Getz ice shelves, while numerous small islands populate areas on the southeastern shelf and near Siple Island, often masquerading as icebergs, or vice versa. Bathymetry is unknown under the ice shelves, which currently occupy up to 25% of the continental shelf area.

Studies of the sea-ice cover using satellite data have typically grouped the Amundsen and Bellingshausen seas, covering the sector from 60° to 130° W. The sea ice displays a later summer minimum than in the Ross or Weddell seas, and a negative trend in ice extent over the three-decade record. Fast ice is more common than are polynyas, which tend to be small and intermittent during winter near the coastline. Satellite feature tracking and modeling of ice drift indicates that a large percentage of the sea ice formed in the southern Amundsen is exported to the Ross Sea, while a large fraction of the sea ice found in the northern Amundsen has been imported from the Ross. Sea-ice drifters set near the continental shelf break in the eastern Amundsen have tracked generally westward over the outer shelf, slope, and rise for periods of 8–16 months. A giant iceberg from the Thwaites Glacier Tongue followed a similar westward path after being grounded for decades on the shelf, then drifted north and east via the Antarctic Circumpolar Current through the Drake Passage.

Ocean properties on the Amundsen Sea continental shelf are transitional between those on the slightly warmer Bellingshausen and the markedly colder and saltier Ross continental shelves. Relatively warm and salty Circumpolar Deep Water intrudes near the sea floor, and is particularly noticeable in Pine Island Bay on the eastern shelf. More than 3°C above the *in situ* melting point, this inflow fuels melting deep beneath the regional ice shelves and glacier tongues, resulting in the upwelling of meltwater along the coastline. In some locations glacier basal melt rates appear to be two orders of magnitude higher than beneath the largest Antarctic ice shelves, and such rapid melting may account for local ice shelf thinning and faster offshore flow of grounded ice. It also influences the local sea-ice cover and could contribute to observed freshening downstream in the Ross Sea. Melting is inferred from measurements of ocean temperature, salinity, helium, neon, dissolved oxygen, and oxygen isotopes and from considerations of glacial mass balance, while thinning is inferred from airborne and satellite altimetry.

The continental shelves of the Amundsen and Bellingshausen seas differ from the other large embayments around Antarctica by the general absence of cold, dense shelf waters. Shelf water production is damped by the southeasterlies that tend to move sea ice more along than away from the coastline, while brine production is limited by the thick ice and snow cover and countered by the melt-driven upwelling. Surface waters on the shelf are generally too light to be overturned to the sea floor, or to mix readily with deep water to form new bottom water. This situation evolves westward as a shelf break frontal region strengthens toward the Ross Sea where recently "ventilated" waters appear to descend along the continental slope.

Seaward of the continental slope and rise, the Ross Gyre extends to 130°–150° W, east of which the Antarctic Circumpolar Current expands southeast toward the continental shelf. That current then tracks eastward into the Bellingshausen Sea, moving faster than the westward drifts on the shelf to its south. The deep Amundsen Sea is thus similar to that in other sectors, dominated by the voluminous Circumpolar Deep Water sandwiched between the more seasonally variable Antarctic Surface Water and the Antarctic Bottom Water that has been generated elsewhere. Incursions of the Circumpolar Deep Water onto the adjacent continental shelf and its spatial and temporal variability in response to climate change are topics of current interest. The properties and circulation of this water, and its influence on ice shelf extent and thickness, could have implications for discharge from the West Antarctic Ice Sheet.

ANARE/AUSTRALIAN ANTARCTIC DIVISION

Exploration, exploitation, and science are inextricably linked, factors particularly true of Australia in Antarctica, which led to the establishment of the Australian National Antarctic Research Expeditions (ANARE) and the Australian Antarctic Division (AAD). In the early nineteenth century, Australia's proximity to the Southern Ocean, the sub-Antarctic islands, and Antarctica led ships to use the ports of Sydney and Hobart as a springboard for Antarctic exploration and in pursuit of whales and seals.

Throughout the 1800s, scientists in Australia, aided by the Royal Societies of the colonies, attempted to establish Antarctic committees to organize expeditions. Those that were organized, such as the proposed Swedish-Australian Antarctic Expedition, were doomed to failure due to lack of financial support, especially from governments. Henrick Bull and Carsten Borchgrevink, residents of Australia, were involved in the *Antarctic* expedition, and Louis Bernacchi, a Tasmanian physicist, accompanied Borchgrevink on his later *Southern Cross* expedition. The Australian government gave financial support to Robert Falcon Scott's 1901–1904 and Ernest

Shackleton's 1907–1909 expeditions, and a number of Australians accompanied these expeditions as well as Scott's 1910–1913 expedition.

Sir Douglas Mawson and Captain John King Davis gained valuable polar experience with Shackleton. They organized and led the Australasian Antarctic Expedition 1911–1914. This expedition of science and discovery was judged by its scale and achievements to be the greatest and most consummate of the era. Increasing national interests and whaling, especially by Norway, saw Mawson and Davis, supported by the British, Australian, and New Zealand governments, conduct two summer voyages in 1929–1930 and 1930–1931. The British, Australian, New Zealand Antarctic Research Expedition (BANZARE) traversed the coastline from 45° to 160° E, making landings and aircraft flights, and proclaiming lands to be British Territory.

A British Order-in-Council dated February 7, 1933, affirmed sovereign rights over the Antarctic territory and placed the region under control of the Commonwealth of Australia. The Australian Antarctic Territory Acceptance Bill 1933 received assent in June 1933 and came into operation three years later. During debate three reasons were given for the Act: territorial/strategic, economic potential, and long-range weather forecasting. As other nations' interests in Antarctica and whaling increased, it became obvious that effective occupation was necessary to preserve Australia's claims. Mawson put forward further proposals for scientific and exploratory expeditions, but these were all put on hold during World War II.

Cessation of hostilities in 1945 saw the resurgence of national interests in Antarctica, including whaling and Byrd's Operation Highjump. These, combined with Mawson's lobbying for an expedition, put further political pressure on the Australian government. On December 2, 1946, an interdepartmental committee was convened by the Department of External Affairs. It recommended to government that preliminary plans be drawn up for an expedition. The *Wyatt Earp,* Sir Hubert Wilkins' old vessel now owned by the Australian government, would be refitted and operated by the navy to find a suitable site for a base on the Antarctic Continent. On December 20, 1946, an announcement was made that a short reconnaissance voyage would be made to Antarctica.

The Executive Committee on Exploration and Exploitation was then formed. As it met, support for establishing meteorological stations at Macquarie Island and other islands in the South Indian Ocean came from the International Meteorological Organization. The Royal Australian Air Force (RAAF) commenced long-range reconnaissance flights over Macquarie Island and the Southern Ocean. In May 1947, Group Captain Stuart Campbell, who had been a pilot on BANZARE, was chosen as executive officer and leader of the expedition by an Executive Planning Committee which included Mawson and Davis, £150,000 was appropriated, and plans firmed for two island stations to be established with around twelve scientists and support personnel at each. Pressure for a Heard Island station came from Britain because of disputed territorial claims. Commander Carl Oom, another veteran of BANZARE, was selected to captain the *Wyatt Earp.* A second ship, a tank-landing LST 3501 *(HMAS Labuan),* was under the command of Lieutenant-Commander George Dixon.

July saw scientific equipment being purchased, and Phillip Law, a lecturer in physics at Melbourne University, chosen as senior scientific officer. He commenced to establish a science program. Shortly afterwards, the official title—Australian National Antarctic Research Expedition (ANARE)—was adopted; "expedition" became plural later. ANARE was attached administratively to the Department of External Affairs and represented all government agencies as well as the nongovernment organizations, including Australian universities and research institutions, foreign organizations, and commercial shipping and aviation firms. As well as having scientific and exploratory aims, it was to maintain Australian interests in Antarctica. Prime Minister Joseph Chifley announced the expedition on November 6, 1947.

The Heard Island expedition station was opened at Atlas Cove (53°05′ S, 73°30′ E) on December 26, 1947, and a station was opened on Macquarie Island (54°30′ S, 158°57′ E) on March 21, 1948 (this station still operates today). *Wyatt Earp* failed to reach the Antarctic continent because of the unsuitability of the ship, ice, and the lateness of the season.

In May 1948, the AAD was established as part of the Department of External Affairs and Stuart Campbell was made officer-in-charge and tasked with administering the Australian Antarctic Territory and the Territory of Heard and McDonald Islands (Macquarie Island is under the administration of Tasmania), providing logistic support for ANARE, and conducting research in a number of disciplines. Campbell returned to the Department of Civil Aviation in January 1949, and Phillip Law became officer-in-charge of the AAD. The position later became titled "director." Law presided over the fledgling organizations in an era of discovery and expansion of both stations and science.

The launching of the Danish ice-strengthened ship *Kista Dan* in 1952, chartered by the AAD in austral summer 1953–1954, facilitated the opening of the continental station in Mac.Robertson Land, Mawson

(67°36′ S 62°52′ E), on February 13, 1954. Mawson Station is named after Sir Douglas Mawson, a fitting tribute to his lifetime of Antarctic exploration and science and his advocacy of Australia's interests. The station is the oldest continuously operated one inside the Antarctic Circle. Heard Island Station was closed in March 1955, and has been reoccupied by a wintering group only once, in 1992; a number of summer expeditions have gone to the islands over the past 30 years.

Activity of the Soviets and the proposals from a number of nations to establish research stations in Antarctica for the International Geographical Year (IGY) 1957–1958 led to the opening of Davis Station (68°35′ S, 77°58′ E) in the Vestfold Hills on January 13, 1957. Davis was closed in January 1965 while a replacement station was being built for Wilkes. Davis reopened in January 1969, as did the new Casey Station (66°17′ S, 110°32′ E), near the US IGY Wilkes station, which had been placed under Australian custody in 1959. Casey Station continues to operate today although at a different site as a new Casey was opened in 1988. The naming of Casey after Lord Casey commemorated a public servant and politician who had done much for Australia's Antarctic interest in the 1920s and 1930s, was Minister of External Affairs when Mawson Station was established, and signed the Antarctic Treaty on behalf of Australia.

Major field traverses by dog sleds or tractors have included Wilkes to Vostok in 1962, Mawson to Southern Prince Charles Mountains and Enderby Land, Mawson to Amery Ice Shelf (where four men wintered in 1968), and Mawson to Davis around the Lambert Glacier basin in 1993–1994 and return to Mawson in 1994–1995. Numerous field camps were established in the Prince Charles Mountains, Enderby Land, Cape Denison, Scullin Monolith, and Gaussberg and on the Law Dome near Casey, a glaciological drilling site. In the 1980s, additional bases included Edgeworth David in the Bunger Hills, Law in the Larsemann Hills, and Dovers in the Northern Prince Charles Mountains. Since 1980–1981, an active marine science program has been supported during summer.

The initial ANARE scientific program expanded as universities collaborated with the AAD, which became the lead agency for Antarctic marine living resources, biology, glaciology, human impact, human biology and medicine, and cosmic ray physics. Other government agencies led atmospheric sciences, geosciences, and oceanography. Traditional disciplinary science has become multidisciplinary, with scientists from many organizations, including specific Antarctic cooperative research centers, all now focusing on priority areas of ice, ocean, atmosphere and climate, Southern Ocean ecosystems, and adaptation to environmental change. Science on ANARE was reduced in the 1960s and 1970s as old stations were rebuilt, Davis closed, and the Prince Charles Mountain surveys deferred.

From its inception, the AAD has advanced Australia's Antarctic interests with its significant research program. Equally important has been its presence in, and administration of, Australian Antarctic and sub-Antarctic territories. A director and four branch heads in Science, Operations, Policy Coordination, and Corporate, together with a staff of over 300, maintain four stations, manage and conduct the research, and provide logistics and transport. Having had a significant role in establishing the Antarctic Treaty, Australia through the AAD continues an important role in maintaining it, by supporting Australia's international obligations with respect to Antarctica. There is close liaison between the division and other government departments, state governments, universities, and international polar agencies, and bodies such as the Scientific Committee on Antarctic Research (SCAR) and the Council of Managers of National Antarctic Programs (COMNAP). The AAD's current vision is "Antarctica valued, protected and understood."

The stations from 1947 to 2004 have had over 200 station years and 3,000 persons wintering in over 4,000 positions; some personnel have spent up to ten winters in Antarctica. Women first traveled on ANARE in 1959, wintering for the first time at Macquarie Island in 1976 and on the continent in 1981. Summer populations are greater than winter populations. Changing scientific and building programs required the ice-strengthened ships *Nella Dan* and *Thala Dan* to be replaced in 1984 by a larger one, the *Icebird,* and the icebreaker *Aurora Australia* in 1989. This enabled more personnel to travel south. Aircraft have been used extensively by ANARE in Antarctica but not from Australia; RAAF flights of the 1950s were replaced by commercial companies and a wide range of aircraft in the 1960s and thereafter. Newer aircraft will commence in the 2004–2005 summer, flying between the stations and field locations. After a number of attempts over many years to provide an intercontinental service, trial flights between Hobart and Casey Station are scheduled to begin in the summer of 2006–2007 as a prelude to regularly scheduled flights the next summer.

In the 57 years of ANARE, the AAD has been part of a plethora of departments; initially with the Department of External Affairs, it has moved through the supply, science, and environment portfolios to its current parent, the Department of Environment and Heritage. As with most organizations totally dependent on government funding, the formulation of government policy depends to a large degree on the Minister and Secretary of the parent department and the director of the AAD, and their interaction; in the case of Antarctica, world politics such as the advent of the Antarctic Treaty has been another potent factor. Although a strong supporter of the Antarctic Treaty, Australia has still exerted the right to change its stance against the majority of Consultative Parties when personal and domestic views deemed it necessary. This was particularly true in the late 1980s with the adoption of the Convention on the Regulation of Antarctic Mineral Resources (CRAMRA) by the Antarctic Treaty Consultative Parties and subsequent reversal of policy by Australia as to signing, and the subsequent substitution with the Protocol on Environmental Protection to the Antarctic Treaty (the Madrid Protocol).

The complex interaction of persons, politics, and policy on the domestic front is illustrated by the 1981 move of the AAD from Melbourne to Kingston, a suburb of Hobart, 10 years after the move was announced. Stuart Campbell was executive officer of ANARE and officer-in-charge of AAD 1947–1949 with the following succeeding him: 1949–1966, Phillip Law; 1966–1970 and 1971–1972, Don Styles (acting); 1970–1971, Bryan Rofe; 1972–1979, Ray Garrod; 1979–1984, Clarrie McCue; 1984–1988, Jim Bleasel; 1988–1998, Rex Moncur; and 1998 to present, Tony Press. Each director influenced the AAD and ANARE in his own way.

Despite the evolution in science, technology, priorities, and personnel, the concept of ANARE—embracing the activities of government and nongovernment bodies and individuals, whether scientists or support, in Antarctica—and its relationship with the AAD are still relevant today. Attempts to remove ANARE from the vernacular have been unsuccessful thus far. As Australian science and exploration in Antarctica approaches 60 continuous years, the AAD and ANARE are on a much more permanent footing than the fledgling organization that struggled for its existence, after a gestation of over one hundred years.

ANDEEP PROGRAMME

ANDEEP (Antarctic benthic deep-sea biodiversity: colonisation history and recent community pattern) is a deep-sea expedition programme conducted from the research vessel *Polarstern* for the investigations of the biodiversity of the Southern Ocean deep-sea fauna. The aims of ANDEEP were to conduct the first base-line survey of the deep-water benthic faunas of the Scotia and Weddell seas, and to investigate the evolutionary and ecological processes and oceanographic changes in space and time that have resulted in the present biodiversity and distributional patterns in the Southern Ocean deep sea.

Unlike the fauna on the Antarctic shelf, which is very isolated and shows a high degree of endemism (*in situ* evolved species), the deep-sea fauna is not isolated. Although deepwater underlies most of the Southern Ocean and is extensive, it is still poorly known especially with respect to the composition and functioning of the Southern Ocean deep sea benthic communities.

It is possible that the Southern Ocean deep sea is a centre of evolution for benthic animals, as the shelf is believed to be. Most Antarctic benthic shelf species are likely to have reinvaded the shelves via the deep sea after glaciation, and Antarctic deep water fauna may have influenced the composition and species richness of the benthic faunas of the world oceans.

In 2002, the ANDEEP I (ANT XIX-2) and ANDEEP II (ANT XIX-3) expeditions from RV

Polarstern recovered a tremendous number of organisms of widely varying size from Drake's Passage, around the South Shetland Islands and Trench, the western Weddell Sea, and the South Sandwich Trough. During this survey it was possible for the first time to compare Southern Ocean deep-sea faunas to those collected elsewhere using standardised sampling strategies and similar apparatus. In March 2005, the ANDEEP III (ANT XXII-3) expedition sampled the deep sea along the Greenwich Meridian in the Cape Basin, Agulhas, and northern Weddell Sea Basins. A variety of sampling apparatus (CTD, a sediment profile imaging system, multiple corer, giant-box corer, epibenthic sledge, Agassiz trawl, and baited traps) were used during all three ANDEEP expeditions. A wide variety of organism taxa were collected from in and on the sea floor and much information on water and sediment quality was gained.

The ANDEEP expeditions revealed surprising results with regard to high benthic species diversity within all size classes. Within many groups of animals more than 80% of the species are new to science. ANDEEP contributes to the abyssal biodiversity data within CeDAMar, which is one of the core field projects of the CoML (Census of Marine Life), and aims at a documentation of actual species diversity of abyssal plains as a basis for global change and for a better understanding of historical causes and recent ecological factors regulating biodiversity.

ANHYDROBIOSIS

Although Antarctica has an enormous amount of freshwater, most of it is locked up as snow and ice or is otherwise unavailable to organisms. On the Antarctic continent organisms are largely restricted to areas of ice-free land (less than 0.5% of the continent is ice free) and to areas which receive sufficient meltwater in summer to support their growth. Sources of water, such as melting snowbanks, may become exhausted and the organisms have to tolerate desiccation. Anhydrobiosis (life without water) is the ability to survive a cessation of metabolism due to water loss.

Anhydrobiotic organisms survive the loss of more than 99% of their water and enter a state of suspended animation, in which their metabolism comes reversibly to a standstill. This ability is found in a variety of organisms, including nematodes, rotifers, tardigrades, some arthropods, some plants (mosses, resurrection plants, pollen, some seeds), bacteria (especially spores and cyanobacteria), fungi (spores, yeast), lichens, and protists (algae, protozoan cysts). These can survive for many years in a desiccated state. Although it has not been explicitly demonstrated in some groups, anhydrobiosis is probably widespread among terrestrial Antarctic bacteria (especially cyanobacteria), algae, mosses, fungi, protozoa, lichens, and terrestrial microinvertebrates (nematodes, rotifers, tardigrades). The mechanisms of anhydrobiosis have been best studied in nematodes, tardigrades, and cyanobacteria.

A slow rate of water loss is essential for anhydrobiosis. Antarctic nematodes and tardigrades living in soil or moss can rely on their environment losing water slowly, whereas those that inhabit more exposed sites (such as the aerial parts of lichens) may themselves control water loss from their bodies. A resistant cuticle with a restricted permeability helps control water loss, as does coiling (nematodes) and withdrawing the legs into the body (tardigrades), thus reducing the surface area exposed to the air. Cyanobacteria secrete a sheath of polysaccharides (large molecules consisting of repeating sugar units). These are hygroscopic (they absorb water) and thus slow down water loss during desiccation and aid water uptake during rehydration. A slow rate of water loss allows the orderly packing of internal structures and biochemical changes that help protect the organism from the effects of water loss. Most anhydrobiotic organisms produce the sugar trehalose and this is thought to protect membranes and proteins by replacing the water that forms part of their structure. There is increasing evidence that desiccation-induced proteins also play an important role in anhydrobiosis. During rehydration there is repair of any damage that occurred during desiccation and the physiological state of the organism is restored before movement and/or normal function commences.

The McMurdo Dry Valleys are the largest area of ice-free land in Antarctica. They are one of the driest places on Earth and evaporation in summer is so rapid that the permafrost (at 10–30 cm depth) cannot supply sufficient moisture to allow microbial growth to stabilise the surface. However, Dry Valley soils, in places, contain a community of organisms—including nematodes and tardigrades. The survival of organisms in this site, and in many other terrestrial Antarctic habitats, must be critically dependent upon anhydrobiosis.

ANTARCTIC ACCOUNTS AND BIBLIOGRAPHIC MATERIALS

Expedition materials range from letters and logbooks, through field notes, sledging books, and diaries to charts, maps, and scientific data in written, graphical, and digital forms. The earliest Antarctic expeditions were those of professional seamen such as James Cook and Fabian von Bellinghausen, who kept detailed logbooks on which the official published accounts could be based. Scientific data from these expeditions included not only direct measurements of physical phenomena, such as temperature and water depth, but also illustrations of the landscape and natural history prepared by draughtsmen. For the whaling and sealing expeditions of the eighteenth and nineteenth centuries, the only surviving records are normally logbooks, although these are extant for only a proportion of known voyages. The largest collection of such whaling logbooks is at the Old Dartmouth Historical Society Whaling Museum in New Bedford, Massachusetts.

The range of journals and other material produced by the expeditions of the "Heroic Age" is much greater. Many of the expeditions required the officers and scientists to maintain diaries that were to be made available to the expedition leader to help him write the official narrative. Often there was an embargo on these unofficial accounts being published immediately after the expedition in case they contradicted the leader or in any way undermined the impression he was at pains to create. However, during the past 100 years a range of contemporary accounts have been published for most major expeditions, often providing those human details missing from the official narrative. Robert Falcon Scott's expeditions have generated the greatest number of separate narratives, and even today some of the important contemporary narratives have yet to be translated from their original language.

The major expeditions produced their scientific findings principally as a range of specially written scientific reports. The most extensive scientific output from a single expedition is probably the eighty-five volumes produced by the First German Antarctic Expedition led by Erick von Drygalski, although the *Challenger* Expedition led by Wyville Thomson produced fifty volumes between 1885 and 1895. The continuing research on whales and the Southern Ocean conducted by the Discovery Investigations eventually led to the publication of thirty-seven volumes.

Special publications associated with overwintering had been produced in the Arctic in the nineteenth century. Recognising this, both Scott and Ernest Shackleton produced midwinter books (*South Polar Times* and *Aurora Australis*), a tradition continued by British Antarctic stations in the latter part of the twentieth century. In the twenty-first century, the continuing records collected in Antarctica are principally digital and, although accounts of visits there continue to be printed as books, online diaries and newspapers are becoming increasingly common.

With its limited history, lack of indigenous inhabitants, and predominantly scientific focus, Antarctica is the only continent for which a complete bibliography of all published scientific papers, books, and popular articles has been attempted. There were some early attempts to list the exploration literature, but these were only partial and generally reflected the country and language of the compiler. The most significant general ones of these were Chavanne et al. (1878), who attempted to encompass all the polar literature to that point; Denucé (1913), who compiled a bibliography for the International Polar Commission; and Breitfuss (1933), whose bibliography came out of his direct experience of working in the polar regions. A variety of specialised bibliographies on ice, whaling, ornithology, meteorology, biology, etc. were produced during the first half of the twentieth century, and there have been many others since.

The exploration literature per se has been followed by an incomplete listing of books, maps, and some papers (Spence 1980), and a beautifully illustrated and annotated list of the 150 most collectable books from Antarctic expeditions (Mackenzie 2001). The latter is remarkable for the illustration of each volume, often with extremely rare dust wrappers. The most recent bibliography of the "Heroic Age" is undoubtedly the best, having been fully researched through many libraries worldwide and providing professional definitive bibliographic details of each volume, including all its reprints and variants (Rosove 2001).

The scientists have been exceptionally well served for almost 60 years. An initial private card-based bibliography put together by John Roscoe (1951), photogrammatist on Operation Highjump and Operation Windmill, was finally published by part of US Naval Intelligence, but without any credit to Roscoe and without his being able to finish organising the entries and annotating them. It lists material in all original languages, organising half of the content under science and most of the rest under individual expeditions. It proved a milestone and an important lever in getting the Department of Defense to begin funding both the *Antarctic Bibliography* and the CCREL Bibliography through a contract to the Library of Congress.

The *Antarctic Bibliography,* which began in 1965, originally provided monthly listings accumulated into annual volumes. Back listing eventually took the bibliography back to 1951, thus incorporating much of the literature of the International Geophysical Year. The efforts of the compilers in Washington ensured that coverage of English and Russian language material was very good, but it proved difficult to collect the growing diversity of material in other languages. Much of this, especially in European languages, has been captured in the catalogue of the Scott Polar Research Institute (SPRI), published by G. K. Hall in 1976 and now available online at www.spri.cam.ac.uk/resources/sprilib/antarctica/.

The last *Antarctic Bibliography* volume was issued in 1995 and was superseded by a subscription-based CD system. The entire bibliography is now available online at http://www.coldregions.org/antinfo.htm.

Antarctic manuscript and journal material is spread throughout the world, in both public collections and privately owned. The largest public depositaries are probably at SPRI, the National Maritime Museum in Greenwich, and the US National Archives, but there are also important collections in the Royal Geographical Society, the Mitchell Library (State Library of New South Wales, Sydney), the Alexander Turnbull Library (Wellington), the Arctic & Antarctic Institute (St. Petersburg,) and the Mawson Centre (South Australian Museum, Adelaide).

ANTARCTIC AND SOUTHERN OCEAN COALITION (ASOC)

The Antarctic and Southern Ocean Coalition (ASOC), formed in 1978, is a global coalition of environmental nongovernmental organizations (NGOs). ASOC aims to achieve permanent protection for Antarctica's wilderness and wildlife through the creation of a "World Park Antarctica" (or a comparable regime), the maintenance of the demilitarised status of the area, and the continuation of international cooperation. ASOC promotes strategic approaches to addressing current and emerging issues facing the Antarctic region and its governance regime—particularly commercial pressures—with a view to long-term ecological sustainability. It also promotes continued openness of the Antarctic Treaty System (ATS) to NGO participation in environmental policy debates.

The interest of public advocacy organizations in Antarctic affairs predates the 1959 Antarctic Treaty, with increased NGO involvement starting in the mid-1970s in the United States, the United Kingdom, and elsewhere. As the exploitation of Antarctic marine living resources intensified, and the exploitation of mineral resources became a distinct possibility, some individuals and NGOs—notably James N. Barnes, a lawyer from the Center for Law and Social Policy, a US public interest NGO—sought to develop a worldwide coalition of environmental organizations to protect Antarctica (Kimball 1988; Suter 1991).

ASOC has been active at key Antarctic meetings since 1978. Its participation was at first limited to lobbying outside the meetings and to NGO representation on some national delegations (initially the United States, subsequently several other parties). The initiation of the negotiations for the Convention on the Regulation of Antarctic Mineral Resource Activities (CRAMRA) in 1982 resulted in a global environmental campaign opposing mining in Antarctica and promoting the development of an Antarctic conservation regime both in land and at sea. ASOC played a key role in this campaign (Elliott 1994; Darby 1994; Firth 2005), jointly with Greenpeace, which went on to develop its own on-the-ground Antarctic program. The NGO campaign combined direct action in Antarctica with analysis (Wallace 1988), political work domestically in most Antarctic Treaty states, and lobbying in Antarctic fora and at the United Nations. In the process ASOC gained participating "Expert" status to the meetings of the 1980 Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) in 1988 and to the formerly secretive Antarctic Treaty Consultative Meetings in 1991. ASOC remains the only environmental NGO with such status in the ATS. Since the early 1980s, ASOC also has attended, as observer, the meetings of the International Whaling Commission.

NGO efforts catalysed the rejection of CRAMRA by Antarctic Treaty states in 1989. The minerals convention was never ratified, and a 50-year open-ended prohibition on mineral resource activities became a key element of the 1991 Protocol on Environmental Protection to the Antarctic Treaty that was negotiated instead. Subsequently ASOC campaigned both domestically and internationally for the protocol's ratification until it entered into force in 1998. Since then ASOC has campaigned to promote the legal and practical implementation of the protocol (Bastmeijer 2003); to stop illegal, unregulated, and unreported fishing activities in the CCAMLR area; and to advance regulation by Antarctic Treaty states of the rapidly growing Antarctic tourism industry and of the fledging bio-prospecting industry.

ASOC is a loose coalition but it has maintained the active support of its key members over the years. ASOC membership includes some of the largest international environmental organizations worldwide, several dozen prominent national and issue-specific NGOs, and individual supporters. ASOC supports its activities with membership dues, foundation grants, and donations. ASOC Secretariats were established at various times in different countries, with the Antarctica Project in Washington, DC being the longest serving.

ASOC's involvement in Antarctic affairs has been variously resented, berated, and commended by governments and industries active in the region. Over the years ASOC has submitted many alternative proposals on Antarctic environmental management and policy issues. A number of these proposals have been rejected, but others have taken root. Several key elements of the Antarctic Treaty System as it is today—such as the prohibition on mining, the environmental protection protocol, the ecosystem management approach of the Southern Ocean fisheries regime, the Antarctic Treaty Secretariat, the Committee for Environmental Protection, the protocol's 2005 liability annex, and the ongoing discussion on the regulation of commercial tourism—resonate with proposals developed or supported by ASOC, and with its long-term goal of a World Park Antarctica.

ANTARCTIC BOTTOM WATER

The world ocean is cold, with an average temperature of 3.5°C. Warm waters are mainly found in a relatively thin surface layer at temperate and low latitudes. Even at the equator, where the surface temperature may be some 26°C–28°C, the temperature decreases steadily downwards, reaching near freezing temperatures (0°C) at some 4000–5000 m depth. Since the very first deep-sea measurements, it has become obvious that the bottom waters obtained their characteristics at high latitudes, and further research has shown that the Antarctic is of paramount importance in supplying cold water to the deep world ocean.

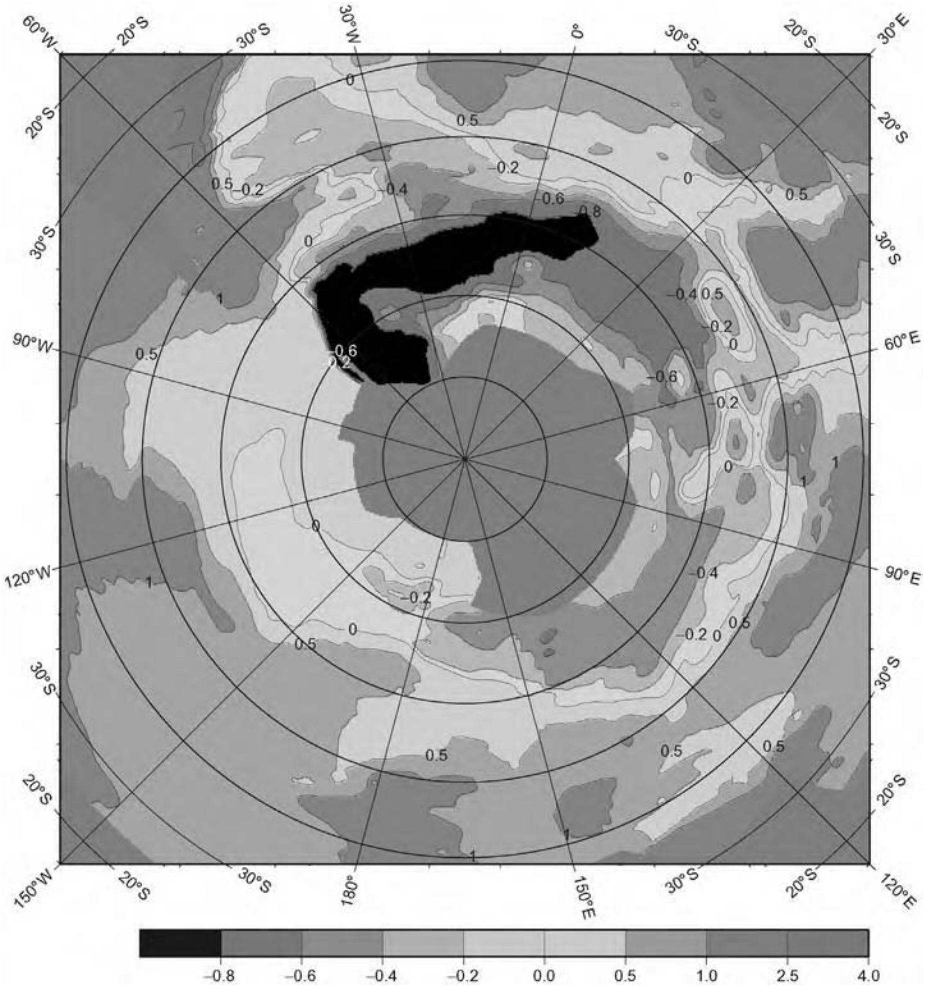
The lowest temperatures in the Southern Ocean appear in the southwest part of the Weddell Sea, and the temperature increases monotonically to the east and north. The data also show a strong correlation between low temperatures and high oxygen values. The impression given is that there is a source of cold, oxygen-rich water in the southern Weddell Sea. This cold, oxygenated water spreading out from the Weddell Sea (and from other sources along the Antarctic continent) is termed Antarctic Bottom Water (AABW). It has been estimated that about 60%–70% of the new AABW flows out of the Weddell Sea. Besides the Southern Ocean, the AABW occupies the deep North Pacific and South Pacific, the Indian Ocean, and the Atlantic Ocean. In the Atlantic, the AABW can be traced north to Bermuda where it meets cold water from the Arctic. Waters of Antarctic origin occupy the major part of the deep world ocean. Knowledge of the processes leading to the formation of AABW is therefore extremely important for an understanding of the climate of the world ocean. The supply of oxygen that is needed by marine life makes AABW equally important for an understanding of the health of the world ocean.

The Floating Ice Shelves

The Antarctic continent is covered with the world's largest ice cap, which contains more than 70% of the world's fresh water. Part of this ice sheet is floating on the sea, and nearly half of the continent is surrounded by floating ice shelves, which provide a large and active interface with the surrounding ocean. The cold water must be formed somewhere on the broad and relatively shallow shelves in the southern Weddell Sea. It can be seen that a major contribution to the formation of AABW is intimately coupled to processes under the floating ice shelves in the Weddell Sea. Several physical processes there are active in the production of the dense water mass that is obviously needed to form bottom water.

Typically, the distance from the ice front of the Filchner-Ronne Ice Shelf (FRIS), in the southern Weddell Sea, to the grounding line is about 500 km; the thickness of the FRIS at the ice front is about 300–500 m; and the depth at the grounding line perhaps 1500 m. The ice shelves constitute the drainage areas for the central ice sheet, and the glacial ice melting near the grounding line may originate from snow falling at a height of 3000–4000 m in the interior.

On the continental shelf during winter, sea water is subject to strong surface heat loss, and the water column is cooled by subsequent mixing and convection. When the freezing point is eventually reached, further cooling induces freezing of ice at the surface. However, when sea water freezes, most of the salt is rejected from the ice. It mixes into the underlying water, which then becomes saltier and denser. The cold and dense water mass thus formed is named high-salinity shelf water (HSSW). The amount of ice being frozen on the shelf near the FRIS is much higher than farther out on the open sea. This is due to offshore winds that carry the newly frozen ice away from the ice front, leaving open water or thin ice exposed to the cooling stress. Also, the tides produce periodic leads near the ice front, and freezing there becomes intense. The total ice production near the ice

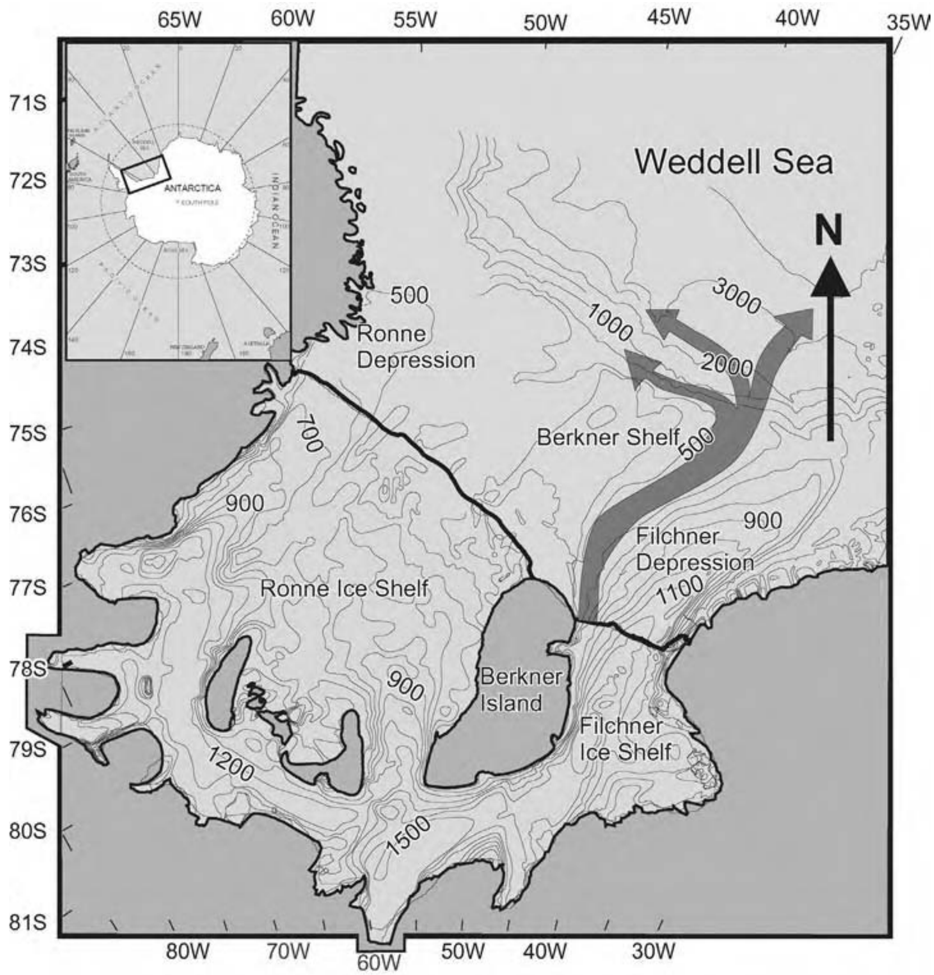


The potential temperature (in °C) near the bottom of the Southern Ocean. Note that the temperature in the deep ocean increases from a minimum in the southern and western Weddell Sea, showing that the source of cold water is located in that region. (Data source: http://woceatlas.tamu.edu)

front may contribute 20–30 times the ice production of the open ocean. This ice factory is the real key to the water mass transformation producing HSSW on the shallow shelf.

The unique thermal ice–ocean boundary of the FRIS plays an essential role in the formation of AABW. The shelf water circulates under the FRIS, and the importance of this ice–water contact is seen by studying the thermodynamics of sea water. The freezing point of sea water decreases with depth at a rate of 0.75°C km^{-1}. For ordinary sea water the freezing point at the surface is about –1.9°C, whereas at 500 m and 1000 m depth it is close to –2.3°C and –2.7°C, respectively. Thus, shelf water outside the FRIS at its freezing point is as cold as it can possibly be due to cooling at the surface. However, when this water moves under the FRIS it appears as a relatively warm water mass that is capable of melting glacial ice at the ice–ocean boundary, since its temperature is higher than the *in situ* freezing point. The meltwater adds to the water column, which becomes colder and slightly less saline in the process. Water having temperatures below the freezing point at the sea surface is termed ice shelf water (ISW). In nature, ISW can form only under floating ice shelves or large icebergs.

The addition of glacial meltwater gives ISW exceptional properties. The glacial ice melting near the grounding line may originate from snow falling over the ice sheet at some 3000 m height or more. For this snow the ratio of the oxygen isotopes O18/O16 is much less than at sea level because the heavier isotope O18 has fractionated out at lower levels. The same holds for other isotopes like helium. The glacial meltwater thus provides the ISW with isotope anomalies that are used as a tool (together with temperature, salinity, etc.) in tracing water masses.

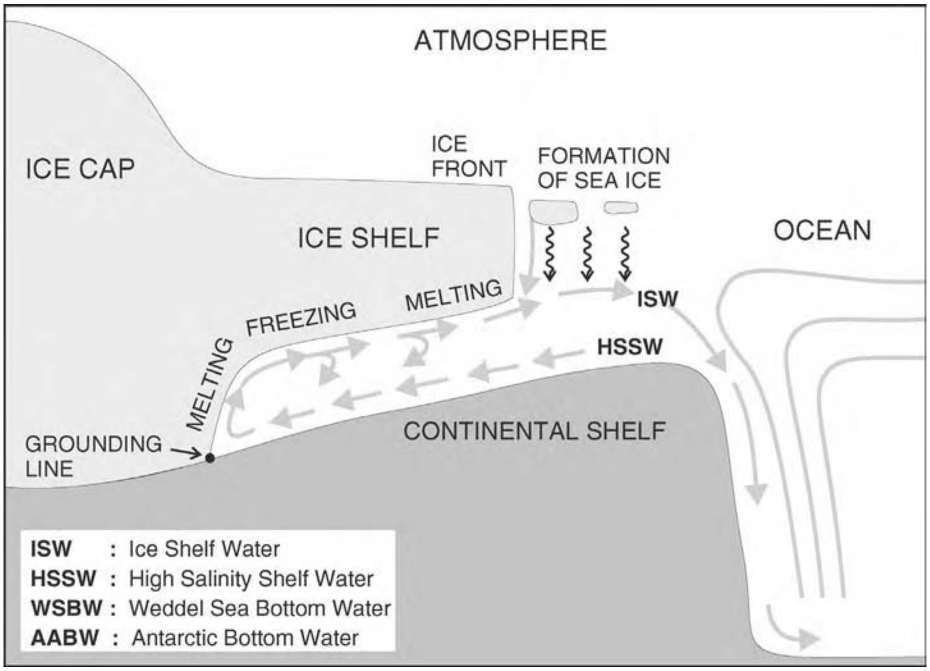


The local topography in the southern Weddell Sea with the floating Filchner and Ronne ice shelves. Depths are in meters. The flow of ISW originating under the FRIS and leaving the shelf break north of the Filchner Depression is shown by the three-pronged arrow. (See also Foldvik et al. 2004.)

The Formation of Bottom Water

The Norwegian Antarctic Research Expedition 1976–1977, in *Polarsirkel,* located a major source of ISW overflowing the sill (~600 m depth) of the Filchner Depression. Field investigations have shown that this ISW water attains its characteristics in several successive steps. First, cooling and surface ice freezing on the Berkner Ice Shelf produce HSSW. Second, the dense HSSW then flows south under the FRIS and around Berkner Island, becoming ISW by the melting of glacial ice and subsequent cooling. The salinity of the ISW becomes less than that of the HSSW, but it is still distinctly higher than that of the shelf water from which HSSW was derived. With its low temperature, ISW becomes sufficiently dense to descend the continental slope. Many years of current meter records of the ISW flowing out of the Filchner Depression area have shown that the annual mean temperature of the flow is –2.0°C and that the average volume flow of ISW is 1.6 Sv ± 30%, where 1 Sv = 10^6 cubic meters per second (21 cubic miles per day). This is considerably more than the total transport of all rivers on the planet Earth together.

This enormous river of extremely cold water rushes down the continental slope at high speed. The overflow may take different paths at the shelf break depending on the actual oceanographic conditions at the time of the overflow. Most of the mixing with the overlying warm deep water (WDW) takes place below 2000 m. The result is newly formed Weddell Sea Bottom Water (WSBW), which then flows west and north and into the deeper parts of the Weddell Sea. The apparent source of cold water is WSBW. The production of WSBW (referenced to –0.8°C) corresponding to the above release of ISW is 4.3 Sv ± 30%.



The circulation of ice shelf water, high-salinity shelf water, Weddell Sea bottom water, and Antarctic Bottom water.

On its way north, the newly formed WSBW mixes with the overlying Deep Water to form AABW. Recent estimates of the rates of production of AABW are about 10–15 Sv.

Sources of Antarctic Bottom Water

A major contribution to the formation of AABW in the southern Weddell Sea is believed to arise from the FRIS area as described previously. However, the ice shelves farther west in the Weddell Sea also produce cold and dense water. The Ross Ice Shelf undoubtedly produces cold and dense water contributing to the formation of bottom waters, but apparently much less than the Weddell Sea. Numerous ice shelves around the Antarctic continent border the sea and modify the adjacent waters. Their quantitative effect on the production of bottom water is not clear.

Bottom water may also be formed by open ocean convection. The best known example is the Weddell Sea Polynya, an enormous area of open water appearing during winter within a region normally covered by sea ice. Open water exposed to very low temperature produces large upward heat fluxes, cooling the water mass and breaking down the stratification. Cold and dense surface waters may then sink and contribute to the renewal of bottom water. The Weddell Polynya was observed during the mid-1970s and has not reappeared. The overall importance of this process for the formation rate of AABW is therefore probably small.

At the continental slope outside the shelf break resides a relatively warm saltwater mass known as the warm deep water (WDW). As long as the HSSW is lighter than the WDW, it will not be capable of moving under the WDW down the slope. However, during winter the density of HSSW increases and may equal the WDW density. Mixing of HSSW and WDW, in any proportion, will then produce a mixture that is denser than any of the two parent water masses and thus able to move down the slope. This shelf-break mixing is known as cabbeling and is due to the nonlinearity of the equation of state for sea water. The extent to which this process contributes to formation of bottom water is not known.

Biological Consequences

The shelf processes of cooling and convection provide efficient contact between the sea water and the atmosphere. This facilitates the uptake of oxygen and other atmospheric gases that are most efficient at low temperatures. The melting of glacial ice at high pressure and low temperature increases the oxygen content even further. These cold and oxygenated waters are advected into the bottom layers of all major ocean basins and are slowly being displaced upwards due to new supplies of bottom water. Since biological processes consume oxygen, the oxygen content of the water diminishes with time and also diminishes from the bottom upwards. There are regions (such as the northeast Pacific) where the oxygen levels are low due to long residence time, but all major ocean basins are oxic within the present climate situation.

Climate change could conceivably change the present situation. The production of HSSW is sensitive to a reduction of cooling stresses (wind strength and temperature). A reduced production of HSSW would reduce the production of ISW and hence the production of AABW. The melting rates under the FRIS might also be altered with consequences for the stability of the ice sheet.

ANTARCTIC: DEFINITIONS AND BOUNDARIES

Antarctica is the continent that lies over the geographical South Pole, the southern end of the Earth's axis of rotation. The floating ice shelves that are seaward extensions of the continental ice sheet form an integral part of the "land" surface of the continent. It is normally considered to include the islands immediately adjacent to the continent, many of which are located within ice shelves or are attached to the continent by ice shelves. Along the western side of the Antarctic Peninsula the off-lying islands such as the Biscoe Islands, the islands of the Palmer Archipelago, and the South Shetland Islands are also regarded as part of the continent.

The Antarctic region has variously defined boundaries for various purposes. The northern limit of jurisdiction for the Antarctic Treaty is the 60° parallel of South latitude, a convenient political boundary that does not relate to any physical feature. The northern limit of jurisdiction for the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) is more complicated because it attempts to follow closely the Polar Front by defining latitudinal boundaries.

The Polar Front (previously known as the Antarctic Convergence) is an oceanographical feature where the cold, dense Antarctic surface waters of the Southern Ocean sink beneath the warmer surface waters of the southern Atlantic, Indian, and Pacific oceans. This is also a climatic boundary and is frequently marked by fog. It is also an ecosystem boundary for many marine species, which is the reason it was chosen by CCAMLR for the extent of its jurisdiction. It is also the boundary adopted by the Scientific Committee on Antarctic Research (SCAR) because it is defined by natural features, including the northern limit of the Antarctic Circumpolar Current.

The Polar Front is widely accepted as the natural northern limit of the Antarctic region but, for juridical and some other purposes, it is more convenient and practical to define a more arbitrary northern limit.

The following islands and island groups lie south of the Polar Front but do not form part of the Antarctic continent: Bouvetøya, Heard Island, MacDonald Islands, Balleny Islands, Scott Island, Peter I Øy, South Georgia, South Orkney Islands, and the South Sandwich Islands.

The Antarctic Circle lies at 66°33′ S and marks the latitude above which the Sun does not rise on Midwinter Day (21 June) and does not set on Midsummer Day (21 December). Moving south of the Antarctic Circle the number of days without the Sun in winter and with 24-hour sunlight in the summer gradually increases. At the South Pole, the Sun rises on 22 September, the vernal equinox, and does not set again until 23 March, the autumnal equinox.

In addition to the geographical South Pole, three other poles are recognized in the Antarctic: the South Magnetic Pole, the South Geomagnetic Pole, and the Pole of Inaccessibility.

The map of Antarctica in a polar stereographic projection showing the whole continent (as opposed to a Mercator projection where the continent is depicted as a wavy border of white at the bottom of the map) can immediately be seen to comprise two parts. Greater Antarctica is the larger part that lies between the Transantarctic Mountains and the coast bordering the Southern Ocean south of the southern Indian Ocean and the southwestern Pacific Ocean. Lesser Antarctica is the smaller part that lies between the Transantarctic Mountains and the coast bordering the southeastern Pacific Ocean and the southern Atlantic Ocean. The Transantarctic Mountains themselves form part of Greater Antarctica.

Commonly used synonyms for Greater Antarctica are East Antarctica and Eastern Antarctica and those for Lesser Antarctica are West Antarctica and Western Antarctica. The justification for West and Western Antarctica is that it lies entirely within the Western Hemisphere but the converse for East and Eastern Antarctica is less precise as it lies largely within the Eastern Hemisphere but partly in the Western Hemisphere. These names also give rise to the seeming paradox that on the Ross Ice Shelf, East Antarctica lies to the west and West Antarctica lies to the east. The terms Greater and Lesser Antarctica have been largely supplanted in the literature by East and West Antarctica, which is a pity as they are neither accurate nor immediately obvious.

Lesser Antarctica comprises the major regions of the Antarctic Peninsula, Ellsworth Land, and Marie Byrd Land, together with the Ross Ice Shelf and the Filchner-Ronne Ice Shelf.

The Antarctic Peninsula (55°–80° W) extends northward from Ellsworth Land for about 1500 km and may be considered to include the off-lying islands of the South Shetland Islands across Bransfield Strait. The section of the peninsula north of a line from Cape Jeremy to Cape Agassiz is known as Graham Land, and that south of the line as Palmer Land. Historically, the northeasternmost part of the peninsula was known as the Trinity Peninsula.

The Antarctic Peninsula is dominated by a high central plateau, very narrow in places, that broadens gradually southward, and then broadens abruptly at the boundary between southern Graham Land and northern Palmer Land. Most of the exposed rock occurs in spectacular cliff faces buttressing the plateau, and on the inshore islands of the west coast. Steep glaciers and ice falls descend from the plateau between the cliffs. There are deep channels between the inshore islands, the best known being Lemaire Channel. Farther south, in Palmer Land and across George VI Sound on Alexander Island, the terrain is more mountainous. The east coast of the peninsula is

The Area of Antarctica

Area	Measurement
Antarctica, including islands and ice shelves	13,829,430 km^2
Antarctica, excluding islands and ice shelves	12,272,800 km^2
Ross Ice Shelf	510,680 km^2
Filchner-Ronne Ice Shelf	439,920 km^2
Ice-free area (0.32% of the continent)	44,890 km^2
Minimum extent of pack ice (March)	4,000,000 km^2
Maximum extent of pack ice (September)	22,000,000 km^2

Other Geographical Data

Feature	Measurement
Highest peak: Vinson Massif, Ellsworth Mountains	4892 m
Height of surface at South Pole	2771 m
Highest point of the ice sheet: Dome Argus	4093 m
Mean height of Antarctica, including ice shelves	1958 m
Mean height of Antarctica, excluding ice shelves	2194 m
Maximum known thickness of ice: Terre Adélie (69°54′ S, 135°12′ E)	4776 m
Mean thickness of ice	1829 m
Mean thickness of grounded ice	2034 m
Total volume of ice sheets, including ice shelves	25.4×10^6 km^3
Lowest temperature recorded: Vostok station	–89.6°C
Largest ice berg approximately 295 × 37 km (satellite image in 2000)	~11,000 km^2
Or possibly approximately 335 × 97 km (sighted from a ship in 1956)	~31,000 km^2

fringed by the Larsen Ice Shelf, the smaller northern parts of which (known as Larsen A and Larsen B) disintegrated in recent years. The peninsula region, particularly Graham Land, is rich with a variety of wildlife. Graham Land and the South Shetland Islands are relatively easy to reach by sea and hence witnessed some of the earliest exploration in the Antarctic. Similarly, in more modern times, many national stations and bases have been built in the region so that, as a result, more scientific research has been done in the region than elsewhere on the continent. More tourists visit this area than any other part of the Antarctic.

Ellsworth Land (80°–103° W) lies at the head of the Ronne Ice Shelf. It includes the Ellsworth Mountains and a number of small isolated groups of hills. The Vinson Massif, the highest mountain in Antarctica, lies in the southern part of the Sentinel Range that forms the northern part of the Ellsworth Mountains. There are several other high mountains in this range. Eights Station and Siple Station (United States) are the only scientific stations that have been built in this region and, as inland stations, they were supplied entirely by air. A commercial airline/tour company has operated from a summer camp at Patriot Hills for some years. The principal clients have been mountaineers climbing in the Ellsworth Mountains, adventurers proposing to walk to the South Pole, and other tourists who fly to the South Pole. It is in the sector of the Antarctic that is unclaimed. It was named after the American aviator Lincoln Ellsworth.

Marie Byrd Land (103°–152° W) is dominated by the western Antarctic Ice Sheet, punctuated by isolated young volcanoes, with outcrops of other rocks closer to the coast. A permanent fringe of sea ice has rendered the region largely inaccessible by ship, and only one coastal station, Russkaya (USSR), has ever been established. Access to the region has normally been by air or by overland tractor train. The United States Byrd Station was established by tractor train, and subsequently supplied by air, from McMurdo Station. A key feature of central Marie Byrd Land is the Bentley Subglacial Trough where the bedrock is deep below sea level. This is the reason that the western Antarctic Ice Sheet is considered to be inherently unstable and would collapse relatively quickly, given sufficient warming of the Antarctic climate. The sector was named for the wife of Richard E. Byrd, whose first expedition (1928–1930) did the initial exploration of the area.

Edward VII Land (152°–158° W) forms the eastern margin of the Ross Ice Shelf. There are some rock outcrops, notably the Rockefeller Mountains, in the immediate hinterland of its northern, seaward coast. To the south there is no outcrop, and the principal features are the five ice streams that flow westward from Marie Byrd Land into the Ross Ice Shelf. This sector was first discovered on the British National Antarctic Expedition (1901–1904) and named after the British monarch. It was initially reached from the Ross Ice Shelf by three members of Roald Amundsen's Norwegian Antarctic expedition (1910–1912).

Filchner-Ronne Ice Shelf (35°–75° W) is basically one ice shelf at the head of the Weddell Sea but it includes Berkner Island, which constitutes a major division between the two parts. Expeditions to the area have been relatively few because the Weddell Sea is permanently filled with ice and represents a largely impenetrable barrier to reaching the coast. Many ships have been ice-bound in the Weddell Sea and Sir Ernest Shackleton's *Endurance* was famously crushed and sunk in 1915. Wilhelm Filchner's German South Polar expedition (1911–1912) discovered the eastern section, and initially named it for Kaiser Wilhelm, but the German emperor asked that it be named for Filchner. The larger, western part was named for Edith Ronne, the wife of Finn Ronne, whose expedition in 1947–1948 discovered and photographed a segment of it. Perhaps the most important aspect of the ice shelf is that it is the source of the cold Antarctic Bottom Water that flows northwards along the abyssal plains into the world's major oceans.

The Ross Ice Shelf (160° E–160° W) is the largest in the world and is about the size of France. It was discovered on a British Antarctic expedition (1839–1843) under the command of James Clark Ross. It then was the Antarctic starting points for several of the expeditions of the "Heroic Era," notably those of Robert Falcon Scott, Ernest Shackleton, and Roald Amundsen in their attempts to reach the South Pole. Subsequently, during the 1920s and 1930s, the American Richard E. Byrd established the series of Little America stations in the area of the Bay of Whales. The glaciers of the Transantarctic Mountains and Marie Byrd Land feed enormous volumes of ice into the ice shelf, which has been the source of most of the largest icebergs recorded.

Greater Antarctica comprises the Transantarctic Mountains, the various named lands that extend eastward around the margin of the continent from the Weddell Sea to the Ross Sea and the major part of the Antarctic Ice Sheet, which covers the interior of the continent and is devoid of rock outcrop.

The Transantarctic Mountains extend from northern Victoria Land on the west side of the Ross Sea past the South Pole to the Horlick Mountains as an unbroken chain. Beyond the Horlick Mountains the outcrop is discontinuous but includes the Thiel Mountains and Pensacola Mountains. This is, perhaps, the obvious geographical extent of the

Transantarctic Mountains but it may be argued, on geological grounds, that they continue through the Shackleton Range and Theron Mountains in Coats Land to Heimefrontfjella and Vestfjella in Dronning Maud Land. The principal feature of the Transantarctic Mountains is that they form the boundary of Greater Antarctica within the continent and, in so doing, provide a dam to the flow of the Antarctic Ice Sheet that can escape seaward only through the many valley glaciers that flow into the Ross Sea and the Ross and Filchner ice shelves. Around 76°30′–78°30′ S lies the area known as the McMurdo Dry Valleys. These are glacially formed valleys in the mountains from which the glaciers have all but retreated. They have probably been ice-free for the past 4 million years. Despite having the coldest and driest climate on Earth, life still survives in the form of endolithic organisms.

Coats Land (37°–20° W) was discovered by William Speirs Bruce on the Scottish National Antarctic Expedition in 1904. The major rock outcrops are found in the Theron Mountains, Shackleton Range, and Whichaway Nunataks, where the initial survey and exploration was done by members of the Commonwealth Trans-Antarctic Expedition in 1957. There are small outcrops near the coast, where Littlewood Nunataks are the site of the Argentine General Belgrano II Station. The British Halley Station is located on the Brunt Ice Shelf. In common with most of the coast of Greater Antarctica, except northern Victoria Land, there is no rock outcrop and the edge of the continent is formed either by the front of ice shelves or by the ice sheet flowing directly into the sea.

Dronning Maud Land (20° W–45° E) is synonymous with the Norwegian territorial claim. The coast is fringed by ice shelves for most of its length but there are some outcrops along the Prince Olav Coast in the east. Inland there are several mountains ranges, all within 500 km of the coast, the spectacular faces and peaks of which provide new challenges to mountaineers and rock climbers. Some of the rocks in the regions are among the oldest in Antarctica, having formed more than 3000 Ma. In many areas there are extensive fields of hard blue ice that can be used by wheeled aircraft. One such area near the Schirmacher Hills forms the Antarctic end of an intercontinental flight from Cape Town, South Africa, using wheeled jet freighter aircraft for rapid deployment of equipment and personnel for the various national research programmes operating in the area. These programmes and stations include those of Belgium, Finland, Germany, India, Japan, Netherlands, Norway, Russia, South Africa, Sweden, and the United Kingdom. The area was first observed in January 1930 during flights by Hjalmar Riiser-Larsen during one of the series of Norwegian expeditions sponsored by Lars Christensen. It was named for the Queen of Norway.

Enderby Land (45°–55° E) was discovered in 1831 by John Biscoe while employed by the Enderby Brothers to seek further sealing grounds. There are groups of mountains close to the coast and farther into the hinterland, very similar in physiography to Dronning Maud Land. The Russian station of Molodezhnaya is located on the coast in western Enderby Land.

Kemp Land (55°–60° E) is a narrow sector that is almost devoid of rock outcrop. It was named for the British sealer Peter Kemp, who sighted the coast in 1833.

Mac.Robertson Land (60°–70° E) includes three major features: the Prince Charles Mountains, Lambert Glacier, and Amery Ice Shelf. The Prince Charles Mountains flank the western side of Lambert Glacier and the Amery Ice Shelf and the Mawson Escarpment lies on the eastern side. The Lambert Glacier is the largest glacier in the world. It is at least 400 km long and up to 64 km wide. It is the principal source of ice for the Amery Ice Shelf that forms the seaward extension of the glacier. The Pole of Inaccessibility for the continent and ice shelves (83°50′ S, 65°47′ E) lies in southern Mac.Robertson Land. The area, which is part of the Australian Antarctic Territory, was identified during the British Australian New Zealand Antarctic Research Expedition under Douglas Mawson, who named it in honour of the expedition's primary benefactor, Sir MacPherson Robertson, an Australian industrialist.

Princess Elizabeth Land (73°–86° E) has a predominantly ice coast but the coastal outcrops that do exist have provided sites for several stations, currently including the wintering stations of Zhong Shan (China) and Davis (Australia). In the past, the Soviet Union also occupied the wintering station Progress, close to the Zhong Shan. Inland are the Grove Mountains and Gale Escarpment. The ice sheet rises southward to Dome Argus (4095 m), the highest point of the ice sheet. Just north of Dome Argus lie the Gamburtsev Subglacial Mountains. This mountain range is entirely covered by ice and is known only from radio echo-sounding. A part of the Australian Antarctic Territory, it was identified during the British Australian New Zealand Antarctic Research Expedition under Douglas Mawson, who named it in honour of the young British Princess who became Queen Elizabeth II.

Wilhelm II Land (86°–91° E) was discovered on the German South Polar expedition (1901–1903) under Erich von Drygalski, who named it for the German Kaiser. It has virtually no exposed rock except for the prominent outcrop of Gaussberg, the core of an extinct volcano, which was named for the ship of the German expedition. The members of Douglas Mawson's Australasian Antarctic Expedition were the second to reach it, in 1912.

Queen Mary Land (91°–102° E) has an ice coast, including the Shackleton Ice Shelf. There is little exposed rock, but the Bunger Hills contain a number of seasonal lakes that are of great biological interest. The Russian station of Mirnyy is located on the coast and two former Soviet traverse stations, on the route from Mirnyy to Vostok Station, are located on the ice sheet to the south. The Shackleton Ice Shelf was first explored by the members of the Western Base on Douglas Mawson's Australasian Antarctic Expedition.

Wilkes Land (102°–136° E) has an ice coast for most of its length but the Australian Casey Station and the former United States/Australian Wilkes Station are both sited on rock. The Russian Vostok Station lies within Wilkes Land and, at 3448 m above sea level, is the highest manned station in the Antarctic. About 3800 m beneath the station is the upper surface of the southern end of Vostok Subglacial Lake, the largest of the known subglacial lakes. The joint French–Italian station Concordia is located on the summit of Dome Circe at 3233 m above sea level. The sector was named for Charles Wilkes, commander of the United States Exploring Expedition (1838–1842), which passed large portions of the area and spied "high land" at several places.

Terre Adélie (136°–142° E) is synonymous with the French territorial claim in Antarctica. The French station of Dumont d'Urville is located on Île des Pétrels in the Archipel de Pointe Géologie. Despite major protests and disruptive actions by Greenpeace, an air strip to accommodate intercontinental flights was completed close to the station by building causeways to join several islands. Subsequently a major storm destroyed part of the air strip and it has not been rebuilt. The South Magnetic Pole is currently located off the coast of Terre Adélie. The sector was named for the wife of Jules-Sebastien-Cesar Dumont d'Urville, the commander of the French naval expedition that discovered it in 1840.

George V Land (142°–155° E) has very little rock outcrop. Cape Denison was the site of the Australasian Antarctic Expedition (1911–1914) base under Sir Douglas Mawson, who named it for the British monarch. It is renowned for the strength and duration of the katabatic winds that can exceed 320 km per hour and is generally regarded as the windiest place in the world. Mawson originally considered Commonwealth Bay to be in "Adelie Land," and "King George Land" to apply to the newly discovered areas east of the Mertz Glacier, but when the French proclaimed sovereignty over Terre Adélie, "British Adelie Land" became part of what was King George Land.

Oates Land (155°–163° E) has little coastal outcrop but the western, inland flank of the Transantarctic Mountains forms much of its eastern margin. The former Soviet station Leningradskaya is located on the coast at 63°30′ S, 159°23′ E. The South Magnetic Pole was located in Oates Land in 1909 when it was approached by members of Ernest Shackleton's British Antarctic Expedition. Oates Land was named for Captain L. E. G. Oates of Robert Falcon Scott's last expedition, on which the coast was surveyed.

Victoria Land (163°–171° E) contains the Transantarctic Mountains from about 70°30′ to about 78°00′ S and includes Ross Island. This region was the scene of many of the early Antarctic expeditions from Sir James Clark Ross in 1840 to the Ross Sea party of Shackleton's Imperial Trans-Antarctic Expedition. Currently there are permanent stations on Ross Island (Scott Base, New Zealand; McMurdo Station, United States) and at Terra Nova Bay (Zucchelli Station, Italy). West of Ross Island in the Transantarctic Mountains is the Dry Valley region which has been largely ice-free for perhaps as long as 4 million years. Mount Erebus (3794 m) on Ross Island is the most active volcano in the Antarctic. The sector was named by Ross for Britain's young Queen Victoria.

ANTARCTIC DIVERGENCE

The term *Antarctic Divergence* is applied, more often in the older literature, to a transitional zone between the eastward-flowing Antarctic Circumpolar Current and westward-flowing currents to the south. The former is driven by strong westerly winds and the latter by easterlies that result from cold, katabatic winds moving off the Antarctic continent. Owing to the Earth's rotation, the Coriolis force deflects the katabatic winds to the left, or the west, giving rise to the Antarctic Coastal Current.

Because surface water moves to the left of the wind in the Southern Hemisphere, Antarctic Surface Water diverges across this transition and upwelling is enhanced beneath. The upwelling may be evidenced by dome-shaped isotherms and isohalines below the sea surface, a salinity maximum near 200 m, or a minimum in surface water thickness. The vertical extent of the upwelling is quite large, as the warm and salty North Atlantic Deep Water rises from a depth of 2500–4000 m to reach the sea surface.

While the Divergence has little surface expression in shipboard or satellite observations, it can be a locus of lower sea ice concentration, fewer icebergs, and increased phytoplankton blooms resulting from the upwelled nutrients. It is not unusual, for example, for the Antarctic Divergence itself to be completely devoid of icebergs, while numerous ones are observed drifting in opposing directions just a few tens of miles away from, but on the opposite sides of, the Divergence. It is also associated with the centers of cyclonic gyres that occur over topographically distinct ocean basins between the Circumpolar and coastal currents. In the Atlantic, Indian, and most of the Pacific sectors, the Antarctic Divergence is found between 63° S and 66° S, but it is farther south in the southeast Pacific sector, reaching as far south as 70° S.

ANTARCTIC FUR SEAL

Antarctic fur seals *(Arctocephalus gazella)* are rapidly becoming one of the most abundant seal species in the Antarctic. From a state of near-extinction in the early twentieth century, the Antarctic fur seal has recovered to a population that could now exceed 5 million. The story of this rapid change reflects both the change in human attitudes to the exploitation of marine mammals and changes in the ecosystem of the Southern Ocean, probably also mediated by the impacts of humans on that environment.

The Antarctic fur seal is the only member of the family Otariidae (fur seals and sea lions) that is endemic to the Southern Ocean. (Otariidae belong to the larger taxon Pinnipedia, which includes all seals, fur seals, sea lions, and the walrus.) Antarctic fur seals are one member of a group known as the southern fur seals, eight species that are distributed from the tropics to the sub-Antarctic. The taxonomic status of the southern fur seals is uncertain, and there is almost certainly a degree of introgression between the populations of each species. Antarctic fur seals are known to hybridize with sub-Antarctic fur seals *(A. tropicalis)* at Macquarie Island, and some species are sufficiently similar morphologically that it might be difficult to recognise them from the local species even if they were present on the breeding colonies. However, Antarctic fur seals are distinct in that they have a breeding chronology that differs from other southern fur seal species. Lactation lasts only 4 months compared with around 9 months in the other species of southern fur seals.

The Antarctic fur seal has a circumpolar distribution. Breeding colonies are located mainly on sub-Antarctic islands, but more southerly colonies are found at the South Shetland and South Orkney Islands. Overall, there is little evidence of strong genetic isolation between any of these populations but there may be a weak division between a western region containing the populations of South Georgia and Bouvetøya, which were the probable sources for populations at Marion Island, the South Shetland Islands, and Heard Island, and an eastern region containing the panmictic populations of Îles Kerguelen and Macquarie Island. The latter region may be a result of a pronounced founder effect, or represent a remnant population that survived sealing at Îles Kerguelen.

During the early twentieth century Antarctic fur seals were thought to be extinct, as a result of harvesting of their fur, but in 1922, three juvenile males were recorded at South Georgia by the captain of a sealing vessel. Surveys in the late 1950s showed a small but rapidly increasing population at the western end of South Georgia and the increasing trend appears to have continued ever since. By the early 1990s, the population at South Georgia had reached 1.5 million and colonisation had spread to other islands where rapid rates of increase were also being observed. The population at South Georgia probably represents more than 98% of the world population of the species and is now so large that surveying its size has not been possible in the recent past. However, given the estimated rates of increase through the 1990s, this population could now exceed 5 million seals.

This rapid increase in the number of fur seals is only partly reflective of the present lack of a directed harvest on the species. Changes in the structure of the community of predators that exploit Antarctic krill *(Euphausia superba),* which is an important component of the diet of Antarctic fur seals, is likely to have been another driving force behind the increase in the number of fur seals. Fur seals at South Georgia are likely to consume about 4 million tonnes of krill each year and, before commercial whaling reduced the number of whales, much of this consumption may have been taken up by whales.

Studies of diving behaviour have shown that female fur seals mainly feed within the upper 50 metres of the water column where the water is mixed by the effects of wind and tide. Males dive deeper—to more than 200 metres—and probably have a greater proportion of fish in their diet than females do, especially in winter. The Antarctic fur seals in the eastern region, where krill are either absent or less abundant, feed mainly on lantern fish (myctophids).

Mothers have restricted foraging ranges when they are supporting their pup. The pups remain at the breeding grounds while mothers travel up to 300 km to feed. In winter, when not constrained by having to return regularly to feed their pups, female fur seals travel much further afield. From South Georgia, they will travel south to the ice edge in the northern Weddell Sea and also as far north as the River Plata and the Falkland Islands. Males appear generally to migrate south in the late summer and then follow the ice edge northwards as the winter sets in.

Fur seals are almost certainly predated by killer whales, and some leopard seals appear to specialise on feeding on fur seals close to colonies. Ultimately, the population of Antarctic fur seals, at least at South Georgia, may be regulated by the availability of krill in the vicinity of the island. Large-scale variability in the trophic structure of the Southern Ocean caused by factors such as the El Niño Southern Oscillation is evident in the growth patterns of fur seals and there is accumulating evidence of their sensitivity to interannual variation in krill availability. This sensitivity is now being used as a way of monitoring changes occurring in the marine environment of the Southern Ocean as part of a system for assessing the effects of fisheries on the environment within the Convention on the Conservation of Antarctic Marine Living Resources.

Antarctic fur seals are colonial breeders. Anybody who visits South Georgia during December will be stunned by the density of seals occupying the available coastline towards the western end of the island. Fur seals are also aggressive animals and are unforgiving towards visitors.

Male fur seals set up territories during early November and females begin to arrive at the breeding grounds during late November. The peak of births occurs at about 7 to 10 December and almost all pups have been born by the end of December. The small, aggressive, inquisitive black-coated pups become the dominant wildlife feature on the beaches.

After giving birth, mothers spend about 6 days with their pups. They are then mated by one of the dominant males holding a territory on the breeding beaches before going to sea to feed for a period of 3 to 6 days. Each mother then returns to feed her single pup for about 2 days and this alternation between feeding at sea and returning to provision the pup continues for a period of about 4 months. Weaning appears to be initiated when the pup abandons the breeding grounds to go to sea during late March or April.

Males hold territory on the breeding grounds for periods of just a day or two to over 30 days. The longer they spend in territory then the more offspring they will sire so there is much competition for territories. This results in overt fighting between males, which has led to advantages for males with large body sizes. Consequently, males are up to 5 times the weight of females (males weigh up to 200 kg whereas females weigh about 40 kg). Males have highly developed neck musculature and, at the beginning of the breeding season, they have an impressive mane of tough hair, which helps to provide some protection against the slashing canine teeth of an opponent.

Owing to their commitment to holding territory, males fast through the breeding season. This means that by late December most males have lost up to one-third of their original body weight. As a result of these stresses, males do not live as long as females (up to 14 years for males compared with over 20 years for females). Many males die as a result of these stresses and large numbers die on the breeding grounds. About half of all these adult males die each year.

Males are also rarely able to breed before they are 7 years of age, whereas females normally begin to breed at 3 years of age. Thereafter, around 80% of females will breed each year. Studies have shown that males often return to breed close to where they were born. This may be because there are advantages to competing with males that are known to one another. Females are probably less likely to return to the location in which they were born; the advantage to females is that pups have a better chance of survival if their parents are not closely related. Once established as a breeder, females return to give birth in the same location in successive years.

Antarctic fur seals have proved to be a highly valuable species for scientific research. Not only is the history of the population recovery a fascinating case study, fur seals are themselves remarkably robust to being the subject of research. Studies of their diving, foraging, diet, behaviour, and population structure have provided insights into the biology of seals. Those who first encounter fur seals are usually overwhelmed by their aggressiveness, but pausing to watch them for a short time will reveal a fascinating world of a species with a complex social structure much of which we still do not understand.

ANTARCTIC ICE SHEET: DEFINITIONS AND DESCRIPTION

The Antarctic ice sheet comprises the vast contiguous coverage of glacial ice that rests on the Antarctic continent and surrounding seas. It is the single largest solid object on the surface of the planet, containing around 90% of the Earth's freshwater and covering around 99.6% of what is generally considered the Antarctic continent. The ice sheet is nourished at its surface by snowfall and frost, which, because of the year-round cold environment, does not melt but accumulates year-on-year. As the surface snows are buried by new snowfall, they are compressed and eventually transform into solid ice, a process that captures a chemical record of past climates and environments. In places, the ice sheet is more than 4500 m thick and the ice in the deepest layers is millions of years old. Glacial flow produces a relentless movement of ice towards the sea, and eventually it either calves away in icebergs or melts directly into the coastal waters. In a sense, the entire Antarctic ice sheet can be considered as an immense conveyor belt, transporting ice from the interior to the coast at a rate of around 2000 billion tonnes per year; a conveyor that is naturally regulated to balance loss by calving and melt with nourishment from snowfall. The continuation of this balance is important because any substantial imbalance would have a noticeable impact on world sea levels.

History of Understanding

During the past hundred years, our understanding of the processes that shape the Antarctic ice sheet has improved, as our ability to map the ice sheet has grown. Only the most primitive mapping techniques were available during the "Heroic Age" of Antarctic exploration, and so most of the maps of the ice sheet that existed even into the 1950s were almost blank. During the International Geophysical Year (IGY; 1957–1958) and the years that followed, extensive scientific traverses were undertaken, which included seismic sounding of the ice thickness and barometric profiling. The maps drawn by Bentley (1964) were based on the very few data collected on traverses, but those maps proved to be a remarkably accurate depiction of the ice sheet and formed the basis of much future work. The next leap forward came as long-range aircraft were equipped with ice-sounding radar in the 1970s, and the joint expeditions undertaken by the Scott Polar Research Institute, the National Science Foundation, and the Technical University of Denmark probably produced the single greatest advance in the understanding of the inner workings of the Antarctic ice sheet. Layering inside the ice sheet observed using radar showed an ordered architecture in the ice sheet that underpins our understanding of glacial flow.

Since that time, satellite data have caused a revolution in our mapping, and our understanding of the ice sheet. Surface elevation, surface temperature, ice flow, and near-surface snow conditions can all be measured from space, and patterns of change in each of these parameters are beginning to emerge. Neither ice sheet thickness nor its internal structure can yet be measured from space, but in recent years feasibility studies have been sponsored by space agencies keen to take this next step in exploring the ice sheet. The mapping and allied experimentation conducted in Antarctica since the IGY have led to a surprisingly thorough knowledge of the ice sheet and its internal working.

Nowadays, thanks to satellite imagery, maps depict the entire Antarctic ice sheet, including its outlying islands—a total area of around 13.7 million square kilometres, much of it featureless tracts of ice. Of this, floating ice shelves comprise around 1.6 million square kilometres. Ice shelves are best considered alongside grounded ice as part of the same ice sheet system. The dynamic interaction between the grounded ice sheet and the ice shelves is a particularly complex one in which ice shelves may provide a buttressing force that stabilizes the grounded ice sheet.

Glaciological Fundamentals

The fundamental concept that underlies the understanding of the Antarctic ice sheet, or indeed any ice sheet or glacier, is related to the interaction between the processes of ice accumulation and those of flow and ablation. Every year ice from new snowfall and hoar frost accumulates on the Antarctic ice sheet. More is deposited around the coast than in the interior, but on average around 190 kg per square metre accumulates each year. For the most part, summer temperatures are insufficient to cause this new snowfall to melt and so it builds up year-on-year—new snow resting on old. Over the millions of years that this process has continued, the ice sheet has thickened and grown, and it would continue to thicken and grow indefinitely if another process did not act in opposition. This process is ice flow, which occurs as ice is subjected to the tremendous forces that exist in the ice sheet. Under these conditions, ice can behave more like an ultraviscous fluid than a solid material (for a detailed description of the processes of glacier movement, see Paterson 1994). On the microscopic scale, slow deformation of crystals occurs, but viewed on the large scale, the ice sheet actually appears to flow. Flow speeds from a few metres per year to a few hundred metres per year are possible due to this deformation, but even greater speeds can occur (more than 1000 metres per year) if the ice begins to slide over its bed. Ice is driven to flow by gravity and, since the ice sheet has a domed topography, flow tends to drive ice towards the edge of the ice sheet where eventually it either melts directly into the sea or calves away in icebergs. The precise interaction between these two processes, nourishment by snowfall and loss through ice flow, has created a self-regulating system of surprising delicacy and precision.

Glaciological Provinces

The Antarctic ice sheet is usually considered in terms of several different provinces, which serve to distinguish dissimilar styles of ice sheet behaviour and to characterize differences in the response to changes. Of these, the East Antarctic ice sheet comprises by far the largest part of the ice sheet, roughly the slice from 30° W, clockwise through the Greenwich meridian, and on to around 165° E. More precisely this is the part of the ice sheet bounded by Filchner Ice Shelf and the Transantarctic Mountains. The East Antarctic ice sheet (EAIS) is generally described as being cold and resting on a bed that is by and large above sea level, or is depressed below sea level by the weight of the ice sheet itself. Much of the ice flow on the interior of the EAIS is slow, and in many areas the ice is frozen to the bed.

This contrasts strongly with the West Antarctic ice sheet (WAIS), the portion occupying the slice from the Transantarctic Mountains through the Siple Coast and Marie Byrd Land and into Ellsworth Land, up to but not including the Antarctic Peninsula. The majority of this ice sheet rests on rock that is substantially below sea level, and would remain so even if the ice sheet were removed. For this reason the West Antarctic ice sheet is described as a "marine ice sheet." The bed beneath the West Antarctic ice sheet is in many areas over 1000 m below sea level—far deeper than most of the world's other continental shelves. The West Antarctic ice sheet is generally warmer, both at the surface and the bed, than its East Antarctic neighbour. In fact, it is close to the melting point over large areas of its bed.

The ice sheet that covers the Antarctic Peninsula is different from either EAIS or WAIS. It consists of much smaller and thinner ice caps that cover the central spine of the peninsula and some of the larger outlying islands. These ice caps drain into the sea through relatively narrow, but steep and fast-moving, alpine-type glaciers. In contrast to WAIS and EAIS, which lose mass primarily through iceberg calving and melt from the base of ice shelves, recent atmospheric warming over the Antarctic Peninsula has had a noticeable impact on its ice sheet. Around ten ice shelves have retreated, and a few (most notably the northern portions of Larsen Ice Shelf) have collapsed spectacularly. Thinning of glaciers has occurred in coastal areas, and some formerly snow-covered islands are now snow-free during the summer.

Together the ice sheets of Antarctica cover more than 99.6% of the entire continent (Fox and Cooper 1994), meaning there is very little exposed rock in Antarctica. In these areas the bed pierces through the ice sheet, or the ice sheet is insufficiently thick to cover the bed, depending on one's point of view. An isolated peak protruding through the ice sheet in this way is called a nunatak, but there are also more extensive mountain areas where many neighbouring outcrops of rock are exposed, including the Dry Valleys of Victoria Land.

An isolated nunatak remains ice-free by virtue of its height above the surrounding ice—the ice-sheet flow is simply diverted around it and it remains protruding above the surface. Understanding how mountain ranges can remain ice-free within an ice sheet is, however, not so simple. If a mountain range were to present a complete barrier to ice flow, the ice sheet would simply thicken until it could surmount the obstacle or flow round it, as is required to achieve a steady-state scenario. And indeed, the ice sheet does cover several mountain ranges (for example, the Gamburtsev Subglacial Highlands in East Antarctica), and in West Antarctica, ice flow is diverted many hundreds of kilometres around the barrier formed by the Ellsworth Mountains. Elsewhere, however, mountain ranges do not present an entirely impenetrable boundary, and where preexisting faults and valleys provide a route, inland ice can flow through the mountain chain in what are called outlet glaciers. The best example of this behaviour is in the Transantarctic Mountains. To an extent, this chain does dam the East Antarctic ice sheet inland and makes it thicker than it would otherwise be, but an entire series of outlet glaciers flow through the range, acting as valves, easing the pressure of ice trying to leave East Antarctica. The outlet glaciers that breach the Transantarctic Mountains are some of the most spectacular on the planet, and glaciers such as Byrd Glacier and David Glacier drain nation-size areas of the East Antarctic ice sheet.

Fast Glacial Flow

Exposed mountain ranges and nunataks are obvious signs of how the flow of the ice sheet is controlled by the underlying bed, but elsewhere the influence of the bed on ice flow is less visible, if no less influential. Even where the ice sheet is several kilometres thick, its flow is strongly influenced by the bed on which it rests. Where geological conditions allow the supply of soft and erodible sedimentary rock, ice flow may be lubricated at the bed by a layer of water-saturated glacial till. This effect allows rivers of fast-flow to develop within a slow-moving part of the ice sheet, and these are called ice streams. Most ice streams are difficult to see from the ground, but many were identified during airborne reconnaissance, and many more have become apparent in recent times. Satellite imagery now allows the mapping of the telltale bands of crevasses that separate ice streams from the slower moving ice, and has revealed a complex pattern of ice streams and tributaries penetrating deep into the continental interior.

More than 40% of the ice leaving the Antarctic ice sheet passes through the twenty largest outlet glaciers and ice streams, and they are thus hugely important in shaping the ice sheet. Furthermore, they are significant in that they appear to transmit the influence of changing ocean conditions over great distances in relatively short periods of time. In addition, ice streams themselves appear to be capable of surprising and quite rapid changes. A little over one hundred years ago, Ice Stream C appears to have stopped streaming, or as it has been described, "switched off." This probably occurred because of a change in the subglacial water pathways, and, in consequence, the part of the ice sheet that once fed Ice Stream C is no longer close to steady state but is thickening at a measurable rate (Joughin and Tulaczyk 2002). For these reasons, outlet glaciers and ice streams have been the focus of a large amount of ice dynamics research in Antarctica in recent times.

The Age of the Ice Sheet

The age of the Antarctic ice sheet is the subject of much debate. It is generally agreed that the East Antarctic ice sheet is much older than the West Antarctic ice sheet, but a great deal of uncertainty still surrounds both ages. The debate concerning the East Antarctic ice sheet centres on some unusual microfossil deposits high in the Transantarctic Mountains, the so-called Sirius Group formations. Depending on the interpretation of those deposits, the age is either put at a little more than 3 million years (implying collapse of the East Antarctic ice sheet during relatively recent Pliocene warm periods) or at some age closer to 20 million years. This greater age coincides with the geological opening of Drake Passage, between the Antarctic Peninsula and South America, which allowed the Antarctic Circumpolar Current to begin, isolating Antarctica and causing a substantial cooling of the climate (for a fuller discussion, see van der Wateren and Hindmarsh 1995).

The West Antarctic ice sheet is probably considerably younger, and may well have been entirely absent in one of the most recent interglacial periods (i.e., at some time since 400,000 years before present), when climate was somewhat warmer than today. Both East and West Antarctic ice sheets have undoubtedly grown and shrunk as Earth passed through glacial cycles, and it is believed that at the last glacial maximum (around 20,000 years ago) the ice sheet extended to the edge of the continental shelf around most of Antarctica. Since then it has retreated and thinned, contributing to many tens of metres of global sea level rise. The question of how much each portion of the Antarctic ice sheet is still responding to climatic changes that occurred more than 10,000 years ago is an open one, but there is clear evidence that some readjustment (i.e., thinning) is still continuing in West Antarctica.

The Changing Ice Sheet

In predicting the future of the ice sheet, these long-term changes in the Antarctic ice sheet need to be considered alongside the responses to contemporary climate change, and the future evolution is likely to be a complex response to many driving forces. Indeed, the shutdown of Ice Stream C is a clear reminder that the Antarctic ice sheet harbours mechanisms that can promote rapid and surprising changes that may have their root not in any climatic forcing, but rather in instabilities in the processes that are normally thought to lead to steady-state conditions.

Recent discoveries made using satellite altimetry data of apparently persistent ongoing surface lowering in the Amundsen Sea sector of West Antarctica have revitalized the debate about a much more

Measured Properties of the Antarctic Ice Sheet from the 5 km Ice Thickness Grid

Parameter	East Antarctica	West Antarctica	Total
Mean ice thickness (m)	2146	1048	1856
Total volume including ice shelves (km^3)	21.8×10^6	3.6×10^6	25.4×10^6
Grounded ice sheet (GIS) volume (km^3)	21.7×10^6	3.0×10^6	24.7×10^6
GIS volume above sea level (km^3)	20.5×10^6	2.1×10^6	22.6×10^6

Data taken from Lythe et al. 2001.

serious type of change that may govern the fate of the West Antarctic ice sheet as a whole—what has been called the "collapse of the west Antarctic ice sheet" (for a fuller discussion, see Bindschdler and Bentley 2002). This hypothesis arose even when most maps of Antarctica were still blank. Weertman's 1974 theoretical analysis of the junction between an ice shelf and an ice sheet suggested that a marine ice sheet (like the West Antarctic ice sheet) could never be stable, but should always be in the process of change, either growing seaward towards the continental shelf edge or shrinking. The reason a marine ice sheet does not float is because it is thick enough to rest on its bed, and so thinning could lead to floatation and eventually to rapid collapse of the ice sheet. It was therefore argued that much of the West Antarctic ice sheet was vulnerable to collapse, especially the portion of the ice sheet feeding the Amundsen Sea, which rests on a particularly deep bed more than 1000 m below sea level and has only narrow ice shelves to buttress the ice sheet. Although the evidence for potentially rapid retreat of marine ice sheets existing in the record of global sea level is difficult to ignore, the general instability of marine ice sheets is not universally accepted, and several researchers have argued that collapse of WAIS is unlikely (Vaughan and Spouge 2002). So, although the recent surface lowering of the ice sheet in the Amundsen Sea sector was taken by some as evidence for emergent collapse, this is certainly not universally accepted, and the future response of the Antarctic ice sheet as a whole is the subject of many programmes of research.

ANTARCTIC IMPORTANT BIRD AREAS

Introduction

The global Important Bird Area (IBA) Programme is an initiative of BirdLife International to protect the world's naturally occurring bird populations and habitats. The IBA Programme aims to identify and protect a network of sites critical for the viability of naturally occurring bird populations across their range. Certain sites are, because of the way biodiversity is distributed, disproportionately important for the survival of the species that are found at them. Protection of such sites is a widely adopted and recognized conservation approach.

BirdLife promotes the conservation of all bird species and seeks to conserve biodiversity by preventing extinctions and by maintaining and improving the conservation status of all bird species, particularly globally threatened birds. The IBA Programme is one of the many programs and initiatives of BirdLife. BirdLife is also working for biodiversity conservation through a variety of international mechanisms and conventions including the Convention on Biological Diversity (CBD), the Convention on International Trade in Endangered Species (CITES), and the Convention on Wetlands of International Importance Especially as Waterfowl Habitat (the Ramsar Convention). Collaboration on issues of regional and international importance is a growing trend of the 1990s and beyond, and this list is by no means exhaustive.

The Antarctic IBA Inventory (comprising the terrestrial Antarctic south of 60° S including some

IBA Criteria and Associated Avifauna Breeding in the Antarctic

Category & Brief Description	Relevant Antarctic Species Common Name, Scientific Name
A1. Globally Threatened Species *The site regularly holds significant numbers of a globally threatened species, or other species of global conservation concern.*	gentoo penguin, *Pygoscelis papua* (VU)* macaroni penguin, *Eudyptes chrysolophus* (VU)* southern giant petrel, *Macronectes giganteus* (LR/NT)*
A2. Restricted-Range Species *The site holds species of a restricted range.*	Not used for Antarctic IBA Inventory
A3. Biome-Restricted Assemblage *The site holds species whose distributions are largely restricted to one biome.*	Not used for Antarctic IBA Inventory
A4. Congregations Categories A4(i) and (ii) not used for Antarctic IBA Inventory. *The site holds or is thought to regularly hold:* *(i) over 1% of a biogeographic population of a congregatory waterbird species.* *(ii) over 1% of a biogeographic population of a congregatory seabird or terrestrial species.* *(iii) over 20,000 waterbirds or 10,000 pairs of seabirds of one or more species.* *(iv) Migratory species at bottleneck sites.*	kelp gull, *Larus dominicanus* Antarctic tern, *Sterna vittata* blue-eyed cormorant, *Phalacrocorax atriceps* Antarctic petrel, *Thalassoica antarctica* snow petrel, *Pagodroma nivea* emperor penguin, *Aptenodytes forsteri* Adélie penguin, *Pygoscelis adeliae* chinstrap penguin, *Pygoscelis antarctica* gentoo penguin, *Pygoscelis papua* rockhopper penguin, *Eudyptes chrysocome* Cape petrel, *Daption capense* sub-Antarctic skua, *Catharacta lonngergi* Antarctic skua, *Catharacta maccormicki* greater sheathbill, *Chionis alba* southern giant petrel, *Macronectes giganteus* Wilson's storm petrel, *Oceanites oceanicus* black-bellied storm petrel, *Fregetta tropica* southern fulmar, *Fulmarus glacialoides* Antarctic prion, *Pachyptila desolata*

*IUCN Red List Conservation Status: VU = Vulnerable, LR/NT = Lower Risk/Near Threatened.

sub-Antarctic islands) commenced in 1999. The Antarctic IBA Inventory is a cooperative effort between BirdLife and the Scientific Committee on Antarctic Research (SCAR) Group of Experts on Birds (GEB, formerly the SCAR Bird Biology Subcommittee, or SCAR-BBS). The Antarctic IBA Inventory is the first practical attempt to take a systematic approach to assessing and prioritizing the need for conservation action at sites by their avian values in the Antarctic, and represents an important preemptive and proactive approach towards the conservation Antarctica's avifauna. The Antarctic IBA Inventory seeks to identify a network of sites in the terrestrial Antarctic based upon their bird values and the application of internationally recognized site selection criteria to existing population data.

What Are IBAs?

The IBA Programme evolved following the compilation of a detailed inventory by the European Union for the identification of prospective sites for designation under the their Wild Birds Directive. This inventory was subsequently updated to become the first official IBA inventory of Europe. Numerous inventories have since been completed or are underway (five regional and forty-eight national as of 2004). The growing recognition of the IBA Programme indicates the substantial contribution it has made to habitat-based conservation on a global scale. The majority of signatories to the Antarctic Treaty (forty of forty-five) have already undertaken or participated in IBA Inventories at national or regional scales.

IBAs are a practical conservation tool that enable the identification of significant sites for the conservation of birds at global, regional, or subregional levels. Seabirds often congregate to breed in high numbers and at high species diversities. Additionally, these sites can be biologically diverse and offer conservation benefits for non-seabird species if they are formally protected. IBAs are selected by the application of internationally uniform criteria that are quantitative and scientifically defensible. These criteria provide a strong foundation for site identification and are a valuable tool for decision makers and managers to use in setting conservation priorities and actions.

Once the initial list of candidate IBAs is compiled, a detailed site description is prepared and circulated for comment. The agreed site accounts, prepared to a standardized format, are then brought together to form an inventory for the country or region. Subsequently the published IBA Inventory can be used to assist in the prioritization of sites for conservation action possible formal protection within the appropriate protected area system. Management and regulation in Antarctica is complicated by unresolved territorial claims, however means for protection do exist within the Antarctic Treaty System and/or under international conventions and agreements. The Antarctic IBA Inventory can assist treaty parties to meet their international obligations to identify and protect a network of sites under Annex V of The Protocol on Environmental Protection to the Antarctic Treaty (the Madrid Protocol).

The Antarctic IBA Inventory

Work on the Antarctic IBA Inventory commenced in 1999. The SCAR-GEB has compiled all available census data of the past 30 or more years on the distributions and abundances of Antarctic breeding birds. These data are the basis for the Antarctic IBA Inventory.

Preliminary Results

The SCAR-GEB and BirdLife cohosted workshops in May 2002 and July 2004 drawing on international expertise to compile and assess published and unpublished data on Antarctic avifauna. The 2004 workshop finalized the list of candidate IBAs. The Antarctic IBA Inventory can be adopted to assist in site prioritization sites for protection within the Antarctic protected area system. For example, sites that meet four IBA criteria may be considered to have a high priority for formal protection.

Completion of the Antarctic IBA Inventory is anticipated for 2007. The Committee for Environmental Protection (CEP) has indicated that upon publication, the results of the IBA Inventory will be assessed to decide how best to implement the required conservation action within the terrestrial Antarctic. The inventory may be adopted by nations with an interest in the Antarctic to assist in setting conservation priorities and to complement the measures already in place within the Antarctic Treaty System. A key factor in the decision-making process is the assessment of threats to identified sites, which will assist in the priority-setting process.

ANTARCTIC INTERMEDIATE WATER

A vertical salinity profile taken almost anywhere in the Southern Hemisphere oceans presents a minimum value within the upper 1000 meters of the water column. Throughout the Southern Hemisphere, this subsurface low salinity layer forms a coherent tonguelike distribution extending from near the surface at high southern latitudes to depths of about 1000 meters at midlatitudes. This water mass, first detected in the South Atlantic and described by German and British oceanographers during the first half of the twentieth century, is referred to as Antarctic Intermediate Water (AAIW; Deacon 1933; Wüst 1935). The northward salinity increase at the salinity minimum (S_{min}) core is due to a combination of mean northward flow and mixing with the saltier waters found in the layers above and below. Since the meridional distribution of sources of heat, freshwater and other properties over the Earth is uneven, by redistributing these properties across latitude bands, such meridional flows play a key role on the climate system. The observation of the S_{min} at the surface near the northern edge of the Antarctic Circumpolar Current suggests that the water mass acquires its characteristics (is formed) at this location. In the process of AAIW formation, water parcels sink and transfer properties and dissolved gases from the near surface layers, where they are in equilibrium with atmospheric concentrations, to intermediate depths, where they can be stored away from the atmosphere for periods of several years to several decades. Thus, AAIW also contributes to the absorption of carbon dioxide and other atmospheric constituents into the ocean interior.

Water Mass Properties

Properties on the low salinity layer vary substantially between ocean basins. These variations suggest either differing property concentrations in the formation regions and/or distinct flow patterns and resident times in different oceans. The mean properties of the AAIW S_{min} in the latitude band between 30 and 40° S are summarized here.

Depth

In the three Southern Hemisphere oceans, the core of the AAIW, as represented by the S_{min} layer, is found at the sea surface between 50°–60° S, deepens northward near 30°–40° S, and then rises again to 750–500 meters towards the Equator. Although the salinity of

Mean Properties of the Salinity Minimum Core in the Latitude Band Between 30° S and 40° S

Basin	Potential Temperature (°C)	Salinity	Potential Density Anomaly (kg/m^3)*	Dissolved Oxygen (mL/L)
Atlantic	3.85	34.25	27.20	5.4
Indian	4.54	34.41	27.26	4.6
Tasman Sea	5.18	34.46	27.23	4.1
W. Pacific	5.15	34.42	27.20	4.4
E. and C. Pacific	5.01	34.29	27.11	5.0

*Potential density anomaly is calculated after removing the pressure effect and is given in kg m^{-3} after subtracting 1000 kg m^{-3}.

the layers above and below the S_{min} are saltier than in the Indian and Pacific oceans, the salinity minimum layer in the Atlantic Ocean can be detected beyond 20° N. In the Pacific Ocean there is an analogue to AAIW formed at high Northern Hemisphere latitudes, the North Pacific Intermediate Water, and both S_{min} layers converge near the equator. In contrast, in the Indian Ocean, the S_{min} is confined to south of 10° S. On average, north of 40° S the S_{min} layer lies at about 800 m in the South Atlantic sector and about 1200 m in the southwestern Indian Ocean. The S_{min} core in the South Pacific rises from about 900 m in the western basin to less than 600 m off southern Chile.

Potential Temperature

To compare temperatures from water at different depths, it is convenient to remove the pressure effect, which contracts the water parcels and slightly increases their *in situ* temperature. For this purpose we use the temperature the water attains when displaced to the sea surface without exchanging heat with its surroundings, referred to as potential temperature (θ). The coldest AAIW is observed in the western South Atlantic (θ ~ 3.8°C). Potential temperature rises eastward across the Atlantic and Indian ocean sectors of the Southern Ocean, reaches 5.2°C in the Tasman Sea and decreases further east to about 5°C in the eastern South Pacific.

Salinity

The lowest salinity (S ~ 34.2) at the S_{min} core is found in the western South Atlantic. Within the South Atlantic basin salinity increases slightly eastward. The saltiest S_{min} is found in the southwestern Indian Ocean and the Tasman Sea (S higher than 34.4). In the South Pacific salinity at the S_{min} core decreases eastward from ~34.42 east of New Zealand and in the eastern South Pacific attains values close to those observed in the western South Atlantic.

Dissolved Oxygen

At or slightly above the core of AAIW salinity minimum, a dissolved oxygen maximum is frequently found. Dissolved oxygen (O_2) primarily enters the ocean from the atmosphere, thus, though it is not strictly conservative due to biological activity, a relative maximum is a signature of more recent layer "ventilation" at the sea surface. The highest dissolved oxygen concentrations at the S_{min} layer (O_2 ~ 5.4 mL/L) are observed in the western South Atlantic. Dissolved oxygen concentrations decrease eastward across the South Atlantic and South Indian Ocean, reaching a minimum in the Tasman Sea (O_2 ~ 4.1 mL/L) and increase further east to ~5 mL/L in the eastern South Pacific.

Potential Temperature-Salinity Distributions

In the Polar Front Zone, south of the Sub-Antarctic Front, there is a low salinity surface layer that connects to the AAIW S_{min} observed farther north. In the subtropical band the circumpolar salinity minimum is observed within the 3.5°C–5.5°C potential temperature range. The South Atlantic presents the lowest S_{min} layer at about 4°C and 850 m. The South Indian presents the saltiest and deepest (~1300 m) AAIW. In the South Pacific the salinity at the S_{min} is ~34.35 and is not as well defined as in the Atlantic and Indian oceans, because the layers above and below are comparatively fresh. Large excess precipitation over evaporation is presumably responsible for the lower salinity of the upper layers in the southeast South Pacific, while mixing has reduced the salinity of deep waters.

Water Mass Formation

There is no universally accepted theory of AAIW formation. The classical view (Deacon 1933; Wüst 1935) ascribes the low salinity layer to sinking along constant density surfaces from the region near the Polar Front Zone, from where the water mass spreads northward. Sverdrup (1940) suggested that AAIW formation is associated to convergence and subsequent sinking of upper layer waters induced by meridional structure of the wind field over the Southern Oceans. The sources for AAIW are mixtures of Antarctic Surface Water and Circumpolar Deep Water upwelled along the axis of the Antarctic Circumpolar Current. Alternatively, it has been suggested that AAIW is a product of relatively deep convection in the Sub-Antarctic Zone, north of the Sub-Antarctic Front. The latter water mass is referred to as Sub-Antarctic Mode Water (SAMW, McCartney 1977). Late winter convection forms relatively thick layers of quasi-homogeneous temperature, salinity, and density. These layers are referred to as thermostads (e.g. are quasi-homogeneous in temperature) or pycnostads (e.g. are quasi-homogeneous in density). Thus, from a volumetric point of view, the products of convection are modes, from which the water mass name is derived. Mode waters are also found in the subtropical and subpolar oceans in the Northern Hemisphere. After convection mode waters flow along constant density surfaces and are capped by the warm, salty upper layer waters characteristic of the midlatitude oceans. Mode water properties depend on the initial temperature and salinity of the surface layer and on the sea-air exchanges of heat and freshwater through the balance between evaporation and precipitation. The coldest, freshest, and densest variety of SAMW is found in the eastern South Pacific. Density progressively decreases eastward as temperature and salinity increase. Because the S_{min} observed in the western South Atlantic is fresher and denser than the densest southeast Pacific SAMW, an Antarctic influence from the Polar Front Zone in the vicinity of Drake Passage and further modifications by sea-air interactions within the southwest Atlantic have been suggested. These AAIW transformations are also apparent in global ocean circulation models. Thus, southwest Atlantic AAIW appears to be formed by a complex combination of the mechanisms described above. Warmer and saltier SAMW is formed throughout the South Indian and western South Pacific oceans, but these waters are significantly lighter than AAIW ($\sim$26.8 kg m^3) and therefore ventilate density horizons shallower than the salinity minimum layer.

Circulation

The most vigorous element of the circulation at the core of AAIW is associated to the circumpolar flow within the Antarctic Circumpolar Current. This flow, primarily along the Sub-Antarctic Front, is a significant conduit of exchange between ocean basins. Farther north, within each ocean basin, AAIW describes a large-scale counterclockwise loop. These flow patterns, also known as gyres, are generated by the curl of the wind stress at midlatitudes, caused by the opposing directions of the trades and the westerlies. AAIW flows northward on the eastern side of each basin, turns eastward at about 20° S and southward along the western boundary. The flow along this path is not uniform; velocity increases as the water approaches the western boundary and is most intense along the so-called western boundary currents that carry AAIW back southward. This asymmetry in the circulation is also reflected on the depth of the AAIW layer, which lies deeper in the western side of the oceans. In the Southern Hemisphere the western boundary currents in the Atlantic, Indian, and Pacific oceans are the Brazil, Agulhas, and East Australian currents, respectively. These are regions of enhanced turbulence associated to eddies and meanders where intense mixing of the different varieties of AAIW is observed. The recirculated AAIW observed at the poleward extensions of the western boundary currents are generally saltier and lower in dissolved oxygen than near the eastern boundary, since they have been subject to vertical mixing with the saltier layers above and below for a longer period of time. Leakage of Indian Ocean AAIW into the eastern South Atlantic via the Agulhas Current leads to increased salinities at the S_{min}. In the western South Atlantic and South Pacific oceans AAIW from the Sub-Antarctic Front flow northward along the western Argentine Basin (the Falkland/Malvinas Current) and the eastern flank of the Campbell Plateau, respectively. The Falkland Current is a substantial source of nutrients that sustains the development of phytoplankton and fishery along the eastern edge of the Patagonian shelf. These waters mix with the recirculated varieties of AAIW flowing in the opposite direction but there is no evidence of northward penetrations of AAIW along the western boundary below the western boundary currents southward extensions as originally thought.

The marked northward penetration of AAIW in the Atlantic is presumably a response to the so-called Global Thermohaline Circulation. In this large-scale flow, dense, salty water sinks to 2000–3500 m depths in the northern North Atlantic, flows southward, and is exported to the Indian and Pacific oceans. Export of deep waters is balanced by a return flow through the South Atlantic and into the North Atlantic, mostly at shallower levels. This return flow is composed by AAIW and thermocline waters. Thus, northward flow of AAIW in the Atlantic is enhanced by this large-scale meridional cell.

Variability

Variability of AAIW can be attributed to a combination of changes in the sea-air heat and freshwater exchanges at the regions of formation, variations in the thermal and haline characteristics of the source water, and variations in the circulation patterns. These processes can lead to changes in water mass properties in a variety of time and spatial scales. Once the water sinks its properties change by mixing with the surrounding waters, but mixing in the ocean interior is weak and the water retains the signature of the formation conditions. Thus, away from the sea surface, water mass variability provides a record of changes at the sites of formation and may serve as indicators of climate variability. Time series are only available at few locations in the Southern Ocean, and knowledge of the variability is mostly based on comparison of the thermal and haline characteristics determined from hydrographic observations occupied at different times. Within these limitations, changes in the AAIW and SAMW properties in the Southern Ocean are now relatively well documented. In the period from the early 1960s to the late 1980s, AAIW and the denser varieties of SAMW throughout the South Indian Ocean and in the Tasman Sea have freshened and cooled. Freshening is consistent with an increased excess precipitation over evaporation in the region of AAIW formation and has been interpreted as a signature of an increase in the strength or intensity of the hydrological cycle. Similarly, warming of the lightest varieties SAMW is associated to long-term warming of the surface waters in the formation region north of the Sub-Antarctic Front. This observation is consistent with predictions of global warming associated to increased atmospheric CO_2. Observations in the South Indian Ocean, including data collected in 2002, suggest that after the late 1980s the warmer varieties of SAMW have become saltier, almost entirely reversing the effect of freshening observed in the previous decades, while the salinity of the colder SAMW continued decreasing. Given the few observations available in the Southern Hemisphere, it is not yet possible to determine whether the observed changes in water mass properties are related to climate trends or to decadal oscillations.

The Antarctic Peninsula.

ANTARCTIC PENINSULA

The Antarctic Peninsula stretches from the continent towards South America in a north to north-easterly trending arc. At its most northerly point (57°18′ W, 63°13′ S), it is 620 miles (999 km) from Cape Horn, separated by the Drake Passage. It is 777 miles (1250 km) long, and ranges from 178 miles (287 km) wide at its most southerly point to 15 miles (24 km) wide near its northern extremity on the Trinity Peninsula. Its southern boundary stretches from Cape Adams westwards, to a point at 73°24′ S, 72°00′ W. The mainland peninsula covers an area of approximately 79,000 square miles (127,000 km^2).

The Antarctic Peninsula separates the Weddell Sea, to the east, from the Bellingshausen Sea to the west. The northern part (north of a line between Cape Agassiz and Cape Jeremy) is Graham Land, and the southern part is Palmer Land. The Antarctic Circle runs through the southern half of Graham Land, at approximately 66°30′ S.

The landscape is dominated by rugged coastline and a dramatic mountain range running along the length of the peninsula, interspersed with a number of ice-covered plateaus, the largest of which is the Dyer Plateau, in Palmer Land. The highest peak is Mount Jackson, at 10,453 ft (3184 m) above sea level, located in central Palmer Land. Approximately 2.6% of the mainland peninsula is free of ice and snow during the austral summer. Rivers or lakes on the mainland peninsula are few, and are mostly restricted to the Trinity Peninsula.

Numerous glaciers run either directly into the sea or feed major ice shelves, the largest of which is the Larsen Ice Shelf, which bounds most of the eastern side of the peninsula. Over the past six decades, 87% of the marine glaciers in the peninsula region have retreated, by on average 50 m a year. Over a similar period, there has been a progressive retreat of most ice shelves, including the Larsen B, which collapsed dramatically in 2002.

Major offshore island groups include the Palmer Archipelago and the Biscoe Islands. The largest individual islands fringing the peninsula are Adelaide Island and Alexander Island, which is separated from the mainland by the permanently frozen George V Sound.

The climate across the peninsula region varies considerably. The west coast experiences the warmer, maritime Antarctic climate. The east coast has the colder, continental climate. In the north, average monthly temperatures exceed zero in the summer. Annual average temperatures have risen by nearly 3°C in the central and southern parts of the west coast of the peninsula over 50 years. This is a larger rise than elsewhere in the Southern Hemisphere.

Due largely to its warmer climate and ice-free ground, the western side of the peninsula (including offshore islands) between approximately 64° and 68° S is biologically richer and far more diverse than the rest of the continent. Sixteen species of seabird breed here, including four species of penguin (gentoo, Adélie, chinstrap, and emperor). Five species of seal (crabeater, elephant, fur, leopard, and Weddell) haul out on the beaches and ice floes, and Ross seals are occasionally sighted on the eastern side of the peninsula. There are no breeding terrestrial mammals. Only one species of higher insect is found, otherwise this simple macroscopic invertebrate ecosystem is dominated by mites and springtails. A much greater diversity is found amongst lower invertebrates.

The terrestrial flora comprises about sixty-seven species of moss, nine species of liverwort, and 265 species of lichen, as well as Antarctica's only two flowering plants—Antarctic pearlwort *(Colobanthus quitensus)* and Antarctic hairgrass *(Deschampsia antarctica)*.

This region contains thirteen Antarctic Specially Protected Areas, which have been adopted under the Antarctic Treaty System, as well as eighteen Historic Sites and Monuments.

The first sighting of the mainland peninsula is claimed by the Russian naval Captain Fabian Gottlieb von Bellingshausen, the British naval Captain Edward Bransfield, and the US sealer Nathanial Palmer, all in 1820. The history of this region, covered extensively elsewhere in this encyclopedia, was principally defined by sealing, whaling, exploration, and scientific discovery.

The peninsula was first claimed by the UK by means of the Royal Letters Patent of 21 July 1908 (amended by the Royal Letters Patent of 28 March 1917) as part of the Falkland Island Dependencies. Later, the Order of Council of 26 February 1962 established British Antarctic Territory as a separate colony. Overlapping counterclaims are held by Chile and Argentina. Territorio Chileno Antártico was established by Presidential Decree of 6th November 1940. In 1943, Argentina stated its sovereign rights over this sector of Antarctica, extending and formalising it as Antártida Argentina in 1947. All territorial claims were laid in abeyance by the Antarctic Treaty (1961).

Mapping and survey of the peninsula has been undertaken principally by the UK from 1944 to the present date. Major aerial survey expeditions include Operation Highjump 1946–1947 (USA), the Ronne Antarctic Research Expedition 1947 (USA), the Falkland Islands Dependency Aerial Survey Expedition in 1956–1957 (UK), and the US Navy TriMetrogon Aerial survey, mainly between 1966 and 1968. Mapping by other Antarctic operators exists locally and around specific sites.

There are seven wintering stations operated by five nations in this region, although only one, Esperanza (Argentina) is located on the mainland peninsula. In addition, there are some ten summer-only stations. The number occupied varies from year to year, and some would appear to have been abandoned. Most stations are resupplied by ice-strengthened vessels during the austral summer. Hard-rock airstrips are located at Rothera Research Station (UK) and Marambio (Argentina). Scientific facilities and programmes vary from globally important to basic, and in some cases, rudimentary.

Due to its relative ease of access, the peninsula is also the busiest region of Antarctica for tourism. The most visited locations include Port Lockroy, Paradise Harbour, and Cuverville and Peterman islands.

ANTARCTIC PENINSULA, GEOLOGY OF

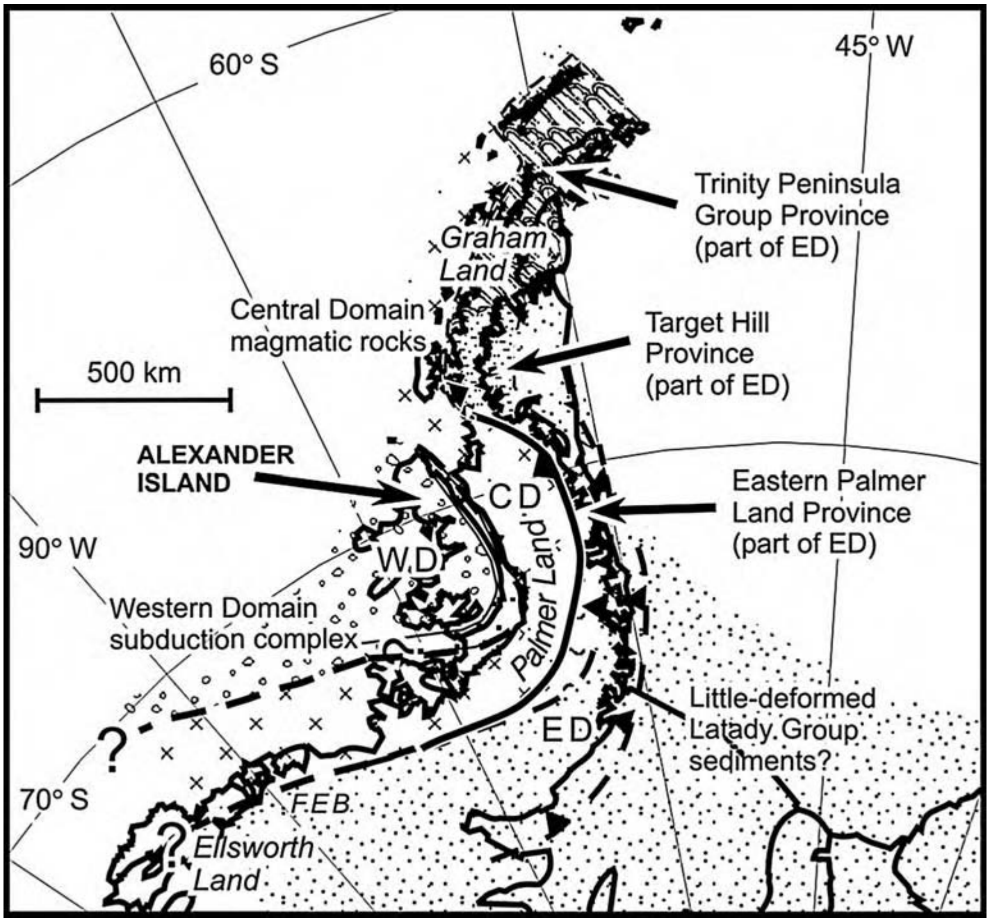
The Antarctic Peninsula is a chain of rugged mountains, up to 4190 metres high, that is divided geographically into a northern and southern portion, Graham Land and Palmer Land respectively. Graham Land lies north of 69° S and is a relatively narrow peninsula with many small offshore islands, whereas Palmer Land is higher and broader with a single large island to the west, Alexander Island.

The geology of the Antarctic Peninsula has been extensively studied since earliest explorers collected rock samples whilst visiting the area in the late 1800s and early 1900s. It is interpreted as the deeply eroded routes of a Mesozoic magmatic arc that formed on Palaeozoic or older continental basement rocks from eastward subduction of proto-Pacific and Pacific Ocean lithosphere. It contains a deeply dissected volcanic province and in some places broad subduction-accretion complexes with thick sedimentary sequences flanking both sides of the peninsula from inverted fore and back arc basins. Eastward subduction of oceanic crust beneath the peninsula occurred from at least the Triassic to Tertiary times, and may have started as early as the mid-Palaeozoic. Subduction ceased due to a series of ridge crest-trench collisions the age of which decreased progressively northwards along the peninsula, occurring off southern Alexander Island between 53.5 ± 1 and 45 ± 3 Ma, and off northern Alexander Island at 32 ± 3 Ma. Plate convergence is still continuing off the South Shetland Islands and South Scotia Ridge where the remnant Drake Plate is subducting beneath the northern tip of the Antarctic Peninsula.

The extent to which the peninsula represents a near complete Mesozoic arc-trench system that formed *in situ* during continuous subduction has been considered; an alternative interpretation has recently been published by Vaughan and Storey (2000) suggesting a new terrane model involving the possible accretion of suspect terranes during the Mesozoic development of the peninsula. The new model is based on the discovery of a major fault zone in the magmatic arc in Palmer Land, which is used to divide the peninsula into geological domains. Two and possibly three separate terranes may have collided resulting in mid-Cretaceous deformation referred to as the Palmer Land orogeny. However, the extent to which terrane accretion has occurred is currently uncertain and does not detract from the basic description of the tectonic elements given here starting with the oldest units.

Basement

The term *basement* is used here to describe the older pre-Mesozoic rocks into which the Mesozoic magmatic arc was emplaced. Its identification has proved difficult due to the intensity of the Mesozoic activity that has reworked or overprinted earlier events and due to the isolated nature of the outcrops. However, its presence and history is extremely important as it provides a window into the evolution of the peninsula prior to the extensive Mesozoic activity. It is now known that the Antarctic Peninsula has a fragmentary geological record that stretches back at least to Cambrian times. Separate Palaeozoic elements have been identified following extensive reliance on precise geochronological dating.



Geological map of the Antarctic Peninsula showing relevant place names.

Palaeozoic Granites and Gneisses

Orthogneisses with protolith ages of circa 450–550 Ma crop out in small areas of eastern Graham Land and northwestern Palmer Land, and paragneisses that are no older than late Cambrian form the basement to Triassic granites and granodiorites in eastern Palmer Land. Carbon and oxygen stable isotopic data on pre-Late Triassic marbles in northeastern Palmer Land suggest marine carbonates are present within the paragneisses. A few small granite bodies are present in eastern Graham Land at Target Hill circa 400 Ma and are present elsewhere on the peninsula as clasts in conglomerates. Locally the Palaeozoic basement underwent metamorphism, migmatisation, and granite emplacement during Carboniferous (c. 325 Ma) and Permian (c. 260 Ma) times. The extent to which these events represent a long-lived magmatic arc extending back into the Palaeozoic cannot be established based on the scarcity of data but they provide a unique window into earliest magmatic and metamorphic events that are recorded in the peninsula.

Palaeozoic Sedimentary Sequences

As well as and in contrast to the Palaeozoic igneous and metamorphic events mentioned above, two unique sedimentary successions, the Fitzgerald and Erewhon beds, have been preserved and discovered within central Palmer Land. The Fitzgerald Beds are cratonic quartzites of possible Lower Palaeozoic age, whereas the Erewhon Beds are Permian quartzose sedimentary rocks that contain the Gondwana Glossopteris fauna. Sandstone detrital modes indicate a minor arc-derived component for the Erewhon Beds. These are undoubtedly typical Palaeozoic Gondwana cover sequences that serve to link at least this part of the peninsula with the rest of Gondwana and suggest that it was not part of the active margin of Gondwana at that time.

The Trinity Peninsula Group is a thick Palaeozoic sedimentary succession that crops out in Graham Land at the northern end of the Antarctic Peninsula and comprises siliciclastic mudstone, siltstone, sandstone, and rare coarser deposits that are metamorphosed to low-grade. Being poorly fossiliferous, its age range is not well constrained but it was probably deposited between the Carboniferous and Triassic. Its tectonic setting is equally enigmatic although most authors agree that it was deposited in a forearc accretionary setting with derivation from arc and continental high grade terranes. The deformational style of the group is consistent with deformation in an accretionary setting.

Mesozoic Magmatic Arc

Mesozoic magmatic rocks are present throughout the Antarctic Peninsula including offshore islands and include the Antarctic Peninsula Batholith and deeply dissected volcanic rocks referred to as the Antarctic Peninsula Volcanic Group.

Antarctic Peninsula Batholith

Plutonic rocks that form the Antarctic Peninsula Batholith were emplaced between c. 240 Ma and 10 Ma, a period which spans the breakup of Gondwana and subsequent segmentation of West Antarctica. The batholith is 1350 km long by less than 210 km wide and intrudes the basement gneisses, coeval volcanic rocks, and fore and back-arc sedimentary rocks. The activity was virtually continuous although there appears to be significant early Jurassic (199–181 Ma) and late Jurassic to early Cretaceous (156–142 Ma) gaps in intrusive activity that may correspond to episode of arc compression. There was a Cretaceous peak of activity that started at 142 Ma and waned during the late Cretaceous. The distribution of the magmative activity varied in time and space throughout the length and breadth of the peninsula and was related to the tectonic history of the arc system through time.

Emplacement of Triassic and Early Jurassic plutons and migmatisation of basement gneisses were widespread in northern Palmer Land at this time (c. 230–200 Ma). The earliest plutons are peraluminous granites, with s-type characteristics that formed largely by melting of local paragneissic basement. By 205 Ma, metaluminous, I-type granodioroite were also being generated. It is speculated that this magmatism may represent the initiation of subduction along the Gondwana margin. During the Jurassic period, magmatism was extensive and corresponded with the breakup of Gondwana. It included extensive silicic volcanism and associated subvolcanic plutonism.

Cretaceous and younger plutons were emplaced along the length of the batholith as a result of east-directed subduction of proto-Pacific oceanic crust beneath the Antarctic Peninsula. These range in composition from gabbro to granodiorite and are dominated by metaluminous, calcic, silicon-oversaturated compositions. Unequivocal subduction related plutonism was initiated by c. 142 Ma, and was most voluminous and widespread between 125 and 100 Ma. The Tertiary part of the batholith is restricted to the west coast of the Antarctic Peninsula, signifying a major westwards jump in the locus of the arc. Subduction and its associated magmatism ceased in the Antarctic Peninsula between circa 50 Ma and the present day, following a series of northward-younging ridge-trench collisions. Subduction continues in one small segment off the South Shetland Islands where the remnant Drake plate is sinking beneath the northern tip of the Antarctic Peninsula. Related back arc extension and associated volcanism is occurring in Bransfield Strait and on Deception Island.

Antarctic Peninsula Volcanic Group

The associated Antarctic Peninsula Volcanic Group dominantly comprises subaerially erupted lavas and volcaniclastic deposits, including numerous ignimbrites. It is up to 3 km thick in places and comprises a calc-alkaline suite consisting mostly of basalts, basaltic andesites, abundant andesites, dacites, and rhyolites. Contacts normally reveal plutons intruding volcanic rocks with unconformable relationships being rare. Dykes cutting plutonic and volcanic rocks are common throughout the Antarctic Peninsula. Most of the dykes are near vertical, up to 10 m wide, mafic, with chilled margins and in places intrude along normal or strike slip faults. They form local parallel swarms, but there is no regionally consistent trend, and cone sheets arrays near intrusions are locally developed. Syn-plutonic dykes are common.

Many of the volcanic rocks exposed on the western side of the Antarctic Peninsula are Cretaceous in age and have intermediate compositions whereas silicic volcanic rocks occur irregularly on the eastern side of the peninsula and are typically middle Jurassic in age. The silicic volcanic rocks are dominated by rhyolitic ignimbrite flows, with individual units up to 80 m in thickness. Rhyolite lava flows, air-fall horizons, debris flow deposits, and epiclastic deposits are volumetrically minor, occurring as interbedded units within the ignimbrite succession.

Eastern Palmer Land Shear Zone

East of the central spine of Palmer Land, a major strike-slip shear zone deforms plutonic, metamorphic, metasedimantary, and metavolvcanic rocks. The shear zone is a complex of ductile and brittle-ductile, reverse and dextral-reverse shears up to 15 km across strike and generally at amphibolite facies. In its northern part, the shear zone forms ductile, reverse, or dextral-reverse mylonite whereas in its southern part, a complex breccia zone crops out. The tectonic significance of this feature is uncertain. It has been used to define the boundary between newly identified geological domains and interpreted as a suture along which an allochthanous central terrane may have collided with the Gondwana margin in mid-Cretaceous times. Although this model remains to be tested for the Antarctic Peninsula, it is consistent with other parts of the Pacific margin of Gondwana.

Fore Arc Region

Accretionary subduction complexes and forearc basin sequences are present to varied extents along the western margin of the Antarctic Peninsula Mesozoic magmatic arc.

Accretionary Complex

The LeMay Group of Alexander Island on the western side of the Antarctic Peninsula is an unusually wide accretionary complex compared with the remainder of the palaeo-Pacific margin of Antarctica. The exposed part of the complex is up to 300 km wide and is preserved in an embayment of the arcuate Mesozoic magmatic arc. It is comprised of deformed trench-fill turbidites, trench slope sequences, and allochthonous slivers of ocean-floor and ocean-island igneous and sedimentary rocks. The age of the complex is constrained by the presence of an Early Jurassic ammonite from accreted tuffs within an ocean island sequence, and by Late Jurassic to Early Cretaceous and mid-Cretaceous radiolarian from accreted cherts. All of the ages are from allochthonous units, which place maxima on the ages of accretion in those parts of the prism where they are exposed. The ages show a pattern of younging towards the margin consistent with an accretionary prism model. On the eastern side, the complex is unconformably overlain and in faulted contact with a forearc basin sequence, which places a minimum Middle Jurassic age on this part of the prism. The complex may have developed by the accumulation of docked exotic terranes in a preexisting embayment along the palaeo-Pacific margin, or alternatively by long-lived subduction and accretion along this segment of the margin. In the latter case, subsequent oroclinal bending of the magmatic arc may account for the unusually wide complex now preserved in the arcuate embayment of the margin.

Fore Arc Basin

The Fossil Bluff Group is a thick (up to 7 km) fore arc basin sequence that sits unconformably on and is in faulted contact with the accretionary complex rocks of Alexander Island. It consists dominantly of silty mudstone, with significant amounts of sandstone and conglomerate. Palaeocurrent and provenance analysis indicate that the bulk of the unit was derived from the volcanic arc to the east, although there is a minor component of accretionary complex-derived material mainly in the western parts of the group. Deposition of the group spanned Mid-Jurassic (Bathonian) to Albian times and has been divided into two major stages of basin development punctuated by short duration tectonically induced events. The oldest Selene Nunataks and Atoll Nunataks formations, exposed on the western side of the basin, record the first stage, the transition from trench-slope to fore-arc basin sedimentation. These units were derived from the accretionary complex rather than the volcanic arc. All other strata in the basin are part of the second stage fore-arc basin sedimentation and form a large-scale, shallow upward cycle of Kimmeridgian to Albian age.

The sequence was deformed by oblique north-northwest to south-southeast trending folds with an associated weak cleavage. The geometry of a range of related structures including bifurcating arrays of sandstone dykes, bedding parallel slip, conjugate normal faults, and steep dextral normal oblique faults have been used to suggest that basin inversion involved dextral transpression.

Magmatic History

The Mesozoic fore arc region on Alexander Island was intruded in Late Cretaceous to Early Tertiary times (80-52 Ma) by subduction-related magmatic rocks, the youngest part of the Antarctic Peninsula Batholith. The rocks occupy what was a fore-arc position 100–200 km trenchward of the main arc on the Antarctic Peninsula. The magmatic rocks become younger northward along the length of the island.

Back Arc Region

Thick sedimentary successions developed within the Larsen and Latady basins on the eastern back arc side of the Antarctic Peninsula Mesozoic magmatic arc during the Jurassic and Cretaceous periods. The earliest of these was probably that on the southeastern margins that was to become the site of accumulation of the Middle-Late Jurassic Latady Formation.

The Latady Formation is a poorly known folded sequence of Jurassic fossiliferous shallow marine to terrestrial sandstones to mudstones. The succession comprises black and grey slate, siltstone, and mudstone with subordinate sandstone and coal; conglomerate is rare. It is estimated to be several kilometers thick. There appears to be a transition in depositional environment from a terrestrial setting near the axis of the peninsula (magmatic arc) into a truly marine environment to the southwest. Nonmarine sedimentary rocks, containing abundant plant fossils and thin coal beds, interdigitate with air-fall and ash-flow tuffs, lava flows, and volcanic breccias at the basin margin. The nonmarine deposits pass laterally through shallow marine, possibly deltaic rocks into open marine deposits. On the basis of locally abundant marine faunas, most of these sediments have been assigned a Late Jurassic age although Middle Jurassic (Bajocian) ammonites and bivalves have been described from eastern Ellsworth Land. Provenance studies suggest that the active magmatic arc was the primary source of sediment, with significant amounts of metamorphic material which may represent erosion of arc basement. At this time much of the northern end of the peninsula was blanketed by deep-sea radiolarian rich muds that formed part of a huge anoxic basin within the proto-South Atlantic region.

The Larsen Basin sedimentary succession is best exposed in the James Ross Island area. It is approximately 5–6 km thick, of Barremian to Oligocene in age and is thought to overlie radiolarian rich mudstones and tuffs of the Nordenskjold Formation. The basin fill forms a retrogressive megasequence that has been divided into three groups, the basal deep marine Gustav Group and the overlying shallow marine to deltaic Marambio and Seymour Island groups.

Late Jurassic fossils common to all of the foregoing regions include ammonites, various representatives of the belemnite family Belemnopseidae, and Bivalves. The Bivalves include genera that are apparently unique to the southern high latitudes and others which form striking cosmopolitan and bipolar distributions. It is possible to trace the Antarctic marine fossil record into the early Cretaceous period using strata exposed in the sedimentary basins flanking both sides of the Antarctic Peninsula, which in some cases include prolific faunas of bivalves, gastropods, and brachiopods. The same localities have also yielded a diversity of plant macrofossils and microfossils. Collectively these suggest that throughout the Late Jurassic to Early Cretaceous much of the Antarctic continent was covered by open-canopied rainforests comprising podocarp and araucarian conifers, associated with ginkgoes, and an understory of ferns, lycopods, and bryophytes. Cool temperate moist climates prevailed in Antarctica throughout the Early Cretaceous.

In mid-Cretaceous times, the sedimentary infill of the Latady basin and associated volcanic rocks were folded and overthrust during a deformation event generally referred to as the Palmer Land event. Folding is on a kilometer scale with variable fold geometries. Folds are open to isoclinal, upright to recumbent, symmetric to asymmetric, and angular to chevron in profile. A penetrative, axial planar cleavage is well developed in finer grained rocks. Overthrust sense and fold vergence is to the east and southeast, and fold axes and faults strike parallel to the curvilinear long axis of the Antarctic Peninsula.

On James Ross Island in the back arc region the near complete sequence of fossiliferous Late Cretaceous sedimentary rocks is one of the most important in the southern Hemisphere. It contains, amongst other things, a distinctive high-latitude fauna of Cretaceous terrestrial vertebrates that includes small hypsilophodontid dinosaurs and therapods such as *Allosaurus* and a probable labyrinthodont. By the end of the Cretaceous, a podocarp-*Nothofagus* rainforest covered much of the area, extending into the Palaeocene to Eocene. It grew under cool-temperate highly seasonal climates with a substantial cooling at the end of the Cretaceous period.

Seymour Island, also within the Larsen Basin, has been referred to as the Rosetta Stone of Antarctic palaeontology, yielding prolific invertebrate and vertebrate faunas. The middle to late Eocene La Meseta Formation is the principal fossiliferous unit providing invertebrate bivalves, gastropods, echinoderms, decapod crustaceans, and brachiopods, and vertebrate sharks, teleost fish, turtles, plesiosaurs, birds (including giant penguins), marine mammals (including whales), and primitive marsupials. The formation shows the first compositional elements of the modern marine fauna.

Isolation of Antarctica

Drake Passage opened 35 Ma and the Antarctic Peninsula ceased to be attached to Southern South America following sea floor spreading in the Scotia Sea. This had a profound affect on Antarctica leading to the development of the circumpolar current, climatic cooling, and the development of permanent ice sheets on Antarctica from approximately 15 Ma. From 23 Ma onwards the sedimentary record is largely one of glaciogenic strata in which the recovery of both macrofossils and microfossils is usually poor.

Subduction also progressively ceased during this time period along the western sea board of Graham Land following a series of ridge crest–trench collisions. Postsubduction alkali magmatism occurred in a few scattered localities along the length of the peninsula. On Alexander Island, basanites, tephrites, alkali, and olivine basalts ranging in age from 15 to less than 1 Ma were erupted on to the Mesozoic accretionary complex. At Seal Nunataks on the eastern side of the peninsula, alkali and olivine and minor tholeiitic basalt occur to the east of the calc alkaline batholith and overlie the back arc sedimentary succession on James Ross Island. Subduction continues to the present day where the remnant Drake Plate is subducting beneath the northern tip of the Antarctic Peninsula.

ANTARCTIC PENINSULA, GLACIOLOGY OF

In a glacial regime, falling snow accumulates and is compacted into ice that flows under its own weight, ultimately to melt or calve as icebergs into the sea. The regime of the Antarctic Peninsula's plateau ice caps, many mountain glaciers, and ice shelves is quite different from that of the flatter, drier, and colder East and West Antarctic ice sheets. Protruding north into the path of the circumpolar westerly airflow and the marine Circumpolar Deep Water current, the climate of this long, sinuous mountain chain is markedly more maritime than polar continental. Relatively mild but stormy weather deposits an average 0.87 m of water-equivalent precipitation annually compared with the continental average of 0.14 m, with up to 10 m of snow falling each year on the high central plateau. Although covering only 3% of the Antarctic continent, the peninsula receives 18% of its snowfall and this maritime climate and high relief give the region a dynamic and diverse glacial regime, one that is currently experiencing rapid change.

Snow falling on the Antarctic Peninsula is drained by over 400 glaciers flowing either west into the Bellingshausen Sea or east into the Weddell Sea. The largely unvisited western glaciers from 63° to 70° S are mostly short, steep, and heavily crevassed. They flow rapidly at up to 6 m per day down deeply incised fjords through the coastal mountain chain before calving into the many ice-clogged bays along this stretch of coast. Further south, in Palmer Land, the plateau broadens and the westward slope is gentler. The glaciers here form a near-continuous ice cover flowing relatively slowly into George VI ice shelf. This cover, the thickest on the peninsula at over 1000 m, is pierced only by isolated mountain peaks.

Although the peninsula's cordillera spine is just 100 to 200 km wide for most of its length, a sharp climatic contrast exists between the east and west coasts. The eastern flank receives cold southerly winds and is protected from the relative warmth of the Circumpolar Deep Water current. Mean annual temperatures are –5°C to –17°C, typically 3°C–5°C lower than the west. In these colder conditions, ice shelves historically have fringed almost all of the peninsula's east coast. These shelves, floating slabs of ice up to 200 m thick, extending up to 200 km offshore and ending in a 1000 km long vertical ice cliff, are supplied by the influx of ice from the glaciers draining east from the plateau drainage divide and by new snowfall onto the shelf. This is balanced by ice loss through iceberg calving, basal melt, and, in the north, surface melting when temperatures rise above freezing in summer.

Today, the Antarctic Peninsula glacial regime continues to adjust to changes in climate, ocean circulation, and sea level over a range of time scales but data on its history are limited. At the height of the last ice age in this region, approximately 35,000 years ago, an ice sheet several hundred meters thicker than present extended 100–200 km out onto the continental shelf to the east and west, drained by large ice streams that created the ice-sculpted form of the current sea bed revealed by recent bathymetric mapping. From 17,000 to 10,000 years ago the peninsula ice sheet thinned and retreated. This is thought to have been driven by a sea level rise of around 100 m brought on by melting of the Northern Hemisphere ice sheets, a rise that would have floated the grounded margins of the peninsula ice. By around 9,500–6,000 years ago, relatively mild and humid conditions were established. Grounded ice cover had retreated to near the present coastline, and the bare rock we see today in some coastal areas was exposed and began to be colonized by penguins, whose relict rookeries can be radiocarbon dated. There followed a partial readvance of glaciers and ice shelves succeeded by the mildest, most humid conditions of the Holocene, the climatic optimum, 3,000 years ago. Another flip back to distinct and rapid cooling culminated in the Little Ice Age glacial advance in the eighteenth and nineteenth centuries CE. The strength of the dominant high-pressure atmospheric system that sits over Antarctica is believed to have been a key control of the region's climate throughout this period.

Over the last century, the Antarctic Peninsula climate has veered into a period of rapid and significant warming. Instrumental measurements since the 1950s show an increase in mean annual temperature of around 2.5°C, four times the global mean. With summer temperatures already around freezing, melting intensity (the number of positive degree–days) has increased by up to 74%. Concurrently, 87% of glacier fronts retreated in a wave of change spreading from north to south. Most notably, seven ice shelves closest to the southward-migrating limit of ice shelf viability, defined by the January 0°C isotherm, have retreated substantially with four disintegrating: a loss of nearly 20,000 km^2. Several had previously disappeared and reformed as the Holocene climate oscillated; however, the latest to collapse, the 11,500 km^2 Larsen B, had existed continuously since its formation 10,500 years ago when the grounded ice sheet receded from the continental shelf. This suggests that the current conditions are unprecedented since before the last ice age, at least 110,000 years ago. Research into the changes on the peninsula suggests three key factors in ice shelf collapse: (1) warmer ocean waters thin and weaken the shelf; (2) a retreating front breaks through the "compressive arch" of flow that helps lock the shelf together in an embayment, allowing it to accelerate and thin further; and (3) summer melting floods crevasses in the shelf, creating a wedge more dense than the surrounding ice that drives through to the base. Weakened in this way, 3250 km^2 of the Larsen B collapsed in less than a month in summer 2002.

The loss of floating ice shelves, although dramatic, does not directly affect global sea level because they are already displacing seawater. Recent satellite observations after the Larsen A and B collapses revealed the more significant consequences of their loss: Their grounded tributary glaciers accelerated by up to eight times, causing rapid thinning as ice stored on land was discharged to the sea. The volume of ice involved and consequent sea level rise was small but this is seen as an important analogue for the much larger ice stream-ice shelf systems of the East and West Antarctic ice sheets, through which 80% of Antarctic ice drains. It is now clear that intact shelves restrict the flow of their tributary glaciers. Their loss allows the glaciers to accelerate and thin, a process that could threaten the stability of the much greater body of ice in the West Antarctic Ice Sheet. The Antarctic Peninsula's changing glacial regime is distinct in several ways from the rest of the continent, but nonetheless it serves as an important bellwether for the future evolution of the Antarctic ice sheets.

ANTARCTIC PETREL

The Antarctic petrel *(Thalassoica antarctica)* belongs to the "fulmarine petrels," a small subfamily of tube-nosed seabirds highly adapted to life in cold polar oceans. The other fulmarines are snow petrel, Cape petrel, the two species of giant petrels, and the southern and northern fulmar. Only the last species has found its way into the Arctic; all others roam the Southern Ocean and breed on the Antarctic continent and sub-Antarctic islands. The Antarctic petrel has a distinctive dark brown-and-white plumage, with a broad white bar over the dark upper wing and tail (where Cape petrels are irregularly spotted) and with white underparts.

In its choice of breeding locations, the Antarctic petrel is the most extreme polar bird on Earth, and because of that still a bit of a mystery bird. Breeding is known only from continental east Antarctica with several colonies on coastal islands and rocky outcrops. But the main concentrations are found on inland nunataks, the exposed mountain peaks protruding from the Antarctic icecap. In late summer at the maximum retreat of sea ice, nunatak colonies may be several hundreds of kilometres away from nearest open water.

The largest known Antarctic petrel colony is on the Svarthamaren Mountains in Dronning Maud Land, with 250,000 breeding pairs and a total of about 820,000 individuals including nonbreeders. Overall, as of 2005, we know about thirty-five Antarctic petrel colonies with a documented total of half a million breeding pairs. However, an estimate derived from at-sea studies in three of four apparent centres of oceanic occurrence around Antarctica suggests a population as high as 4–7 million breeding pairs (10–20 million individuals). In spite of the tentative nature of such an estimate, the disparity with the colony-derived figure suggests potential existence of large, as yet undiscovered colonies. Such colonies may particularly exist in the inland parts of western Antarctica and Victoria Land, where a complete mismatch exists between known colonies and bird numbers at sea. Antarctic petrels nest fully in the open in large tightly packed colonies on exposed boulder slopes, but nevertheless the vast interior of the Antarctic continent can still hold mysteries.

At sea, Antarctic petrels prefer the subzero temperature waters within and just north of the marginal ice zone. Here they are seen in fast flying flocks or in large concentrations roosting on icebergs. During winter, they remain in this narrow latitudinal band around the sea ice. They seem not to visit the breeding colonies over winter, nor do they migrate farther north. Already in sub-Antarctic waters, the species is an unusual observation, and unfortunate stragglers that end up near the Southern Hemisphere continents are a rarity.

Breeding is highly synchronized among Antarctic petrels even between the coastal and inland colonies. In spring (late September to early October), Antarctic petrels aggregate near the ice edge and then depart south for their prebreeding visit to the colony. At this time of year, the combined flight distance over sea ice and ice cap to the colony may exceed 2000 km of flight one way. With such flight capacities, birds from deep inland colonies may be able to cross the Antarctic Peninsula. Quite a challenge for a typical seabird! But radar echo images from Halley Station suggest that in spring, Antarctic petrels may be commuting between their inland colonies and open water at altitudes of 1000 m.

After this long flight, Antarctic petrels show up at the colonies in the second week of October. For about two weeks they remain there to reestablish partner bonds and nest ownership, clearing away snow, engaging in courtship and copulating. Towards the end of October, all birds depart for the long return flight to open water to replenish their energy reserves. The colonies are totally deserted during this "prelaying exodus."

But within 3 weeks all of them return. The females immediately lay the single egg that can not be replaced if lost. The nest is not more than some rock fragments and dirt scraped together. Virtually all laying is synchronized between 20 and 30 November. Females leave the males behind for the first long incubation shift, which may last up to two weeks. The whole incubation takes almost seven weeks in which males and females alternate incubation duties in gradually shortening shifts. Chicks hatch in the second week of January, after which it takes another seven weeks before they are ready to fledge in late February to early March. Parents guard the chick for the first 10–15 days. During this time, failed and nonbreeders also still attend their nest sites, but towards the end of January all adults leave and only successful breeders pay short visits to feed the chicks. After the colony period, adults return to sea to moult their plumage. Some birds may make short colony visits in late April to early May, but most probably stay out at sea until the next spring.

Under the extreme Antarctic conditions, where Antarctic Petrels breed earlier than the other petrels, breeding success is often low, and typically well under 50% of initial attempts. But the adults are long-lived (over 97% adult annual survival), so frequent breeding failure can be compensated by high life expectancies.

As far as is presently known, Antarctic Petrel populations are currently stable. But on a local scale, serious effects of climate change have been observed. Increased snowfall in Wilkes Land not only caused increased egg freezing but made colonies accessible to predatory southern giant petrels *(Macronectes giganteus)*. Predation strongly reduced breeder survival and indirectly caused near total breeding failure as temporarily abandoned eggs were taken by South Polar skuas *(Catharacta maccormicki)*.

The diet of Antarctic petrels is dominated by fish, mainly Antarctic silverfish and lanternfishes. Squids are also a common prey for self-provisioning birds. Crustaceans such as krill and amphipods are an extremely common diet item but only occasionally dominate other prey in diet mass. Opportunistic feeding may include jelly-type prey. This diet of Antarctic petrels should not lead to a lack of concern about potential competition with commercial krill harvesting. Indirectly, compared with direct krill consumption, their diet may put heavier demand on krill stocks because the fish and squid themselves may depend on krill.

ANTARCTIC PRION

The Antarctic prion (*Pachyptila desolata* Gmelin 1789) is a member of the order Procellariiformes or tube-nosed seabirds—the petrels, albatrosses, and shearwaters. *P. desolata* is one of the most ubiquitous petrels of the Southern Ocean. These birds can often be seen flying in large, erratic swarms resembling flocks of pigeons or doves in flight over the ocean. Perhaps it is this image that suggests their other common names—dove prion, dove petrel, and whalebird.

Antarctic prions belong to the genus Pachyptila (*pachy,* broad; *ptila,* wing), the taxonomy of which is still debated. *P. desolata* are midsize petrels, weighing between 150 and 160 g with a wingspan of about 65 cm. At sea, these birds can be seen individually, in small groups, or in flocks of several thousand birds. Like other prions, *P. desolata* is a cloudy, blue-gray color, with a dark "M" mark across the backs of the wings. The blue-gray on top is contrasted by a white belly and under parts. The forehead, crown, and nape of the neck are also blue-gray color, with a grayish-black suborbital patch on each side of the head. This coloration allows them to blend into the backdrop of the ocean when they are viewed from above or to the side. Procellariiform aficionados are fond of noting that prions are so effective at camouflage that navy ships even co-opted their blue-gray color, presumably to reduce their visibility to the enemy.

Antarctic prions were also colloquially known as "scoopers" by whalers because of their unique style of foraging. These birds capture their prey by hydroplaning over the surface of the ocean with their wings extended and their heads submerged. At the same time, the bill is open exposing an upper mandible with a set of fringed strainers that are reminiscent of a whale's baleen. As the bird flies, water and crustaceans are flushed through the strainers, assisted by the tongue and other muscular movements of the bill, while, in the meantime, the skin of the bottom mandible extends into a pouch to hold the prey items. Thus, by skimming along the surface of the water, the bird is able to filter fine crustaceans and other zooplankton from the ocean's surface without ever seeing them at all. Antarctic prions are versatile in their foraging habits. In addition to filter feeding, they can also dive to at least 3 m and are capable of hunting prey by snatching it with their bill. In addition, detailed sensory studies have shown that Antarctic prions have reduced binocular vision compared with other petrels, suggesting that visually pinpointing and grasping prey may not be as essential to their daily routine as it might be for other tube-nosed species. These birds also have a remarkable sense of smell that allows them both to track their prey by smell like a bloodhound and to detect productive areas of ocean where prey aggregations are likely to be found. Results from numerous experiments suggest that olfaction is critical to their ability to find their prey, which includes a variety of crustaceans, mesopelagic fish, and squid.

Antarctic prions have a near-circumpolar distribution and are currently not globally endangered. These birds are currently found nesting on a number of sub-Antarctic islands including South Georgia, the South Sandwich Islands, the South Orkney Islands, the South Shetland Islands, Îles Crozet, Îles Kerguelen, Heard Island, Macquarie Island, the Auckland Islands, and Scott Island. These birds breed in a more southerly range than other prion species, and historically have nested even on the Antarctic continent. *P. desolata* nests underground, either in burrows or in rocky crevices that can be up to 1 m deep. Birds tend to nest together in loosely aggregated or dense colonies, depending on the habitat and location. Antarctic prions are subject to predation by other birds, including South Polar skuas *(Catharacta maccormicki)*. This threat restricts them to a nocturnal lifestyle on land. Prions, in general, are also particularly vulnerable to rats (*Rattus* spp.) and feral cats *(Felis catus),* which can decimate populations in breeding colonies.

As with other procellariiforms, Antarctic prions are long lived and assumed to be monogamous because they return to the same burrow year after year to rear their offspring. The breeding season lasts throughout the summer months from late September through March or early April, depending on the location. Birds nest annually and rear a single offspring. Pairs come back to the nesting colony in spring, mate, and then go back out to sea for a "honeymoon" period (also known as the pre-egg exodus) while the egg develops. This might be a period in which the couple explores nearby foraging location, but its purpose is still open for speculation. Once the egg is laid, it must be incubated for at least 42 days, but eggs can also tolerate considerable neglect if foraging conditions are not good for the parents. In such cases, incubation can last as long as 50 days. Antarctic prions can recognize the scent of their burrow, and use olfaction to locate it within the colony. Recent studies have also shown that these birds are sensitive to individual-specific odors, and may even use odor cues to recognize the scent of their mate. Prions are also noisy in breeding colonies and pairs can frequently be heard vocalizing to each other in the burrow during incubation shift changeovers.

The way in which Antarctic prions provision chicks has been studied in detail at Îles Kerguelen and at South Georgia. At Kerguelen, researchers have shown that Antarctic prions provision chicks using a dual foraging strategy. Here, parents alternate long foraging trips of about a week with a cluster of shorter trips of 1–2 days. The long foraging trips allow parents to feed themselves while the short foraging trip allows them to collect food for the chick. Food for the chick is regurgitated as concentrated stomach oil, which is the primary way nearly all procellariiforms feed their young. Although they are fed daily, the growth rate of the chicks depends on the quality of the food available. Thus, if krill (*Euphausia* spp.) is farther offshore, chicks may grow more slowly than when krill is readily at hand. Meanwhile, at South Georgia, researchers have shown that Antarctic prions can successfully rear young even in low quality years when other procellariiforms fail. This is because, unlike many other species, Antarctic prions have the ability to switch among available food resources, possibly due to the fact that they can resort to filter feeding on calanoid copepods close to shore during time when a high-quality food resource like Antarctic krill is not available.

Chicks fledge at about 45 days and adults leave the colony by late summer, typically at least a week before their young have fledged. Because Antarctic prions are too small to carry satellite transmitters, little is currently known about their behavior once they leave the nest.

ANTARCTIC SURFACE WATER

In the Southern Ocean, the strong eastward flow of the Antarctic Circumpolar Current is characterized by continuous fronts that circle the globe. These fronts are readily distinguishable by the isopleths of properties sloping upward to the south. The fronts are manifested at the surface as strong horizontal gradients in temperature, salinity, and other oceanic properties over distances of $\sim$10 km. These property gradients form boundaries between water masses, separating the relatively warmer sub-Antarctic surface waters of the north from the colder Antarctic Surface Water to the south.

World ocean water masses are typically identified by distinctive signatures of temperature, salinity, dissolved oxygen, and nutrients. Drake Passage is the narrowest passageway through which the Antarctic Circumpolar Current must squeeze and therefore provides a convenient chokepoint where Southern Ocean water masses and their variations can be readily measured and studied. The temperature and salinity data collected in Drake Passage represent one of the longest, year-round time series for examining property characteristics and variability in the upper waters of the Southern Ocean. At other longitudes there are likely to be small variations in the horizontal property distribution of the upper ocean water masses, as the Antarctic Circumpolar Current meanders north and south in response to changes in bottom topography. In Drake Passage the main fronts of the current are distinct features that divide zones of uniform water properties, while in other regions the fronts may split or merge to reveal a more complex, filamented structure.

Property Characteristics of Upper Ocean Water Masses in the Southern Ocean

Between 58° S and the continental margin of Antarctica at 62° S, the Antarctic Surface Water (AASW) is defined by surface waters with subzero temperatures and salinities fresher than 34 above 150 m. During the Southern Hemisphere winter, the AASW is colder, slightly more saline, and extends to the sea surface, where temperatures can reach as low as –1.9°C, near the freezing point of water at these salinities. Surface heating and ice melt during the spring and summer months warms and freshens the AASW in the upper 50 m. A remnant of the deep winter mixed layer persists throughout the austral summer and is generally marked by a subsurface temperature minimum, typically below 0°C and centered around 100 m. This cold subsurface layer is often referred to as Winter Water (WW). The large temperature change at the northern extent of the WW marks the position of the Polar Front, one of the major circumpolar fronts associated with strong flows in the Antarctic Circumpolar Current. The Polar Front is dynamically determined as the region where cold AASW sinks beneath the warmer sub-Antarctic surface waters to the north, and can be defined as the northern extent of waters colder than 2°C at 200 m. The Polar Front can appear in satellite observations as a strong gradient in sea surface temperature (SST), particularly in winter months when the 2°C isotherm outcrops into the surface layer. Summer heating of the surface layer results in a more southerly position than that determined from subsurface temperature measurements. In Drake Passage the mean Polar Front location is at 58.3° S in both seasons, but its location is more variable during winter. Although Polar Front meanders at other longitudes result in more seasonal variability, the dynamic expression of the Polar Front still separates the Antarctic and sub-Antarctic surface water masses.

Below the AASW lies the relatively warmer and more saline Upper Circumpolar Deep Water mass (UCDW), which has a temperature maximum near 2°C at 300 m. UCDW displays the least temporal and spatial variability in temperature of all upper ocean water masses in the Southern Ocean. In contrast, salinity increases from 34.0 at the base of the AASW to 34.7 at 600–700 m at the top of the underlying Lower Circumpolar Deep Water (LCDW). Salinity controls the density, and thus the stability, of the water column at these latitudes. The UCDW is largely a product of mixing between deep waters formed in the North Atlantic and in the western Indian and eastern Pacific sectors of the Southern Ocean, which gives it low oxygen and high nutrient concentrations. The UCDW and LCDW shoal poleward beneath the sea surface, providing a marker for the southern extent of the Antarctic Circumpolar Current.

The relatively fresh surface water in northern Drake Passage is Subantarctic Surface Water (SASW), which is also warmed by heating at the surface during summer. Its surface temperature and salinity ranges (4°C–14°C; 33.5–34.0) are larger than in AASW due to greater variations in solar heating, precipitation and evaporation at lower latitudes. Below the surface layer lies the Subantarctic Mode Water (SAMW), characterized by low variability in temperature and salinity from 300 to 700 m. SAMW temperatures range from 4°C–5°C while salinities range from 34.1 to 34.2. The southern extent of the SAMW in this depth interval, the Subantarctic Front, marks the northern boundary of the Antarctic Circumpolar

Current, located near 56° S in Drake Passage. As with the Polar Front, the Subantarctic Front also meanders and can appear to be filamented with longitude around the Southern Ocean.

Between the Polar Front and the Subantarctic Front is a transitional region for Antarctic and Subantarctic surface waters. Though a southward shoaling of isotherms is characteristic, individual vertical profiles in this zone commonly show water mass interleaving and temperature inversions. Warm-core and cold-core eddies extending from the surface layer to depths below 700 m also frequently populate the region. These eddies may be an efficient mechanism for the exchange of water mass properties and biological organisms such as phytoplankton across the Antarctic Circumpolar Current.

The Role of Surface Waters in the Meridional Overturning Circulation

The strong westerly winds that encircle the globe in the vicinity of the Antarctic Circumpolar Current drive a northward flow, or Ekman transport, in the surface layers. V. W. Ekman developed a theory in 1905 showing that wind stress acting on the surface layer is affected by the Earth's rotation, such that flow is to the left of the wind in the Southern Hemisphere (and to the right in the Northern Hemisphere). As the surface waters move northward, surface temperatures increase from 1°C to 4°C–5°C, implying an oceanic heat gain south of the Polar Front. This is also a "buoyancy" gain and is thought to be achieved by north-south excursions of atmospheric and oceanic frontal storms, which provide the heat and fresh water that reduces the density of the surface waters.

South of the westerly wind stress maximum, the Ekman transport is divergent, and mass conservation requires that this northward motion be balanced by a southward flow. Evidence suggests this compensation can generally be attributed to the southward shoaling UCDW. Since Drake Passage latitudes have no topography above 2000 m to support an east-west pressure gradient to drive a southward geostrophic flow, the poleward transport and upwelling of the UCDW is probably accomplished by eddies. North of the westerly wind maximum, the Ekman transport is convergent so that the surface waters are driven down into the ocean interior. In addition, a buoyancy loss results from air-sea cooling in winter, deepening the surface layers and leading to the formation of the SAMW near the Subantarctic Front. While SAMW is generally characterized by a well-mixed layer of high oxygen content, its properties may also vary due to the north-south meandering of the Subantarctic Front. The coldest, densest SAMW is the Antarctic Intermediate Water (AAIW), which originates as a low-salinity layer formed in the region of deepest mixed layers in the South Pacific just west of Chile. Uncertainty remains about the role of the northward transport of cool, fresh surface waters in maintaining the volume and thickness of SAMW, but its distinctive low-salinity, high oxygen properties provide a clear signature that can be traced throughout the global ocean. The intermediate depth water masses that are formed from these surface waters are known to "ventilate" a substantial fraction of the world ocean volume.

The upper ocean meridional (north-south) circulation described above is historically known as the Deacon Cell, after Sir George Deacon who described it in 1937, and in more recent literature as the upper cell of the Meridional Overturning Circulation. Surface waters transported northward in the Ekman layer as part of this circulation play an important role in the exchange of heat and fresh water with the overlying atmosphere and sea ice in the Southern Ocean and beyond. Variability in atmospheric forcing and climate in this region can be directly communicated via water properties to the ocean interior and thereby influence the storage of heat and freshwater at lower latitudes. Because the solubility of carbon dioxide increases with colder water, the Antarctic surface waters and the Meridional Overturning Circulation are thought to play a key role in regulating the ocean's capacity for the uptake of this greenhouse gas. Temperature and salinity variations in Antarctic surface waters may thus have important implications for global climate change.

ANTARCTIC TERN

Breeding populations of this species are distributed on Tristan da Cunha, Gough Island, Bouvetøya, the Prince Edward Islands, Îles Crozet, Îles Kerguelen, Île Amsterdam, Île St. Paul, Heard Island, Macquarie Island, the Campbell Islands, Auckland Islands, Snares Islands, Antipodes Islands, Bounty Island, and offshore islands of New Zealand. In the region of the Antarctic Peninsula, breeding populations reach 68° S. They also breed on the South Shetland Islands, South Orkney Islands, South Georgia, and the South Sandwich Islands. The total population may be 50,000 breeding pairs.

Antarctic terns breed on the coasts and islands of the Antarctic and sub-Antarctic seas, especially on cliffs, rocky islets, and beaches with or without vegetation, but also on gravel beaches and moraines. In the northern area of their distribution, they breed in different places: on Tristan da Cunha they are found on ledges on offshore islands, and on the Snares and Bounty Islands they nest solitarily on cliff ledges. In many of these islands, the original breeding places have been abandoned following the introduction of predators, and the birds have moved to safer places without rats (*Rattus* spp.) or cats *(Felis catus)* (e.g., on Île Amsterdam, where they are now found on coastal cliffs inaccessible to cats).

Outside the breeding period, they have been observed to be more oceanic, occurring near ice edges in Antarctica, and also on rocky headlands and beaches in South Africa or in the area of the cold-water currents of South America. Antarctic terns are not ship-followers. There are few data on the movements of Antarctic terns, but the species is believed to be only partly migratory. In the region of the South Shetland Islands, in the maritime Antarctic, birds have been observed throughout the year. Large winter flocks roost in South Africa.

The birds return to breed in loose colonies adjacent to coastal waters, in some colonies very early (mid-September in the South Shetlands Islands). Courtship behaviours such as courtship feeding and coordinated flights occur and prospecting for nest sites has been seen in early spring. The nests are shallow scrapes in pebbles or shells. Some birds prefer slight depressions in bare rocks or a thin layer of soil or vegetation. On sub-Antarctic islands, thin layers of leaves are used for nest building. Most scrapes contain small stones. Laying occurs between mid-November and February, later in more northern areas than in the south. There are usually no more than forty widely distributed nests in any one locality. This species is assumed to be monogamous, and the pair bond may be maintained between breeding seasons. The birds defend a small area around the nest. They lay two to three mottled eggs in open, shallow, pebble- or shell-lined scrapes on the ground. Incubation begins when the first egg is laid. Incubation is by both parents for 23 days, with the chicks hatching from December to late February. The nests are difficult to see as the eggs and chicks are well camouflaged. Adult Antarctic terns cooperate to defend their colonies from predatory birds and mammals, although skuas (*Catharacta* spp.) and kelp gulls *(Larus dominicanus)* still occasionally manage to take eggs or chicks from unattended nests. Skuas are the main predators. The high rate of predation is the reason for frequent re-laying. Fledging of the chicks occurs from January through to May, 23–32 days after hatching. The parents attend their young for several weeks after fledging, occasionally feeding their chicks.

Breeding success fluctuates greatly; on King George Island, for example, it ranges between 3% and 86%. The most important factors are human disturbance, bad weather conditions (especially snow in spring), and a high predation rate, especially by skuas and, in northern areas, also by rats. Antarctic terns move their colony not only from year to year but also during the breeding season after human disturbance or predation by skuas.

Antarctic terns feed mainly on small fish like the Antarctic herring and on crustaceans such as krill, amphipods, and isopods, and sometimes on molluscs (limpets), polychaetes, algae, and insects. There are different foraging methods, the shallow plunge with full submersion or sometimes only surface plunging or dipping. This depends on the conditions at sea. If there is a calm sea, they prefer plunging to catch fish or dipping to catch crustaceans but, in a rough sea, surface plunging is the only effective means of obtaining food. They also forage inshore or in lakes.

Their social behaviour has been studied in detail on King George Island. Agonistic behaviour is the vicious defence of the nesting territory against other Antarctic terns and other species. There is a very interesting bill-down threat display with loud calls, pressing the body forward with tail up and bill pointed down. The wings are away from the body. This behaviour is also shown by the neighbours, and is repeated sometimes. A similar behaviour is the bill-up threat display against overflying birds, where the bill is pointed skyward. There are some very common forms of behaviour of varying intensities: crouching, bowing, the aggressive upright, and the bent posture for territory defence. Sometimes there are aerial fights between neighbours. When skuas intrude into a tern colony, the terns chase and mob the intruders.

Sexual behaviour includes ground courtship, courtship flights, a greeting ceremony, and courtship feeding. The courtship flights occur before egg-laying. The male arrives carrying a small fish, which is offered to the female. After the female has eaten the fish, the pair tests several nest sites by pressing their breasts into the potential scrape and scraping with the feet. During courtship feeding, the female holds her wings low and utters begging calls. During parading, the male makes small steps, with lowered wings and raised head. The greeting ceremony includes erect and bent postures, and involves lowering the wings, raising the tail and tilting the head. Copulation occurs six days before egg laying.

A chick begs by rubbing its bill against that of its parent. After this, the chick is fed by the adult, not necessarily by the parent that has come from the sea. Normally the foraging adult arrives with a fish and lands 10–20 m away from the nest. The begging chick runs out of its shelter (vegetation or stones) to the adult and is fed the fish. The chick then returns to its original place and the adult goes foraging again. Hiding in vegetation or behind stones is a very important antipredator behaviour of chicks.

ANTARCTIC TREATY SYSTEM

Who governs Antarctica? That was the issue that faced twelve countries that had been active in the Antarctic during the International Geophysical Year (1957–1958). Almost 50 years on, there is still no answer to that question upon which all parties could agree other than "the Antarctic Treaty System." Practical? Yes. Legally watertight? For as long as the system exists that question does not need to be answered—it works.

The Antarctic Treaty System (ATS) is the whole complex of arrangements made for the purpose of regulating relations among states in the Antarctic. At its heart are the Antarctic Treaty itself, numerous Recommendations, Measures, Decisions, and Resolutions adopted at meetings of the Antarctic Treaty Parties, and which have become effective in accordance with the terms of the treaty, the Protocol on Environmental Protection to the Antarctic Treaty, and three separate conventions dealing with the Conservation of Antarctic Seals (London, 1972), the Conservation of Antarctic Marine Living Resources (Canberra, 1980), and the Regulation of Antarctic Mineral Resource Activities (Wellington, 1988). Although the last convention, negotiated between 1982 and 1988, was destined, in the event, not to enter into force, it marked a considerable advance in the attitude of Antarctic Treaty Parties to environmental protection. Many of the concepts featured in the Protocol on Environmental Protection were first elaborated in the mineral resources convention.

The ATS also includes the results of Meetings of Experts and the decisions of Special Consultative Meetings and, at a nongovernmental level, reflects the pervasive effects on many aspects of the system of the work of the Scientific Committee on Antarctic Research (SCAR) and, since 1989, of the Council of Managers of National Antarctic Programs (COMNAP). Measures and actions have been adopted or taken as and when a present or future need for them has been perceived. The practice has been essentially pragmatic, and it was not until the conclusion of the Protocol on Environmental Protection in 1991 that there was a systematic attempt to provide a code for the regulation of all Antarctic activities other than those covered by the two separate conventions dealing with the conservation of seals and marine living resources.

The Antarctic Treaty

The original parties to the treaty were the twelve nations that were active in the Antarctic during the International Geophysical Year of 1957–1958, and then accepted the invitation of the US government to participate in the diplomatic conference at which the treaty was negotiated in Washington in 1959. The treaty entered into force on 23 June 1961 following ratification by Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, South Africa, the Soviet Union (now Russia), the United Kingdom, and the United States. These countries have the right to participate in meetings provided for in Article IX of the treaty ("Consultative Meetings") and are accordingly known as Consultative Parties. The treaty provides for accession by any state that is a member of the United Nations, and for accession by any other state by invitation of all Consultative Parties. It provides for such states as have acceded to the treaty and have demonstrated their interest in Antarctica by carrying out substantial scientific activity there to become Consultative Parties. Thirty-three states have acceded to the treaty, and of those sixteen states have become Consultative Parties by becoming active in the Antarctic (in addition to the original twelve).

Every year (before 1991 it was every 2 years) the Consultative Parties meet "for the purpose of exchanging information, consulting together on matters of common interest pertaining to Antarctica, and formulating and considering and recommending to their Governments measures in furtherance of the principles and objectives of the Treaty." Since 1983, those countries party to the treaty that are not Consultative Parties have been invited to take part in these meetings as observers. In addition, special Consultative Meetings are convened as deemed appropriate by the Consultative Parties. Those convened to acknowledge the Consultative Party status of countries that have acceded to the treaty and have demonstrated their interest by carrying out substantial scientific activity in the Antarctic have not been attended by non-Consultative Parties. The non-Consultative Parties were invited to take part in the IVth and XIth Special Consultative Meetings, respectively on Antarctic minerals and environmental protection, as observers. Finally there have been four meetings of experts to consider questions of Antarctic telecommunications, one to consider questions of air safety, one to consider issues relating to environmental monitoring, one to consider shipping guidelines, and one on tourism and nongovernmental activities.

The Purpose of the Antarctic Treaty

The primary purpose of the Antarctic Treaty is to ensure "in the interests of all mankind that Antarctica shall continue forever to be used exclusively for peaceful purposes and shall not become the scene or object of international discord." To this end it prohibits "any measures of a military nature" but does "not prevent the use of military personnel or equipment for scientific research or for any other peaceful purpose." The treaty provides for "freedom of scientific investigation in Antarctica, promote[s] international co-operation in scientific investigation in Antarctica," encourages "the establishment of cooperative working relations with those Specialized Agencies of the United Nations and other international organizations having a scientific or technical interest in Antarctica," prohibits "any nuclear explosions in Antarctica and the disposal there of radioactive waste material" and provides for detailed exchanges of information. "To promote the objectives and ensure the observance of the provisions of the...Treaty," Consultative Parties "have the right to designate observers to carry out any inspection of...all areas of Antarctica, including all stations, installations and equipment, and all ships and aircraft at points of discharging or embarking cargoes or personnel in Antarctica."

The treaty applies to the area south of 60° S, including all ice shelves, but nothing in the treaty "shall prejudice or in any way affect the rights, or the exercise of the rights, of any State under international law...with regard to the high seas within that area." The broad practical effect of this article has been that whereas the Consultative Parties have proceeded by means of measures provided for under Article IX when dealing with matters pertaining to land and ice shelves in Antarctica, they have proceeded by means of separate conventions, with independent ratification and accession procedures, when dealing with matters that affect their rights or the exercise of their rights with regard to the seas within the area of application of the treaty—hence the conventions on the conservation of seals and marine living resources.

The Sovereignty Question

At the root of the Antarctic Treaty lies its fourth article dealing with territorial sovereignty. It safeguards the positions of three groups of states which are parties to the treaty: those that had "previously asserted rights of or claims to territorial sovereignty in Antarctica" (Argentina, Australia, Chile, France, New Zealand, Norway, and the United Kingdom), those that consider themselves as having "a basis of claim to territorial sovereignty in Antarctica" (Russia [then the Soviet Union] and the United States), and those that do not recognize "any other State's right of or claim or basis of claim to territorial sovereignty in Antarctica." The same article, however, goes on to provide that "no acts or activities taking place while the present Treaty is in force shall constitute a basis for asserting, supporting or denying a claim to territorial sovereignty in Antarctica or create any rights of sovereignty in Antarctica. No new claim, or enlargement of an existing claim, to territorial sovereignty in Antarctica shall be asserted while the present Treaty is in force." It is this "no prejudice" that has underlain the development of the Antarctic Treaty System over the years.

The safeguards of Article IV are not, however, limitless. They might not, for example, protect a state from consequences of acting in a manner that was contrary to its known position on the sovereignty issue. Some parties have attempted to proceed on an assumption that Article IV had somehow "solved" the sovereignty issue. But they, along with all other Consultative Parties, have had to recognize that if they push their view on sovereignty, whether for or against, to what would in their view be a logical conclusion, Article IV would not be able to take the strain. Following recent extensions and definitions of coastal state jurisdiction in accordance with international law, it was recognized that events (e.g., unregulated fishing or prospecting for minerals) could give rise to such strains. Consultative Parties that assert territorial claims would not accept that others should take their fish or minerals without their leave. Neither would those Consultative Parties that do not recognize territorial claims accept that their access to fish or minerals in the Antarctic Treaty Area could be denied on the basis of territorial sovereignty and coastal state jurisdiction.

Recognition of the potential for dispute inherent in these issues of economic exploitation, from which, once embarked upon, there could be no retreat by either side, gave birth, as an exercise in preventative foresight, to the living resources convention and then to the minerals convention. In the negotiation of both conventions the two sides of the sovereignty argument fought vigorously for their respective positions. The resulting conventions are expressions, on the one hand, of the strength of national interest and, on the other hand, the accommodations that could be accepted by both sides within the safeguards provided for in Article IV. It is thus that qualities of foresight in dealing with issues before they become insoluble, restraint in the pursuit of national interest, and recognition of the national interests of others, have come to mark the ATS.

The Protocol on Environmental Protection to the Antarctic Treaty

The publication in 1987 of the discovery of the "ozone hole" over Antarctica first demonstrated that humankind really was capable of changing the environment on the global scale. It acted as a catalyst for three major Antarctic events: the demise of the minerals convention four years later, the conclusion in 1991 of the Protocol on Environmental Protection to the Antarctic Treaty, and the frustration of an attempt within the United Nations to overturn the Antarctic Treaty. The protection of the Antarctic environment became the international political imperative.

The Convention on the Regulation of Antarctic Mineral Resource Activities, concluded in 1988 in Wellington following 6 years of innovative negotiation, was replaced by a ban on all mineral resource activities (except scientific research) under the terms of Article 7 of the protocol. But the scope of the protocol is a great deal wider than was recognised by those who saw in it only the minerals ban. Its objective is to ensure that "the protection of the Antarctic environment and dependent and associated ecosystems...shall be fundamental considerations in the planning and conduct of all activities in the Antarctic Treaty Area."

The environmental protection protocol establishes certain environmental principles; says that nothing in the protocol "shall derogate from the rights and obligations of Parties to the protocol under other international instruments in force within the Antarctic Treaty system"; provides that environmental impact assessment shall be the primary mechanism to ensure that the environmental principles are adhered to; establishes a Committee for Environmental Protection, full membership of which is not restricted to Consultative Parties; provides for annexes on any matter to do with the protection of the Antarctic environment to be added to the protocol; and establishes a procedure for the compulsory settlement of disputes, arising from the interpretation or application of the protocol. So far there have been five annexes to the protocol, dealing with environmental impact assessment (I), conservation of fauna and flora (II), waste disposal and management on land (III), prevention of pollution at sea (IV), and area protection and management (V). The primary purpose of distinguishing between the protocol itself and annexed measures is to provide for "amendments and modifications [of an annex] to become effective on an accelerated basis."

Scientific Committee on Antarctic Research

As befits developments under a treaty dealing with a part of the world about which comparatively little is known, and of which one of the main purposes is to establish and maintain freedom of scientific research, there is a close relationship between science and the consultative machinery of the treaty established under Article IX. Frequently a problem may be identified about which scientific advice is needed before deciding what, if any, action is required. The channel for requesting such advice is through the respective governments of the Consultative Parties to their National Antarctic Committees normally established under the auspices of their national Academy of Science or National Research Council. These National Antarctic Committees will, in turn, through their delegates submit the request for advice to the Scientific Committee on Antarctic Research (SCAR) established by the International Council for Science (ICSU).

The primary purpose of SCAR is to formulate and coordinate Antarctic scientific research programmes. The Consultative Parties have frequently needed scientific advice on a matter in hand but for the first 30 years there were no formal links between SCAR and the treaty system: the necessary channels were through national committees. A request for scientific advice would emanate from a treaty meeting, it would be referred to one of the SCAR Working Groups (now known as Standing Scientific Groups), and the advice would then be transmitted back through national committees and treaty governments to a Consultative Meeting for consideration. The advantage of these arrangements was that it distanced the science from the politics, ensuring a fair degree of independence. But things changed with the adoption of the Protocol on Environmental Protection. Its Committee on Environmental Protection implied "hands on" use of science in pursuit of environmental objectives. Thus the protocol provides for the president of SCAR to participate in the Committee on Environmental Protection, and SCAR has established a Standing Committee for the Antarctic Treaty System. There is little else in the way of formal relationship between the treaty governments on the one hand and SCAR on the other. But the system allows for the treaty governments to have access to a wide spectrum of independent scientific advice available through the scientific unions and committees of ICSU. From time to time the scientists in SCAR may, on their own initiative, seek to advise treaty governments of some concern that they feel should be taken up intergovernmentally within the consultative machinery of the treaty.

Council of Managers of National Antarctic Programmes

In the early days of the treaty there were concerns about the practical way of doing things in the Antarctic—how to design weatherproof buildings or how to get a tractor out of a crevasse. Meetings were held under the auspices of SCAR. Proven techniques could be adopted more widely; dead ends could be avoided. These meetings developed into the SCAR Working Group on Logistics. In 1989, a Council of Managers of National Antarctic Programs (COMNAP) was established to provide a freestanding forum for consultation and cooperation between countries active in Antarctica at the practical level. It has a Standing Committee on Antarctic Logistics and Operations to provide practical and technical advice. COMNAP is now less concerned with practical allowances/prohibitions and more with the nuts and bolts of cooperation on the ground so that the best use is made of costly Antarctic logistics.

International Organisations

The Consultative Parties, as and when the need has arisen, have involved other international organizations in the work of the Antarctic Treaty System. The World Meteorological Organization and the International Telecommunications Union have had representatives at specialist meetings on Antarctic meteorological telecommunications; the Food and Agriculture Organization, the International Whaling Commission, the Intergovernmental Oceanographic Commission, the International Union for the Conservation of Nature and Natural Resources (IUCN, now known as the World Conservation Union but, like ICSU, has maintained its previous acronym) are among the international organizations participating in the work of the Commission established by the Convention on the Conservation of Antarctic Marine Living Resources. Since the XVth Antarctic Treaty Consultative Meeting nine intergovernmental organizations (IOC, ICAO, IHO, IMO, IUCN, UNEP, WMO, WTO, IPCC, and PATA) have been invited to participate in the work of Consultative Meetings relevant to their respective interests. In addition, two umbrella nongovernmental organisations, the Antarctic and Southern Ocean Coalition (ASOC) and the International Association of Antarctic Tour Operators (IAATO), participate in Consultative Meetings as experts.

Has It Worked?

When the treaty was negotiated at the height of the Cold War no one knew whether the then-superpowers would be able to cooperate in the interests of maintaining the peace in the Antarctic, or whether agreement between states claiming sovereignty and those that did not recognise such territorial claims would be possible. Some said that competition for Antarctic resources would wreck the treaty. The treaty's genius was that it said only what it had to be said to provide a framework within which peace could be maintained and no more, but how it was to be maintained was left to the parties. Some thought that it should be put on the shelf until such time as a problem arose; others recognised that unless the consultative machinery was exercised it might not stand the strain when the need came. Cooperation needed to become the habit rather than the exception. Much of what the treaty has achieved over the years has been about the encouragement of that habit. The Antarctic Treaty System will continue for as long as governments maintain their interest in the Antarctic. The risk otherwise is that the treaty area might become the "scene or object of international discord"—surely unthinkable.

An afterthought: As a consequence of the provision in the Moon and Celestial Bodies Treaty of an article derived from Article IV of the Antarctic Treaty, the only part of the universe where humankind can exercise exclusive jurisdiction on the basis of territorial sovereignty is that part of planet Earth outside the Antarctic Treaty area—no shots have been fired inside the Antarctic Treaty area. For almost fifty years the Antarctic has been a political laboratory where the respective merits of jurisdiction based on territory and on nationality have been fought out in debate marked by forbearance—a tribute to those who engaged in the debates but, more than anything, to the unique and all-pervading nature and force of the Antarctic itself.

ARCHAEOLOGY, HISTORIC

Historical archaeology in Antarctica and on the continental and sub-Antarctic islands has been mostly limited to site surveying to provide basic documentation of historic sites, the removal of ice within historic huts, and a few excavations.

There are a wide variety of sites of interest to historians and archeologists associated with early sealing and whaling, farming activity, science, shipping, and exploration. Most are located in coastal areas where there was ready access from the sea and are generally of great archaeological significance.

For Antarctica and the continental islands the sites include:

- Evidence of British and American sealers and whalers, dating back to the late 1700s with remains of ships; rock and wood huts and occupied caves found in the South Shetland Islands off the Antarctic Peninsula.
- Industrial sites associated with whaling on the island of South Georgia and Deception Island.
- Wooden and rock huts, caves, camp sites, middens, supply depots, message posts, cairns, memorial crosses, and graves associated with the "Heroic Era" of exploration (1895–1917) in the Ross Sea region, including the Trans-Antarctic Mountains and Commonwealth Bay; the remains of two ships, *Antarctic* and *Endurance,* in the Weddell Sea off the Antarctic Peninsula; and artifacts and a tractor on the sea floor at Cape Evans, Ross Island.
- Wooden huts, middens, and equipment associated with sites occupied during the British "Operation Tabarin 1" (1943–1944), the United States Antarctic Service Expedition (1939–1941), the Finn Ronne Antarctic Research Expedition (1947–1948), and the former United States (1957–1959)/Australian (1959–1960) Wilkes Station.

The sub-Antarctic islands, which include six groups between latitudes 50°–60° S and the more temperate island groups south of New Zealand (Campbell, Auckland, Bounty, Antipodes, and the Snares), all have important archaeological sites associated with sealing, whaling, farming, and science. Included are try works and remains of huts, castaway depots, cemeteries, and villages. On Auckland Island is located the extensive Enderby settlement, a cemetery, and sites of military significance, from the "Coast Watchers" in World War II.

In the 1960s, when New Zealand field parties removed ice from within three huts associated with the expeditions of Carsten E. Borchgrevink (1899–1900), Robert Falcon Scott (1901–1904 and 1910–1913), and Ernest Shackleton (1908–1909 and 1914–1917), there was little emphasis on archaeology as we know it today. Excavation methods were essentially the use of pick and shovel with the main emphasis on artifact recovery and making the huts snow-proof. Only sparse records were maintained and artifact conservation was not thought of. Subsequent work also saw considerable information lost during the clearance of middens about the huts that had the potential to provide significant knowledge on the occupation and privations suffered by early expeditions, and locations of artifacts about the huts was seldom recorded.

In the late 1970s, however, New Zealand led the way when for the first time systematic archaeology was demonstrated outside Scott's hut at Cape Evans. This pioneering work, which involved the use of heavy black polythene to help thaw surface deposits and the detailed recording of many artifacts located in the volcanic scoria, was followed closely in January 1978 by Australia, at Mawson's huts on Cape Denison, Commonwealth Bay. Here artifacts located inside the ice-filled huts were carefully documented and replaced in their original position, and the work was recorded on plans and with video and still film.

The establishment in New Zealand of a Historic Sites Management Committee in 1980 led to the compilation of the first Management Plan for the huts erected by Scott and Shackleton on Ross Island. This in turn resulted in the formation in 1987 of the Antarctic Heritage Trust and guidelines determining how future archaeological work should be undertaken. In the period 1988–1990, archaeologists using a range of equipment including a small electric percussion drill, excavated a stores annex and stables at Cape Evans and the unroofed "stores hut" at Cape Adare.

At Cape Denison Australian archaeologists working alongside artifact conservators in the 1990s introduced an important new phase in the way in which excavations were undertaken at historic sites. On Livingston Island, South Shetland Islands, a comprehensive survey of early sealing sites and shipwrecks was completed in 1957–1958 by scientists from the British Antarctic Survey and further work has been done by scientists from Chile. Since 1988, archaeologists from Argentina have removed ice from the wooden hut built on Snow Hill Island for Otto Nordenskjold's Swedish South Polar expedition (1901–1904). Further artifacts were removed from Nordenskjold's rock hut on Paulet Island; however, no detailed plans were compiled for either archaeological site.

Historical archaeology also includes site surveys, and, with support from the British Antarctic Survey and the United States National Science Foundation, artifacts at Port Lockroy on Gauvier Island and at East Base on Stonington Island have been carefully documented. With exception of some recording within the remains of a hut at Port Lockroy built for Operation Tabarin 1, no archaeological excavations have been carried out.

On the sub-Antarctic islands, extensive recording of historic sites associated with sealers and some archaeological work on hut remains has been done by Australian scientists on Macquarie Island and on Heard Island. Field work on New Zealand's sub-Antarctic islands has been mostly concerned with site surveys and documentation.

In contrast to work done at temperate latitudes, field work in Antarctica is restricted to a few weeks each summer and is reliant on fine weather. While much has already been achieved at the key historic sites, there is still potential for further work; however, sites such as Cape Adare, Cape Denison, and Cape Evans (the largest site from the Heroic Era) must each be treated differently. They have a variety of problems that determine how archaeology can be done and these range from the effects of penguin guano and fungi on artifacts and the huts to metal corrosion, the effects of ultraviolet light, high relative humidity, damage by wind, and unknowing damage by visitors from tour ships and national programmes. Recent sites such as East Base and the former Wilkes Station also offer great possibilities for historic archaeology.

Strict controls are now in place for any work through national programmes, and all archaeology at historic sites, whatever it may be, must be weighed against the relevant conservation plans for the sites, formally sanctioned, and subject to permits. In Antarctica all historic sites are protected by the 1991 Protocol on Environmental Protection to the Antarctic Treaty, while historic sites on sub-Antarctic islands are protected by legislation of the country responsible for the islands. In the case of New Zealand this is by the Department of Conservation, which limits numbers of visitors and also issues permits for any archaeology. It is vitally important that all archaeological work, including excavation, takes into consideration the ICOMOS 1990 Charter for the Protection and Management of the Archaeological Heritage.

Historical archaeology in Antarctica and the sub-Antarctic can provide a better understanding of the cultural heritage and while there is a great future for the discipline, it can be argued that this may always remain second to such sources as published works, diaries and other manuscripts, and museum collections.

ARCTIC AND ANTARCTIC RESEARCH INSTITUTE, RUSSIA

The Arctic and Antarctic Research Institute (AARI) in St. Petersburg originated as the Northern Scientific Commercial Expedition on March 4, 1920. In 1925, the Expedition became the Institute of Northern Studies, and in 1930 the All-Union Arctic Institute. In 1939, it was renamed the Arctic Research Institute. In 1958, by the decision of the government of the USSR, it was entrusted with organization and coordination of national studies and operations in the Antarctic, after which it received its present name. In 1963, AARI was placed under the control of the Main Administration of the Hydrometeorological Service of the country (present Federal Service for Hydrometeorology and Environmental Monitoring).

AARI is one of the world's largest centers of polar scientific research. It became widely known in the 1930s after conducting numerous successful Arctic expeditions in the marginal Siberian shelf seas and the central Arctic Basin. These include the first voyage of the icebreaking vessel *Sibiryakov* (1932) in one summer navigation period from Arkhangelsk to Vladivostok, organization of the first drifting North Pole station (1937–1938), and an airborne expedition to the area of the Pole of Relative Inaccessibility (1941). One of the major directions in AARI's activity since the 1930s has been providing scientific-operational information and forecasts on the state of water, ice, and atmosphere along the Northern Sea Route. In the 1970s, such navigation on some segments of this route was year-round. In support of shipping, detailed investigations were made on the peculiarities of ice regimes, tides, sea-level oscillations, currents, waves, physical and mechanical ice properties, and characteristics of the ice performance of different types of ships in the Siberian shelf seas and river mouths.

Full-scale materials for scientific studies of the Institute were collected by means of numerous drifting, marine, airborne, river, and land expeditions over the entire far north of the country and in the near-pole areas of the Arctic. In addition, data of coastal and island polar stations and transport vessels and icebreakers were subjected to scientific analysis and generalization. In the 1970s and 1980s, the Arctic region covered by scientific studies by AARI was significantly expanded when a fleet of seven research vessels was built for the Institute. The Greenland and Norwegian seas and the North Atlantic were a major study area at that time. Comprehensive large-scale experiments were conducted throughout the entire Arctic aiming to reveal the natural ocean–atmosphere interaction mechanisms in the region. These studies were called the Polar Experiment–North. As a result, the processes of genesis and transformation of water masses, specific features of water circulation and ice, and their seasonal and interannual variability were investigated. Main regularities and types of the atmosphere circulation, their relations to the helio-geophysical processes, characteristics of the Arctic Ocean freshwater balance, etc., were determined.

Modern scientific studies of AARI in the Arctic are conducted within a wide range of Earth sciences: climatology, meteorology, oceanography, land water hydrology, geophysics, ecology, glaciology, geomorphology, sea-ice/offshore structure interaction, and polar medicine.

The AARI staff began regular studies in the Antarctic in 1956 within the framework of the national Arctic expeditions of the USSR Academy of Science. Since 1958, the activities of the Russian (Soviet) Antarctic Expedition (RAE) have been organized and coordinated directly at AARI. These functions are fulfilled by the departments of logistics support and perspective planning of RAE activity. The AARI specialists participated directly in the discovery and study of many geographical features of East Antarctica. When the geographical stage of studies of Antarctica was replaced by investigations of the regular features of formation and variability of natural processes, the Institute's scientific programs began to play the leading role in the national Antarctic program of the country. Studies in meteorology, aerology, oceanography, geomagnetism, structure and dynamics of the ionosphere and ozonosphere, limnology, glaciology, geomorphology, paleoclimatology, and polar medicine that were mainly performed by AARI staff allowed a detailed investigation of the main environmental compartments of the region. The results of these studies were published in two volumes of the Atlas of the Antarctic (1966 and 1969), which received wide recognition among scientists in many countries.

The AARI staff has become most renowned for the results of the cycle of studies of structure and dynamics of geomagnetic processes in polar caps when a specially developed PC index was proposed as an integral numerical indicator of the magnetic perturbation state. Another example is a wide known curve of four paleoclimatic cycles obtained from the ice core data at Vostok station for the last 420 kyr. Studies of crystalline composition and gaseous content of congelation ice from the lower horizons of Vostok ice core formed of frozen water of the subglacial Lake Vostok have won worldwide recognition. Modern AARI research in the Antarctic is carried out within the framework of the subprogram "Study and Research of the Antarctic" of the Federal Program "World Ocean" where the Institute is a principal executor in fourteen of nineteen projects in the direction "Fundamental studies." These are studies of the processes of current climate formation and its future changes, determination of the climate-forming role of the Southern Ocean, studies of paleoclimatic changes based on ice-core data from deep boreholes and bottom sediments of the water bodies, study of the subglacial Lake Vostok, assessment of the structure and dynamics of geophysical processes in polar caps, mechanisms of impact of helio-geophysical perturbations on living organisms, study of aerosol-optical properties of the atmosphere, and generation of the geoinformation system of Antarctic data. The activities in the direction of the subprogram "Scientific-applied studies and developments," "Monitoring of natural media of the Antarctic," "Environmental protection" and "Logistics support for operation of the Russian Antarctic Expedition" are carried out by AARI staff in the RAE structure.

At the present time, the AARI staff numbers 880 specialists, among which 330 work at seventeen scientific departments of the Institute. In addition to scientific departments, the Institute's structure includes RAE, Fleet Department, and Center of Ice and Hydrometeorological Information "Sever." The AARI runs the R/V *Akademik Fedorov* and *Professor Multanovsky*.

The experimental ice tank operates at the Institute testing models of ships and engineering structures.

AARI has wide international relations actively cooperating with research institutions of Australia, Germany, Norway, the United States, France, and Japan. The Institute's structure includes the Russian-German and the Russian-Norwegian Scientific Laboratories where joint studies are conducted and where young scientists of these countries work under special grants.

In 1994, AARI was assigned the status of the State Research Center—the highest level of recognition of research institution in Russia regardless of its agency affiliation.

In different years, such prominent polar explorers as Rudolf Samoilovich, Vladimir Viese, Viktor Buinitsky, Georgy Vangengeim, Alexander Girs, Pavel Gordienko, Mikhail Somov, Aleksey Treshnikov, and Yevgeny Korotkevich worked at AARI.

ARCTIC TERN

The Arctic tern *(Sterna paradisaea)* has a circumpolar distribution, breeding abundantly in the Arctic and sub-Arctic regions of Europe, Asia, and North America in colonies on coastlines, islands, and occasionally inland on tundra near water. During the nonbreeding period, Arctic terns migrate annually to as far south in the Southern Hemisphere as the edges of the Antarctic pack ice.

This species is highly migratory, flying from its Arctic breeding grounds to its wintering areas in the Antarctic. This migration ensures that this bird sees more daylight than any other creature on the planet. The journey, of at least 19,000 km one way, is the longest known migration of any species. One particularly spectacular example was of an Arctic tern banded as a chick, not yet able to fly, on the Farne Islands off the Northumberland coast of eastern England in the summer of 1982. This bird reached Melbourne, Australia, in October of the same year, having flown over 22,000 km in just 3 months from fledging—an average of over 240 km per day and one of the longest journeys ever recorded for a bird. The length of this migration suggests that in its lifetime an average Arctic tern will travel a distance equal to going to the moon and back.

The nonbreeding areas in the Antarctic pack-ice zone are mainly between 55° E and 155° E in the Indian Ocean sector, but the species has been seen all around the Antarctic continent. There are two main migratory routes: from breeding sites in Siberia and Alaska southward along the Pacific coasts of North and South America (in limited numbers also across the central Pacific) between August and December, then across the Drake Passage to Antarctica. Birds from Atlantic breeding places in North America, Greenland, islands in the Northern Atlantic Ocean, Europe, and coastal Siberia migrate over the Atlantic Ocean near western Europe and West Africa, partly in a broad front or crossing the Southern Ocean. Few birds have been reported in the Indian Ocean. Circumnavigation of the Antarctic continent has been reported, and some of the nonbreeders remain in the Southern Hemisphere and do not migrate to the north.

Breeding Behaviour

Egg laying takes place from May to July, depending on the latitude of the breeding locality, air temperature, and food availability, in colonies ranging in size from just a few to 300 pairs. Two to three eggs are laid and incubated for 22–27 days. The chicks fledge after 21–24 days. The Arctic tern is the most aggressive tern, fiercely defensive of its nest and young. It will attack humans and other large predators, usually striking the top or back of the head. Although it is too small to cause serious injury, it is capable of drawing blood.

Like all *Sterna* terns, the Arctic tern feeds by plunge-diving for fish, usually from the sea, although occasionally also fishing in coastal freshwater lagoons. It often dives from a "stepped-hover." The offering of fish by the male to the female is part of the courtship. In the Antarctic, Arctic terns feed in water near the edge of pack ice, especially between ice floes. They mostly take food from just below the water surface by dipping. They feed on fish, crustaceans (copepods, amphipods, and also krill), and, in the Arctic, on insects.

ARGENTINA: ANTARCTIC PROGRAM

Argentine Antarctic activities started early in the nineteenth century when sealers and whalers sailed south of South America looking for new hunting areas. Scientific activities started at the beginning of the twentieth century when José María Sobral (later PhD in geology from the Uppsala University in Sweden) joined the Swedish South Polar Expedition (1901–1904) commanded by Otto Nordenskjöld, which wintered two years in Antarctica. Around the same time, W. S. Bruce, leader of the Scottish National Antarctic Expedition, turned over to Argentina the meteorological and geomagnetic observatory (today Orcadas Station) located on Laurie Island, South Orkney Islands; this observatory continues to run at the start of the twenty-first century, having run without interruption for more than a century. In 1951, Argentina set up the first worldwide institution fully dedicated to Antarctic research: the Instituto Antártico Argentino (IAA). Logistic operations started with the rescue of the Nordenskjöld expedition carried out by the Argentine Navy's corvette *Uruguay* under the command of Lieutenant Julian Irizar in 1903.

The Argentine Antarctic Program is composed of several organizations forming the highest levels of the National Government. Logistics are provided by the Argentine Army, under the Defense Ministry, whereas all other activities are ruled by the Dirección Nacional del Antártico–Instituto Antártico Argentino of the Ministry of Foreign Affairs. The program spends approximately the equivalent of \$10 million to \$12 million US each year for Antarctic activities. The purpose of the Argentine Antarctic Program is to support, strengthen, and increase the Argentine sovereign claims over the portion of the Antarctic continent and surrounding seas from 25° W to 74° W and from 60° S to the Pole ("Sector Antártico Argentino").

Argentina is the closest country to Antarctica and runs six permanent scientific stations, the most of any country. They are Orcadas (60°44′ S, 44°44′ W), Laurie Island, South Orkney Islands; Jubany (62°14′ S 58°40′ W), King George (25 de Mayo) Island, South Shetland Islands; Esperanza (63°24′ S, 57°00′ W), Hope Bay, northern tip of the Antarctic Peninsula; Marambio (64°14′ S, 56°38′ W), Seymour (Marambio) Island, northwestern Weddell Sea; San Martín (68°08′ S, 67°06′ W), Barry Island, Margarite Bay, and Belgrano II (77°52′ S, 34°37′ W), Bertrab Nunatak, southeastern Weddell Sea. Additionally, Argentina maintains seven seasonal (nonpermanent) stations: Brown (64°53′ S, 62°53′ W), Paradise Cove; Primavera (64°09′ S, 60°58′ W), Danco Coast; Decepción (62°59′ S, 60°41′ W), 1° de Mayo Bay, Deception Island; Melchior (64°20′ S, 62°59′ W), Observatory Island, Melchior Archipelago; Matienzo (64°59′ S, 60°07′ W), Larsen Nunatak, Weddell Sea; Cámara (62°36′ S, 59°56′ W), Half Moon Island, South Shetland Islands; and Petrel (63°28′ S, 56°12′ W), Welchness Cape, Antarctic Strait.

Orcadas Station is the oldest Argentine station in the Antarctic, and Marambio the newest and the only one built after the Antarctic Treaty was signed. It has a dirt airstrip that allows year-round landing of heavy-duty planes with conventional wheels (C-130 Hercules) carrying up to 12 tons of cargo. Belgrano II is the southernmost active station in the Weddell Sea area and the departure and return point of the two land-traveled Argentine expeditions to the South Pole carried out up to now.

The logistic support for Antarctic activities is provided by the Argentine Army. The Argentine Navy runs Orcadas Station and operates a large icebreaker named *Almirante Irizar,* built 25 years ago in Finland specially for the Argentine Antarctic Program; an oceanographic vessel *(Puerto Deseado);* and several smaller patrol vessels. The icebreaker brings two heavy-duty Sea King–type helicopters. Air operations from South America and within Antarctica is provided by the Argentine Air Force through several C-130 Hercules planes, a small DHC-6 Twin Otter plane year round based on Marambio Station, and Bell 212 helicopters deployed in Marambio Station during the summer. The Argentine Army provides support running three permanent stations (including the two southernmost ones) and supporting scientific land expeditions. The Dirección Nacional del Antártico operates Jubany Station and provides logistic support to the scientific field camps and refugees. Jubany Station holds the Argentine-German Dallmann Laboratory dedicated to marine biology and geological studies.

The science program is run by the Instituto Antartico Argentino (IAA). The scientific priorities were set according to the National Antarctic Policy to investigate, understand, and preserve natural resources, to protect the environment, and to maintain the historical monuments. Accordingly, the main research lines are focused on fisheries, marine ecosystems, mineral resources, climate change, environmental protection, and history of human activities in Antarctica. To accomplish this task the IAA is comprised of scientific departments (biology, geology, glaciology, oceanography, etc.) grouped into three major areas: life sciences, Earth sciences, and ocean and atmospheric sciences. The research programs, run by members of the IAA permanent staff, are open to any scientist from Argentina. Presently the IAA scientific program consists of more than thirty research projects and fifteen scientific activities carried out in cooperation with other national (mainly universities and the Argentine National Council of Sciences) and international (US, France, Germany, Italy, Spain, Japan, Canada) scientific institutions.

ART, ANTARCTIC

Because the physical environment of the Antarctic is so foreign to human experience, most of the art made about it by the fewer than two hundred artists to have visited the continent has been landscape work with a strong topographical nature, in particular panoramic views. In addition there have been various records of the expedition activities as well as some important natural history illustrations recording new species.

The first artist to cross inside the Antarctic Circle was William Hodges (1744–1797), a classically trained British landscape painter who sailed on Captain James Cook's second voyage to the Pacific Ocean in 1772. Although they never sighted the continent itself, Hodges painted the panoramic coastal profiles required by the Royal Navy as far as the island of South Georgia, as well as images detailing ships among icebergs.

During the nineteenth century expedition leaders such as the Frenchman Jules-Sébastien-César Dumont d'Urville and the American Charles Wilkes made paintings and drawings, as did their artists, who included Louis Le Breton and Alfred Agate, the latter being the first to picture the continent itself in 1840. J. E. Davis, sailing under James Clark Ross into the Ross Sea during 1841, made views of the Great Ice Barrier, Mount Erebus, and Ross Island. The first significant Antarctic artist, however, was Dr. Edward Wilson, who served as physician to both of Scott's expeditions. A self-trained artist strongly influenced by J. M. W. Turner, he created extensive topographical profiles in the Ross Sea region, but also more than 400 finished natural history and landscape paintings. There have been several other talented amateurs over the last century.

Photography was first used in the Antarctic in 1874, and by the turn of the century was extensive. Photographers Herbert Ponting with Scott's second expedition and Frank Hurley with Shackleton defined the Heroic Age of Antarctic exploration with romantic images of ships frozen into the ice. Swiss photographer Emil Schulthess brought modern photography to the continent during the International Geophysical Year (1957–1958), and was followed by noted color photographer Eliot Porter in 1975.

Edward Seago, better known for his British landscapes and circus paintings, visited the Antarctic Peninsula in 1956. During the 1960s, two Australian painters broke away from the topographical style of earlier artists. Sydney Nolan introduced expressionism as a way of interpreting the Antarctic, and Nel Law produced abstractions of ice patterns. Visiting artists programs administered by national Antarctic programs subsequently broadened the aesthetic range. Although landscapes by painters such as David Robertson (US), David Smith (UK), and Keith Grant (UK), and photographers Neelon Crawford and Jody Forster (US) continue to dominate Antarctic art, more contemporary painters such as Nigel Brown, Margaret Eliot (NZ), and John Jacobsen (US) have expanded the expressive interpretation of the continent. Panoramic photographs by Stuart Klipper (US) and minimalist studies by Anne Noble (NZ), the modernist sculptures of Gabriel Warren (US), installation work of Virginia King (NZ), and mixed-media work by Stephen Eastaugh (AUS) and John Kelly (UK) have created an Antarctic art that is less representational and more symbolic, an aesthetic evolution that demonstrates increasing familiarity with the continent by both artists and audiences.

ASTRONOMICAL OBSERVATIONS FROM ANTARCTICA

Astronomy is the study of the universe in which we live. In recent years there has been rapid progress in the understanding of the cosmos, with the first detections of planets around other stars, of a black hole in the centre of our own galaxy, and of a mysterious "dark energy" that appears to be repelling galaxies. However, many important questions remain, ranging from fundamental questions about the origin, structure, and evolution of the universe to perhaps the most exciting question of all: Are we alone in the universe, or do some of the recently detected planets around other stars harbour alien life?

In the quest to provide answers, astronomers observe over the full range of the electromagnetic spectrum, from radio waves to high-energy gamma rays. Astronomy has traditionally progressed by building bigger and better telescopes and deploying them to the best observing sites known. Antarctica—and particularly the high Antarctic Plateau—offers many advantages to astronomy. Many of these advantages are associated with minimising the corrupting effects of the Earth's atmosphere. The atmosphere does three undesirable things. First, it absorbs some of the radiation from the astronomical object, reducing its intensity and, at some wavelengths, rendering the object completely unobservable. Second, it emits its own radiation, particularly in the infrared, creating an unwanted background signal. Finally, the fluctuations in the refractive index of the air, principally as a result of turbulent cells of differing temperature, cause blurring and other unwanted effects on the images.

Placing a telescope in space has the obvious advantage that there is no atmosphere. For some observations, for example in the study of x-rays and gamma rays, there is no alternative to a space-borne observatory. However, the cost of a space observatory is ten to one hundred times that of a ground-based one, providing a powerful incentive to astronomers to take advantage of the best ground-based sites available.

Although the South Pole was recognised as a potentially useful observing site for many years, it was not until 1979 that the first optical observations were carried out there, by a US/French team. This research, led by the US astronomer Martin Pomerantz, took advantage of the continuous daylight at the South Pole during the summer to study the sun for long, unbroken periods.

A few years later, a pioneering experiment to study submillimetre wavelength emission from the Galactic Plane was set up at the South Pole. In the years that followed a gradual buildup of astronomical facilities took place, largely as a result of the activities of the US Center for Astrophysical Research in Antarctica (CARA), which established telescopes spanning the spectrum from millimetre waves to the infrared.

Optical

For optical astronomers the main advantage of Antarctica is the extreme stability of the atmosphere. The high plateau of Antarctica has the lowest wind speeds on earth, in stark contrast to the coast where winds can exceed 300 km/hr. Low surface wind speeds allow a simple telescope and dome structure to be constructed. More important, however, is that the wind speed above the Antarctic Plateau is usually very low throughout the entire thickness of the atmosphere. It is the turbulent mixing of air of different temperatures that the wind inevitably creates that leads to a degradation of image quality.

This image degradation, known as "seeing," sets a limit to the resolution of an optical telescope. Measurements of the atmospheric turbulence above the Antarctic Plateau site, Dome C, by groups from France and Australia have shown that the seeing is substantially better than anywhere else on Earth—a factor of 2–3 times better than at the best observatory sites in Chile, Hawaii, and the Canary Islands. On some occasions, the atmosphere becomes so stable that images comparable to those from the Hubble Space telescope should be obtainable.

An effect related to seeing, but dependent more on the amount of high-altitude turbulence, is the constant fluctuation in the observed intensity of a star, known as scintillation. This familiar "twinkling" of stars is greatly reduced in Antarctica, making it an ideal location for precision measurements of stellar brightness.

A recent development in astronomy is the use of adaptive optics. In this technique the shape of a flexible mirror is altered at high speed in response to atmospheric fluctuations. By reflecting the light from the star from this adaptive mirror, the effects of atmospheric turbulence can be at least partially eliminated. Only with the help of an advanced adaptive optics system will astronomers be able to take full advantage of the next generation of extremely large telescopes (ELTs). The low wind speeds throughout the Antarctic atmosphere, combined with the already very stable turbulence structure, imply that the Antarctic Plateau may be the best location for these huge telescopes.

One of the most advanced of the ELT designs is a 21-metre diameter optical telescope called the Giant Magellan Telescope, to be built in northern Chile. A second version proposed for Antarctica would be easily the most powerful telescope in the world, with a unique ability to detect Earth-like planets around other stars and probe the earliest stages of the universe.

Infrared

Infrared astronomy, where the heat radiation from a star is observed, is extremely difficult from a ground-based site. This is not only because large regions of the infrared spectrum are blocked by absorption in the Earth's atmosphere, but because the atmosphere (and even the telescope itself) emits strongly in the infrared. This additional "background" emission reduces the sensitivity of the telescope to the true astronomical signal. For infrared astronomers the Antarctic Plateau has the advantage that it is very cold and exceedingly dry. Both of these things contribute to better atmospheric transmission and to a lowering of the background emission from the telescope and the sky by as much as a factor of 100. The first infrared telescope to explore these conditions was SPIREX (South Pole Infrared Explorer), a 60 cm infrared reflector that operated at the South Pole from 1993 to 1999.

Submillimeter

Submillimeter astronomy, in the frequency range 0.3–10 THz (wavelengths of 1 mm–30 microns) is extremely difficult from a ground-based observatory because of absorption by water vapour in the Earth's atmosphere. For this reason, almost all submillimeter astronomical research to date (especially at frequencies above 1 THz) has been from high-altitude balloons, from stratospheric aircraft, or from space. The air above the Antarctic Plateau is extremely dry, containing one tenth to one one-hundredth as much water as the air at temperate sites. This opens up new observing "windows" at wavelengths opaque from other sites. Dome A, at 4100 m the highest point of the plateau, is expected to be the best observing site on Earth for terahertz astronomy.

The Antarctic Submillimeter Telescope and Remote Observatory's (AST/RO) submillimeter telescope, with a 1.7 m diameter off-axis dish, has operated at South Pole since 1995.

Microwave and Millimetre Waves

Studies of the cosmic microwave background (CMB) give information about the early universe. This all-pervasive radiation, discovered by Penzias and Wilson in 1965, gives a unique view of the universe when it was a mere 400,000 years old. Although remarkably uniform in distribution and appearing to have a single, well-defined temperature of 2.7 K, the CMB shows minute deviations from uniformity and from a pure blackbody spectrum. Studying these deviations requires an observing site that is clear, transparent, and extremely stable.

The Degree Angular Scale Interferometer (DASI) experiment at the South Pole is one example of how the improved observing conditions in Antarctica can lead to crucial breakthroughs: DASI was the first experiment—ground-based or in space—to detect polarization in the CMB.

Yet another way of studying the CMB is with a long duration balloon (LDB), which takes advantage of the stable and predictable high-altitude winds that circulate around the coast of Antarctica. Launched from an appropriate site such as McMurdo, an LDB can travel around the continent before returning to the launch site some two weeks later. In this way astronomers can obtain hundreds of hours of data from a single flight. The BOOMERanG experiment, a collaboration between Italian and US teams, has shown how effective this technique can be for CMB studies, producing the important result (subsequently confirmed by the space mission WMAP), that the universe is geometrically "flat." This result implies that 90% of the universe consists of something we currently know almost nothing about, while the observable universe of stars, gas, and dust accounts for a mere 10% of its mass.

An important future development for CMB studies is the South Pole Telescope (SPT), currently under construction. The telescope is a 10 metre diameter off-axis paraboloid dish optimised for cosmological studies.

Particle Astronomy

Another tool available to astronomers is particle astronomy, which studies cosmic rays and elusive subatomic particles such as neutrinos. Cosmic ray research was amongst the first scientific studies to be carried out in Antarctica. Neutron and muon detectors have operated continuously at the coastal station of Mawson since 1956. For the most part, it is Antarctica's geographic location that is favoured. However, at the South Pole the vast volume of pure ice has been put into service as AMANDA (Antarctic Muon and Neutrino Detector Array). This project, which has operated now for a decade, consists of hundreds of photomultiplier tubes lowered into bore holes in the ice. AMANDA detects the Cerenkov radiation of relativistic muons created when neutrinos interact with matter. An even more ambitious neutrino detector, IceCube, will place photomultipliers into the ice throughout a volume of 1 cubic kilometre, giving a major increase in sensitivity.

Meteorites

Meteorites, preserved where they fall in the pristine snow of Antarctica, can be used to trace the chemical and physical history of the solar system. The first such meteorite was discovered by members of Douglas Mawson's Australasian Antarctic Expedition in 1912. More recently, astrogeologists have taken advantage of the concentrating effect of ice movement and sublimation to find accumulations of meteorites in particular locations. It was in the Allan Hills meteorite field that the Martian meteorite ALH 84001 was discovered in 1984. Microscopic structures within the meteorite led to speculation, still not fully resolved, that they represented an ancient form of Martian bacteria.

Disadvantages

Operating an astronomical observatory in Antarctica is more difficult than at a temperate or tropical site. Special measures are required to allow the telescope to operate reliably at the very low temperatures. Antarctic stations, although operated year-round, are cut off from the rest of the world for six months or more each year. As well as logistic difficulties there are also some astronomical limitations. Less of the sky is visible from Antarctica than from sites closer to the equator. In addition, there is less truly "dark" time, as the sun spends a smaller fraction of the time well below the horizon. Aurora and other forms of airglow are detrimental to optical astronomy, although their impact has yet to be properly quantified.

Observing Sites

The US-operated Amundsen Scott Station at the geographic South Pole is currently host to Antarctica's most comprehensive astronomical observatory. Viewed from the South Pole, all celestial objects beyond the solar system move across the sky at constant elevation. This is particularly advantageous for studies of the CMB and for detailed studies of how the light from individual stars varies over time.

Concordia Station, at Dome C, was opened for year-round operation in 2005. This joint French/Italian facility will support a variety of research programs, including astronomy. Already proposals have been made to construct optical telescopes there of over 2 metre diameter, as well as submillimeter telescopes and interferometers. At 3250 m elevation, Dome C is higher, colder, and drier than the South Pole. In addition, the wind speed and the low-altitude turbulence is significantly lower.

Other potential observing sites include the Russian station at Vostok, the Japanese station at Dome F, and the highest point on the plateau, Dome A.

ASTRONOMY, INFRARED

In order to learn as much as possible about astronomical objects such as planets, stars, and galaxies, astronomers observe them at a variety of wavelengths. Infrared radiation is invisible to the unaided eye, but carries a wealth of information about objects in the universe. However, observing in the infrared from ground-based telescopes is challenging, for the simple reason that the Earth's atmosphere and the telescope itself both emit copious quantities of infrared radiation that can overwhelm the small signals from space; an analogy is attempting optical astronomy in broad daylight with a telescope that is made from fluorescent light tubes. The obvious solution to this problem is to take the telescope to a very cold observing site, such as Antarctica.

While the potential benefits of Antarctica for infrared astronomy were realised by the 1980s, it wasn't until the early 1990s that US and Australian astronomers deployed experiments to test the quality of the sites, and to ascertain the practical difficulties of operating telescopes there. The first infrared telescope in Antarctica was the 0.6 meter South Pole Infrared Explorer (SPIREX), which operated at the US Amundsen-Scott South Pole Station from 1993 until 1999. From 1994 to 1996, the IRPS experiment measured the near-infrared sky brightness at the South Pole; later in the 1990s NIMPOL (for N-band Imaging Polarimeter), SPIRAC (for South Pole Infrared Array Camera), and AASTO (for Automated Astrophysical Site-Testing Observatory) extended this data to longer wavelengths. These experiments showed that Antarctica offers factors of at least 10, and up to 100, reduction in the infrared signal from the Earth's atmosphere when compared with temperate latitude observing sites. Furthermore, the atmospheric signal is very constant with time, making it much easier to correct for.

SPIREX and other experiments also showed that the turbulent layer of air in the lowest 200 meters at the South Pole results in star images that are somewhat blurrier than those taken from temperate observatories. This fact effectively thwarted plans for building a large infrared telescope in Antarctica, and it wasn't until 2004 that enthusiasm was rekindled following the confirmation by French and Australian astronomers of spectacularly low levels of turbulence at the Franco-Italian Concordia Station at Dome C, a location on the high Antarctic Plateau at a latitude of 75° S. The next step in the development of infrared astronomy from Antarctica may well be a 2 meter aperture telescope at Dome C, followed by a 4 meter and then an 8 meter. Other sites on the Antarctic Plateau, such as Dome A and Dome F, are also potentially excellent, although they currently lack the infrastructure to support an observatory.

The unique atmospheric conditions above the Antarctic Plateau also offer exciting advantages for infrared interferometry. An interferometer consists of two or more telescopes separated by perhaps 100 meters, and could be used to directly image planets orbiting around stars other than the Sun. Interferometers can also detect planets indirectly by observing the very small changes in the relative positions of stars as planets orbit around them. This latter technique benefits greatly from the stability of the atmosphere above high plateau sites such as Dome C.

ASTRONOMY, NEUTRINO

The Universe is the site of nuclear processes more violent than those created by earthbound particle accelerators. Nature accelerates cosmic elementary particles to energies in excess of 10^{20} electron volts, a macroscopic energy of 50 joules carried by a single elementary particle. It is not known where these particles originate or how they are accelerated. Because such "cosmic rays" are electrically charged, their paths are scrambled by galactic and, in some cases, intergalactic magnetic fields so their arrival directions at Earth do not reveal their origin. The puzzle persists almost a century after the discovery of cosmic radiation. Cosmic rays are poor astronomical messengers for another reason—they self-destruct in collisions with microwave photons to vanish into electrons and positrons. They therefore only reach Earth from the nearby cosmic neighborhood. They share this problem with photons, the particles of light, thus essentially eliminating conventional astronomical techniques. The Universe, as revealed by photons and protons, is mostly obscured from view at these high energies.

Since its discovery in the 1950s in the radiation of nuclear reactors, the neutrino has been recognized as the ideal particle for this "extreme" astronomy. With essentially no mass and no electric charge it matches the photon as a cosmic messenger. It differs in one important attribute, however: Its interactions with matter are extremely feeble, even allowing high-energy neutrinos to reach Earth unscathed from the edge of the universe and the inner neighborhood of black holes and, hopefully, from the nuclear furnaces where cosmic rays are born. They may give information about cosmic sites never "seen."

In summary, neutrinos can reach Earth undeflected and unabsorbed, even from optically shrouded sources. Unfortunately, their feeble interaction with matter makes cosmic neutrinos also very difficult to detect; trillions fly through every individual's body every second, at most a few will stop in a lifetime. Immense particle detectors are required to collect them in sufficient numbers to do science. One possibility has been to transform the deep Antarctic ice sheet below the South Pole into a neutrino telescope. Even extreme neutrinos will routinely stream through the detectors without leaving a trace; the unlucky one that makes a direct hit on a nucleus in the ice will blow it to pieces creating secondary particles of all kinds. The key is that these will radiate a glow of blue light, dubbed Cherenkov radiation, which will spread through the incredibly transparent natural ice over hundreds of meters. The origin of this radiation is the same as the blue glow shining from the water shielding nuclear rectors. Neutrino astronomers embed optical sensors into Antarctic ice to detect the faint light from a nuclear reaction initiated by a single neutrino.

In general, a neutrino telescope must be:

- Kilometer-size, to detect the low fluxes of neutrinos over cosmic distances;
- Transparent enough to allow light to travel through a widely spaced array of optical sensors;
- Deep, in order to be shielded from surface light and radiation; and
- Affordable.

Only dark oceans and deep glaciers of ice satisfy these constraints. Pure, highly transparent, and free of radioactivity, Antarctic polar ice has turned out to be an ideal medium to detect neutrinos. The difficulty of the remote site has been overcome by exploiting the infrastructure of the US Amundsen-Scott South Pole Station.

An international collaboration has constructed a first-generation neutrino telescope called AMANDA (Antarctic Muon and Neutrino Detector Array). It is the proof of concept for a kilometer-scale neutrino observatory, IceCube, now under construction. Its basic detector component is a photomultiplier housed in a glass pressure vessel, somewhat larger than the size of a basketball. Photomultipliers transform the Cherenkov light from neutrino interactions into electric signals by the photoelectric effect. The signals are captured by a computer chip that digitizes the shape of the current and sends the information to the computers collecting the data, first by cable to the "counting house" at the surface of the ice sheet and then via satellite to the scientists' office computers. One can think of IceCube as 5,000 freely running computers sending information that allows the scientists to infer the arrival directions and energies of the neutrinos. The detector components transform a cubic kilometer of ice at a depth of 1450–2450 meters into a neutrino detector (i.e., one mile below the surface and one quarter mile above bedrock).

Optical sensors produced at collaborating institutions in the United States, Sweden, and Germany are shipped to the international Antarctic center in Christchurch, New Zealand. These are subsequently transported to the South Pole via McMurdo Station. Drillers use a five megawatt jet of hot water to melt a hole in the ice, roughly half a meter wide and 2.5 km deep. Because ice is an excellent insulator, the water does not freeze for several days, ample time to deploy the optical sensors attached to cables that will power them and will also transmit their digital signals to the surface. Each of eighty holes will hold sixty sensors evenly spread over one kilometer between depths of 1450 and 2450 meters.

With some 650 optical sensors in place since February 2000, the AMANDA detector has been collecting neutrinos at a steady rate of four per day. These "atmospheric neutrinos" are the byproduct of collisions of cosmic rays with the nitrogen and oxygen in the atmosphere at the North Pole. Note that at the South Pole one observes neutrinos that originate in the Northern Hemisphere, using the Earth as a filter to select neutrinos. No photons, or any other particles besides neutrinos, can traverse the whole planet to reach the detector. The signals from the atmosphere are not astronomy yet, but they are calculable and can be used to prove that the detector performs as expected.

As in conventional astronomy, AMANDA will have to look beyond the atmosphere for cosmic signals. AMANDA data is now scrutinized for hot spots in the northern sky that may signal cosmic sources. In the south, meanwhile, in 2006, the initial IceCube deployments began augmenting AMANDA. Data obtained less than two weeks after deployment showed that everything was working immediately. A key part of IceCube was IceTop, a surface cosmic-ray air-shower detector array, which was the first part of the project to be installed and will eventually consist of 160 ice-filled tanks distributed over 1 km^2. IceTop will tag IceCube events that are accompanied by cosmic-ray showers, study the cosmic-ray composition up to 10^{18} eV, and serve as a calibration source to tag directionally the cosmic-ray muons that reach iceCube.

ASTRONOMY, SUBMILLIMETER

Submillimeter (also known as microwave) radiation has a longer wavelength than visible light and occupies the position between the infrared (IR) and radio parts of the electromagnetic spectrum. As the name suggests, this radiation has wavelengths somewhat less than one millimeter (mm): Its range traditionally extends from 1 mm down to around 0.3 mm. It is produced predominantly by atoms and simple molecules inside cool, dense clouds of gas and dust found in between the stars (the interstellar medium) in our own Milky Way as well as external galaxies. These clouds are very important since they represent the raw material from which stars and planets form. It is virtually impossible to study these objects at visible wavelengths since the radiation is almost completely blocked by dust. However, at these longer wavelengths the clouds are more transparent so we are able to study directly the processes occurring inside them.

Submillimeter telescopes look very similar to radio telescopes in that they most commonly use parabolic dishes to collect and focus the radiation. However, due to their shorter wavelengths, the surfaces of the dishes have to be made to much higher accuracies (often to within a few millionths of a meter) compared with the dishes used in radio telescopes. There are two main methods for detecting submillimeter radiation: bolometers, which measure the total intensity of the radiation over a wide range of wavelengths by converting the radiation into heat that is then registered as a corresponding temperature change; and heterodyne receivers, which mix the astronomical signal with an artificially generated signal (the local oscillator or LO) to produce an intermediate frequency (IF), which is then amplified and detected. From this signal a plot of intensity against wavelength (a spectrum) can be extracted over a narrow range of wavelengths. The special mixers used in these receivers employ superconducting junctions that have to be cryogenically cooled to a few degrees above absolute zero (–273°C) with liquid helium (at –269°C).

Submillimeter radiation is very effectively absorbed by water vapor in the lower atmosphere, so it is virtually impossible to detect from sea level. Therefore, submillimeter astronomy can be undertaken only from high and dry observing sites. Good examples are the Caltech Submillimeter Observatory (CSO), the James Clerk Maxwell Telescope (JSMT), and the Submillimeter Array (SMA) facilities, all on the 4000-meter summit of Mauna Kea in Hawaii. However, even at this location observations at these wavelengths are not always possible. An even better place for submillimeter astronomy is the high Antarctic Plateau, where the cold temperatures and dry conditions allow routine observations year round (although observing conditions are best during the long, cold, dark winter months). The 1.7 m Antarctic Submillimeter Telescope and Remote Observatory (AST/RO), located at the Amundsen-Scott South Pole Station, has been surveying the submillimeter radiation from neutral carbon atoms and carbon monoxide molecules in the interstellar medium continuously since its installation during the austral summer of 1994. In addition to making the most comprehensive submillimeter observations of the southern sky to date, the data from this pioneering instrument is greatly increasing our understanding of the role of atomic and molecular gas in the interstellar medium. After nearly a decade of observations it is becoming increasingly clear that the Antarctic Plateau is probably the prime location for submillimeter astronomy on the Earth's surface.

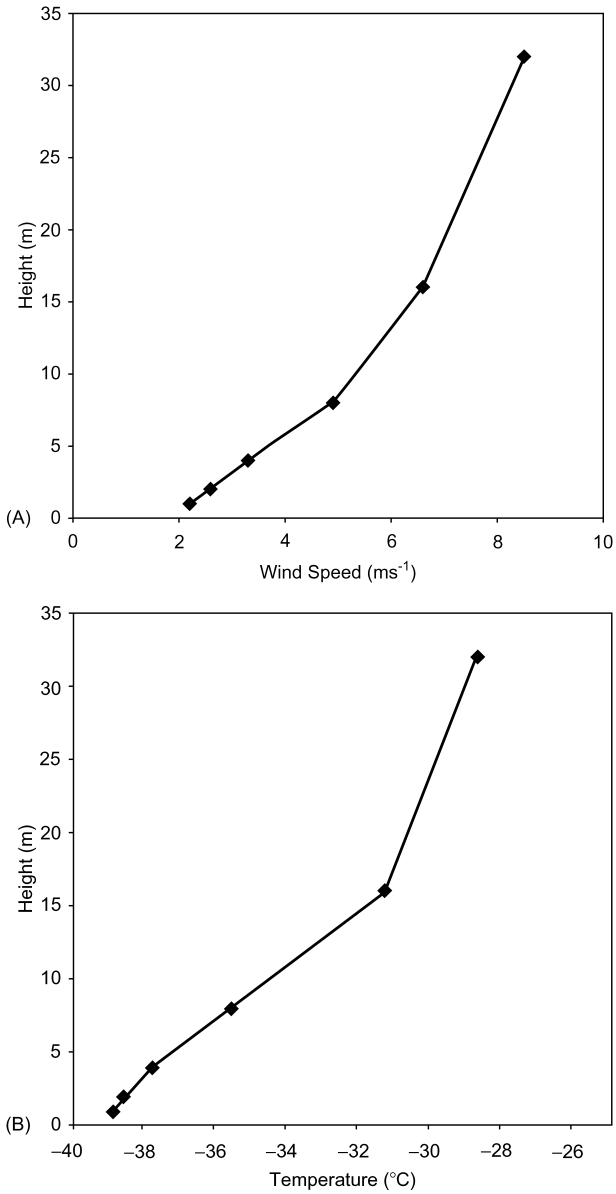
ATMOSPHERIC BOUNDARY LAYER

The atmospheric boundary layer may be defined as the part of the atmosphere that is directly influenced by the underlying surface. It is the layer through which heat, momentum, water vapour, and trace constituents are exchanged between the free atmosphere and the surface by the action of turbulence. In midlatitudes, the atmospheric boundary layer typically extends several hundred metres above the surface, whereas in the Antarctic it may be as shallow as 50 metres. The atmospheric boundary layer plays a key role in the Antarctic climate system, as it connects the atmosphere with the other main components of the climate system: ice sheets, ocean, and sea ice. Many Antarctic meteorological phenomena, such as katabatic winds and wind-borne transport of snow, are controlled by boundary-layer processes. The study of the atmospheric boundary layer in the Antarctic is thus important for the understanding of regional climate.

The structure of the atmospheric boundary layer is determined by the processes that generate and dissipate turbulence. In all boundary layers, turbulence is produced mechanically as a result of vertical variations in wind speed ("wind shear"). The rate of mechanical turbulence production depends on the wind speed and the roughness of the underlying surface. Turbulence can also be produced by convection in a boundary layer heated from below, such as when cold, continental air flows offshore over a coastal polynya. In the opposite case of a boundary layer cooled from below, as is seen over much of Antarctica during the winter, a surface temperature inversion (temperature increasing with height) develops and turbulence is damped by the stable thermal stratification (cold air underlying warmer air) of the atmosphere. Hence, both the nature of the underlying surface and the surface energy balance will affect the structure of the atmospheric boundary layer.

Convection occurs relatively rarely over the Antarctic continent. During the winter, solar heating of the surface is either absent or very small, while, even in summer, the low solar elevation and high albedo (the fraction of incident solar radiation that is

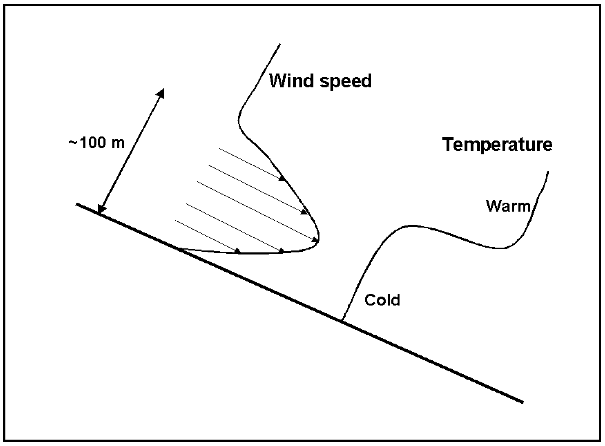


Typical vertical profiles of wind speed (A) and temperature (B) through the lower part of the atmospheric boundary layer during the Antarctic winter. (Data are from measurements made at Halley Research Station on July 7, 2003.)

reflected from the surface) of the ice sheets mean that relatively little energy is available to drive convection. The boundary layer over the continent is thus characterised by stable stratification for much of the year. The combination of stable stratification with very smooth underlying snow and ice surfaces leads to low levels of turbulence and a correspondingly shallow atmospheric boundary layer, typically between 50 and 200 m deep. Within this layer, wind speed, wind direction, and temperature vary rapidly with height. Vertical temperature gradients of more than 1°C m^{-1} are commonly seen in the lowest few metres of the boundary layer during the Antarctic winter. The strongest temperature gradients develop when wind speeds (and hence the rate of turbulent mixing) are low. At coastal locations, strong stable temperature gradients develop as the surface starts to cool after the passage of a storm. Cooling continues for, typically, 2–4 days until the next weather system brings in warm air that temporarily halts the cooling. The turbulence generated by the strong winds associated with the storm mixes the boundary layer and destroys the strong temperature gradient. Cooling resumes as the storm passes and the process repeats itself. A similar cycle may be seen in parts of the interior of Antarctica, although storms occur less frequently in this region than around the coast. Over much of the interior, however, katabatic winds (discussed later) rather than winds associated with storms are the major control on boundary layer structure.

Over sloping regions of the Antarctic ice sheets, near-surface air that has cooled becomes denser than the overlying air and will tend to flow down the local slope, generating a phenomenon known as a katabatic wind. In Antarctica, surface cooling persists for long periods and the slopes may extend for several hundred kilometres. When they blow over such distances, katabatic winds are further influenced by the Earth's rotation and, rather than blowing directly downslope, are directed between 30 and 60 degrees to the left of the fall line. Katabatic winds over the interior of Antarctica typically have speeds in the range 5–10 m s^{-1} and exhibit high directional constancy since they are strongly controlled by the local slope. In coastal regions, convergence of katabatic flows into glacial outlet valleys can generate katabatic winds of extraordinary strength, such as those encountered by Douglas Mawson's party at Cape Denison in 1912–1914 during the Australasian Antarctic Expedition.

Katabatic winds are quite shallow—often 100 m or less—as significant cooling is restricted to the shallow atmospheric boundary layer. Within this shallow layer relatively high wind speeds maintain high levels of turbulence that are very effective at mixing heat within the layer. The temperature profile through the atmospheric boundary layer in regions dominated by katabatic winds thus differs from that seen over flatter parts of Antarctica. Instead of the strong surface temperature inversion that typifies these latter regions, the katabatic boundary layer is characterised by a layer of uniform temperature extending through the shallow katabatic wind, which is capped by a layer of warmer air aloft. Within the cold katabatic layer the wind speed often exhibits a jetlike profile.



Schematic of wind and temperature profiles through a katabatic wind layer.

Because Antarctica has the form of a high dome, sloping downwards from the plateau of East Antarctica to the coast, the surface wind field is dominated by katabatic winds over a wide area. On the scale of the continent, there is a net northward transport of cold near-surface air. This is replaced by an inflow of warmer, moister air from the north, which slowly sinks into the atmospheric boundary layer. The katabatic flow thus exerts important controls on the atmospheric circulation and the heat and water budgets of the Antarctic region. Where they reach the coast, katabatic winds help to keep coastal polynyas open by driving sea ice offshore. Cooling of the open water within the polynya by the cold katabatic flow contributes to the rapid formation of sea ice in such regions.

Katabatic winds generally cease to flow when they encounter a region of negligible slope. The cessation sometimes takes the form of an abrupt "katabatic jump," where the wind speed can decrease from 10 m s^{-1} or more to near calm over a horizontal distance of less than 100 m. Strong turbulence and vertical motion accompany the jump, which is often marked by a "wall" of blowing snow and capped by small clouds. On occasions, however, katabatic winds have been observed to propagate well beyond the slopes on which they originate. Satellite imagery of the Ross Ice Shelf frequently shows warm surface signatures extending onto the flat ice shelf beyond the termini of glaciers, which drain through the Transantarctic Mountains. These signatures have been identified as continuations of the katabatic winds flowing down these valleys. Wind speeds are higher in the katabatic stream than elsewhere over the ice shelf, resulting in greater mixing and warmer surface temperatures in the region of the stream.

Boundary layer processes can affect the surface mass balance of the Antarctic ice sheets in two important ways. One way is through sublimation of snow (direct conversion of ice into water vapour) from the surface. In the cold Antarctic atmosphere, sublimation rates are generally quite small. Measurements at Halley station show that sublimation is negligible there during the winter months but can remove up to 25% of the snow falling during the warmer November to March period. The other important contribution to surface mass balance from boundary layer processes is the redistribution of snow by the wind. If the surface wind becomes strong enough (generally greater than about 7–10 m s^{-1}), snow grains become dislodged from the surface and are "lofted" by atmospheric turbulence to create a layer of blowing snow. Although few grains are lofted above 10 m, considerable amounts of snow can be transported horizontally in the shallow blowing snow layer. Where there are horizontal variations in wind speed, corresponding variations in the snow transport rate will generate regions where surface snow is eroded or deposited. In extreme cases, blowing snow transport can remove all of the snowfall from a region, leading to the formation of a blue ice field. On the scale of the Antarctic continent, the flux of blowing snow across the coastline makes a negligible contribution to the overall mass budget of the ice sheets but may locally be a significant source of fresh water in the coastal region.

The structure of the atmospheric boundary layer over the sea ice zone can be much more complex than that over the continent. An unbroken cover of sea ice insulates the atmosphere fairly effectively from the ocean, and the boundary layer that develops in such circumstances may resemble that found at continental coastal locations, with strong, stable temperature gradients. However, sea-ice cover is almost always broken by areas of open water—leads and polynyas. The sea surface temperature within such features is usually close to the freezing point, but this is still much warmer than typical air temperatures over the winter pack ice. Hence, vigorous convection develops in the atmosphere over leads and polynyas, leading to a rapid transfer of heat from ocean to atmosphere. This heating is mixed through a boundary layer that can be several hundred metres deep. As the air moves away from the lead or polynya, some of this heat remains in the atmosphere while a proportion is transferred back to the surface where it warms the surrounding sea ice. The structure of the boundary layer in the pack ice zone thus depends strongly on the fraction of the surface occupied by leads and polynyas.

The importance of boundary-layer processes in controlling Antarctic climate was recognised early in the development of Antarctic meteorology, and considerable effort has been put into studying the Antarctic atmospheric boundary layer. The prevalence of surface temperature inversions first became apparent from the pioneering upper-air measurements made by George Simpson during Robert Falcon Scott's 1910–1913 expedition. However, systematic studies of the boundary layer began with the Norwegian-British-Swedish Antarctic Expedition to Maudheim (1949–1952), and continued at several stations during the 1957–1958 International Geophysical Year. A major programme of atmospheric boundary layer measurements at Plateau station between 1965 and 1969 revealed the structure of the very stable boundary layer that develops on the East Antarctic Plateau in winter. Measurements of atmospheric turbulence require sensitive, fast-response anemometers and it was not until the development of the ultrasonic anemometer in the 1970s that such measurements became feasible in Antarctica. Since then, major atmospheric boundary layer studies, including turbulence measurements, have taken place at a number of locations, including Halley, Neumayer, Amundsen-Scott South Pole, and Dome C stations. In order to obtain the detailed vertical profiles of temperature and wind speed required by these studies, instrument packages have been mounted on a variety of lifting platforms, including small tethered balloons and kites. Acoustic remote sensing, or Sodar, has also proved to be a useful tool for studying the Antarctic boundary layer. Sound pulses fired vertically into the atmosphere are scattered by turbulent layers and can provide a qualitative (but continuous) record of the turbulent structure of the boundary layer up to 500 m. Vertical profiles of wind velocity can also be obtained by measuring the Doppler shift of the scattered sound pulses. Records from such systems reveal the complex structure of the boundary layer in the Antarctic winter. Turbulence often occurs in thin, layered structures that can persist for days at a time and wavelike motions are frequently observed propagating through these layers. The importance of these phenomena for Antarctic weather and climate is a topic of current research.

ATMOSPHERIC GAS CONCENTRATIONS FROM AIR BUBBLES

Over large parts of Antarctica, the ice sheet surface temperature does not reach the melting point, even during summer days. Ice is formed at such places by a dry sintering process. Snow crystals with their magnificent forms decay, driven mainly by temperature gradients, in a few days after deposition, into so-called firn grains. The firn is compacted by the weight of the snow cover above, first by rearrangement of the grains, and at a greater depth by the sintering process that causes the contact areas between neighboring grains to grow. Atmospheric air, filling the pore space between firn grains, is more and more driven out with the densification of the firn. A final amount of air, about 10% by volume, is enclosed in bubbles at the firn-ice transition, which occurs in Antarctica in a depth typically between 80 and 110 m below the snow surface. This air has the composition of the atmosphere at the time of enclosure. The enclosure takes place, depending on temperature and snow accumulation, typically between 200 and 5,000 years after snow deposition. Therefore, the air in bubbles is younger than the surrounding ice. By the analysis of air extracted from well-dated ice samples, the atmospheric composition in the past can be determined.

The main goals of such measurements are to reconstruct the increase of the atmospheric concentration of greenhouse gases caused by humans and possible natural variations, and to determine their causes in earlier times and their interaction with climate.

For the measurements, air has to be extracted from the ice. One method is to melt the ice and to collect the escaping air. However, for certain gases (e.g., CO_2 [carbon dioxide]), the meltwater can react with impurities and contaminate the sample. In this case, air has to be extracted by a dry-extraction method, opening the bubbles mechanically by grinding or milling the ice at low temperature. Antarctic ice just below the firn–ice transition has about 600 bubbles with a diameter of about 0.6 mm per gram of ice. However, the diameter of the bubbles shrinks with depth due to the increasing hydrostatic pressure. At a certain depth (Vostok: between 500 and 1300 m below the surface), bubbles are transformed into air hydrates. These hydrates are difficult to open mechanically, and great care is needed to avoid fractionation during extraction. The extracted air is analyzed mainly by gas chromatography, laser absorption spectroscopy, or mass spectrometry.

Measurements in different laboratories and on various ice cores from Antarctica and Greenland show that the atmospheric concentrations of the important greenhouse gases CO_2, CH_4 (methane), and N_2O (nitrous oxide) were rather stable during the first part of the past millennium but started to increase with the epoch of industrialization and accelerated growth of the global population about 200 years ago (IPCC 2001). Results from very young ice samples agree well with direct continuous measurements on atmospheric air, which, however, did not start before the second half of the past century for all three components.

Measurements on ice cores from Antarctica and Greenland also provide evidence for significant natural variations of the atmospheric concentration of the three greenhouse gases. The atmospheric CO_2 concentration shows only relatively small variations during the last glacial epoch (Indermühle et al. 2000), but with the transition from the glacial epoch to the Holocene (present warm epoch), it increased by about 76 ppmv (parts per million by volume). The increase was practically synchronous with the temperature increase, represented by the hydrogen isotope record. This synchrony between atmospheric CO_2 concentration and Antarctic temperature supports the idea that the Southern Ocean played a key role causing the increase of atmospheric CO_2 (Monnin et al. 2001). There is ample evidence that the CO_2 increase is an important amplification factor for the global temperature increase from the last glacial to the Holocene epoch. The atmospheric CH_4 concentration shows larger variations during the glacial epoch. They are synchronous with temperature variations in the Northern Hemisphere, where most of the natural CH_4 sources (wetlands) are located. The CH_4 concentration increased from about 400 ppbv (parts per billion by volume) during the last glacial maximum to about 730 ppbv at the beginning of the Holocene. The CH_4 increase had only a minor influence on the global temperature increase from the glacial to the Holocene epoch. Atmospheric CH_4 is well mixed and its concentration shows only small variations geographically. The large and rather fast variations of the concentration during the last glacial epoch are observed in all ice cores and can be used to synchronize age scales (Blunier and Brook 2001). The sources for N_2O in preindustrial times were terrestrial wetlands and the ocean. The general trend of the variations is similar to that of CH_4.

The ice core from Vostok Station allows us to extend the CO_2 and CH_4 records back to 420,000 years. It shows that the atmospheric concentration of CO_2 and CH_4 was, during this time, never as high as at present (Petit et al. 1999).

Results reported so far are based on measurements on different ice cores, and they can be considered as reliable. However, much more detailed features could be affected by artifacts due to a small enrichment or depletion of certain gas components by a fractionation during air enclosure or by chemical reactions between impurities in the ice.

A small enrichment of heavier gas molecules occurs according to the barometric formula, because air mixing in the firn layer takes place only by molecular diffusion. The effect for CO_2 in an 80 m deep firn layer at –50°C is only about 0.5 ppm (compared with an average concentration of 280 ppm).

The O_2/N_2 ratio in atmospheric air is 0.2386 at present. This ratio could have been higher during glacial epochs by about 0.0015 due to the reduced biosphere. It would be interesting to measure this effect in ice cores. However, to reconstruct this ratio with this precision seems not to be possible. Measurements on different ice cores show that O_2 is slightly depleted (Bender et al. 1995). It is assumed that a fractionation between O_2 and N_2 occurs either at the enclosure of air in bubbles or during a possible minor gas loss during storage of ice cores.

AUCKLAND ISLANDS

Located 460 km south of the South Island of New Zealand, the Auckland Islands group comprises the main Auckland Island (50,990 ha), five other islands—of which Adams Island and Enderby Island are the largest—and many islets, with a total area of 62,564 ha. Rising to 705 m, the islands are the remains of two coalescing shield volcanoes formed between 25 million and 10 Ma, centred respectively around Musgrave Peninsula in Carnley Harbour and Disappointment Island. Coastal erosion has removed much of the western sector of the volcanoes, forming a line of cliffs up to 400 m high. Pleistocene-age glaciers have carved the eastern coast into a series of fiords, along with cirques, U-shaped valleys, and moraine-dammed lakes. Cloudy, windy and wet weather predominates.

The mean annual temperature is 8°C, with an annual rainfall of 1000–1500 mm and light winter snowfalls. Peat soils, up to 8 m thick, are widespread. The vascular flora consists of 233 species (84% indigenous), of which five are endemic. A coastal fringing forest to 50 m altitude is dominated by the southern rata *Metrosideros umbellata,* accompanied in sheltered places by the world's southernmost tree fern, *Cyathea smithii,* and the tree fuchsia, *Fuchsia excorticata.* Upslope, this grades into shrubland of *Dracophyllum, Coprosma, Myrsine, Ozothamnus, Pseudopanax,* and *Hebe,* replaced above 300 m by grassland dominated by *Chionochloa antarctica,* interspersed with megaherbs including three species of *Pleurophyllum,* and giving way around 500 m to fellfield of bryophytes, mosses, lichens, and sedges.

The islands are the principal breeding ground of the New Zealand (Hooker's) sea lion *(Phocarctos hookeri),* one of the world's rarest seals (population 12,000–16,000). Southern elephant seals breed in small numbers, and leopard seals are occasional visitors. The islands are the main breeding ground in the southwest Pacific for a population of about 1,000 southern right whales.

The three outstanding seabirds are Gibson's albatross *(Diomedia gibsoni)* (6,000 pairs, mainly on Adams Island), southern royal albatross, and white-capped albatross *(Thalassarche steadi)* (65,000 pairs on Disappointment Island). The yellow-eyed penguin is the most conspicuous of the three penguin species breeding, and the endemic Auckland Island shag *(Leucocarbo colensoi)* (about 1,000 pairs) is prominent. Among the smaller seabirds breeding are terns, petrels, and prions. There are seventy-six species of land birds (forty-six breeding), of which six are endemic: the flightless teal *Anas aucklandica aucklandica,* the rail *Rallis pectoralis muelleri* (rediscovered on Adams I. in 1989), the rare banded dotterel *Charadrius bicinctus exilis,* the snipe *Coenocorypha aucklandica aucklandica,* the pipit *Anthus novaeseelandiae auklandicus,* and the tomtit *Petroica macrocephala marrineri.*

Some 180 insect species are recorded, one-third of which are endemic. Since 1987, goats and rabbits have been eradicated, and mice have been eradicated from Enderby Island, while pigs and cats are currently targeted for eradication.

Maori may have briefly occupied the Auckland Islands 700 years ago and were transient settlers in the mid-nineteenth century. European sealers discovered the islands in 1807 and seals were eliminated by the 1830s. American, French, and British exploring expeditions visited in 1840. An ill-fated British colonial shore-whaling enterprise existed from 1849 to 1852, and a German astronomical base was established in 1874 to observe the transit of Venus. At least eight ships were wrecked on the islands between 1864 and 1907, with the loss of more than 100 lives. Supply depots and boats were provided for castaways until 1929. There were several unsuccessful attempts at pastoral farming prior to 1910. Two coastwatching stations were occupied from 1941 to 1945. Since then, there have been sporadic scientific and conservation expeditions, and small numbers of seaborne tourists visit selected sites each year under strict controls. The islands are a nature reserve and World Heritage site. A 484,000-ha marine reserve surrounds the islands to 12 nautical miles (22 km), prohibiting the taking of fish or other marine species for commercial or recreational purposes.

AURORA

The Aurora Australis is a luminous glow in the night sky of the Southern Hemisphere, most commonly in the polar region over Antarctica. It has a great variability in brightness, from a feeble glow to a brilliant display of many colours. And it can transform from quiet arcs stretching from horizon to horizon to a sky filled with spectacular dancing rays and bands. It is analogous to the Aurora Borealis in the Northern Hemisphere.

The existence of these "southern lights" was first suggested in Europe in 1733 by de Mairan, in the first textbook published that was devoted to the aurora. They were confirmed by Captain James Cook, who observed the phenomenon during his voyage of discovery to Australia in *Endeavor* in 1770. During his subsequent expedition to the Antarctic in *Resolution* (1772–1775), he and his crew had several sightings. He then coined the term Aurora Australis, and compared its colours and motions to those of the Aurora Borealis that they had viewed over Sweden. Subsequent voyages of Antarctic exploration pushed farther south and reports of auroras became common in ship's logs—such as in 1831 from John Biscoe, captain of the ship *Tula,* when surrounded by icebergs at the Antarctic Circle:

> At the same time, nearly the whole night the Aurora Australis showed the most brilliant appearance, at times rolling itself over our heads in a beautiful column, then as suddenly forming itself as the unrolled fringe of a curtain, and again suddenly shooting to the form of a serpent and at times appearing not many yards above us; it was decidedly transacted in our own atmosphere, and was without exception the grandest phenomenon of nature of its kind I have ever witnessed.

The Aurora Australis occurs well to the south of inhabited regions and only very major ones expand equatorward sufficiently to be seen over such continents as Australia (and there only a very few times a year). One of the earliest reported from Australia was by Francis Abbott in Hobart, Tasmania:

> On August 29, 1859 there appeared a most brilliant Aurora Australis extending from the W. through the S. to the Eastern part of the horizon in one continued arc of about 190 degrees and shooting up to the zenith.... The phenomenon had for thirty minutes a most magnificent appearance, the bands [i.e., rays] being in complete repose formed a truncated cone of glory, the apex of which, if projected, would have terminated in the zenith....
>
> A second display of the Aurora appeared on the night of 2nd September following, equally brilliant and extensive, but less transitory, and with this difference, that from Sunset the whole of the southern sky was of deep ruby colour....
>
> From 12 to 1 o'clock on the morning of the 3rd the Aurora broke out into flickering streamers and coruscations, as brilliant, and with as much diversity of colour as on the 29th of August, forming in the zenith a well defined corona, which shortly after became diffused and then dispersed....

These two auroras were also seen in North America, Jamaica, Rome, and Athens and are on the list of historical great auroras. The latter one was also viewed and sketched from Melbourne.

Many countries sent expeditions to the Antarctic in the early part of the twentieth century. One was the British National Antarctic Expedition of 1901–1904. On this, Robert Falcon Scott and his party were forced to establish winter quarters on Ross Island, near McMurdo Sound. Many sightings of auroras were made from there. Douglas Mawson, a member of Ernest Shackleton's British Antarctic Expedition of 1907–1909, recorded very detailed observations of the aurora. He continued these scientific studies during his 1911–1914 Australasian Antarctic Expedition.

The geographical distribution of the aurora in the Southern Hemisphere was first reported by Boller in 1898, based on some 780 nights during which auroras were observed. There were several later efforts to map the southern auroral zone but it was not until the International Geophysical Year (IGY) during 1957–1958 that more observational data allowed Feldstein to produce much improved maps of both auroral zones. His southern map showed that this auroral zone roughly encircled Antarctica, well poleward of the southern continents, and that the percentage of nights that one would expect to see overhead auroras in major capital cities was very low (Hobart, 3; Sydney or Auckland, 1; Capetown, 0.5; Buenos Aires, .01). It is not surprising that observations and studies of the Aurora Australis in early times were scanty, compared with the much more extensive studies of the Aurora Borealis, which in contrast occurred over many populated areas.

The Aurora Australis generated several legends and beliefs among early natives of Australia and New Zealand, even though it occurred usually well to the south of them and perhaps was not an integral part of their culture. The auroras they saw were usually red, so they quite naturally associated them with glowing fires. The Maori of New Zealand believed that some of their ancestors had journeyed far south by canoe and become trapped in ice. Their descendants in that inhospitable zone sometimes lit huge bonfires signaling their kinsmen in hope of being rescued. Thus, the Tahu-nui-a-Rangi (Great Glowing of the Sky) was a reflection of these great fires in the night sky.

Certain aboriginal people in Northern Australia viewed the aurora as the feast fires of the Oolapikka folk—ghostly beings who sometimes spoke to the people through these auroral flames. Only the elders dared look at the lights and interpret their messages. Those in the south explained auroras as the campfires of spirits, flickering over Kangaroo Island off the south coast of Australia. Among the Kurnai people of southeast Australia the aurora needed no interpretation: it was an unequivocal and terrifying warning from the Mungan Ngour, the "Great Man," and a sign of his wrath. The Kurnai would run about trying to fend it off, and shouting at it to go away.

It had been long recognized that the southern and northern lights had some similarity and that the magnetic field of the Earth exerted some influence over them. There was some evidence that auroral displays occurred simultaneously in both hemispheres. A literature study about 1865 revealed that of thirty-four displays seen in the Southern Hemisphere, twenty-three were coincident with auroras reported in North America. Photographs taken in 1968 from coordinated aircraft flying over Alaska and south of New Zealand showed auroras that were near mirror images of each other. More detailed studies with spacecraft imagers have since established that the two auroras are conjugate (occurring on both ends of the same magnetic field line). Comparisons of such joint images show some small differences in detail (intensities and form), explained as due to irregularities in the geomagnetic field. So, the southern and northern lights can be considered integral parts of a global phenomenon. Comments that follow can therefore apply equally to either the southern or the northern lights.

As for general characteristics, the aurora varies in brightness from a faint glow at quiet times to a brightness approaching that of the full moon during active periods. It is a permanent optical feature of the upper atmosphere, appearing in each hemisphere as an oval about 100 km or more above the earth. Its position varies with geomagnetic activity. During moderate activity the aurora is located about 23 degrees from each magnetic pole on the night side of the Earth and about 15 degrees on the dayside. During magnetically quiet times the oval shrinks poleward by as much as 5 degrees, significantly reducing the size of the polar cap, that region poleward of the aurora. The South Magnetic Pole is near Vostok Station, Antarctica, and the southern "auroral oval," the zone of most frequent auroral occurrence, roughly encircles the Antarctic Continent. It is only during very major disturbances that the southern lights move sufficiently equatorward to be seen over continents such as Australia.

While spectacular auroral displays have been recorded through history as far back as 500 BC, it has been through concerted international efforts, such as the IGY, and succeeding *in situ* balloon, rocket, and satellite investigations that most understanding of the phenomenon has emerged. The aurora is caused by particles, mainly electrons, bombarding the upper atmosphere gases. Its visible spectrum consists mainly of emissions from excited oxygen atoms (green and red emissions) and nitrogen molecules (violet and pink). The variation in colour seen in different displays is due to differing depths of penetration into the atmosphere by the bombarding electrons.

The emission spectrum extends over a wide frequency range extending from x-rays to radio emissions. Some major emissions are in the extreme ultraviolet region and are absorbed by the atmosphere, but can be detected from above by spacecraft imagers. Orbiting satellites such as the Dynamics Explorer, Viking, Polar, and Image have been used routinely since 1981 to photograph the aurora globally, even in the presence of full sunlight. They have verified that the aurora is a permanent optical feature, consisting of two full haloes encircling the earth. Viewed around this "24-hour oval" there are typically quiet arcs in the evening sector, dynamic brighter auroras in the midnight sector, diffuse auroral remnants in the morning sector and faint, red aurora through the noon sector.

The IGY prompted the establishment of many Antarctic bases in the 1950s, many of which have had active research programs, including auroral studies. At the Australian Mawson station and the Japanese Syowa station, aurora can be seen on practically every clear night. They are about 25 degrees from the South Magnetic Pole. Amundsen-Scott South Pole Station, established in 1956, is just poleward of the center of the auroral zone, but an ideal location for studies of auroras near midday—aided by several months of 24-hour darkness each year.

The period 1996–2003 went from solar minimum (~1996) to solar maximum (~2002) and the observations and photographs of Robert Schwarz, a scientist then at Amundsen-Scott Station, illustrate how auroral activity and poleward expansion increase with solar activity during the 11-year sunspot cycle. They are in agreement with the more extensive evidence from the Northern Hemisphere.

Auroral activity is controlled to a major degree by solar activity and the solar wind, that continuous stream of electrons and protons emanating from the sun. Major auroras are due to coronal mass ejections (CMEs) from the sun, while auroral substorms are usually triggered by changes in the solar wind. Auroral substorms occur periodically and typically last for about 3 hours. The first sign is a sudden brightening of the quiet auroral arc in the midnight sector. This brightening spreads westward along the auroral oval, then the aurora expands poleward (termed the expansive phase). During this time the aurora is most active and colourful, with draperies, transient rays, and rapidly moving arcs. The aurora then fades and recedes to lower latitudes and is replaced by fainter patches, often pulsating. This recovery phase lasts for up to 2 hours.

Great auroras expanding down to low latitudes and lasting up to 2 days occur very occasionally, and have been marvelled at through the ages. They are marked by their near global extent, their long duration, their brightness, and their vivid colour. As they expand to lower latitudes they usually exhibit a deep red colour. Global power inputs via particle precipitation have been estimated as high as 1000 gigawatts during the peak of such auroras. They tend to occur around or following the peak of the 11-year cycle of solar sunspot activity (but can occur any time). While there may be something special causing these very unusual auroras, so far it appears they are just "bigger" than the usual substorms and not greatly different.

One of the great auroras of the past century occurred on March 13–14, 1989, with sightings reported from Argentina, Britain, and much of North America. Satellites recorded images of greatly expanded auroras over both southern and northern latitudes. That aurora lasted more than 30 hours and caused a major power disruption along the American eastern seaboard. Another aurora approaching the same magnitude was on April 6–7, 2000. The bright red glow lasted for three hours in South Africa, north of Capetown. It was also viewed over much of Europe and throughout North America.

One last example was the great Aurora Australis seen on March 30–31, 2001. As reported in detail by the Royal Astronomical Society of New Zealand, it was visible over much of New Zealand and Southern Australia through the whole night and was often red in colour. There were Aurora Borealis sightings at the same time over much of North America and across Norway.

It is noteworthy that for the latter two auroras there was a full array of spacecraft in orbit and it was possible to trace their full evolution from beginning to end. The spacecraft SOHO (for Solar and Heliospheric Observatory) observed the solar CMEs, which caused them. The progress of the clouds and the solar wind streaming earthward were monitored by the ACE (for Advanced Composition Explorer) and WIND satellites, and the auroras resulting some 2–3 days later (the sun-earth transit time) were recorded by several satellites.

It is difficult to get auroral observations from the ground in both hemispheres simultaneously, due to the asymmetry of seasons. The best opportunities are around the equinoxes, when there are similar day and night conditions in both auroral zones. Fortunately, auroral activity is somewhat greater through the spring and autumn seasons due to increased magnetic activity, which adds to the chances of joint observations. Major displays of Aurora Australis were reported by viewers in New Zealand and Australia on May 4, 1998, October 24 and November 4, 2001, October 23, 2003, and November 7, 2004.

Poleward of the auroral zones there are often auroras, referred to as "polar auroras." They were first noted by early Antarctic (and Arctic) explorers. They are of similar origin to lower latitude auroras but are somewhat different in appearance and character. They occur under quiet magnetic conditions when auroral oval activity is minimal. They consist of very narrow arcs, usually faint and colourless, and they are always aligned along the Sun-Earth line. They usually are seen to split off the poleward edge of the auroral oval and drift across the polar cap, or to linger for hours depending on the state of the solar wind.

There is now a general understanding of auroral phenomena, but some questions still remain and these are now being addressed by several countries in ongoing research on the Aurora Australis in Antarctica, at over twenty stations located around the continent. This work has been recently extended with the addition of several remote automated geophysical observatories on the continent, and with an array of auroral radars that cover much of the southern auroral zone. So, while historically much of the knowledge about auroras came from observations of the Aurora Borealis, the Aurora Australis has captured its proper share of attention during the past half-century with the establishment and operation of the Antarctic research bases.

AURORAL SUBSTORM

A repeatable large-scale brightening of the aurora on the nightside of the Earth at polar latitudes, the auroral substorm was identified and defined in 1964 by Japanese scientist S. -I. Akasofu from all-sky camera movies of the aurora taken during the International Geophysical Year 1957–1958. The substorm takes its name from the magnetic storm, of which it was thought to be an integral part. However, it is now uncertain whether this is true since a magnetic storm can occur in the absence of substorms, and vice versa.

The auroral substorm begins with substorm onset when a discrete auroral arc brightens near the equatorward edge of a preexisting latitudinal band of discrete arcs. There follows an expansion phase in which the brightening expands eastward, westward, and poleward. This lasts 20–30 minutes until the brightening reaches its maximum poleward extent. The substorm then enters a recovery phase of 1–2 hours duration, during which the aurora fades to pre-onset levels. During the course of a substorm, about a thousand million million joules of energy are dissipated in the Earth's auroral atmosphere at about 100 km altitude, similar to the energy of a hurricane.

The location of substorm onset is roughly around midnight local time near the Arctic and Antarctic circles. More precisely, its location is ordered with respect to the geomagnetic pole and the Sun. Defining a magnetic coordinate system in which ±90° geomagnetic latitude is at the North/South Magnetic Pole and 12 hours magnetic local time (MLT) is the magnetic longitude closest to the Sun, the most common substorm onset location is 67° geomagnetic latitude and 23 MLT. As a result, Syowa is probably the most favourable Antarctic station at which to observe substorms.

The waiting time between one substorm onset and the next is quite variable. The most common waiting time is 3 hours but substorms can be separated by over a day. The average waiting time is about 6 hours and hence a ground-based observer may typically expect to see one or two auroral substorms per night, assuming there are no clouds to obscure the view of the aurora.

Since its discovery, the auroral substorm has been found to correlate with changes in many other phenomena in the near-Earth space environment, including electrical currents, the geomagnetic field, ionised particles, and electromagnetic waves. (Collectively, these signatures define the magnetospheric substorm, the magnetosphere being the comet-shaped region of near-Earth space dominated by the geomagnetic field.) It has been shown that the substorm onset follows a growth phase of typically 40–60 minute duration during which energy is slowly accumulated in the geomagnetic field before its relatively sudden release at substorm onset. This energy is extracted from a flow of ionised material from the sun called the solar wind, whenever the solar magnetic field within it is directed southward. It may thus be feasible to predict substorm onset from measurements made in the solar wind by spacecraft, but knowledge is not yet sufficiently developed to do this.

AUSTRALASIAN ANTARCTIC EXPEDITION (1911–1914)

The Australasian Antarctic Expedition (AAE) was an impressively planned and executed three-base expedition under the command of Douglas Mawson, then a lecturer in geology at the University of Adelaide, that was remarkable in both its scientific research and its geographical accomplishments. However, the achievements of the AAE were overshadowed by the disasters of Robert Falcon Scott's last expedition, and their full significance was not widely appreciated outside Australia at the time. It was an Englishman, J. Gordon Hayes, who first put them into proper perspective: "Sir Douglas Mawson's Expedition," he wrote, "judged by the magnitude both of its scale and of its achievements, was the greatest and most consummate expedition that ever sailed for Antarctica."

From the outset, the AAE was conceived by Mawson as a vast project. His hand-drawn plan of action (February 1910) shows a 2,000-mile (3200 km) arc of coast from Cape Adare west to Gaussberg in Kaiser Wilhelm II Land: all this was to be explored. There were to be three continental bases, each with teams striking east and west, and one going south as well. No expedition on this scale had ever been conceived for Antarctica.

In December 1911, the expedition left Hobart, its first stop being at Macquarie Island, where a five-man base under George F. Ainsworth was set up to serve as a meteorological station and wireless-relay point for the Antarctic bases. In the next 2 years extensive geological, biological, botanical, and survey and charting work was also done there.

In early January 1912, with the expedition ship *Aurora* unable to approach a landing site as quickly as he hoped, Mawson was forced to reduce the continental bases from three to two. Ultimately, they found a suitable site for the Main Base (or Winter Quarters, as Mawson often called it) at Cape Denison in Commonwealth Bay, Adélie Land. Mawson and seventeen other expedition members were landed here. *Aurora* then sailed 1,500 miles (2400 km) west in search of a place to land the men chosen for the Western Base. This was found on what was later named the Shackleton Ice Shelf, and, with great unease, John King Davis, second-in-command of the expedition and captain of the *Aurora,* allowed the Western Base to be set up on the ice shelf under the command of Frank Wild, whom Mawson had originally met on Ernest Shackleton's British Antarctic Expedition (as he had Davis). Under Wild's command were seven men with no previous Antarctic experience.

At Cape Denison, Mawson oversaw the construction of two prefabricated wooden huts that were joined into one and a small magnetograph hut. Unfortunately this turned out to be perhaps the windiest place on the continent, so that winter and most of spring were spent indoors on scientific work, largely biological, zoological, and meteorological. Likewise, difficult conditions for the members at the Western Base kept them in their hut most of the winter. It was not until November 1912 that the serious sledging program was able to begin and the teams set out on their journeys. A total of 2,600 miles (4200 km), out and back, were sledged over territory entirely unknown until then. This figure included, in addition to Mawson's own ill-fated journey 310 miles (500 km) to the southeast and marches by support parties, a journey of 160 miles (260 km) to the west, one of 300 miles (480 km) to the south-southeast to within 50-odd miles (80 km) of the areas of the South Magnetic Pole, and another of 270 miles (430 km) to the east, much of which was over sea ice. At the same time, from the Western Base, 800 miles (1280 km) were traversed, including a journey of more than 200 miles (320 km) west to Gaussberg, and another of around 100 miles (160 km) east to the Denman Glacier. All of this was—for journeys from both bases—frequently in the face of appalling weather. During the 91 days of Mawson's own journey, for instance, there were 43 days with winds of force 8 or stronger, 17 days with winds of force 10 and over, and seven days with winds of force 12 (80 mph or 128 kmph).

In addition to the exploratory activity, there was pioneering wireless work (including the use of wirelessed time signals to establish the fundamental longitude for Cape Denison), exploratory and oceanographical work aboard *Aurora* (under Davis), and diverse scientific work at each of the bases.

Hayes made a very telling point in distinguishing between territory *discovered* and territory *explored*—that is, charted. By this test, the Norwegian explorer Roald Amundsen—the first to the South Pole—discovered 1,300 miles (2080 km) of land and 450 miles (720 km) of shelf ice, but explored very little of it. Scott's first *(Discovery)* expedition discovered 1,050 miles (1680 km) but explored only about 200 (320 km); his second *(Terra Nova)* expedition discovered about 285 miles (460 km) of new ground but explored only 100 (160 km). And Shackleton's British Antarctic Expedition discovered 1,035 miles (1660 km) of new land and explored most of it. Hayes tabulated the results in very clear form, concluding (1928: 257):

> As [Mawson] discovered and explored so much, care has been taken not to over-estimate his results. Amundsen, owing to his skill in the use of dogs, comes next in geographical discovery alone; but his maps make accuracy very difficult, and his work was not on the same level as that of the other explorers. Mawson's result, for one expedition, is magnificent, when his scientific work is included also.

Even at the time, as the AAE was returning to Australia in February 1914, there was one man qualified to judge who summed things up correctly—W. S. Bruce, leader of the Scottish National Antarctic Expedition of 1902–1904. "It is not too much to say," Bruce wrote Mawson, "without any intention to flatter, that your expedition has been the most successful of any recent Antarctic expedition. As a scientific man you have trusted your own powers to conduct the expedition entirely on scientific lines without seeking to secure popular éclat by proposing a sensational advance of an athletic kind" (Bruce 1914).

The great value of the AAE, then, consisted in the extent of its geographical exploration and the quality of its scientific leadership. Unlike Shackleton's and Scott's expeditions, it always put science first, the scientific ideal embodied in the commander, an academic and field geologist. In preparing for it, Mawson relied on support from private sources, from Federal and State Governments, and from the Australasian Association for the Advancement of Science (AAAS), of which Mawson was a member. Essentially, however, it was a private expedition. The scientific personnel were chosen by Mawson (theoretically the AAAS had a watching brief on this), and all the preparations were in his hands. It was his affair. He organised the funding, selected the men, the ship, and the equipment, and there was no one to nay-say him. The avant garde nature of Mawson's AAE is most epitomised in two things. First, he was the initial man to take an airplane to the Antarctic, and, indeed, it was the most advanced form of airplane of that period, a monoplane: a French REP (after its owner-developer, Robert Esnault-Pelterie), notable for its tapered, tubular-steel fuselages, generally triangular in section but lozenge-shaped on the latest D-type that Mawson chose. There was also a single control for pitch and roll, an advanced feature. The five-cylinder engine was fan-shaped. With ski undercarriage, the cost was £955 4s 8*d*. The extremely windy conditions at Cape Denison prevented its being flown there, and instead it was used (briefly) as an "air-tractor," dragging supplies. Prior to being taken south it was test-flown (crashed and repaired) in Adelaide in 1911 as a publicity stunt to raise funds for the AAE. Mawson was also the first explorer to take colour photography to the Antarctic—Lumière Autochrome plates, 400 of them, many preserved today in the Mawson Antarctic Collection in the South Australian Museum, Adelaide. Mawson selected and purchased the cameras for the expedition (with the latest German Zeiss Tessar lenses, also a Busch telephoto lens), and appointed Frank Hurley as the expedition's photographer. Hurley was a more imaginative and daring photographer than Scott's, Herbert Ponting. Hurley's work on Shackleton's Imperial Trans-Antarctic Expedition (1914–1917), including flash photography of the breakup of *Endurance* at night, is justly famous, but his glass-plate photographs (including stereos and Autochromes) of the AAE are equally fine and dramatic. Like the photographic materials, all the scientific equipment on the AAE was the very best. Some was loaned by the Prince of Monaco, an oceanographer of international repute. Other pieces were supplied by Negretti and Zambra, and some were loaned by the Admiralty and the Royal Geographical Society. The wireless equipment was produced by Telefunken.

In addition to its geographical and scientific aspects, the AAE undoubtedly had an unspoken strategic dimension. The Australian government contributed £10,000 for a reason. Discovery implies ownership. Australia is an isolated outpost of European civilisation between East Asia and Oceania. Its strategic approaches are the oceans that surround it. The Russians and Germans had long since shown an interest in Antarctica. Neither was necessarily friendly to the British, and Australians were, at that time, British. It made sense for the Australian government to contribute to the funding of an expedition that promised to chart and claim for Australia, as part of the British Empire, a vast arc of Antarctica directly to the south and southwest of the Australian continent. Mawson's Antarctic expeditions of 1929–1931 were more overtly imperial, and as a result of these expeditions and the AAE, Australia claimed fully 40% of the Antarctic continent as its own.

Although there were seven major sledging parties (not including the depot or support parties), the event for which the AAE is best known was Mawson's heroic month-long survival trek. On November 10, 1912, he set out from the Main Base with two young companions, Dr. Xavier Mertz (a Swiss prize-winning skier) and Lieutenant Belgrave Ninnis, heading southeast and then east, across the Mertz and Ninnis glaciers and the plateau of George V Land. A month out, 311 miles from Main Base, Ninnis fell hundreds of feet down a crevasse (deceptively covered by a snow bridge) with his dogs and sledge, which carried practically all their food, the main tent, Mertz's warm Burberry trousers and helmet, their eating utensils, sledge mast, sail, and other materials. Mawson and Mertz were left with their sleeping bags, 10 days' supply of food, a spare tent without poles, their private bags, and a cooker and kerosene. Their dogs were in poor condition and there was nothing to feed them except each other. "We considered it a possibility to get through to Winter Quarters by eating dogs," Mawson wrote in his sledging diary, "so 9 hours after the accident started back, but terribly handicapped.... May God help us."

What followed was a wild dash across the plateau of King George V Land, including the upper reaches of the Ninnis and Mertz glaciers. They travelled by night, the Sun low down and the crisper surface offering less resistance to the sledge. Across ice fields ribbed with slippery sastrugi, dog after dog gave out and was shot. More than half the way back Mertz sickened, delaying progress, and after a few days he died. It was not until February 8 that Mawson finally reached Main Base, by which time *Aurora* had come, picked up most of the men, and—only hours before—sailed off to collect those at Western Base. A small party had remained behind at Main Base to await Mawson's return, and with these he spent the rest of 1913 in Antarctica, continuing to make scientific observations and, eventually, carrying out a small sledging programme. The next summer, after great difficulty in raising the financing for a relief voyage south, Davis and *Aurora* picked up the men still at the Main Base and, following yet more exploratory and oceanographic work, arrived back in Australia in late February 1914.

The scientific results of the AAE were published in a long series of *AAE Scientific Reports,* authored by Mawson and others (he farmed them out to specialists all over the world). His published account of the expedition, in two volumes, *The Home of the Blizzard,* appeared in London in 1915. It is thorough and well written (Mawson was assisted by one of his expedition members, Dr. Archibald McLean, who heavily worked over the drafts). There are numerous photographic plates, and the entire work reflects the scientific spirit that infused the AAE from its inception.

AUSTRALIA: ANTARCTIC PROGRAM

After some 150 years acting as stepping off or returning point for expeditions representing many nations (Wilkes, Ross, Dumont d'Urville, Borchgrevinck, Amundsen, Mawson, and Ellsworth), Australia established its own continuing, government-funded program with stations on Heard Island and Macquarie Island late in 1947. The closure of Heard Island late in 1954 permitted resources to be allocated to building Mawson Base on the Antarctic mainland early in 1954; Mawson has been occupied continuously since and is the longest continuously occupied station on the mainland of Antarctica.

At the outset, a decision was made to have the core of the Australian program—the Australian National Antarctic Research Expeditions (ANARE)—conducted by a government institution that would have dual functions of support and research. After belonging to many different federal government departments, this institution—the Australian Antarctic Division (AAD)—now resides in the Department of Environment and Heritage. Scientific activities in the AAD were to be conducted in disciplines not covered by other government organisations; thus the AAD conducts programs in biology (terrestrial and marine), glaciology, upper atmosphere and cosmic ray physics, human impacts, and polar medicine. These subjects are aided by a technical support group. Earth sciences originally were to be conducted by the Bureau of Mineral Resources (now Geoscience Australia), meteorology by the Bureau of Meteorology, and ionospheric studies by the Ionospheric Prediction Service. A major development since the AAD moved to Tasmania early in 1981 has been the increasing role of the Commonwealth Scientific and Industrial Research Organisation (CSIRO) both in cooperation directly with the AAD or through its involvement in cooperative research centres. The government program was, and still is, supplemented to a large extent by projects conducted in all disciplines in most Australian universities, particularly the University of Tasmania, which has established the Institute of Antarctic and Southern Ocean Studies (IASOS). The AAD makes available grant money in support of researchers from outside government agencies.

Internationally, the Australian program has been a significant participant in the Scientific Committee on Antarctic Research (SCAR) and its instruments in both management and scientific cooperation. With the advent of Antarctic Treaty instruments such as the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR), which was signed in, and has its headquarters in, Hobart, and the Protocol on Environmental Protection to the Antarctic Treaty the research program has evolved to meet new requirements specific to these agreements.

Currently, the program operates from three permanent continental stations—Mawson (67°36′ S, 62°52′ E: 1954–present), Davis (68°36′ S, 77°58′ E: 1957–present, excepting 1965–1969) and Casey (66°18′ S, 110°32′ E: 1969–present). Casey was at first the United States station of Wilkes established for the International Geophysical Year but assumed by the Australian program in 1969; it has been moved twice to ever newer sites. All have year-round scientific programs. In addition there is a permanent station on Macquarie Island (54°30′ S, 158°5′ E; 1947–present), which is part of the state of Tasmania. Provisions also exist for operation of summer programs at Heard Island (initially at Atlas Cove; 53°01′ S, 73°23′ E), Larsemann Hills (Law Base), Bunger Hills (Edgeworth David Base), and Prince Charles Mountains. In addition to the land-based program, a diverse marine science research program in biology, sea-ice studies, and oceanography is conducted from FRV *Aurora Australis* and the earth sciences from *Aurora Australis* supplemented by use of other vessels, either nationally or in concert with other nations.

Observatory functions are an important component of the program and all stations have meteorology observatories. All stations have some combination of seismological and magnetic observations and Mawson is one of the primary sites for monitoring in support of the Nuclear Non-Proliferation Treaty.

The headquarters of the program was initially at a variety of sites in Melbourne, Victoria, but a government decision led to the move from Melbourne to Kingston, Tasmania. The new headquarters were opened in April 1981 by HRH Prince Charles. There are now over 300 staff in the AAD. Annual budget for 2000/2001 for the AAD alone was AU$98.94 million.

At first, all transport between Australia and Antarctica depended on chartering of foreign vessels, in particular the Danish MV *Kista Dan, Magga Dan, Thala Dan,* and *Nella Dan.* In the 1980s, following the loss of MV *Nella Dan* off Macquarie Island, the government decided to build, in Australia, an icebreaking research and supply vessel—FRV *Aurora Australis*. This has been in service since 1990. It was supplemented for many years by the German cargo ship MV *Icebird* (now *Polar Bird*). In the 1960s, the AAD was served by fixed wing aircraft but this ceased after losses. After detailed study, it was decided to resume air transport, and fixed wing aircraft began flying within Antarctica in the 2004–2005 austral summer. During 2005, the government made finance available to fly routinely from Australia to a compressed-snow runway at Casey. Initial experimental flights are scheduled for the 2005–2006 summer. It is expected that this will increase flexibility and allow improved servicing of distant field sites in Antarctica.

The goals of the program vary in line with government policy and at present the four goals are to:

- Maintain the Antarctic Treaty and to enhance Australia's role in it;
- Protect the Antarctic environment;
- Understand the role of Antarctica in the global climate system; and
- Undertake scientific work of practical, economic and national significance.

To achieve these ends the AAD program is organised into a series of branches:

- Directorship,
- Science,
- Operations,
- Policy coordination,
- Polar medicine, and
- Corporate.

In 1990, the Australian government instituted a Cooperative Research Centres program and one of these, at the University of Tasmania, was dedicated to research into Antarctic and Southern Ocean Climates. A new Cooperative Research Centre into Antarctic Climate and Environment (CRC-ACE) followed, also in Hobart.

The Australian Antarctic program has been a major contributor to Antarctic scientific literature and in recent years there have been symposia to consolidate knowledge of particular areas.

Major scientific achievements in recent years have included the move into all areas of marine science (especially since 1981), glaciology traverses into the hinterland between Mawson and Davis and ice coring near Casey, establishment of a LIDAR (for "light detection and ranging") facility at Davis, modernisation of the observatory functions as part of a redevelopment of the station buildings, major inland earth science studies in the Prince Charles Mountains and in the Vestfold Hills, environmental research designed to rectify past damage and to improve operational environmental care, and recognition that the region is a leading source of information on the evolution of the Antarctic environment over the last 200 million years, including the drilling of four legs of the Ocean Drilling Program (ODP).

Planning is now active for involvement in the International Polar Year of 2007/2008, including a leading role in the Census of Antarctic Marine Life (CAML).

AVIATION, HISTORY OF

For the first time in history, new land was being discovered from the air, declared Sir Hubert Wilkins in 1929 on his return from a flight that turned a key to unlock the exploration of Antarctica in the twentieth century.

Even as Amundsen, Scott, Shackleton, and Mawson struggled to reach their polar goals, in another part of the world an air age had dawned. But almost two decades would pass before the Wilkins-Hearst Expedition's slim Lockheed Vega in a take-off from a volcanic airstrip on Deception Island signalled a most dramatic change in humankind's striving to lift the veil of the last unknown continent.

In an age of ponies, dogs, and man-hauled sledges, the old explorers would be content with maybe 20 miles a day, maybe 10 or less. Tramping a cruel, snow-crusted surface would cost them in starvation, isolation, tragedy. The new explorers spoke in terms of hundreds of miles a day, if not thousands;

starvation and isolation were mostly put behind them, but regrettably, not always the tragedy.

The full implication of the airplane to Antarctic exploration was little realised when Captain Robert Falcon Scott, in a balloon named *Eva,* rose above the Great Ice Barrier on February 4, 1902. The German explorer Erich von Drygalski followed with a balloon flight from the ice of Kaiser Wilhelm II Land, a few months later, drawing on advanced technology, Drygalski was able to talk from his balloon by telephone to the crew watching anxiously below.

The Australian explorer Douglas Mawson planned to include a heavier than air machine in his Australasian Antarctic Expedition of 1911. But the Vickers REP monoplane broke its fragile wings and in the reduced role of an "air tractor" enjoyed short-lived service before succumbing to the cold of Commonwealth Bay.

Pioneering the Antarctic skies would be left to another man from South Australia, Sir Hubert Wilkins, who had already won fame on the battlefields of World War I and in Arctic aviation. Though a pilot himself, Wilkins preferred to have the seasoned polar aviator Carl Ben Eilson at the controls when the Wilkins-Hearst Expedition reached the Antarctic Peninsula in 1928. Their two Lockheed Vega highwing aircraft, *San Francisco* and *Los Angeles,* acknowledged the generosity of William Randolph Hearst, the Californian press magnate who financed their exploits.

In *San Francisco,* Wilkins and Eilson made a brief yet historic test flight on November 26, 1928, from a rough volcanic scree strip they had scraped alongside the whaling station at Deception Island. The following month was spent in further test flights, including one in which *Los Angeles* suffered wing damage when it broke through the ice, leaving them with one fit aircraft. Wilkins and Eilson knew they must take a chance. Five days before Christmas, in *San Francisco,* they went aloft on a course of 1,000 miles across the Antarctic Peninsula, photographing, sketching, and gazing in wonder—and at the end of 10 hours were back on Deception Island, in time for a dinner where they toasted the new age of air exploration.

Commander Richard E. Byrd, USN, led the United States to dominance of the Antarctic skies, beginning with his first expedition in 1929. From Little America I, located on the Bay of Wales at the far eastern edge of the Great Ice Barrier (Ross Ice Shelf), he operated three aircraft—a Ford trimotor for long distance missions, supported by a Fokker, the *Virginian,* and a Fairchild, *Stars and Stripes*. On November 28, 1929, the Ford trimotor *Floyd Bennett,* piloted by Bernt Balchen, achieved Byrd's goal of first flight to the geographic South Pole, covering 1,750 miles and completing the historic and hazardous return journey in 17 hours 28 minutes. Byrd, now promoted to Rear Admiral (retired) placed more emphasis on photomapping when his second expedition resumed operations at Little America II in December 1933. *William Horlick,* a Curtis Wright Condor biplane, was the largest of the four aircraft; the other three were a Fokker, *Blue Blade,* and a small Fairchild, *Miss American Airways,* both high wing monoplanes, and a Kellett K-4 autogiro, the first rotary wing machine taken to Antarctica. The latest still and movie cameras were among his equipment, as was short wave radio that (being a superb publicist) he used in weekly broadcasts to American households.

Inspired, maybe, by Admiral Byrd's exploits, a New York adventurer-millionaire, Lincoln Ellsworth, made three attempts to fly across Antarctica, beginning in 1934. With Sir Hubert Wilkins as his manager and, initially, with Bernt Balchen as chief pilot, Ellsworth chose a sleek Northrop Gamma 28 all-metal low wing monoplane named *Polar Star* to make the crossing, starting from a base on the Antarctic Peninsula. By the time of his third expedition, a Canadian, Herbert Hollick-Kenyon, was the replacement pilot, while Wilkins stood by with Ellsworth's ship, *Wyatt Earp.* From a snow strip on Dundee Island, Ellsworth finally reached the Bay of Whales on December 15, 1935. The flight of 2,340 miles occupied 20 hours and 15 minutes, but allowing for landings due to adverse weather, took 13 days to accomplish—including a trek on foot for the last 100 miles to reach the shelter of Byrd's deserted camp.

Renewed interest in Antarctica during the 1930s prompted other nations with eyes on the White South to begin adding aircraft to their expeditions—Norway from its whaling fleets, Australia from the Mawson-led BANZARE (British, Australian, New Zealand Antarctic Research Expedition), and Nazi Germany under Hitler's orders.

Norwegian Aerial Efforts

The Norwegian whaling magnate Lars Christensen introduced aircraft to his whaling fleet in 1929 when the catcher *Norvegia* was modified to carry two float planes—an F.18 Hansa Brandenburg (a type used by the Navy) and a Lockheed Vega high wing monoplane, similar to the type flown by Sir Hubert Wilkins. During December, the experienced aviators Hjalmar Riiser-Larsen and Finn Lützow-Holm began flights along the coast of Enderby Land. On December 22, after stopping at Cape Ann, they raised the Norwegian flag and deposited a notice of the visit in a metal cylinder. Tragedy struck another whaling expedition at this time when, on December 25, pilot Lief Lier and Dr. Ingweld Schreiner disappeared on a flight from the factory ship, *Kosmos* near the Balleney Islands. Their deaths were the first recorded in Antarctic aviation.

A series of flights by Christensen's float planes in January 1930 emphasised Norway's territorial interests. Names were given to the Prince Olav Coast and Sor Rondane Mountains and numerous other features, reflecting the economic importance of claiming prior rights to the wealth of the whaling grounds.

The depot tanker *Thorshavn* sailed south from Cape Town for the 1934 hunting season, carrying an Avro Avian float plane (similar in size to the de Havilland Moth). Between January and February, Lieutenant Gunnerstad completed a series of runs along the Lars Christensen Coast, bestowing names on the King Leopold and Queen Astrid coasts. The third *Thorshavn* expedition of 1936 continues coastal exploration with the aid of radio communication between ship and plane. In the following year a Stinson float plane with a 750-mile range was transferred to the catcher *Firern,* allowing a closer approach to the continent; an obliquely aimed camera recorded parts of the West Barrier, including Olav Prydz Bay and the Kemp and Enderby coasts. On January 27, Ingrid Christensen, the owner's wife, became the first woman to sight Antarctica from the air when the Stinson pilot, Viggo Wideroe, took her on a course above the ice-free Vestfold Hills. Three women friends travelling with Mrs. Christensen were also given the opportunity to fly. When the program ended in early February, 30 hours and 50 minutes had been spent in photomapping, the results to be deposited with the Norwegian Geographical Society. (On January 14, 1939, King Haakon formally claimed Queen Maud Land for Norway, stretching from Coats Land (Britain) to Australian Antarctic Territory, 20° W to 45° E.)

BANZARE and Its Aftermath

Douglas Mawson, Australia's foremost polar explorer, would wait almost 20 years to reach the Antarctic skies after the failure of his first aircraft at Commonwealth Bay in 1911—and his lost chance to wear the laurel of Antarctica's aviation pioneer.

Mawson returned to Antarctica in 1929, leading BANZARE (British, Australian, New Zealand Antarctic Research Expedition) with a de Havilland Moth float plane crewed by two RAAF pilots, Stuart Campbell and Eric Douglas, carried aboard the vessel *Discovery.* Flights were made in January 1930 along the coast of Enderby Land, one of which resulted in the naming of Mac.Robertson Land, in honour of BANZARE's benefactor, a Melbourne toffee manufacturer. The Casey, David, and Masson ranges were also sighted and named.

On the second BANZARE voyage of 1931, further flights of the de Havilland Moth explored the coast of Wilkes Land. On February 9, with Campbell as his pilot, Mawson named Princess Elizabeth Land, after the young woman who would become England's Queen. Other sightings and namings made before the expedition turned for home include the Amery Ice Shelf and the Scullin and Murray monoliths.

In a UK Order-in-Council of February 7, 1933, formal claim was made over the area now known as the Australian Antarctic Territory beyond latitude 60° S and lying between 45° E and 160° E, representing an area of 2,472,000 square miles, equivalent to some 42% of the continent.

Australia sent another expedition to Antarctica in December 1935, on an urgent mission to find the missing American millionaire, Lincoln Ellsworth, and his pilot, Herbert Hollick-Kenyon. RAAF aircraft and pilots Eric Douglas and Alister Murdoch were aboard the vessel *Discovery II,* which left Australia on Christmas Eve. On January 12, 1936, Douglas and Murdoch in a de Havilland 60 Gipsy Moth float plane searched for open water leads through the Ross Sea pack. Two days later, Ellsworth and Hollick-Kenyon were located at the deserted Little America II base on the Bay of Whales. The rescue mission came to a bizarre conclusion when a frustrated Ellsworth protested, "But we're not lost!"

John Rymill was a lesser-known Australian explorer who used aviation to maximum advantage on his small expedition. Born in South Australia, Rymill gained his polar experience in the Arctic and in 1934 formed the 16-man British Graham Land Expedition to map a remote section of the Antarctic Peninsula. Equipment aboard Rymill's motor-assisted schooner, *Penola,* included a motor boat, a tractor, and a de Havilland Fox Moth modified for photo surveying, flown by Wilfred Hampton. Operations were conducted from a first base on the Argentine Islands, then relocated southward to a second base at Marguerite Bay. Rymill insisted on photomapping accuracy through the presence of ground control parties; 1,000 miles (1600 km) of Graham Land's west coast were recorded on camera. The slender but efficient expedition closed in March.

Antarctic Aviation in International Politics

Nazi Germany was not to be excluded from the rush to explore and claim Antarctic territory in the 1930s. Under Adolf Hitler's orders, the Neu Schwabenland Expedition anchored off the Princess Martha Coast of Norwegian-claimed Antarctic territory. Dr. Alfred Ritscher led the ship-based expedition, carrying the Dornier Super Wal flying boats *Passat* (D-ALOX) and *Boreas* (D-AGAT), which were launched by catapult from the seaplane tender, *Schwabenland.* The pilots, Rudolf Wahr and Dicki Shirmacher, and supporting crew had been drawn from Luft Hansa's trans-Atlantic air mail service. A photo-surveying program began between 14° W and 20° E, utilising colour stereo photography, though devoid of adequate ground fixes. Between January 19 and February 5, the Dorniers were aloft for 86 hours, with 63 hours spent on photo missions which covered 140,000 square miles. The numerous German names added to the map were testimony to Hitler's ambitions in the South, which included territorial support claims made through the dropping of swastika-tipped javelins during the Dornier flights. The onslaught of World War II brought Nazi plans for Antarctica to an end.

The end of World War II saw aviation resume over Antarctica, drawing upon vast resources of personal skills and modern equipment that were no longer required for battle. In August 1946, presidential approval was given for the launching of the US Navy Antarctic Developments Project 1947. Known as Operation Highjump, with 4700 members of the Army, Navy, Marine Corps, and Air Force embarked in 123 ships and with twenty-three aircraft, it was the world's largest Antarctic expedition. More correctly described, in a time of cold war tensions, it was a massive polar military exercise.

Rear Admiral Richard E. Byrd (ret.) was officer-in-charge while tactical command belonged to the younger Rear Admiral Richard Cruzen. In October the expedition fleet departed port, bound for a new central base of Little America IV on the historic Bay of Whales. Two additional ship-based groups equipped with Martin Mariner PBM flying boats were sent east and west for exploration of coastal regions below the Pacific and Indian oceans.

On January 29, 1947, six R4D transports (a naval equivalent of the Dakota or DC3) equipped with combined wheel-ski landing gear took off beyond the pack ice from the carrier *USS Philippine Sea.* Led by Commander William ("Trigger") Hawkes, the flight safely reached Little America IV where an advance party of the Seabee construction corps had built a landing strip.

During February a weather-delayed major air operation sent the R4D aircraft on twenty-nine photo-mapping missions covering 22,800 miles (36,480 km) in 220 hours aloft. Flights were made to the South Pole and Victoria Land, beyond McMurdo Sound; by the end of the month the programmed thirty-three flights were completed. A Western Group PBM, piloted by Lt David Bunger, reported sighting an estimated 100 square miles of mostly ice-free rocky coast in region of Vestfold Hills. A landing was made on an open water lake and the water sampled. Late in February final PBM flights of Western Group reached Princess Ragnhild coast of Queen Maud Land; by this time Highjump forces reported having sighted 12.5 million square miles and photomapped one-third of the continent with 65,000 trimetrogon camera exposures; 5,400 miles of largely unknown coast had been sighted.

In contrast to the lavish Highjump, America's most austerely financed and equipped South Polar endeavour was also organised and led by a naval officer. Commander Finn Ronne was the son of Martin Ronne, a sailmaker who served with Amundsen and Byrd; Finn Ronne had been on Byrd's 1933 expedition and in 1940 was second in command of the US Antarctic Service force at Marguerite Bay. Stowed on a former harbour tender that Ronne had "borrowed" from the Navy were three aircraft, also "loans" by courtesy of the Air Force—a Norseman, a Stinson L5, and a twin-engined Beechcraft.

After landing in March 1947 at the derelict US station on Stonington Island, the aviation program commenced on September 22, with an unscheduled rescue flight by chief pilot Captain James Lassiter, USAF, to rescue three Britons who had been forced down when their aircraft failed. Major flights as the summer season advanced were made across the Filchner Ice Shelf and to Gould Bay and the Ellsworth Highland; all were supported by surface sun sights, requiring eighty-six field landings. When the expedition returned in 1948, Ronne's air program had recorded 346 hours aloft and from the Beechcraft's trimetrogon cameras an area of 250,000 square miles were mapped.

The International Geophysical Year

Declaration of 1957–1958 as an International Geophysical Year (IGY) of intense scientific study, much of it focused on the polar regions, signalled the start of an immense logistics support effort in which aircraft were again a prime means of transport and exploration. The US Navy's aviation program commenced in December 1955 with the dispatch of six aircraft to pioneer the 2,400-mile (3840 km) air link between Christchurch, New Zealand, and McMurdo Sound, Antarctica. Led by Rear Admiral George Dufek, commander of Task Force 43—for publicity, known as Operation Deep Freeze—the two R5D Skymasters, and two P2V Neptunes landed on a Seabee-prepared runway at McMurdo after flying time averaging 14 hours. (Two R4D Skytrains were turned back by adverse weather.)

The new year's aviation activity saw a P2V Neptune make a 3,400-mile (5440 km) flight across the South Pole to the Weddell Sea; another flight to Wilkes Land scanned the Davis Sea for a sighting of the first Soviet expedition.

On October 13, an R4D named *Que Sera Sera* achieved the first aircraft landing at the geographic South Pole. Rear Admiral Dufek commanded the flight with pilots "Trigger" Hawkes and Conrad Shinn at the controls. Their journey of 780 miles climaxed on the hard-ribbed snow of the Pole at an elevation of 9,200 ft in –50°C (–58°F) temperature and 15-knot wind. The thrust of all fifteen JATO (jet-assisted takeoff) bottles was needed to lift their aircraft back into the chill air at the bottom of the world for the return flight to McMurdo. The *Que Sera Sera* exploit paved the way for the building of America's IGY Pole observatory, known as Amundsen-Scott Station, which would open on July 1, 1957. To deliver construction material, C-124 Globemasters of the USAF contributed a thrice-daily routine of supply drops which totalled 750 tons by the close of the summer season.

For IGY missions, personnel and cargo lifts to distant bases, and photomapping exercises, fixed wing aircraft of the Navy's special Antarctic VX-6 Detachment included four P2V Neptunes, two R5D Skymasters, nine UC-1 single engine Otters and a number of R4D Skytrains; all except the Skymasters were configured for ski operations. USAF provided summer support of eight C-124 Globemasters (until 1963). In meeting the 1957–1958 IGY requirements, VX-6 crews recorded 1646 separate flights, totalling 5450 hours with an airlift of 5277 passengers and 4050 tons of freight, including oil fuel for interior stations; photo surveys covered 106,000 square miles. Globemasters completed thirty-seven crossings of the Southern Ocean on the route between New Zealand and McMurdo Sound.

Though the IGY closed on December 31, 1958, by presidential decree the Navy's Deep Freeze program continued in support of the National Science Foundation.

Long-Distance Aviation

The turn of the 1960s introduced a decade of larger and more powerful aircraft flying some of the most gruelling exploration missions yet attempted. The first flight from Antarctica to Australia was made on October 24, 1960, by the R7V *El Paisano,* fitted as an airborne laboratory for the Project Magnet hydrographic surveys. The Super Constellation type Navy aircraft completed the 3,700 mile (5920 km) track from McMurdo, across the Pole, to Hobart in 14 hours. The addition of R7V Super Constellations boosted passenger comfort and capacity and travelling time between New Zealand and Antarctica—which, in favourable wind, *Phoenix Firebird* reduced to a record 8 hours and 18 minutes.

Introduction of the C-130BL Hercules transports, mounted on stout wheel-ski gear, began a new era of polar access. On February 22–23, 1963, a C-130BL Hercules (later reclassified LC-130) piloted by Commander William Everett flew a major triangular course from McMurdo to the geographic South Pole and the "most interior point" Pole of Inaccessibility, making a total of 3,600 miles (5760 km) in 10 hours and 40 minutes. Rear Admiral Jim Reedy, commander of the Deep Freeze Task Force 43, was aboard the flight and planned a series of follow-up intercontinental and trans-Antarctic missions, utilising the extended range given by a 3600 gallon auxiliary fuel tank, which fitted within the Hercules' cargo space. With the improved endurance, a Cape Town–McMurdo link was accomplished, via the Pole, across a distance of 4,700 miles (7250 km) in a flying time of 14 hours and 31 minutes.

The LC-130 *Adelie* carried Admiral Reedy and his crew on the final and longest intercontinental journey, which followed a course from Melbourne, across the South Magnetic Pole and geographic South Pole, to Byrd sub-ice station on the Rockefeller Plateau. The flight of September 30, 1964, set the records of first flight from Australia to the Pole and of time and distance spent aloft: from Melbourne, via the Pole, to Byrd Station measured 4,420 miles (7050 km) taking 15 hours and 39 minutes; inclusion of the Byrd–McMurdo leg made the total distance 5,330 miles (8528 km) for 19.5 hours flying time.

Jet age transport came to Antarctica in 1968 with assignment of USAF C-141 Starlifters to the Christchurch-McMurdo route, offering a 40,000 lb payload, and flying time reduced to five hours. (In 1989, the C-5B Galaxy followed, having three times the C-141's payload.)

Commercial aviation history was also made at McMurdo Sound on October 17, 1957, when a Pan American Stratocruiser arrived on a military charter carrying several US and New Zealand dignitaries and two flight attendants. The aircraft spent four hours at the Deep Freeze Base before returning to Christchurch. More than 20 years later, commercial aviation faced a tragic aftermath when, on November 20, 1979, the tourist flight of an Air New Zealand DC10 to McMurdo Sound crashed in whiteout conditions on Mount Erebus, a 12,000 ft volcano, with the loss of all 257 passengers and crew.

That Antarctica had become a vast scientific observatory that permitted the two major aviation participants, the United States and the Soviet Union, to scatter their bases across the continent without fear of trespass or conflict—and air operations were conducted within this same context. The long-range exploration and mapping flights of the Soviet Antarctic Expedition resulted not infrequently in visits to the US Navy's Deep Freeze bases and to those of other participating nations.

The first Soviet expedition of 1956 numbering 100 men, led by Dr. Mikhail Somov, an Arctic expeditionary and Hero of the Soviet Union, established Mirnyy base on the Davis Sea. An aviation program directed by I. I. Cherevichny proceeded within weeks of landing using ski-fitted Li-2 (Dakota style) transports and An-2 single engine cabin biplanes.

By the following summer, an 8,000-ft skiway had been completed at Mirnyy. Li-2 transports began taking off in December on parachute supply drops to the tractor expedition driving an 870-mile (1390 km) traverse to establish Vostok, Antarctica's highest and coldest base at 11,500 ft elevation. A 14-hour flight by an IL-12 across the Pole in October 1958 enabled a Soviet party to make their first visit to the Operation Deep Freeze command at McMurdo Sound.

Major flights completed over the next few years included one of 2,250 miles, carrying expedition leader Dr. Alex Dralkin, from Mirnyy to the subordinate base of New Lazarevskaya on the Princess Astrid Coast of Queen Maud Land. Chief pilot Boris Osipov followed with a major 4,160-mile (6650 km) return flight from Mirnyy to New Lazarev and Wilkes bases. Senior pilot A. Pimenlov took an IL-14 on an 11.5-hour program of photomapping the Pravda Coast and Polar Plateau.

In yet another season of aviation records, chief pilot V. M. Petrov achieved a landing at the Pole of Inaccessibility, 1,367 miles (2185 km) from the coast, on an elevation of 13,450 ft.

Concluding a 15,000-mile (24 000 km) pioneering flight from Moscow, an IL-18D four-engine turbo-prop passenger aircraft accompanied by An-12 transport reached Mirnyy on December 27, 1961, in an airborne time of 44 hours and 46 minutes. Three days later, an Li-2 arrived at Mawson to carry an Australian base member suffering a brain haemorrhage to Mirnyy, 720 miles (1152 km) to the east. Then on January 2, the IL-18D departed Mirnyy on a 1,700-mile (2720 km) mercy mission to McMurdo where the Australian patient was then transferred to a Navy LC-130 for the journey to Christchurch. Within a few years, a schedule of annual intercontinental flights had been established from Moscow, via Mozambique, to the centralised base of Molodezhnaya.

Establishment of More Bases

Two Auster aircraft purchased from the RAF and previously used in the Norwegian-British-Swedish Expedition were taken on the *Kista Dan* voyage of 1955 to make Australia's first permanent base in continental Antarctica.

A three-man RAAF detachment, headed by Flt Lt Doug Leckie, were part of the ANARE (Australian National Antarctic Research Expedition) team that watched their leader, Dr. Phillip Law, raise the Australian flag at Mawson Base on Horseshoe Harbour in Mac.Robertson Land.

With a ski-fitted Auster and a de Havilland Beaver adapted for wheels, skis, or floats, the RAAF crew through the coming summer seasons conducted a wide-ranging series of ferry, supply, and exploration missions. For winter shelter, the hangar built at Mawson was reputedly the then largest structure in Antarctica. Midwinter flights were made to observe the spread of sea ice.

Flights led to the sighting of the Prince Charles Mountains, 160 miles (256 km) south of Mawson, and the Lambert Glacier, 250 miles (400 km) long, varying to 40 miles (64 km) wide, the largest Antarctic glacier, if not the world's largest. Delivery of a second Beaver aircraft allowed expansion of the aviation program including a survey of the Vestfold Hills, 340 miles (545 km) east of Mawson to select a position for ANARE's second base. In September 1957, the first flight arrived at the Soviet expedition's Mirnyy base, 800 miles (1200 km) from Mawson.

Disaster struck the slender RAAF resources on December 28, 1959, when a blizzard with 120-mph wind gusts enveloped Mawson, destroying both Beavers despite tie-down precautions.

ANARE's first twin engine aircraft, an ex-RAAF Dakota, accompanied by its RAAF support crew reached Mawson aboard the supply ship for the 1960–1961 season. Equipped for JATO, trimetrogon cameras and with a four-ton payload, the Dakota promised considerably expanded supply, exploration and mapping programs. However the aircraft's value was short-lived when on December 9, 1960, winds of 116 mph wrecked Mawson's airstrip, tearing both Dakota and Beaver from the tie-down cables and smashing them beyond repair. The remains of the Dakota were found miles away, partly wedged in a crevasse.

In 1963, the RAAF withdrew from Antarctic operations; ANARE flights were transferred to commercial subcontractors, with wider use of helicopters.

The first direct flight from Australia to the South Pole was accomplished on September 30, 1964, by a US Navy LC-130 Hercules transport with two Australian observers among the crew. The 3,600-mile crossing of the Southern Ocean and Australian Antarctic Territory included an overflight of the South Magnetic Pole. After a mail drop at Amundsen-Scott South Pole Station, the historic flight touched down at Byrd Station in the Rockefeller Plateau with a record Antarctic flying time of 15 hours and 39 minutes.

RAAF C-130H transports from No. 36 Squadron joined the supply flights between Christchurch and McMurdo Sound between 1978 and 1982.

On December 29, 2004, 75 years after Douglas Mawson's BANZARE, Australia established an air service to Antarctica, flying in at the beginning and end of the season. The Australian Antarctic Division's two CASA 212-400 aircraft, named *Ginger* and *Gadget,* reached Casey Base after a 2,125-mile (3400 km) flight across the Southern Ocean. A total of twenty-two interstation flights were made before the aircraft returned to Hobart on March 3.

Aviation in the Antarctic Peninsula Region

In postwar years, Argentina and Chile—two South American nations with territorial interests in the Antarctic Peninsula region—renewed an energetic exploration and research program, depending largely on the use of aircraft.

One of the first long distance flights was that of an Avro Lincoln bomber from the Argentine Air Force base at Rio Gallegos in December 1947 which covered the peninsula's northern coasts to observe British military activity. Seaplane flights in 1951 positioned a naval detachment at Esperanza base on Hope Bay. Avro Lincoln flights supplied Army personnel isolated by pack ice at Barry Island and Marguerite Bay. Air operations were expanded to include Beaver, Otter, Neptune, Albatross, DC3 and DC4 aircraft, and naval PBY Catalina and PBM Martin Mariners, with landings on the harbour of Deception Island.

The first Argentinean flights to the South Pole occurred in January 1962. Two DC3 transports commanded by Captain Hermes Quijada presented a plaque to Deep Freeze personnel, honouring the achievements of Amundsen and Scott. Again, in November 1965, an Air Force DC3, configured for JATO propulsion and two Beavers reached the Pole; the DC3 continued to McMurdo Sound, completing Argentina's first trans-Antarctic flight.

By far the longest mission was that of December 6, 1973, when a C-130 transport, commanded by Air Force Chief Brigadier General Hector Fautario, made an 18-hour proving flight of 5,000 miles from Buenos Aires to Canberra, Australia, refuelling en route at Marambio, on Seymour Island.

Chile's already active and successful aviation program incorporated tourism in December 1956, when a national airline DC-6B carried sixty-six passengers from Santiago on a long-range sweep across the Antarctic Peninsula. Grumman HU-1B Albatross flights were later introduced to take passengers and freight to King George Island where visitor accommodation was installed.

While not prominent in long distance aviation, British aircraft made a significant contribution to understanding the Antarctic Peninsula. After World War II, aircraft appeared as an aid to the British whaling industry, commencing off Enderby Land in November 1946. Two Walrus amphibians with a 5.5-hour endurance were stowed aboard the 15,000-ton factory ship *Balaena,* which had been purpose-built with hangar, flight deck, catapult, and crane; the aircraft's original role of assisting navigation through pack ice gradually expanded into whale spotting for the catcher vessels.

Into the 1950s, FIDS (Falkland Island Dependencies Survey, later renamed British Antarctic Survey [BAS]), assumed responsibility for the air exploration program. The FIDS aviation wing comprised Auster, Beaver, and Otter aircraft. In 1955, an aerial contractor, Hunting Aerosurveys Ltd., managed by Chief Surveyor Peter Mott, undertook mapping of the Peninsula and employed two Canso flying boats. Accidents in early years cost BAS the loss of the Beaver and Otter machines.

Crossing the Continent and After

Achievement of the first single engine crossing of Antarctica belonged to a de Havilland Otter cabin aircraft attached to the Commonwealth Trans-Antarctic Expedition (CTAE). As a function of IGY, flights commenced at Shackleton base on the Weddell Sea and then transferred to a subordinate base, known as South Ice, 270 miles (432 km) from the coast. Following the trail of the surface expedition, the course would take them across the South Pole to reach the expedition's goal of Scott Base on Ross Island.

On January 6, 1958, after storm conditions drove a first attempt back to South Ice, the heavily loaded Otter, under the command of chief pilot and RAF aviator Squadron Leader John Lewis, began the 1,430-mile (2290 km) journey. Though facing adverse weather conditions, and climbing to 12,000 ft to surmount the Polar Plateau, 11 hours later the team met an aerial "guard of honour" as they descended to the runway at McMurdo Sound.

Polar aviation profited from the post-IGY enactment of the 1959 Antarctic Treaty in which signatory nations agreed to a "freezing" of their territorial claims and raised no barrier to the continued interchange of weather information and access to the various bases; and to help in the times of need, as testified by an extraordinary record of medical emergency flights, sometimes made in hazardous winter darkness.

The first 50 years of Antarctic aviation were a heroic age of airborne exploration. The great routes were flown. The most remote corners were mapped. Expeditions and their freight were landed to build the bases. Aviation technology progressed amazingly across these decades. Aircraft of the twenty-first century are larger, safer, and packed with electronic aids; satellites underwrite navigation; jet power reduces time and distance. Other more subtle changes have also come to the polar sky. The Navy and its operation Deep Freeze have long departed McMurdo Sound, although there is still a large US aviation presence supported by the US Air National Guard and private helicopter contracts. The Russian Antarctic programme has flown Ilyushin 76TD aircraft from Capetown to Novolazarevskaya in Dronning Maud Land. Many of the air tasks once in the hands of military or government forces have transferred to commercial contractors whose helicopters perform lengthy missions at bases or into the field.

Antarctica no longer belongs to an exclusive club—for the price of a ticket, anyone can gaze from the window of a Boeing 747 on iceberg and glacier. Of course, those who most benefit from air transport in the region today are the scientists and other personnel representing the national programmes conducting work in the Antarctic. Aviation heroes of the first 50 years piloted these paths across the polar sky that, with more comfort, speed, and security, others enjoy today.

B

BALLENY ISLANDS

Comprising three large islands (Young, Buckle, and Sturge) and numerous islets and stacks (including Sabrina, Row, Borradaile, Chinstrap, and Monolith), the Balleny Islands are located 66°15′ to 67°10′ S, 162°15′ to 164°45′ E, which is approximately 150 miles (240 km) off the coast of Victoria Land in the Ross Sea region of Antarctica. The archipelago forms a chain that is about 100 miles (160 km) in length, and straddles the Antarctic Circle. Its highest point is Brown Peak (roughly 6000 feet, 1800 m). Sturge Island is the largest, approximately 20 miles long by 8 miles wide (32 by 13 km). The islands are heavily glaciated, with cliffs of rock or ice and a few gravel beaches, and are volcanic in origin, although no recent seismic activity has been recorded.

The Balleny Islands are the only truly marine or oceanic islands (as opposed to continental islands) other than Scott Island on the side of Antarctica that they are on, making them distinctive from any neighboring areas. Their biological diversity exceeds that of any other site in the Ross Sea region.

In 1966, Sabrina Island, located south-southeast of Buckle Island, was designated a Specially Protected Area (SPA), mostly on account of its large colony of Adélie penguins. An attempt was made in 1999 by New Zealand to extend the SPA to cover the entire archipelago within a sea boundary of 12 nautical miles (22 km). Because of their remote geographical location and the difficulty of making a landing on many of the islands, they have been protected from human activities, but, as a consequence, they are also poorly documented. While a preliminary soil fauna analysis has detected mites, nematodes, and bacteria, a comprehensive study of the islands' vegetation is yet to be conducted.

The islands have at least seven species of breeding bird, four species of seal, and twenty-five species of echinoderm. Confirmed bird breeders include Adélie and chinstrap penguins, Cape petrels, snow petrels, Antarctic petrels, southern fulmars, and Wilson's storm petrels. In addition, southern giant petrels, prions, sooty shearwaters, Arctic terns, and skuas have been identified here. The colonies of southern fulmars are estimated to number between 10,000 and 20,000 pairs on the northwest coast of Sturge Island, while up to 10,000 pairs of snow petrels have been estimated on the western cliffs. Approximately 6000 southern fulmars have been counted on Row Island.

The largest colony of Adélie penguins is on Sabrina Island, where approximately 3500 pairs were counted in 1984. Chinstraps are found in smaller numbers, the most notable being the three groups on Buckle Island: Cape Cornish (c. 530 pairs), Cape Davis (c. 500 pairs), and Southeast Promontory (c. 320 pairs).

Seals do not breed on the islands, although several species haul out on the islands' beaches. Weddell seals have been recorded on Row and Borradaile islands, while Weddell, crabeater, and southern elephant seals have been observed on Borradaile Island. Leopard seals have been observed cruising in the offshore waters, probably hunting penguins.

Discovery of the islands occurred on 9 February 1839, when John Balleny of the schooner Eliza Scott and Thomas Freeman of the cutter Sabrina saw them after sailing south from New Zealand in search of new sealing lands on behalf of the Enderby Brothers.

BASE TECHNOLOGY: ARCHITECTURE AND DESIGN

The Heroic Era

The early expeditions to Antarctica at the end of the nineteenth and the beginning of the twentieth century were organised to enable new areas and a new continent to be explored. Scientific objectives were set for some of the expeditions, and marine- and land-based surveys were completed. To enable the expeditions and surveys to be supported effectively, buildings and prefabricated structures were erected near the coast, where access was easiest and supplies could be delivered.

The British Antarctic *(Southern Cross)* Expedition of 1898–1900, led by Carsten Borchgrevink, constructed two huts at Cape Adare. They were built from interlocking wooden boards, tightened with steel rods. The roofs were weighed down with bags of coal and boulders to keep the structures in place through the worst of the winter storms. The hut used for living had a double floor and walls, which were insulated with paper. Sliding panels and curtains on the bunks gave some privacy to the occupants of the 19.5- x 16.5-foot (6- x 5-m) structure. A saloon lamp from the supply ship and a double-glazed window with an exterior shutter provided lighting. Medical supplies, bottled provisions, and spare clothing were stored in the loft space. On either side of the porch were two small rooms lined with wool and fur, which were used as a photographic darkroom and for instrument storage and taxidermy. The smaller stores hut was a less developed building and comprised a single-layer uninsulated structure.

The British National Antarctic Expedition (1901–1904), under Robert Falcon Scott, erected the Discovery Hut, measuring 24.5 by 22 feet (7.5 x 6.75 m) at Hut Point in McMurdo Sound in 1902. This structure, as with many of the early buildings, remains today where it was originally erected, in a preserved condition. Discovery Hut served as a storeroom, laboratory, and theatre for the expedition members who lived on the ship *Discovery,* moored alongside in Winter Quarters Bay. Purchased in Australia at a cost of just over £360, the hut was supplied in prefabricated form with an awning on three sides. This type of building was very common in Australia at the time and has double-thickness walls and floor, insulated with felt. The hut was subsequently used by three other expeditions of the Heroic Era.

Many other buildings erected at the turn of the nineteenth century were of a similar prefabricated form to Discovery Hut. Admundsen's Framheim base of 1911, however, included a building that he described as an ordinary Norwegian house. Copying the Scandinavian building techniques of the time, the insulation was significantly enhanced. Using sandwich-type layered walls, a central 3-inch-thick layer of cellulose pulp was surrounded on each side by 3-inch-thick wood, fabricated from interlocking wooden planks. Between the wooden planks and the inner and outer 1-inch-thick wooden layers was a 1-inch air gap. A weatherproof layer was affixed to the inside of the outer wooden layer.

That many of these early structures still remain is testament to the skills of the many individuals who repair and maintain the buildings. The dry atmosphere in Antarctica also helps to ensure that the wooden structures are preserved.

After the Heroic Age, surveys and expeditions continued with some buildings and bases erected to support activities. The increase in science at the bases led to laboratory space's becoming a more important feature, as equipment and technology started to develop. The buildings were still rather primitive and were usually pitched-roof wooden huts with limited insulation.

World War II prompted a limited building campaign. In 1943, the British government sent members of Operation Tabarin to the Antarctic Peninsula to establish small bases to deny shelter for enemy ships and submarines and to assert territorial claim. Prefabricated wooden buildings manufactured by a company called Boulton and Paul were supplied for Tabarin. Erected on rock foundations, these buildings had facilities for biology, geology, and meteorology but were essentially wooden shells with limited insulation.

Facilities to Support Science

It was not until the 1957–1958 International Geophysical Year (IGY) that building work in Antarctica started in earnest. The major investment in science that was prompted by IGY had to be matched by new buildings and bases to support the science. Bases used to support field surveys and expeditions started to become stations with infrastructure and accommodations to enable complex science programmes to be developed.

The majority of the buildings in Antarctica are still built near the coast on rock foundations. Portal frame buildings with either wood or steel frames are erected on concrete piers or plinths. Most structures use prefabricated sandwich panel walls and floors with integral insulation, vapour barriers, and an outer protective skin. Wood is a very effective building material. Coated fibreglass and other materials have been used, but often suffer from UV degradation and can fracture in very low temperatures. Steel is used as a structural component but care must be taken to avoid cold bridging where the low external ambient temperature is conducted through to the inside of the building. As older buildings are replaced, insulation is improved, environmental impact is reduced, and the demand for more highly serviced facilities increases to meet the needs of science.

Building on the Ice Shelf and Polar Plateau

New stations were erected for IGY far inland, at Amundsen-Scott South Pole Station (US) and Vostok Station (Russia). Building inland and on ice presents many challenges that are not apparent near to the coast and on rock foundations. All materials, equipment, fuel, and consumables must be shipped to the base. The climate is normally less hospitable than at the coast and the period available during the Antarctic summer to erect new buildings is more limited. Compromises have to be made between the size of prefabricated sections that can be transported to the site by aircraft or tractor train and the number of personnel needed to build the structure. Both the South Pole (9500 feet or 2900 m) and Vostok (11,443 feet or 3488 m) are at high altitude, and simple tasks become difficult. The extreme cold necessitates the wearing of thick and often bulky clothing, which restricts movement and slows assembly work; the lowest-ever-measured temperature on earth of –89.3°C was recorded at Vostok. Any materials or tools left on the surface are warmed through solar radiation and sink into the ice; spare tools and materials must be taken to the site. The difficulties associated with building inland and in extreme conditions require innovative design, and the logistics associated with moving materials to site are challenging.

In addition to these construction and transportation issues, snow accumulation, drift, and melt create another set of challenges. Snow is blown from the centre of Antarctica to the edge of the continent, causing drifts and an increase in the mean snow level. This effect is particularly pronounced away from the centre of Antarctica. Any structure on the surface impedes blown snow, reducing the velocity of the snow, leading to snow drifting. Moving snowdrifts is an expensive and time-consuming operation.

Even at the South Pole the level of the snow increases by several centimetres per year, causing any structures to sink below the surface over time unless remedial action is taken. A dome structure was erected at the South Pole in the early 1970s. The dome is now well below the surface and being crushed by the surrounding ice. A new building is being erected on legs that can be jacked to keep the building above the surface. Extensive snow modelling was undertaken at the design stage to ensure that the building was oriented at the most suitable angle to reduce snow drifting. Snow modelling is achieved through numerical models, which are run on computers. Physical models are also built and particles suspended in water flow around model buildings, developing drifts. Considerable experience of the polar environment is needed to interpret the models to ensure they are representative of the real environment.

Halley Station was first built by the UK for the IGY on the Brunt Ice Shelf. Halley is located at the southern end of the Weddell Sea off the Caird Coast of Coats Land. The surface of the floating ice shelf, which is up to 1300 feet (400 m) thick, increases in height by between 3 and 5 feet (1 and 1.5 m) each year due to blown snow. This increase in the average height of the ice shelf is offset by melting from underneath the shelf. As a floating ice shelf, it is connected to the continent and flows towards the sea at between 1300 and 2600 feet (400 and 800 m) per year. Any building constructed on the surface and inland from the ice edge gradually sinks below the surface and also reaches the edge of the ice shelf. The current Halley Station, Halley V, is built on jackable legs, which are raised each year to overcome the effects of the buildup of snow. All previous stations were built on the surface and allowed to sink. Access was by vertical shafts and slopes for vehicles. The stations were occupied until they became unacceptably deep for personnel or distorted due to pressures in the ice. Other techniques to overcome the buildup of snow have included large ski-mounted buildings, which are moved each year onto raised ice platforms.

Design for Liveability

The majority of the structures erected in Antarctica have been designed by engineers for ease of construction, maintainability, and reliability. Architectural considerations have often been secondary, with personal space for staff limited and the delights of home added by the personnel who winter on the station. The challenges of construction in a hostile environment and the high cost of construction limit the budget available for enhanced features. The designs of the next generation of stations, started by the US Programme at the South Pole, followed by the UK at Halley VI and the German Alfred Wegener Institute (AWI) at Neumayer 3, have all been led by architectural teams. Although there will always be a need to ensure that any structure in Antarctica is maintainable, architects are being used to provide an environment for staff that will motivate them, living in a hostile working environment.

Environmental Considerations

As well as the introduction of architectural features to enhance living conditions for personnel, producing a sustainable building with low environmental impact is now very important. The Swedish Polar Institute recognised the value in a low-energy facility when building Wasa Station at Vestfjella in Queen Maud Land between 1988 and 1989. The design incorporates a wide range of technologies to reduce energy consumption and solar panels to generate most of the electrical power. The foundations are designed to be easily removed when the station is decommissioned. A very high level of insulation is used to reduce the demand for supplementary heating. Although only 57 by 25 feet (17.5 x 7.6 m), the building houses up to sixteen people and has a kitchen, common room, sauna, shower, and laundry room, demonstrating what can be achieved to reduce the impact of human habitation on Antarctica.

BASE TECHNOLOGY: BUILDING SERVICES

The stations and bases erected in Antarctica at the beginning of the twentieth century were often poorly insulated and had very rudimentary services installed. In the second half of the century, as Antarctic bases have increasingly been built to support science activities, building services and facilities have been greatly enhanced to meet the expectations of staff and to enable high-quality science to be delivered. Ensuring that the buildings have minimal impact on the Antarctic and that energy demand is reduced, are also major objectives. All basic services and utilities including electrical power, water, sewage, and communications have to be produced and/or delivered on site in Antarctica.

Power Supply

There are no readily available sources of hydrocarbon fuels in Antarctica. Renewable-energy systems are being installed to provide electrical power and heating; however, mature and reliable technology and equipment that will continue to function under the extremes of the Antarctic environment are difficult to source. Imported hydrocarbon-based fuels continue to be an important source of energy to power the building services that are essential for living and working effectively.

Electrical power is the primary utility. It is used to directly or indirectly provide water, heating, and sewage disposal and treatment and to operate other services and facilities including communications. There are normally three generator sets on each station, although some sites have multiple generators, which are brought on line as power demand increases. The traditional layout of three generator sets is configured with one generator on line, another on standby, and the last undergoing maintenance. Loss of electrical power can have serious consequences and a standby set is essential. As an example of the potential impact of the loss of a generator, electrical power is often used to heat pipes that carry fluids; a loss of power rapidly leads to burst pipes and leaking of fluids into the environment. The frequency and voltage of electrical power supplies are generally the same as are found in the parent country that operates the station.

Hydrocarbon Fuels

Hydrocarbon fuels used in the generator sets are derivatives of either aviation turbine fuel or marine gas oil. Aviation fuel, known as JP1 or AVTUR, has the advantage of a lower freezing point than marine gas oil. It has a lower lubricity than marine gas oil and lubrication oil is often added to reduce engine wear. Marine gas oil (MGO) is similar to the diesel fuel used in cars and trucks, although additives are included with the fuel to stop waxing or solidification in subzero temperatures.

Fuel is supplied to Antarctic stations in bulk, carried by supply ship or tanker, or in 45-gallon drums. To transfer the fuel to inland sites either aircraft tankers or tractor trains are used. The Protocol on Environmental Protection to the Antarctic Treaty places great emphasis on eliminating fuel spills and in consequence all new fuel facilities have double-skinned fuel tanks or bunds to stop fuel from escaping into the environment should a leak develop. The Council of Managers of National Antarctic Programmes (COMNAP) has provided guidelines for storage and transport of fuel. Ensuring the safe and effective delivery and storage of hydrocarbon fuels is a very resource-intensive process. Delivering energy-efficient power-generation systems with reduced hydrocarbon consumption is a key objective for nations operating in Antarctica.

To reduce the use of fuel, the most effective approach is to reduce the need for energy by enhancing building insulation and encouraging efficient use. Energy recovery can also be maximised by extracting waste heat from generator cooling jackets and exhaust stacks for use in heating buildings and for converting snow and ice into water. Balancing power loading through the day by, for example, not washing clothes or showering when cooking ovens and other high-demand facilities are operating also improves fuel use efficiency. The very severe external environmental conditions on Antarctic Stations necessitate that reliability be considered as well as energy efficiency. Renewable-energy systems have applications in Antarctica, but their suitability requires very careful consideration.

Wind, Solar, and Water Power

For wind generators to work most effectively, a consistent wind speed, predominantly from one direction, is required. Wind gusts can cause damage to turbine blades. Ideal wind conditions are not readily available in Antarctica, with high winds often followed by days of calm. In coastal and marine areas, riming or ice buildup on turbine blades can lead to early equipment failure. Gearbox failure due to very low temperatures is another challenge. Despite these challenges, there are successful wind-power installations in Antarctica. The Australian Antarctic Division has three 300-kW wind turbines at their Mawson Station. In operation, these turbines, which are assembled without gearboxes, produce an average power output of 100 kW.

To enhance output efficiency, power-storage systems are needed to store power when wind is generated at optimum speed. Energy-storage technology remains a challenge for temperate climates as well as Antarctica, and backup hydrocarbon-fuelled generators are essential.

Photovoltaic (PV) cells harnessing solar energy are another renewable power source used in Antarctica. The lack of overhead sun means that the angle of elevation and operating efficiency can be low. During the summer months it is possible to also collect light through reflection off the snow surface. During the long winter there is no incident radiation and no electrical power produced. PV panels have many applications for powering instrumentation, communication systems, and other field camp equipment, but their application for building services requires careful evaluation.

On sub-Antarctic islands where there is free-running water in the summer months, water turbines have been used to generate electrical power. Wave generators offer an opportunity for the future when the technology has matured. These systems make use of sea swell, which is at its maximum in the polar regions. Polar operators continue to research and develop new opportunities for installing renewable-energy systems on Antarctic stations whilst reflecting on the need to maintain reliable power.

Water Production

Although 70% of the world's fresh water is in Antarctica, it is locked into the continent as snow and ice. The simplest form of technology used to produce water is a snow melter. Snow and ice are put into a tank and heat applied to produce water. Waste heat from generators is often used and passed through heat coils around or inside the tank.

A mechanical means of moving snow and ice, or personnel using shovels, is a feature of snow melters. One technique used to eliminate the moving of snow is to construct a Rodriques Well. Hot water is produced at a high pressure, then pumped into the snow. As the snow melts, the accumulated water is pumped to the surface. This technique has been successfully employed at the South Pole Station but requires a significant volume of fuel to produce the hot water needed to pump into the snow.

Stations built near to the sea can make use of alternative techniques to produce water. The most common approach is the reverse-osmosis system. These units pass water at a pressure of 70 Bar through a membrane. Pure water passes through the membrane, and brine that does not pass through is returned to the sea. The fresh water produced is very pure and soft; minerals are added to balance it. Desalination can also be achieved using evaporators where seawater is heated and the fresh water condensate is extracted.

Reticulation of water through external pipework requires insulation around the pipework to protect against freezing. Heat tracing of the pipes is also often needed. Either electrical heating tape or small-bore hot water pipes are wrapped along and around the pipes carrying the freshwater. Heat-trace systems add to the overall energy budget of the station.

Waste Treatment

The processing of sewage and bulk waste fluids is essential unless all waste is returned via ship. The large volume of sewage makes removal by ship impractical for most sites. Untreated human sewage is passed through macerators, which cut and chop the solids into small pieces suspended in the waste water. At coastal sites the wastewater may be pumped into the sea for natural biological processes to digest the sewage. At inland sites the waste or grey water can be pumped into the ground. The temperature of the grey water is sufficient to melt the ice and develop a chamber where the waste is stored. Although the numbers of personnel on most Antarctic stations are low and the current procedures are within the requirements of the Protocol on Environmental Protection, most Antarctic operators are now installing sewage-processing systems. Both first-stage and biological processing systems are being installed to ensure that the waste water that is left on the continent is as pure as possible and does not contain any pathogens. Recovered solids are dried and removed from Antarctica. The sewage-treatment plants, like the heat-trace systems, add to the overall energy budget for the station.

Heating

Waste heat produced by generators and other plants can be recovered and used to provide background heating for buildings. If high-U-value insulation material is used in structures, then the heat-recovery system can provide most of the heating needs of the structure during the winter months. Boilers using hydrocarbon fuel are required to back up the recovered heat systems and are also needed where no heat-recovery systems are installed. MGO and AVTUR are the primary sources of fuel for the boilers. The heat is distributed around the buildings using radiators and hot water or via pumped air when the buildings are air-conditioned. Buildings are either double- or triple-glazed to avoid heat loss.

Fire Protection

The environment in the Antarctic is very dry and buildings are normally constructed from wood. The combination of the dry atmosphere, wooden buildings, and heavily serviced facilities ensures that fire detection and protection procedures are always considered when risks are assessed. Fire remains a significant risk in Antarctica. Should a fire develop in the middle of winter, personnel on site may have great difficulty in fighting the fire when there is a very low external temperature or there are high winds. All station personnel have to be trained to deal with a fire should one develop. Only the very large stations have a full-time fire service.

Fire and smoke detectors are installed in all buildings unless they are very remote or it is difficult to connect the building to the fire-detection system. Station personnel are trained to extinguish a fire, but should it take hold, the structure will be left to burn through. Emergency shelters or alternative buildings with food and supplies would be activated if a fire engulfed an accommodation building.

On some stations, fire-suppression systems are installed to stop flames from spreading should a fire develop. Standard water sprinkler equipment and mist systems are installed to protect accommodation buildings and other important structures. Should the sprinklers be activated, they soak a structure in water to stop the fire. In winter the structure may then be uninhabitable. It is therefore important to reduce the risk of any fire developing and ensure that personnel are aware of the hazards and how to reduce risks.

Communication Systems

Communication systems are installed by the Antarctic operators for sending logistical and scientific data to their headquarters. These systems are also used for transmitting data on the performance of the services installed on stations to enable engineers to monitor the sites. Although installed for operational reasons, communications are also important for the morale of station personnel. Being able to contact family and friends and other Antarctic stations is very important to staff.

Satellite communications carrying voice and fax use dial-up carriers with bandwidths of up to 64 kbps and similar to a home computer dial-up connection. Broadband connections with 24/7 availability enable Internet access and e-mail. Despite the availability of satellite communications, around Antarctica, high-frequency (HF) and very-high-frequency (VHF) radio systems are still used for routine communications.

Services on Antarctic stations ensure that personnel have access to facilities that enable them to deliver high-quality science and maintain a comfortable living experience. The challenge for the engineer providing the buildings and facilities is to ensure that they are sustainable and have a minimal environmental impact. These goals often conflict with the need to keep systems reliable and maintainable. As technology develops and stations are replaced, matching reliability with sustainability becomes more achievable.

BEACON SUPERGROUP

H. T. Ferrar (1907), the geologist on the British National Antarctic *(Discovery)* Expedition, named Beacon Sandstone for nearly horizontal, light-colored sandstone intruded and commonly capped by dark dolerite sills. The name came from extensive exposures of sandstone on Beacon Heights, a group of hills in the upper reaches of the Taylor Glacier, 130 km due west of the Discovery Hut and the present McMurdo Station. The name has since been used informally for just about any late Paleozoic–early Mesozoic sandstone in East Antarctica, but mainly refers to the sedimentary sequence above Proterozoic–lower Paleozoic igneous and metamorphic basement (Kukri Erosion Surface) and below volcanics of the Jurassic Ferrar Group in the Transantarctic Mountains. Harrington (1965) formalized the term Beacon by giving it supergroup status, subdividing it into the Taylor Group of Devonian age separated by a major disconformity from the Upper Carboniferous to Upper Triassic Victoria Group. These groups have been further subdivided into local formational units throughout the Transantarctic Mountains.

The age of the Beacon has been determined by a series of historic discoveries. Plant remains and trace fossils were found in the McMurdo Sound region during Robert Falcon Scott's 1901–1904 *Discovery* Expedition, but were not diagnostic in assigning an age at the time. During the 1907–1909 Nimrod Expedition, Shackleton's party collected fossil wood from a moraine near "The Cloudmaker" on December 11, 1908. Six days later, higher up the Beardmore Glacier, they reported several coal seams in the upper part of a 1500-ft-thick Beacon sandstone sequence on the east side of Buckley Island (Shackleton 1909). The fossil wood was identified as coniferous and dated as no older than Lower Carboniferous or Upper Devonian. Beacon ages were finally established by collections from Scott's 1911–1913 *Terra Nova* Expedition (Scott 1913). On February 8, 1912, on return from the South Pole, Scott's party collected plant-bearing samples from the east face of Buckley Island on the upper Beardmore Glacier. During the following summer the rescue party recovered these samples from Scott's last camp. From this collection Seward (1914) identified leaves of Glossopteris, a late Carboniferous–Permian plant. Also, during the *Terra Nova* Expedition, Debenham found well-preserved Upper Devonian fossil fish plates in Beacon erratics in a moraine on the Mackay Glacier near Granite Harbour in the McMurdo Sound region (Woodward 1921). Gunn and Warren (1962) eventually found outcrops containing fragmentary fossil fish remains in the Boomerang Range, Lashly Mountains, and Mount Feather along the margin of the polar plateau in the McMurdo Sound region. Gunn and Warren (1962) also extended the upper age limits of the Beacon by finding a Triassic Dicroidium flora at several localities along the margin of the polar plateau. Long (1964) extended Beacon ages downward with the discovery of a Lower Devonian marine invertebrate fauna in the Ohio Range.

The Glossopteris flora in Antarctica was proof of Gondwana connections, but Seward (1914) was more concerned with the climatic implications than how the flora got there. He did mention a possible land bridge between South America and the Antarctic Peninsula. Woodward (1921) compared Upper Devonian freshwater fish fossils in Antarctica with those of Europe and North America, but did not speculate on how they were dispersed across the globe. In spite of convincing evidence of a Gondwana supercontinent put forward by Alfred Wegener (1929) and Alexander du Toit (1937), most geologists in North America and Europe did not accept continental drift theory until the late 1960s, when accumulated geophysical evidence of plate tectonics became overwhelming. Geologists of the International Geophysical Year (1957–1958) and later had already recognized the similarities in the geology of Antarctica and other Gondwana continents. Long (1964), working in the Horlick Mountains, was the first to identify the uppermost Carboniferous–Lower Permian glacial beds. These have since been found throughout the Transantarctic Mountains and in the Ellsworth Mountains. Undeniable proof of a direct connection between southern Africa and Antarctica came with a series of reptile and amphibian fossil finds in the Beardmore and Shackleton glacier areas (Barrett et al. 1968; Elliot et al. 1970; Hammer 1995). The Lystrosaurus and Cynognathus zone faunas from Antarctica have several species in common with South African faunas from the Karoo Basin.

The Beacon was deposited in sedimentary basins roughly along the trend of the present Transantarctic Mountains (Collinson et al. 1994). These basins appear to have been extensional until the mid-Permian when an oceanic trench and volcanic arc developed along the Panthalassan Ocean margin of West Antarctica. In the Late Permian and Triassic the Transantarctic basins evolved into an elongate basin bordered by a mountainous fold belt in West Antarctica. Beacon deposition ended by the Early Jurassic with rifting related to the dispersal of the Gondwana continents.

The Permian–Triassic Transantarctic basin may have been contiguous with similar basins along the Panthalassan Ocean margin in Australia (Sydney-Bowen basin) and in South Africa (Karoo basin) (Collinson et al. 1994). The stratigraphic sequence in Victoria Land is similar to that of Australia, whereas the sequence in the rest of the Transantarctic Mountains is similar to that of South Africa. The Beacon sequence is also typical for Gondwana because these continents shared similar climatic histories in a southern polar region. The Victoria Group begins with Upper Carboniferous to Lower Permian marine or terrestrial glacial deposits. Post-glacial black shale, representing a vast inland sea, extends from the Nimrod Glacier to the Horlick Mountains. This seaway may have extended to the Ellsworth Mountains in West Antarctica, the Karoo Basin in South Africa, and the Paraná Basin in southern Brazil. The middle to Upper Permian throughout Antarctica is represented in coal-bearing river deposits. Coal deposition stopped abruptly at the end of the Permian. Early Triassic global warming permitted reptile and amphibian faunas from South Africa to migrate into polar Antarctica, where they were buried in river channels and on floodplains. Coal deposition resumed again in the Middle and Late Triassic.

Although parts of the Beacon might be good reservoir rocks for oil and gas deposits, marine organic source rocks are sparse. In addition, the heat and hot fluids generated by the intrusion of Ferrar dolerite throughout the Beacon sequence in the Transantarctic

Mountains have driven out most of the volatiles in the organics and coal, rendering them unsuitable for exploitation (Rose and McElroy 1987).

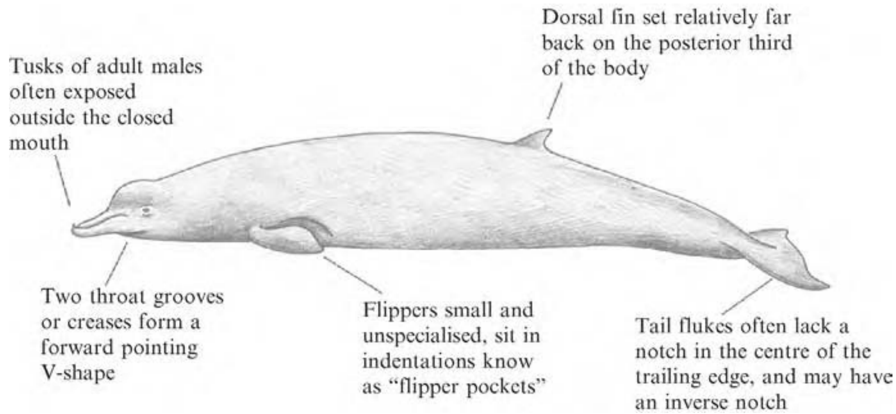
BEAKED WHALES

The beaked whales or ziphiids—so called due to their family name of Ziphiidae—are the most enigmatic of the families of toothed whales (the odontocetes). In fact, they are so difficult to observe at sea that several species have never been seen alive! They are medium-sized cetaceans (the group comprising whales, dolphins, and porpoises), with adults ranging from 3–13 m in length. They tend to live far offshore in areas of deep water (usually over 300 m deep), where they perform long, deep dives in search of their squid and fish prey. In addition, many beaked whale species are similar in external appearance, so their identification at sea is often difficult for an inexperienced observer. Together, these have made the study of beaked whales much more difficult than that of more accessible, near-shore cetacean species, and as a result we know relatively little about this group of animals.

This situation has improved in recent years; with rapidly developing techniques in molecular analysis, and field efforts to obtain skin samples from different species, there has been a surge in knowledge about beaked whale systematics and biology. Currently there are thought to be twenty species from six genera in this group. However, the taxonomy of this group is still relatively uncertain and new species are regularly described and old species revised.

The common name of the family, beaked whales, refers to their long and slender rostrum, which results in a prominent beak in most species. This beak blends into their high forehead (or melon) without the break or groove that is characteristic of most other delphinids. An evolutionary trend in most ziphiids has led to



A typical beaked whale showing characteristic features.

a reduction in their number of teeth. Females and immature males are essentially toothless (the teeth do not erupt), and adult males have retained only a single pair of teeth in the lower jaw. Two exceptions are the genus *Berardius,* which has two pairs of mandibular teeth in the lower jaw of both adult males and females, and *Tasmacetus,* which has a full set of teeth in both upper and lower jaws of both sexes. These teeth in adult males are often exposed outside the closed mouth and so can be considered tusks. Males of different species have these teeth in different positions in the lower jaw, and the teeth often vary in size and shape, becoming much enlarged in some species. These are often the most reliable way to tell different beaked-whale species apart, but in rough sea conditions it is usually difficult to see the teeth well enough for this, even if an adult male is present!

Other features that distinguish beaked whales from other groups include the possession of two conspicuous throat grooves or creases that form a forward-pointing V shape, and the lack of a notch in the tail flukes. Their flippers are relatively small and unspecialised and often sit in "flipper pockets," indentations in the body thought to increase streamlining. The dorsal fin, which is set relatively far back on the posterior third of the body, is small and triangular rather than falcate. Their skull morphology is also unique, exhibiting elevated maxillary ridges behind the nasals. Most beaked whales have asymmetrical skulls, although *Berardius* and *Tasmacetus* have nearly symmetrical cranial characteristics.

Population Status, Distribution, and Habitat Use

Of twenty species of beaked whales currently known (new species were recognised in 1995 and 2002), eleven may be encountered in the Antarctic or at the waters of the Polar Front. The majority of beaked-whale species are found offshore in deep waters. The two species found farthest south are the southern bottlenose whales and Arnoux's beaked whale, which may be observed near the ice edge in summer. These two species have the largest body size of the beaked whales found in the Antarctic. Gray's beaked whale and the strap-toothed whale are found south of the Polar Front from 30°–60° S. There are also occasional sightings of Cuvier's beaked whales this far south. Andrew's beaked whale, Hector's beaked whale, and Shepherd's beaked whale tend to be found slightly farther north, generally north of the Polar Front. The ginkgo-toothed beaked whale has been observed south of New Zealand and the Chatham Islands; True's beaked whale is known only from strandings in South Africa and southern Australia, while the recently identified spade-toothed whale is known only from two specimens in New Zealand and one in the Juan Fernandez Islands.

The most common beaked whale in the Antarctic is the southern bottlenose whale, of which there are thought to be about five hundred thousand in summer. However, difficulty in detecting and identifying other beaked whales has meant that there are no estimates of abundance for other species. The status of all beaked whales is currently listed by the IUCN (International Union for the Conservation of Nature) Red Book as "insufficiently known."

Life History

Based on data on ectoparasites and stomach contents, it has been suggested that southern bottlenose whales may undertake seasonal migrations between subtropical and colder waters, with sightings off Durban

Antarctic Beaked Whales

Species	Latin Name	Adult Size (m)	Distribution	Group Size	Lifespan
Arnoux's beaked whale	*Berardius arnuxii*	M <9.8 F 9.8	Southern ocean to ice edge; northerly limit 34° S	Usually around 10; up to 80	Unavailable (B. bairdii male 84 years, female 54 years)
Southern bottlenose whale	*Hyperoodon planifrons*	M 6.9 F 7.5	Southern ocean to ice edge	Less than 10	Unavailable (H. ampullatus at least 37 years)
Cuvier's beaked whale	*Ziphius cavirostris*	7	Global	-	Probably 40 years, possibly more than 60
Shepherd's beaked whale	*Tasmacetus shepherdi*	6–7	Southern temperate	-	Unavailable
Strap-toothed beaked whale	*Mesoplodon layardii*	M 5.9 F 6.2	Circumglobal in temperate and sub-Antarctic southern waters	Up to 3	Unavailable
Gray's beaked whale	*Mesoplodon grayi*	M 5.7 F 5.3	Circumglobal in temperate waters of Southern Hemisphere (30°–45° S)	1–2 (stranding of 28)	Unavailable
Hector's beaked whale	*Mesoplodon hectori*	4.2	Circumglobal in temperate waters of Southern Hemisphere	-	Unavailable
Ginkgo-toothed beaked whale	*Mesoplodon ginkgodens*	M 4.8 F 4.9	Temperate and tropical Indo-Pacific, records off New Zealand and Chatham Islands	-	Unavailable
True's beaked whale	*Mesoplodon mirus*	5.3	Temperate North Atlantic and temperate Southern Indian Ocean	-	Unavailable
Spade-toothed beaked whale	*Mesoplodon traversii* (previously *M. bahamondi*)	?	Southern temperate	-	Unavailable
Andrew's beaked whale	*Mesoplodon bowdoini*	M 4.5 F 4.9	South circumpolar, north of Polar Front	-	Unavailable

(30° S) showing peaks in February and October, potentially representing northward and southward migration. Sightings surveys have also shown a reduction in beaked-whale density in Antarctic waters after mid-January. However, sparse data are not ideal for identifying movements of animals, and so these results should be viewed with caution until more rigorous methods of identifying migration with some degree of certainty have been obtained.

As with other cetaceans, the best method of age determination is the examination of growth layer groups (GLGs) in the teeth. These are similar to tree rings, so counting the layers in the teeth allows researchers to calculate an animal's age. In general, many beaked whales appear to reach sexual maturity at 7–10 years and live to approximately 30 years of age. However, teeth from few Antarctic beaked whale species have been analysed.

Social Structure

The social organisation of the majority of beaked-whale species is poorly known. Their shyness at sea means that for many beaked-whale species, the data that we have on group sizes are nonexistent or based only on occasional sightings or strandings. These limited observations have suggested that many species may be found in small groups of one to six animals. However, mass strandings are occasionally reported, including a stranding of twenty-eight Gray's beaked whales in New Zealand. Arnoux's beaked whales are the most gregarious of the Antarctic beaked whales, often gathering in groups of six to ten and occasionally up to fifty or more, and showing behavioural synchrony during diving and surfacing.

The composition of their social groups is similarly unknown, particularly for Antarctic species. Based on the linear scars that crisscross the bodies of many adult males, it seems that the tusks of males are used as weapons in aggressive encounters with each other, presumably for access to females. The two beaked-whale species that have been studied in most detail are the northern bottlenose whale and Baird's beaked whale, in the North Atlantic and North Pacific, respectively. Northern bottlenose whales possess only small teeth, but instead male–male conflict appears to consist of head-butting using the large flattened melon (and underlying enlarged maxillary crests). However, long-term photo-identification studies have suggested stronger associations between males than between females in this species. Anatomical studies of groups of Baird's beaked whales taken in the continuing fishery off Japan suggest an unexpected social structure in this species. Both males and females of this species possess erupted teeth, and females are slightly larger than males. Males appear to reach sexual maturity at an average of 4 years earlier than females and may live for up to 30 years longer. This has led to speculation that males may be providing parental care in this species, although further work is needed to confirm this.

Diet and Trophic Interactions

The majority of beaked whales are thought to feed primarily on epibenthic and mesopelagic squid, although some mesopelagic fish may also be taken. The reduced dentition of these species is thought to be due to this dietary specialisation. Shepherd's beaked whale, the exception to this, has a diet that appears to consist primarily of bottom-dwelling fish. The reduced dentition of the beaked whales, together with their narrow jaws and throat grooves, has been suggested to function in suction feeding. Among the males of species such as the strap-toothed whale, the elaborate growth of the strap-like teeth may limit the aperture of the gape to a few centimetres, and it is difficult to see how prey-capture techniques other than suction feeding could be successful.

Beaked-whale species are known to be excellent divers. Dives of up to 1 hour have been recorded from several beaked-whale species, although many of these records have been based on surface observations of diving whales and so there is a possibility that some of the breathing events might have been missed accidentally. Small microcomputers that record depth at preset time intervals are becoming widely used to look in detail at the diving behaviour of marine mammals, although the attachment of these to cetaceans is not easy (particularly for beaked whales, which are notoriously difficult to approach). Results from a handful of animals (thus far northern bottlenose whales and Cuvier's beaked whales) corroborate previous suggestions as to the deep and long dives of these whales.

Acoustics

Different beaked-whale species appear to exhibit quite different acoustic repertoires. Some species (such as Baird's beaked whale) produce the social whistles characteristic of other toothed whales, although others (such as the northern bottlenose whale or Cuvier's beaked whale) produce primarily or solely echolocation-type clicks. Recordings made from Baird's beaked whale and Arnoux's beaked whale included frequency-modulated whistles, burst-pulse clicks, and discrete clicks in rapid series. Other than these, only a few records of the acoustic behaviour of other species of beaked whale exist, and the majority of these were obtained from beach-cast or rehabilitated animals and so may not represent natural behaviour.

In the long term, the acoustic repertoire of beaked whales may allow researchers to find and identify animals at sea via the sounds they make. Such a technique will be particularly helpful for these species, which are difficult to find and identify visually. However, in order for this to be achievable, a comprehensive and accurate database of species-specific call types and structures needs to be established. This presents somewhat of a "catch-22" situation, as obtaining this ground-truthing data for beaked whales is extremely difficult, so progress on acoustic survey techniques for these species is limited.

Conservation

Their pelagic habitats and lack of concentrated populations have meant that most beaked whales have had little interaction with humans. The exceptions were the northern bottlenose whales in the North Atlantic and Baird's beaked whales in the North Pacific, both of which were quite heavily exploited in whale fisheries. Among the Antarctic beaked whales, only a few Arnoux's beaked whales and southern bottlenose whales have been killed during whaling for research purposes, and one Hector's beaked whale was apparently taken in the 1800s in New Zealand. Southern bottlenose whales have also been recorded as accidental victims of the driftnet fishery in the Tasman Sea.

The ecological role of beaked whales as top predators exposes them to increased levels of chemical pollutants. Cetaceans store energy (and pollutants) in their blubber, and have a lower capacity to metabolise some PCB isomers than many other mammals. Foreign and toxic substances are therefore often biomagnified as they move up the food chain. Toothed whales, which are usually quite high up their food chains, can have quite high levels, and even species such as beaked whales that live offshore and in relatively clean environments such as the Antarctic will be exposed to pollutants. High contaminant levels can have two major effects: (1) inhibition of the immune system's capacity to respond to naturally occurring diseases, and (2) potential reproductive failure.

There is also increasing concern about the effect of anthropogenic noise in the marine environment. Beaked whales appear to be particularly susceptible to the effects of low-frequency, high-intensity underwater sounds. Several beaked-whale stranding events have coincided with military naval exercises and the increased noise levels associated with these. It is unknown why beaked whales are particularly sensitive to such events, whether these are related to the deep-diving behaviour of these whales or the soft-tissue structure of their ears. However, regardless of the mechanism involved, caution needs to be exercised in terms of increasing sound levels in the habitats of these species. Increasing levels of underwater noise in the oceans are therefore currently a major concern for this group of animals.

BELGIAN ANTARCTIC *(BELGICA)* EXPEDITION (1897–1899)

In 1895 the Sixth International Geographical Congress in London passed a resolution to the effect that the Antarctic was the most important remaining field for geographical exploration. Remarkably, the first country to respond to this call was Belgium, a country with no significant recent maritime tradition and no earlier history of polar exploration. The person responsible was a young Belgian naval officer, Adrien de Gerlache de Gomery. Early in 1895 he had submitted his plans for an Antarctic expedition to the Royal Belgian Geographical Society; they were readily approved and a public subscription was opened. The proposed expedition received the patronage of HRH Prince Albert, and the government contributed 100,000 francs. In July 1896, de Gerlache bought the former Norwegian whaler *Patria,* a three-masted bark with an auxiliary steam engine of 35 hp; she was renamed *Belgica*. De Gerlache's stated plans did not initially envisage the ship wintering.

The expedition personnel represented an interesting mix of nationalities. The scientists included two Poles, Henry Arçtowski and Antoine Dobrowolski; a Belgian, Emile Danco; and a Romainian, Emile Racovitza. First Officer was a Belgian, Georges Lecointe; second officer was a Norwegian, Roald Amundsen, later to become one of the most famous polar explorers; third officer was a Belgian, Jules Melaerts. The medical officer was an American, Dr. Frederick Cook, who joined the ship at Rio de Janeiro on its way south. The crew consisted of Belgians and Norwegians.

Belgica put to sea from Antwerp on August 16, 1897, and from Ostend a week later. Having called at Funchal (Madeira), Rio de Janeiro, and Montevideo, she reached Punta Arenas on December 1. Naturalist Racovitza traveled to Punta Arenas independently, ahead of the ship. From there he made an extended collecting trip inland on horseback. Having penetrated as far as Lago Sarmiento and the Cerro Paine, he rejoined Belgica at Punta Arenas on December 3.

Belgica next called at the Argentine government coal depot at Lapataia on Canal Beagle, Ushuaia, the Reverend Bridges' estancia at Harberton (where it ran aground and was refloated only with great difficulty), and the penal colony at San Juan on Isla de los Estados. Thus it was not until January 14, 1898, that *Belgica* started south across the Drake Passage. The passage took the expedition between Snow and Smith islands in the South Shetlands on January 20, and to the east of Low Island on the 22nd, when a storm broke. While trying to clear blocked scuppers, a seaman, Karl Wiencke, fell overboard and was drowned.

Pushing south into Hughes Bay, de Gerlache next headed southwest into the wide strait (now named after him) between Liège, Brabant, and Anvers Islands and the Antarctic mainland. Over the next three weeks *Belgica* cruised among the complex scattering of islands in this strait, many of which still bear names bestowed by the expedition. A remarkable twenty landings were made by boat, while the islands were surveyed and the geology, flora, and penguins were studied. De Gerlache and Danco made a week-long sledge trip on Brabant Island, the first such scientific excursion in the Antarctic.

Running south through Neumayer Channel to Bismarck Strait and Flandres Bay, after passing Cape Renard and Lemaire Channel, De Gerlache continued south, crossing the Antarctic Circle on February 15. On the 16th, Adelaide Island was sighted, and Alexander Island soon afterwards. On February 28, relatively loose pack ice to the south offered the possibility of penetrating in that direction. Arguing that James Ross had found the open waters of the Ross Sea south of a significant belt of pack ice, and anticipating that the same situation might exist in the Bellingshausen Sea, de Gerlache headed south into the pack, although aware of the risk of becoming beset for the winter. That possibility became a reality on March 2, 1898, at 71°30′ S, 85°16′ W.

The upper deck was partially housed in with canvas, and the ship banked with snow for insulation. Accommodations were reorganized to save fuel. Huts and snow-houses for scientific investigations sprang up on the ice around the ship and a complex program of observations began in the areas of meteorology, oceanography, biology, and magnetic studies.

The sun was last seen on May 17. The ship drifted with the ice in complex loops and zigzags, but generally in a westerly direction, roughly along the 70° S parallel. By mid-winter, scurvy was affecting most of the ship's company, including de Gerlache. Cook managed to combat the disease by a diet of seal and penguin meat. But he also had to contend with mental illness. One of the Norwegian seamen developed a severe persecution complex. He began sleeping in obscure corners all over the ship, and on one occasion disappeared from the ship and was only found out on the ice after a protracted search.

Quite early in the wintering Emile Danco, who had been suffering from a heart complaint for some time, was forced to give up his studies of magnetism, and soon afterwards he took to his bunk. He died on June 5, 1898, and was buried through a hole in the ice 2 days later.

The sun returned on July 21, but breakup of the ice was still a long way off. In January 1899, work began on cutting a channel towards an area of open water some 600 yards (545 m) away. But after a month of laborious toil, the ice moved and the channel closed. Then on February 15 the ice opened again, steam was raised, and the ship reached a large polynya. It was not until March 14, 1899, however, that *Belgica* finally reached the open sea.

After being almost driven ashore during a gale, *Belgica* managed to enter the Canal Cockburn, and dropped anchor at Punta Arenas on March 28; she reached Antwerp on November 5, 1899.

Largely due to luck, the expedition had survived the first Antarctic wintering of any vessel. It had accumulated a vast amount of scientific data. The Belgica Commission, charged with publishing the expedition's results, ultimately issued ten volumes on almost every aspect of the expedition's work.

BELGIUM: ANTARCTIC PROGRAM

Belgian interest in Antarctica began in 1894 when Adrien de Gerlache unfolded his plans for a Belgian scientific expedition to Antarctica to the Société Royale Belge de Géographie and the Royal Academy. Although the ensuing *Belgica* expedition (1897–1899) was to a large extent privately funded, the impressive series of Résultats de voyage de la Belgica (sixty-five volumes) was commissioned and published by the Commission de la Belgica under the aegis of the Royal Academy.

The emphasis placed by the Special Committee for the International Geophysical Year (IGY) on the establishment of a geophysical network in Antarctica during the 1957–1958 IGY and the memory of the historical Belgica expedition convinced Belgium to join ten other countries and to establish a scientific station, Base Roi Baudouin, in Dronning Maud Land, a virtually unexplored part of Antarctica at that time. Twice for 3-year periods (1958–1961 and 1964–1966) this station fulfilled its role as a geophysical observatory and as an operating base for geographical, glaciological, and geological mapping of the neighboring coastal and mountain areas. After the closure of the base in 1967, three further summer expeditions were sent, but in 1971 all governmental support for Antarctic research was temporarily halted.

In 1985, the Belgian government took the initiative for a more structured approach with respect to its activities in Antarctica and started a series of multiannual scientific research programs managed by the Federal Science Policy Office. In this way Belgium could honor its obligations as a founding member of the Antarctic Treaty System, contribute to the knowledge required for conservation and management measurements of the Antarctic environment, and strengthen its research activities with respect to global environmental change. A call for research proposals was issued every 3–4 years among all university and federal scientific institute-based scientists, and the proposals selected on the grounds of a scientific assessment by foreign experts. The first three phases of the Belgian Scientific Research Program on the Antarctic (1985–1988: 2.3 million Euro; 1988–1992: 2.4 million Euro; 1992–1996: 3.9 million Euro) covered research projects in the domains of "Marine Biogeochemistry and Ecodynamics," "Hydrodynamics and Marine Geophysics," and "Glaciology and Climatology." The fourth (1996–2000: 6.3 million Euro) and fifth (2000–2005) phases were launched under the umbrella of a Multi-Annual Support Plan for a Sustainable Development Policy. Phase four covered "Marine Biota and Global Change," "Dynamics of the Southern Ocean," and "Paleoenvironmental Records," and Phase five "Climate and Atmosphere" and "Biodiversity."

Following an external assessment of the Belgian Antarctic Program, the Council of Ministers in its meeting of February 2004 took the decision to establish a new scientific station on the occasion of the International Polar Year in 2007–2008. The design and prefabrication of the summer-only base would be assured by the private sector thanks to the support gathered by the International Polar Foundation (IPF, projected cost of 3.0 million Euros). For the management of the station, a yearly sum of 1.2 million Euro is provided. Both the management as well as the scientific program will fall under the responsibility of the Federal Science Policy Office. A site survey in December 2004 allocated the planned new base close to Utsteinen Nunatak at the foot of the Sør Rondane Mountains, 180 km south of the former Belgian Roi Baudouin Station.

BELLINGSHAUSEN, FABIAN VON

The Baltic German Fabian Gottlieb Benjamin von Bellingshausen (other versions of his name are Thaddeus von Bellingshausen and Faddej Faddeevich Bellinsgauzen) was a Russian seafarer born on the Estate of Lahhetagge/Lahetaguse on the Island of Ösel/Saaremaa in the province of Livonia on 20 September 1779. He was the fourth child in the family of the infantry soldier Fabian Ernst von Bellingshausen and his wife Anna Catharina (born von Folckern). After the father's death in 1784, the family suffered financial pressures and moved to Arensburg/Kuressaare. Although his brothers were sent to study at traditional military schools, von Bellingshausen was sent to a naval academy, something that at that time had no major tradition in Russia. He studied at public cost at the Naval Cadet Corps in Kronshtadt (1789–1797). He was very much a mediocre student, finishing his studies among the bottom five of his course.

In 1795, von Bellingshausen was promoted to gardemarine, and in 1797 he finished the Cadet Corps, attaining the rank of midshipman. From 1797 to 1803 he served in the Russian Baltic Sea squadron. In 1803–1806, he participated in the first Russian circumnavigation of the earth under the command of Adam Johann von Krusenstern, sailing on the frigate *Nadezhda*. He was an excellent cartographer, and drew all the maps later published from the expedition. After the expedition, von Bellingshausen was promoted to captain-lieutenant, and from 1807–1810 he continued his service on the Baltic Sea. During the period 1810–1819, he sailed on several ships in the Black Sea. He improved considerably the sea charts of the eastern coast of the Black Sea based on his own observations (Russwurm 1870; Paatsi 2000).

On 24 April 1819, at the recommendation of Makar Ivanovich Ratmanov and von Krusenstern, von Bellingshausen was appointed the leader of the South Pole group and the captain of the sloop *Vostok* (the captain of the transport ship *Mirnyy* was Mikhail Petrovich Lazarev) of the Russian expedition to the North and South Poles. The main goals of the expedition were to improve the map of the southern part of the Pacific Ocean and to approach as close to the South Pole as possible, making new discoveries in the Antarctic Ocean.

Following the expedition (1821), von Bellingshausen was promoted to captain-commodore, and he served in the Baltic Sea as the commander of the 15th unit of the navy (1821–1826). During this period, he also arranged his expedition materials and compiled a manuscript of the travel account in Russian, which he submitted to a Department of Admiralty in 1824 (it was published in 1831) (von Bellingshausen 1945).

In 1826–1827, von Bellingshausen cruised in the Mediterranean Sea with in a squadron of two ships and was promoted to rear admiral. In 1828–1829, he participated in the Russian–Turkish War and in the attack on the Varna fortress as the leader of a naval guard unit. From 1830 to 1839, von Bellingshausen was the commander of the 2nd division of the Baltic fleet, following which, from 1839 to 1852, he served as the harbour master and military governor of Kronshtadt. In 1843, he was promoted to admiral, and in 1844, he was appointed a member of the Council of Admiralty. Von Bellingshausen contributed greatly to the development of the harbour and town of Kronshtadt. He succeeded in widening the harbour considerably, at the same time founding parks and encouraging other developments that helped turn the rough naval base into a city appropriate also for a civilian population (Korguev 1900). In appreciation for his efforts, the inhabitants of Kronshtadt later set up a monument of von Bellingshausen, which was opened in 1870. Von Bellingshausen died in Kronshtadt on 25 January 1852.

Personal data on Bellingshausen are scanty and rather contradictory—on the one hand, he was valued highly as a very conscientious and educated seafarer; on the other, his education was considered limited and he was thought superior and arrogant. None of his contemporaries, however, was doubtful of his abilities in cartography or his seamanship, the latter of which included a special study in how to aim at a target in the sea (Bellingshausen 1839). There are numerous geographical objects that have been named after von Bellingshausen: a hollow and an atoll in the Society Islands in the Pacific Ocean; a cape on Sakhalin Island and another on South Georgia; a sea in the Antarctic (named by Jean-Baptiste Charcot in 1908–1910); a coast on Peter I Øy; a shelf glacier, a mountain, and a Russian station in the Antarctic; and islands in the Aral Sea and in the South Sandwich Islands.

BELLINGSHAUSEN SEA, OCEANOGRAPHY OF

Location

Named after Thaddeus von Bellingshausen, who led the Russian expedition to the south polar region in 1819–1821, the Bellingshausen Sea lies west of the Antarctic Peninsula at the southeast extremity of the Pacific Ocean. Situated between Alexander and Thurston islands, it lies north of Ellsworth Land and adjacent to the Amundsen Sea in the west. Due to its remote location and extensive sea-ice coverage, the region is relatively undersampled. The Russian expedition was followed by *Belgica,* which over-wintered in the ice (1897–1899), but only in the last two decades has interest developed with projects under the auspices of international programmes such as IGBP-JGOFS (Joint Global Ocean Flux Study), GLOBEC (Global Ocean Ecosystem Dynamics), and WCRP-WOCE (World Ocean Circulation Experiment). Much information has been obtained remotely by satellites, such as passive microwave measurements of sea-ice extent, sea-surface temperature from advanced very-high-resolution radiometers (AVHRR) and along-track scanning radiometers (ATSR), and surface chlorophyll from Coastal Zone Colour Scanner (CZCS) and sea-wide field-of-view sensor (SeaWiFS) satellites. Numerical modelling of the area has been included in regional and global ocean-circulation models.

Setting

The shelf width ranges from 100 to 450 km, with average water depths varying between 350 and 650 m. Ocean depths extend to 3500 m. Locally deep troughs are cut into the shelf. The upper continental shelf is steeper in the eastern Bellingshausen Sea (13°–17°) than in the west (1°–4°). The lower slope is cut by erosional channels extending across the continental rise down to the abyssal plains. Elongated sediment mounds, associated with the channels, rise 1000 m above the adjacent sea floor. Features such as Peter I Island and Marie Byrd Seamount are volcanic peaks. The region is volcanic in origin, formed by the subduction of Pacific oceanic lithosphere beneath the continental margin of Gondwana, with the break-up of Gondwana leading to movements of crustal blocks along the region. The Antarctic Peninsula and eastern Ellsworth Land form a deeply eroded magmatic arc with much of the shelf and islands formed of clastic and volcanogenic sequences. The ice cap of the Antarctic Peninsula is drained by valley and outlet glaciers into the eastern Bellingshausen Sea. Locally these coalesce to form ice shelves, whose flow is confined by the local topography, islands, and peninsulas.

Climate

The climate is determined by the Antarctic circumpolar atmospheric pressure trough lying north of the coastline, which is characterised by many deep depressions and generally brief anticyclonic episodes. The leading modes of climate variability are the Antarctic

Oscillation (AAO) and changes in the semiannual oscillation (SAO).

The AAO is the leading principal component of sea-level pressure south of 20° S. Most variability associated with the AAO is zonal, but a nonannular component can be found, with a low-pressure anomaly west of the Antarctic Peninsula for high values of the AAO index. The AAO has a clear and strong impact on the structure of the ocean currents over large parts of the water column. At the surface, transport anomalies associated with a positive phase of the AAO are directed toward the northwest at high latitudes (south of 45° S), inducing an upwelling that features a maximum at around 65° S and a downwelling at about 45° S, which is balanced by a southward return flow below 1500 m. The nonannular response of the AAO gives rise to a low-pressure anomaly in the Amundsen-Bellingshausen Sea sector during positive AAO years, when the Weddell and Bellingshausen seas are subject to more northerly winds, which induces a warming at the surface and a decrease in their ice-covered areas. The reverse is true of the Ross and Amundsen seas; hence, integrated over the Southern Ocean such regional differences cancel out.

The SAO is a twice-yearly contraction of the circumpolar pressure trough due to differences in energy uptake between Antarctica and its surroundings. It results in a half-yearly wave in baroclinicity and depression activity. Latitudinal sea-ice extent in the Amundsen and Bellingshausen seas fluctuates with the movement of the circumpolar pressure trough, so a weakly developed SAO suppresses sea-ice growth.

Sea Ice

The climate is strongly influenced by sea-ice extent. Synoptic scale weather patterns, air temperatures, and the regional atmospheric circulation are all affected by the extent of sea ice.

The annual cycle of sea ice cover in the Bellingshausen Sea is unusual in its symmetry between ice growth and retreat. The more typical Southern Ocean cycle is one of slow growth and rapid retreat. Since rapid retreat in spring exceeds the available air–sea heat flux, the heat deficit must be made up from the underlying deep water. A more gradual retreat in the Bellingshausen Sea implies less deep-water influence, consistent with a relatively low-salinity surface layer. The Amundsen and Bellingshausen seas also exhibit a low seasonal range in sea-ice extent compared to other sectors of the Southern Ocean. Sea ice is sensitive to changes in atmospheric circulation and the frequency, depth, and track of depressions in and to the north of the circumpolar pressure trough. When depressions are slow moving and there is persistent meridional wind, large sea-ice anomalies may become established and can persist for several seasons.

Exceptional sea-ice retreats and advances occur in the Bellingshausen Sea, including sea-ice retreat during winter. It is usually associated with a combination of enhanced poleward flow and warm-air convection. The winter of 1993 was remarkable for the amplitude of excursions in the sea-ice edge. The changes were so pronounced because of the strong meridional winds induced by strong high–low pressure couplets on either side of the Antarctic Peninsula and the marked changes of near-surface temperature they brought about, which fluctuated rapidly. The rapid melting and refreezing of ice led to extensive movements in the ice edge.

Strong feedback between temperature over the Antarctic Peninsula and sea-ice cover in the Amundsen and Bellingshausen seas is at least partly responsible for anomalous warming of this region in the last 50 years. A major decrease in sea-ice extent in the Bellingshausen Sea began in the late 1980s. The retreat was correlated with increasing surface air temperatures on the west coast of the Antarctic Peninsula and coincided with more northerly surface winds and greater cyclonic activity. The last 2 decades have been the warmest in the last 5 centuries. During that time, the occurrence of the minimum extent of sea ice moved from March to February. The ice retreat, which was first observed in summer, now extends through all seasons, and the mean latitude of the Amundsen and Bellingshausen ice edge has shifted southward by about 1.5° latitude per °C temperature.

Oceanography

The Bellingshausen Sea lies in the Antarctic Zone of the Southern Ocean, where the ocean circulation is dominated by the wind-driven, eastward-flowing Antarctic Circumpolar Current (ACC). While the main part of the current passes to the north, the broadening of the flow as it crosses the Southeast Pacific Ridge brings the southern ACC boundary into the Amundsen and Bellingshausen seas. The Antarctic Zone comprises the flow between the core of the ACC at the Polar Front and the southern ACC boundary. The zone south of the ACC lies between the southern ACC boundary and the coast. Prevailing easterly winds south of 65° S drive a westerly to southwesterly flow of water, but the current regime is complex, with meanders and cyclonic gyres and no dominant pattern of flow.

Water masses upwell along isopycnals within the ACC, bringing warm, saline Circumpolar Deep Water (CDW) toward the sea surface. There is no marked front along the shelf break, allowing CDW to upwell onto the continental shelf where it causes intense melting at the base of the ice shelves. Limited observations confirm the lack of shelf water in the Bellingshausen Sea, one of the two prerequisites for the formation of bottom water. Thus, production of cold, dense water that sinks beneath CDW is unlikely. Rather, bottom water formed in the Ross Sea is circulated cyclonically around the deep southeast Pacific to reach the Bellingshausen Sea in modified form. Modified deep water from the Weddell Sea spreading westwards around the tip of the Antarctic peninsula may spread further westwards in a narrow, weak bottom current observed on the continental slope. The surface layer consists of cold ($<-1.5°C$), low-salinity Antarctic Surface Water.

Biogeochemistry

The upwelling of CDW across the southern ACC boundary provides a nutrient-rich input to the upper layer of the water column. Nutrient concentrations below 100 m are consistently high. In the surface layer, nutrient concentrations reflect recent biological activity; for example, in late spring, nitrate, phosphate, and silicate decrease from south to north while nitrite, ammonium, biogenic silica, and chlorophyll increase.

Micronutrient measurements are few. Observations of dissolved iron show low levels, while the range of values includes the lowest measurements made in the Southern Ocean. Some enhancement of iron concentrations occurs to the north of the Polar Front and towards the Antarctic continent, where deeper waters may be affected by input from the continental margin sediments.

The Bellingshausen Sea acts as a sink for atmospheric carbon dioxide during summer, probably due to biological activity. Periods of increased uptake of carbon dioxide may be caused by enhanced productivity or changes in circulation, and demonstrate that the area has the capacity for rapid and large changes in carbon uptake.

Marine Flora and Fauna

A major feature of the Bellingshausen Sea is its paucity of marine fauna. Satellite observations show the remote southeast Pacific to be unproductive, with little algal biomass, which is undoubtedly linked to the relatively low numbers of zooplankton and higher predators such as cetaceans and seabirds.

Exceptional blooms of phytoplankton occur in inshore waters and in offshore waters associated with the marginal ice zone. However, a classical ice-edge bloom, stabilised by melt water from retreating ice, has not been observed *in situ*. Rather, enhanced productivity is associated with frontal zones to the south of the ACC. Macronutrients are not limiting, but low levels of dissolved iron are, and iron stress limits all sizes of phytoplankton. Composition of the phytoplankton community varies with the dominant water masses reflecting nutrient characteristics; in particular, diatoms are restricted to silicate-rich waters south of the Polar Front.

Only the abundance of bacteria and protozoa (microzooplankton) is higher in the Bellingshausen Sea than other regions. The under-ice community is dominated by bacteria where phytoplankton are minimal, but their importance diminishes away from the ice, where phytoplankton increase in importance. High-standing stocks of protozoa in the marginal ice zone are important in that they exert a significant impact on phytoplankton, grazing in excess of 100% of the phytoplankton population. Through exerting a continuous high grazing pressure, protozoa are more important than krill, which have a localised, episodic impact.

The abundance and biomass of zooplankton in the Bellingshausen Sea are among the lowest recorded for the Antarctic. Copepods dominate numerically, but species vary from year to year through variability of ice conditions. In warmer years with less ice, then, salps can show a dramatic increase in biomass. Sea-ice conditions between the Bellingshausen Sea and Antarctic Peninsula region are closely linked, which would support similarities within the krill stock composition between the two regions.

Cetaceans, mainly minke and humpback whales, tend to be associated with the ice edge and coastal habitats and are found in the greatest numbers when the sea-ice boundary is located over the shelf edge. Although humpback whales are migratory, individuals have been observed during austral winter in shelf areas of the Bellingshausen Sea. Krill predators other than whales are also found in higher abundance in the same area as whales. Seabird density is similar to other continental shelf areas but significantly lower than the Ross Sea. Birds are more abundant near ocean frontal zones, the ice edge, and the shelf break, either because habitats of different species overlap, as at frontal zones, or because processes in the region, such as the shelf break, concentrate the variety of prey (zooplankton, fish, squid) eaten by Antarctic seabirds.

BENTHIC COMMUNITIES IN THE SOUTHERN OCEAN

On land and on the shore, Antarctica seems a barren land, with transient penguins and seals being the most striking examples of life. For most of the year the sea is measurably the clearest in the world; there may be masses of krill, comb jellies, and salps in the water, but these are few in species. Life on the sea bed could not be a greater contrast; below the shallows, which are scoured by the abundant small icebergs, the rocks are densely covered by a rich variety of colourful animals. On sediments too there are a wide variety of organisms, from ancient and massive sponges to burrowing bivalve molluscs, scavenging amphipods, and predatory seastars.

For decades this secret world has been accessible mainly just to scientists working from Antarctic bases, but tourist vessels are increasingly gaining the capacity to glimpse the bottom by using Remote Operated Vehicles (ROVs) or SCUBA diving. Perhaps the most striking feature to a viewer would be how little life there appears to be in the shallowest water and how rapidly this increases to coral reef–type densities and diversities by 25–40 m. This is because of ice scour (and, at very high latitudes, anchor ice). The sea bed in the shallowest water is permanently in a state of recolonisation from the scraping and gouging action of icebergs. With increasing depth, therefore, the communities tend to be older on average and succession can be seen from the weedy pioneers (such as bryozoans, stalked ascidians, and hydroids) to the longer-lived and slow-growing volcano sponges. Experimental settlement panels have been put out in shallow water by marine biologists at various locations around Antarctica to investigate how quickly animals colonise and how rich these early communities are. The results have been quite varied, some showing very slow rates of recolonisation and some (such as at McMurdo Sound) suggesting long periods of years when little settles followed by a brief major pulse in recruitment. Another highly visual and striking feature is how few organisms are moving—most of the benthos is sessile (nonmobile), and even the mobile scavengers and predators are in no rush. Viewing the same site a week later can reveal sea slugs (nudibranchs), sea spider (pycnogona), nemertean worms, or other predators still in the same place eating the same meal. This is life in the slow lane. The tick-over (metabolism) and growth of the Antarctic invertebrates measured to date is slow. A dominant lifestyle is suspension feeding, so the observer in summer would see a crowded mass of tentacles from (polychaete) worms, bryozoans, hydroids, sea cucumbers (holothurians), brittle stars (ophiuroids), and basket stars (crinoids) straining plankton from the water. Ascidians (sea squirts), sponges, brachiopods, and other peculiar animals (such as Entoprocts) would be doing the same but less, obviously, and without tentacles.

Their food is, like the light climate, very seasonal. For a few months a year (December–February) there is a very intense phytoplankton bloom, typically dominated by tiny diatoms. Many of these suspension feeders (often referred to as "filter feeders") eat even smaller organisms in the water called ciliates, flagellates, or even bacteria. It was thought for a long time that such animals would have to hibernate for most of the year and resume activity during the brief polar summer, but it now appears there are a great variety of strategies. Some species even feed all year round—on what, though, is a mystery. Other aspects of their environment are also very seasonal—it is not so obvious, but the sea temperature rises dramatically in the summer from around freezing (just below –1.8°C) to just above freezing briefly. This may not seem much but, as on coral reefs, the upper summer temperatures are close to the thermal limits for many species. At just 2°C, some animals may have their ability to function normally severely affected and at 5°C many may die (they are very steno-thermal). At some localities, such as McMurdo Sound (Ross Sea) and Ellis Fjord (East Antarctica), the benthic communities live in the most thermally stable environment known on earth. Being cold and well mixed, the water holds gas very well, and the high oxygen concentrations have enabled some organisms (sea spiders, amphipods, and isopods) to attain giant sizes. Paradoxically, other groups, such as many molluscs, are very small. A common feature of polar benthos (Antarctic and Arctic) is great longevity: some brachiopods, bivalve molluscs, and sponges may live to 100 years old or more.

Even on most coral reefs it would be hard to see as many different types of animal in any particular spot. It is frequently stated by biologists that there is a global (bio)diversity cline (a decrease of species from tropics to poles). There is much supporting evidence for this idea in the Northern Hemisphere seas, but in the Southern Hemisphere the sea bed around Antarctica is very species rich (in contrast to impoverished Arctic sea beds). Thus, patterns of richness strongly differ between hemispheres because of the difference between how many species live in the north versus south polar sea beds. The richness in Antarctic waters is not evenly distributed either by geography or between animal types. To date, particularly high numbers of benthic species have been found in the Scotia Arc, the Weddell Sea, and the Ross Sea. Comparisons are difficult though, because these areas have been well sampled, whereas others, such as the Amundsen Sea, have only rarely been visited. Some types of animals, polychaete worms, sea spiders, and a few other groups, have a much higher proportion of the world's species than would be predicted on the basis of habitat (continental shelf) areas. Why should this be? It is likely to be a combination of factors, but compared to the Arctic, for example, the sea bed around Antarctica is very old. But the animals around Antarctica are not just unusual because there are lots of them; it is that most of them occur nowhere else. Between 70% and 90% of species from most groups of animals are endemic (only occur there). There are, of course, some exceptions, but also the macro-algae in Antarctic waters are a subset of those north of the Polar Frontal Zone (PFZ) and thus occur in, for example, Patagonia. For the most part, though, there is an abrupt change in the fauna across the PFZ—the animals living at South Georgia are very different to those of the Falkland Islands and Patagonia.

Despite the high levels of richness, the observer of the ROV pictures or using SCUBA would come across many of the same animals in the shallows almost wherever they went around the Antarctic. Certain species are particularly ubiquitous and many even seem circumpolar. The limpet, *Nacella concinna,* the burrowing clam, *Laternula elliptica,* the giant yellow nemeratean worm, *Parbolasia corrugatus,* the bright red sea urchin (echinoid) *Sterechinus neumayeri,* the red sea star, *Odontaster validus,* and the stalked ascidian, *Molgula pedunculata,* are examples. The west wind drift and Antarctic Circumpolar Current (ACC) may aid such distributions by carrying larvae around the margins of Antarctica, although new investigations of cryptic speciation (species which look morphologically similar but which are genetically different) may reveal that there are many fewer circumpolar species than are currently thought. It is notable that within many major groups of animals many Southern Ocean species brood their young but also that the most abundant species do not. In some groups, brooders have had greater evolutionary success (generation of many species) but those with planktonic larvae have had greater ecological success (more abundant and ubiquitous). It has been theorised that the alternating conditions of ice sheets bulldozing the fauna to the deep edges of the continental shelves during ice ages followed by rapid retreats in interglacials may be responsible for such a pattern. Certainly the species with long-lived planktonic larvae (broadcast spawners) would seem to have a strong potential to rapidly recolonise the empty sea bed after each ice sheet retreats. In recent time our current picture of the rich benthos fighting for space on the shallow Antarctic sea bed is not really a "normal" one: in the last 430,000 years ice sheets have covered the land and sea (as during ice ages) 90% of the time.

Some scientists believe the benthic communities around Antarctica are the oldest in the world; they are certainly quite different in character and behaviour to those anywhere else. To date, they, together with the deep abyssal plains and trenches, are probably the environment least influenced by man.

The whaling and sealing must have made tremendous changes to the functioning of the pelagic ecosystem in Antarctica, as fishing has disastrously for coastal ecosystems elsewhere. Much of ice-free Antarctica has also been dramatically altered indirectly or directly by human activities, most notably in the form of recent invading species. The benthic communities of Antarctica have experienced a warmer period before, but it seems likely they face rapid warming, accelerating melting and collapse of ice shelves, and invaders clinging to the hulls of ships. In shallow water Antarctica's benthos can be considered to represent a last frontier, but their resilience to crushing from massive icebergs and to the bulldozing of ice ages may be tested much more severely if some of the predictions of current climate-change models become reality.

BIODIVERSITY, MARINE

Biodiversity can be defined as the collection of genomes, species, communities, and ecosystems in space and time. In the Antarctic marine environment it expands from surface-water and ice-algae assemblages over phytoplankton and zooplankton down to benthic assemblages. Knowledge of biodiversity of geographic areas is essential for conservation: species, assemblages, and communities can only be assessed for their importance or protection requirements. Large-scale patterns of biodiversity feed and underpin theoretical ecology and paleoecology once they have been recognised. Biodiversity means ecological diversity, genetic diversity, and whole-organism diversity. The population is the unit of organisms that fundamentally links these components. On the background of the Antarctic Treaty, knowledge of biodiversity is crucial for all marine and terrestrial habitats of Antarctica.

The most fundamental step to biodiversity research is the accurate recognition of specific taxonomic levels (usually species) and classification of variation within these and of assemblages. Such information is essential for identifying patterns of biodiversity and for understanding how these patterns change over space and time. A visitor walking Antarctica's coast would see that most of the coastline is ice shelf, but even shores away from the ice shelves seem barren of life. Yet new research is revealing that even here in this ice, wave, and ultraviolet light–hammered habitat there is considerable biodiversity. Below the surface, snorkellers, SCUBA divers, or surface watchers of Remote Operated Vehicle cameras (ROV) would see a very patchy environment. There are sheltered areas that teem with benthic life but much of the shallows is criss-crossed with gouge marks from previous ice scours. Nevertheless, shallow boulder fields may have levels of richness equal to or higher than those in southern Patagonia. The biodiversity in any one place may depend most on when it was last crushed by icebergs, and thus how long it has had to recover. Similarly, but on a larger scale in time and space, the biodiversity of continental shelves in Antarctica at any one point in time will be linked to the last time ice ages (glacial maxima) scraped away most of the fauna and how much time they have had to recover (in interglacial periods, such as the present time).

Our understanding of the biodiversity of the past depends on the quality of palaeontological data. The vast majority of biologists are interested in the biodiversity of the present and believe in a biodiversity crisis caused by species becoming extinct at an alarming rate; our estimates of future biodiversity depend on sound modelling of data from the past and present. The present-day biodiversity of the Southern Ocean marine faunas has been strongly influenced by continental drift, the subsequent change of the hydrography and the paleoseaways, regional and global climate change, dispersal capabilities of the organisms, physiological adaptations, and the zoogeography and evolution of the species, which result from this geological framework. Plate tectonics, palaeoceanography, and the subsequent development of the Antarctic Circumpolar Current (ACC) and the psychrosphere fuelling the cold world's deep-sea bottom water (which is linked to the surface water) have enhanced successive cooling and glaciation of Antarctica. This cooling was probably a key event for the evolution of many Antarctic marine taxa.

A remarkable oxygen and carbon isotope change occurred in Antarctic waters about 57 Ma, indicating rapid global warming and oceanographic changes that caused one of the largest deep-sea benthic extinctions of the past 90 million years. In contrast, the oceanic plankton were largely unaffected, implying a decoupling of the deep and shallow ecosystems. There are three hypotheses for the deep-sea benthic crisis: (1) a rapid warming of the deep ocean in bottom water sources; (2) a deep-sea oxygen deficiency due to the sudden warming and change in circulation of deep water; (3) a sharp drop in surface ocean productivity that reduced trophic resources available for deep-sea benthic organisms.

In the 1970s, it was postulated that marine biodiversity is higher in the deep sea than on the shelf or on the continental slope, and a number of hypotheses have been used to explain high deep-sea species diversity. These include, for example, the stability–time hypothesis (maintenance of environmental stability characterizes the deep sea and leads to the development of a highly diverse community), and the biological disturbance theory describing processes of contemporaneous disequilibria (habitat change or heterogeneity and biological disturbance in terms of interspecific and intraspecific interactions lead to faunal diversification). Predation and competition are also disequilibrium explanations of high species diversity, which might be as important as productivity (food availability and/or dietary specialization).

Numbers of Species Known for Selected Southern Ocean Taxa

Phylum	Taxon Name	Number of Species
Macroalgae	Rhrodophyta	75
	Phaeophyta	26
	Chlorophyta	17
Porifera	Demospongiae	182
	Calcarea	14
	Hexactinellida	29
Cnidaria	Hydrozoa	155
	Alcyonaria	28
Arthropoda/Crustacea	Amphipoda	>800
	Isopoda	>600
	Cumacea	~123
	Mysidacea	59
	Tanaidacea	~110
	Ostracoda	323
	Decapoda	37
	Cirripedia	50
Arthropoda/Chelicerata	Pycnogonida	180
	Nemertea	30
Sipunculida	Sipunculida	16
Echiurida	Echiurida	9
Annelida	Polychaetes	645
	Pogonophora	3
Mollusca	Bivalvia	123
	Gastropoda	497
	Cephalopoda	34
	Scaphopoda	10
	Aplacophora	>25
Tentaculata	Bryozoa	281
	Brachiopoda	19
Echinodermata	Ophiuroidea	119
	Asteroidea	108
	Echinoidea	74
	Crinoidea	28
	Holothuroidea	106
Tunicata	Ascidiacea	118
Pisces	mostly Notothenioidei	208

Updated from Clarke and Johnston 2003.

Productivity is directly dependent on solar energy, and this is, of course, much lower at the poles than in the tropics. Productivity, climatic variations, and size of the habitats are some causes being discussed as potential reasons for global latitudinal gradients in species biodiversity observed for many taxa from shelf to deep-sea environments. These theories still have to be tested for the Southern Ocean deep sea, because as of the mid-2000s only about forty stations were sampled during the ANDEEP expeditions.

There are a number of large-scale Southern Ocean currents, fronts, and water masses that are notable in connection with biodiversity. Today, the Southern Ocean is isolated by the Polar Front (sometimes called the Antarctic Convergence). The Polar Front is the strongest jet of the ACC and the northern limit of the cold surface-water masses. Antarctic Bottom Water (AABW) is generated at the Southern Ocean ice margins; it is cold and highly saline, and it led to the isolation of the benthic faunas when, in the Oligocene/Miocene, temperatures decreased. Its high density causes the sinking of this water mass down the continental shelf and slope into the Southern Ocean deep sea, where it carries oxygen to the deep-sea basins of the other world oceans. From sampling the Southern Ocean deep sea, we can postulate that the Southern Ocean deep-sea fauna are not isolated and share faunal elements with other deep-sea basins further north. Deep-water Antarctic organisms may also have strong connectivity with the shelf fauna as well, due to the absence of a thermocline and similarity of some physical conditions in shallow and deep waters.

During the gradual physical isolation of the Antarctic continent from the Late Cretaceous to the early Cenozoic, the "Weddellian Province" was established and characterised by a number of distinctive epifaunal taxa. This fauna was affected by the mass extinction event in the Late Cretaceous, but some (e.g., benthic Mollusca) crossed the K-T boundary in Antarctica. The successive cooling, glaciation, and isolation of the continent had a strong influence on the evolution and radiation of many Antarctic marine taxa and shaped the evolution of many key elements of the present-day benthic marine fauna. Notothenioid fish, peracarid crustaceans, polychaete annelids, and pycnogonids radiated in the Southern Ocean, resulting in a high biodiversity of these taxa. Molecular evidence dates the radiation of the Notothenioidei to the Middle Miocene. A key physiological and evolutionary acquisition of the Notothenioidei is the antifreeze glycopeptides in their blood, a development coincident with the onset of the temperature drop and freezing seawater. Moreover, the extinction of most decapod crustaceans and bony fishes (Teleostei) caused the emergence of new ecological niches previously occupied, and this process might have opened opportunities for spectacular adaptive radiations, like for the brooding peracarid crustaceans. Molecular systematics has revealed that the numbers of species in the Southern Ocean (as in many other regions) are probably underestimated because of the existence of cryptic species that cannot, or cannot easily, be differentiated morphologically.

Radiations of species result from the evolution in isolation over long periods of time. Taxa that have radiated are therefore often characterised by high degrees of endemism (60%–90% in bryozoans, peracarid crustaceans, and notothenioid fish). The cooling of the Southern Ocean from the late Cretaceous is likely to have particularly influenced sensitive early life-history stages. This would suggest that species with larval stages might have had selective disadvantages and brooding was favoured. Certain types of echinoid (sea urchins) and peracarid crustaceans provide evidence of this. Peracarids, for example, have a marsupium and exhibit brood protection, which reduces the migration potential of offspring. This may have helped local speciation and finally led to adaptive radiations which have been described for the Epimeriidae and Iphimediidae (Amphipoda) or Antarcturidae and Serolidae (Isopoda) on the Southern Ocean shelf, and for the asellote isopod family Haploniscidae in the Southern Ocean deep sea.

Although brachyuran crabs and balanomorph barnacles are absent from the Southern Ocean benthos, eleven species of lithodids have been reported south of the Polar Front, and anomuran and brachyuran larvae have been reported from the Bransfield Strait of the Antarctic Peninsula. The absence or scarcity of these higher predators from the Antarctic shelf ecosystem may well have favoured the evolution of the peracarid crustaceans. However, the recent records of anomuran lithodid crabs in the Southern Ocean deep sea of the continental slope raise the question of whether crabs are returning to the Antarctic after their extinction in the Lower Miocene (15 Ma) and possible consequences of such a return for benthic communities. Potential factors underlying crab transport and establishment in the Southern Ocean range from travelling in ocean eddies and hitching a ride on ships (perhaps in ballast water), to regional warming changing survivorship levels.

We have to assume that many shelf species can physiologically tolerate life at greater depths. It has been demonstrated that larvae of Sterechinus neumayeri might be extremely temperature and pressure resistant. It is, however, unknown whether the development of the deep-water production influenced the migration potential larvae in general and thus enhanced submergence of some species.

The present-day Southern Ocean biodiversity is the result of different and simultaneously occurring biogeographic and evolutionary processes. These include the progressive retraction of taxa of a former cosmopolitan distribution established during the Jurassic and Cretaceous periods, of disjunct distributions of genera or species due to continental drift vicariance, active migrations of taxa in and out of the Southern Ocean, and radiation events due to the emergence of new adaptive zones. Whatever the true causes are for the biodiversity observed, the Islands of the Scotia Arc, the sub-Antarctic Islands around the Antarctic Peninsula and the western Weddell Sea have been identified as centres of high biodiversity, and the Gunnerus and Astrid Ridge, for example, as areas of lower biodiversity.

Rates of species description for many Southern Ocean taxa show no sign of approaching asymptote (tailing off).

The most speciose taxa of the Antarctic benthos are the Polychaeta, Gastropoda, Bryozoa, Amphipoda, Isopoda, and Porifera. Sessile taxa are certainly well represented. Many other epifaunal taxa appear to have adapted well to the coarse-grained glacial substrates, as in many areas on the Antarctic shelf suspension feeders are especially prominent. Dense communities of sponges, ascidians, anemones, hydroids, gorgonians, bryozoans, and crinoids are characteristic of the modern Antarctic shelf fauna below the zone of the influence of ice scour and anchor ice formation. This fauna often forms stratified communities of three-dimensional shape (as seen in coral reefs and tropical rain forests). Associated with these sessile forms are errant and vagile taxa such as echinoderms (ophiuroids, asteroids, echinoids, and holothurians), pycnogonids, isopods, amphipods, nemerteans, and gastropods. Polychaetes are speciose in the Southern Ocean, occurring with more than 600 species, and peracarid crustaceans have radiated. It is thought that the adaptive radiation of some families of the Amphipoda (e.g., Epimeriidae, Iphimediidae) and Isopoda (Antarcturidae and Serolidae) is due in part to the extinction of many of the decapod crustaceans in the Southern Ocean. However, possible radiation processes resulting in complexes of rather similar species have recently been described for the Southern Ocean deep sea.

In general, the species composition of abyssal deep-sea communities is poorly known in comparison with shelf and upper-slope environments. The extent to which deep-water fauna depend on biotic versus abiotic parameters, their speciation processes, and their regionalisation is even more poorly understood. Species diversity and benthic community patterns may vary tremendously between deep-sea habitats. Explanations of such variability in deep-species biodiversity have suggested depth, latitude, or sediment-structure influences. Theories such as latitudinal gradients in species diversity are hotly debated in science, but the basis for these arguments is still weak, as vast areas of the deep sea, especially of the Southern Hemisphere, remain unexplored.

Some Southern Ocean deep-sea genera have eyeless species or species with rudimentary eyes, whose phylogenetically related shelf species possess well-developed eyes and are endemic to the Southern Ocean. It seems probable that these deep-sea species (e.g., Serolidae and Antarcturidae isopods) descended into the deep sea from shelf ancestors with highly developed eyes. Other eyeless isopod species are representatives of families that have lived in the deep sea for long periods of time. These have probably developed in the deep sea *in situ,* where they possibly also radiated before they ascended onto the continental shelves, especially at higher latitudes because of the absence of a thermocline (e.g., the asellote isopod families, Munnopsididae and Haploniscidae).

The wider bathymetric distribution of Antarctic invertebrates (when compared to other seas) suggests that eurybathy might be a result of the physical changes of the continent due to the dynamic climate changes of the neogene resulting in alternating phases of glaciation and deglaciation. The heavy weight of the ice cap is generally regarded as the prime reason of the fact that the Antarctic shelf is usually much deeper than those of other continents. The subsequent changes in the ice-shelf extension probably also led to speciation processes on the Antarctic continental shelf, and in some taxa even to adaptive radiations. For this reason some authors refer to Antarctica as an "evolutionary incubator." It is unknown to what extent species have migrated up and down the Antarctic continental shelf and slope following ice extensions and retreats during glacial maxima and minima. This possible biological consequence of climate changes might also alternatively have led to the high eurybathy of many Southern Ocean species seen today. Crucially, the fauna, being pressure tolerant, may have migrated up and down the Antarctic continental shelf and slope in the past or in and out of abyssal plains of other world oceans.

The Antarctic Deep Water (ADW) production plays a crucial part for the deep-sea Isopoda for colonising the deep sea of the world oceans. It might serve as some sort of a diversity pump, though to what extent remains unclear. It is possible that the ADW production in the Weddell Sea acts as a distribution mechanism, enhancing the migration potential of species, driving Antarctic deep-water fauna northwards into the Atlantic Ocean over evolutionary time scales. In this respect, the Weddell Sea may be an important source for taxa presently living in the Atlantic and other neighbouring parts of the deep oceans. This assumption is underpinned by the more-or-less isothermal water column of the Weddell

Sea, and the surroundings of the Antarctic continent provide an obvious conduit for the migration of shallow-water species into the deeper waters.

The Antarctic shelf is well isolated from the shelves of the former Gondwana continents and therefore serves as a beautiful evolutionary laboratory. On the contrary, the deep-sea fauna are not isolated, and huge areas surrounding the Antarctic continent are deep sea, and our knowledge of the Southern Ocean deep-sea fauna is scarce. Recent Southern Ocean benthic deep-sea biodiversity studies (ANDEEP) have been aimed at the conduction of the first baseline survey of the deep-water benthic faunas of all size classes from meiofauna to megafauna of the Scotia and Weddell seas.

Within the meiofauna, three groups are very abundant in the Southern Ocean deep sea. These are the Foraminifera (protistan meiofauna), Harpacticoida (copepods), and Nematoda (worms). Recent deep-sea foraminiferan biodiversity research has particularly focussed on the diverse and usually neglected soft-shelled species (e.g., allogromiids, saccamminids, and komokiaceans), the vast majority of which are new to science. Interestingly, many of the better-known calcareous species in these samples also occur in the Northern Hemisphere. For example, *Epistominella arctica,* which is fairly common on the Weddell Abyssal Plain, was first described from the Arctic Ocean. No obvious morphological differences have yet been found between specimens of *E. arctica* from the polar regions. The metazoan meiofauna of the Southern Ocean deep sea was little known below generic level. However, the few studies undertaken have revealed a high diversity with as many as forty genera present in individual samples. A similar situation has been observed for harpacticoid copepods, and several new species are currently being described. Data on the entire metazoan size fraction (32–1000 μm) from the South Sandwich Trench revealed unexpectedly high standing stocks, predominantly of nematodes. These were higher values than known for deep-sea areas of the other world oceans. In particular, the deepest trench sample (6300-m water depth) yielded unusually high meiofaunal abundances, despite apparently low food availability. It might be that turbidites are responsible for these findings in a very steep trough, which might serve as some sort of a "sink" for the animals.

Data on the macrofauna from the Southern Ocean deep sea have shown that, in very general terms, this faunal component is similar in composition at a higher taxonomic level to that of other deep-sea regions of the world oceans. Nevertheless, most of the macrofaunal species are new to science, and many of these are so rare that it will be difficult to describe them all. For example, Southern Ocean deep-sea Isopoda show a high degree of endemism, being almost as high as on the shelf (85%), probably due to the negligible sampling effort in the Southern Ocean deep sea in the past. From 317 species of Isopoda sampled during the recent Southern Ocean deep-sea expeditions (ANDEEP), 141 were only found at a single station, and sometimes represented by few specimens or even just one. Similarly, a further 79 species were only found at two stations and only 91 (of 317) at more than two stations. Interestingly, the percentage of Amphipoda was much higher than known for other deep-sea areas. By contrast, within the Polychaeta many more species seem to have crossed the barrier between the Southern Ocean and adjacent oceans, possibly due to the differences in biology. As far as we know, brooding is much less common among polychaetes, and larval dispersal might be a reason for the wide distributions observed. Data on reproductive stages of some species suggest that these are limited to abyssal depths and are also reproducing there, while other species with broader depth ranges may be receiving recruits from slope depths. The deep-water bivalve fauna of the Southern Ocean is poorly known; however, the fauna sampled during ANDEEP was species-rich, indicating a lack of decline in diversity with depth in Antarctic bivalves. Current bivalve species richness in Southern Ocean deep water is probably a major underestimate due to the paucity of sampling.

Underwater photography has demonstrated megafauna to be less diverse in the Southern Ocean deep sea, especially below 2300 m. Evidence to date suggests the most abundant taxa are Porifera, Mollusca, Echinodermata, and Brachiopoda. However, within all taxa new species are being discovered. There seem to be gradients in species composition within the Weddell Sea from west to east, with a higher species richness in the western Weddell Sea, as has been found in some of the macrofauna (e.g., the Peracarida).

Many more expeditions and sampling in remote and inaccessible areas will be necessary to improve our knowledge and understanding of Southern Ocean biodiversity and its functioning. The IPY (International Polar Year 2007–2008) offers a unique chance to fill in the gaps.

BIODIVERSITY, TERRESTRIAL

According to the Convention on Biological Diversity, biological diversity (or biodiversity) means the variability among living organisms from all sources, including *inter alia,* terrestrial, marine, and other aquatic ecosystems, and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems. There are a variety of other definitions of biodiversity, but this one has considerable importance because many countries have signed and ratified the Convention on Biological Diversity, which has as its objectives "The conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of the benefits arising from the utilization of genetic resources."

Although biodiversity includes all levels in the genealogical (genes to higher taxa) and ecological (individuals to ecosystems) hierarchies, there are significant relationships between various components of biodiversity. For example, strong relationships exist between numbers of species (richness) and numbers of higher taxa such as genera, families, and orders, between numbers of species and numbers of characters (or morphological features), and between numbers of species and the diversity of functional roles in an ecosystem that any one assemblage might have. Much present knowledge of biodiversity concerns patterns in species-richness variation across space and through time. Therefore, the relationships between species richness and other components of biodiversity mean that at least the fundamental patterns of this variation, if not the mechanisms underlying it, are reasonably well understood.

Spatial patterns in biodiversity are complex and three-dimensional. Species richness in marine, terrestrial, and freshwater systems varies with both latitude and longitude. Arguably the best-known pattern in species-richness variation is the latitudinal gradient in diversity, which encompasses a decline in richness from the tropics to the poles. It was first documented by Alexander von Humboldt (in 1804), and has been the subject of intense debate ever since. In marine and freshwater lake systems richness also varies with depth, whilst in terrestrial and freshwater stream systems, richness also changes with altitude. In virtually all cases, the gradients are neither linear nor symmetric, but show substantial variation depending on the region, the system (marine, freshwater, terrestrial), and the organisms of interest.

Ultimately, the species richness of an area depends on four main processes: speciation, extinction, immigration, and emigration. The relative importance of these processes depends on both the spatial and temporal scale of interest. More proximate determinants of richness variation include available energy (e.g., coming in as infrared, visible, and UV radiation, and often measured as temperature or net primary productivity), area (larger areas have more species for a variety of reasons), evolutionary rates (faster life cycles and high-energy environments lead to more speciation), and the effects of history of an area, which might substantially influence present diversity. The proximate determinants also include a null model, which posits that because of the constraints of a bounded domain, richness must be highest in its centre, so accounting for tropical peaks in richness.

From a terrestrial and freshwater perspective, the low-energy environment and isolation of Antarctica mean that it is species poor. Indeed, terrestrial and freshwater systems of Antarctica represent the end-point of the global cline in diversity. Where life can exist, richness is typically low, and continental Antarctic systems represent some of the simplest in the world. For example, some endolithic communities are restricted to a few species of algae, fungi, and bacteria. In Ellsworth Land (75°–77° S) the simplest faunal system comprises five tardigrade and two rotifer species. Even the nematode worms, which are known from harsh, poor environments such as the Dry Valleys, are absent here. In lakes the systems are dominated by phytoplankton and the microbial loop, with few invertebrates and no fish. Nonetheless, gradients in diversity exist on the continent in terrestrial and freshwater systems and are especially pronounced along the Antarctic Peninsula. The sharp distinction between the biotas of the peninsula and the continental Antarctic is also an important terrestrial biogeographic feature, with the peninsula biota typically representing more recent colonists and that of the continental sites including several Gondwana relics. Richness variation in continental Antarctica is spatially complex, reflecting regional and local variation in conditions as much as it does the increasingly low energy and isolated environment towards the pole. This variation is poorly understood owing to limited sampling in many areas, especially of the East Antarctic. Nonetheless, it is apparent that in many groups the species are wholly endemic (i.e., restricted to the region) to Antarctica (nematode worms) or nearly so.

Although the terrestrial and freshwater environments are species poor, the species often occupy environments that are otherwise not utilized elsewhere, show a range of remarkable strategies for overcoming Antarctic environmental challenges, and inhabit ecosystems which are often dominated by groups which are less noticeable elsewhere on the planet. For example, molecular techniques are now starting to reveal that the diversity of microbes in the Antarctic is complex and rich. Just how diverse it is by comparison with other systems is difficult to ascertain given that the techniques used for studying such diversity are novel. However, it seems likely that the microbes of Antarctica will prove to be extraordinary from a variety of perspectives. In the case of another group, the algae, the diversity of lifestyles is remarkable, including species which live within rocks with no obvious connection to the outside, as well as those that occupy small, seasonally liquid depressions on the surface of glaciers. In lakes, many protozoan species are mixotrophic such that they can alternate between particulate feeding and photosynthesis. In the most southerly lakes, these species are dominant and feed on bacteria during the winter and produce energy by photosynthesis during the summer.

Terrestrial and freshwater diversity increases rapidly from the maritime Antarctic to the sub-Antarctic islands. On the latter, variation in richness is comparatively well understood, especially in the case of vascular plants and insects, and to some extent in the bryophytes. Although the ways in which species have come to be present on the islands has been a controversial topic, there is increasing evidence for the importance of dispersal by wind, especially for the bryophytes and for some of the insects. Vicariance (or the presence of the species on a landmass as a consequence of its connection once to another landmass) is also though to be important for some groups. Richness variation of the indigenous vascular plants and insects is a consequence of energy availability, island area, and to a lesser extent isolation. The differential effects of glaciation, once though to be important for this variation, are less significant than variation in available energy. Thus, the largest and most northerly islands generally have the highest plant and insect species richness.

In marine systems the picture is much more complex. The biogeography of the region is influenced by the oceanic fronts, such that pelagic plankton can be divided into Antarctic, sub-Antarctic, and sub-Tropical assemblages. However, species-richness gradients are not straightforward. In some groups, such as the decapod and stomatopod crustaceans and bivalves, richness is low, and brachyuran crabs (i.e., typical crabs) are entirely absent from the region. However, in others there seems to be almost no decline in Antarctic waters (or a converse pattern). Thus, the pycnogonids (sea spiders), echinoderms (sea urchins and their relatives), and polychaetes (segmented worms) are especially rich in the Antarctic region. Indeed, in the case of the sea spiders the Antarctic region may be the area of highest richness globally. Other groups, such as the notothenioid fish, have also diversified dramatically in the Antarctic. Although the Antarctic fish fauna is notably species poor, this is not true of the notothenioids. Of the 174 benthic or demersal fish species known from the Southern Ocean, 55% are notothenioids, and these fish commonly represent more than 90% of the individuals collected. The group has undergone a remarkable adaptive radiation in shallow water around Antarctica and dispersal through the Polar Front has resulted in divergence of other sub-Antarctic notothenioid species. These fish are endemic to the Antarctic region, although recently a Patagonian toothfish was discovered off Greenland, lending support to the idea that transequatorial dispersal events can take place in deep, cold water.

Although the distribution of benthic and pelagic diversity across the Southern Ocean is poorly understood for most groups owing to the paucity of information, especially for the East Antarctic, one group is especially well known. The seabirds, which are essentially pelagic species that return to land to breed, have been well documented both in terms of their breeding populations and their at-sea distributions. Species richness peaks in the vicinity of the Polar Front, and globally the proximate determinants of this richness are primary productivity, sea-surface temperature, wind speed, and to a lesser extent the accessibility of breeding sites. The majority of these variables reflect the overwhelming importance of energy availability in determining richness of this pelagic group of animals.

In terms of functioning, terrestrial ecosystems are influenced predominantly by temperature and water availability, though nutrient availability is also important. Both human (cloche-type enclosures) and natural (heated-ground) experiments have demonstrated the influence of temperature and water availability on the identity and abundance of species in Antarctic habitats. Terrestrial systems are dominated by particulate feeding and detritivorous heterotrophs, and one or two species are most abundant at a given site. Predation is not uncommon, but it is rarer than elsewhere, and parasitism is infrequent. Functional roles typical of warmer climates, such as pollination, are poorly represented in the Antarctic. In freshwater ecosystems, food webs tend to be simple, and connections may span several levels. Marine systems in the Southern Ocean are complex and incorporate a wide range of ecological processes, ranging from disturbance such as ice scour in shallow-water environments to considerable trophic complexity associated with pelagic top predators such as whales, seals, and penguins. The sea-ice environment plays an especially important role in ecosystem dynamics in the Southern Ocean, and recent changes to sea ice are having far-reaching biodiversity consequences. Genomic studies are proving instrumental in unravelling survival strategies and ecological interactions in marine and terrestrial systems.

Antarctica was not always glaciated. Indeed, the first continental ice sheets appeared in Antarctica about 34 Ma. In consequence, the fact that Antarctica supported a diverse terrestrial biota, including plants, insects, and even dinosaurs is not surprising. However, the extent of this fossil biota is only beginning to be explored, and remains poorly known for many groups. For example, the first Cretaceous fossil that can definitely be placed within the modern bird radiation hails from Antarctica. From about 10 Ma, Antarctic ice sheets were substantial and well established, and would have extirpated the bulk of the terrestrial and freshwater biotas, though some terrestrial relict species remain. Orbital forcing is thought to have driven expansion and contraction of the Antarctic ice sheet, so periodically covering and exposing continental shelf habitat in the sea surrounding Antarctica. These changes are likely to have subdivided populations and caused substantial changes to their ranges, promoting speciation. This mechanism is thought to be one of the causes of high diversity in several Antarctic marine groups.

Subsequent to the development of the Antarctic Circumpolar Current, the continent has remained relatively isolated. However, this isolation is not complete and organisms have migrated both into and out of the region. Aeolian (wind) transport of propagules (cysts, eggs, larvae, seeds, spores, plant parts) from South America to the Peninsula region are not uncommon, especially under stormy weather conditions, and kelp rafts (and more recently floating plastic debris) may form another source of transport of colonists across the Southern Ocean. In addition, a wide range of pelagic mammal and seabird species regularly migrate into and out of the region, so overcoming the isolation barrier. However, even for those propagules that can cross the barriers which separate Antarctica from the other continents, the low temperature and low productivity environment (in the winter in marine systems) represent a significant challenge to establishment and survival.

More recently, the routes for colonization have increased substantially thanks to human traffic to Antarctica, first by ship and now by aircraft too. Thus, humans have introduced a wide range of alien, and in many cases invasive, species to Antarctica and the sub-Antarctic islands. These include microbes (and the diseases they cause in some cases), algae, fungi, bryophytes, vascular plants, invertebrates, fish, birds, and mammals. These species have come to survive, and in some cases dominate, terrestrial, freshwater, and marine habitats, in some regions causing considerable damage by way of species extirpations and wholesale alteration of ecosystems. On the sub-Antarctic islands the effects of invasive species are well known. For example, rats and cats have caused the disappearance of seabird species from several islands, whilst eradication of the alien species has seen the return of the birds. Alien plants reduce local diversity by as much as 40%, and invasive rodents have caused wholesale alterations to ecosystem functioning. The indirect effects of species such as insects, mice, reindeer, and salmonid fish are only beginning to be appreciated. Alien species arrive in a multitude of ways: in clothing and personal baggage, attached to fresh vegetables, in vehicles, affixed to the hulls of ships and inflatable rubber boats, and as unwanted passengers on anchor chains, in sea chests, and in ballast water.

Across the Southern Ocean islands there is a strong relationship between the numbers of humans that visit an island and the numbers of species that have successfully been introduced to an island. This relationship between visitor frequency and numbers of alien and invasive species has been established elsewhere and seems to be a general rule. Moreover, there is also a strong relationship between energy availability and numbers of alien species on the Southern Ocean Islands, suggesting not only that warmer islands are more at risk, but also that climatic amelioration is likely to enhance the risks of invasion.

Recent increases in human activity in the Antarctic have been considerable. For example, in the 2001–2002 season, Treaty nations deployed 4390 personnel at 67 stations or field camps in Antarctica. They also made use of some sixty ships, departing from about thirty cities around the world, to offload personnel and cargo. Tourist numbers doubled from approximately 6000 in 1992 to about 13,600 10 years later, most of whom visited the Peninsula region. From 1996 to 2006, the numbers of ships and passengers visiting South Georgia have increased threefold to fourfold. In 2001–2002, nearly 7000 people visited a single site: Whalers Bay, Deception Island.

Moreover, in the Peninsula Region, and at many sub-Antarctic sites, climates have warmed dramatically over the past 50 years, making these environments more benign than they once were. Thus, both the isolation and the climatic barriers that long meant low colonization rates of Antarctica are being influenced by human activities. In consequence, the chances of successful colonization of the Antarctic by alien species are likely to increase substantially unless appropriate mitigation measures are put in place. In this instance, prevention is more economically viable than eradication programmes, which are usually expensive and often long-term.

Although the Convention on Biological Diversity calls for the conservation of biodiversity via a variety of measures, including the prevention of invasion and/or eradication of alien species, it does not apply to the Antarctic Treaty area. However, it does apply to the sub-Antarctic islands that have been annexed by those nations which have ratified the Convention. Many sub-Antarctic islands are managed as IUCN Category 1 Nature Reserves. Nonetheless, the conservation regulations at the islands vary widely, from extremely strict (e.g., no tourism, no fresh produce ashore at the Prince Edward Islands) to much less demanding (e.g., Îles Kerguelen and South Georgia). A formal, spatially explicit conservation assessment of the Southern Ocean islands has shown that by strictly conserving 15 of the Southern Ocean Islands, 90% of species richness can be captured, whilst only 50% of the alien species are included. Unfortunately, the generally strong relationship between alien and indigenous species richness means that some level of the latter will always be included. Moreover, planning for the biodiversity effects of climate change is made difficult both by the high levels of endemism in the region and by the likelihood that climate change will favour alien over indigenous species. Nonetheless, the formal analysis demonstrated that using spatially explicit data and modern analytical methods provides a more robust approach than expert consultation, which in this particular case rarely proved better than simply picking islands at random.

In the Treaty Area, the conservation of biodiversity is undertaken by the Antarctic Treaty Consultative Parties under the auspices of the Committee for Environmental Protection, established under the Protocol on Environmental Protection to the Antarctic Treaty. Conservation is also facilitated by other organs of the Treaty system, such as the Convention for the Conservation of Antarctic Seals and the Convention for the Conservation of Antarctic Marine Living Resources. Whilst there are a wide range of measures in place for the conservation and sustainable use of biodiversity in the region, rational, spatially explicit conservation planning, which has been undertaken for many other parts of the globe, lags far behind in the Antarctic. In some cases, such as for marine benthic and pelagic diversity, this is a consequence of data deficiency, and only a sustained survey effort is likely to alter the situation. However, there are spatially explicit data for some groups, such as the seabirds and increasingly the seals, and much local-scale data on terrestrial biodiversity is available as a consequence of the requirements for the establishment of Antarctic Specially Protected Areas (ASPAs) and Antarctic Specially Managed Areas (ASMAs). However, these data have yet to be used to develop a formal, spatially explicit conservation planning framework for Antarctica. If the biodiversity of the region is to be conserved and used in a sustainable manner, then such a framework, which incorporates the likely substantial changes that will be wrought to marine, freshwater, and terrestrial systems by climate change and the patterns of human use of the region, is urgently required.

BIOGEOCHEMISTRY, TERRESTRIAL

Biogeochemistry is the study of cycling of the biologically essential elements, principally: carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur. In terrestrial Antarctica, biogeochemical cycling is controlled by the extreme climate, limited biodiversity, and biological activity, and by ecological "legacies" that influence the spatial distribution and availability of resources necessary to support life: water, organic matter, and inorganic nutrients. An ecological legacy is a carry-over effect or influence of past climates, geological events, or previous biological activity that is imprinted on the contemporary ecosystem. Examples of legacies that affect terrestrial ecosystems include paleolake sediments, glacial tills, and avian colonies. The consideration of legacies is vital to understanding the biogeochemistry of terrestrial Antarctic soils and neighboring ecosystems such as streams, lakes, and glaciers.

Carbon is the most fundamental of the biogeochemical cycles. Extreme climate limits photosynthesis (carbon fixation) by plants, lichens, and algae and by chemautotrophic bacteria, and as a result, Antarctic soils have among the lowest organic carbon concentrations found in terrestrial ecosystems. Sources of organic carbon include lake sediments, algal mats, and mosses in saturated soils adjacent to streams and lakes, avian rookeries, rock-dwelling lichens, and endolithic microbial communities, and higher plant communities on the Antarctic Peninsula. The chemical and isotopic signatures of carbon and nitrogen in the McMurdo Dry Valley soils indicate that the deposition of carbon-rich paleolake sediments formed under previous climates accounts for much of the organic matter supporting current biogeochemical activity. Rates of carbon cycling, measured as carbon dioxide (CO_2) flux from soils, are among the lowest reported anywhere in the world.

While carbon is limiting to terrestrial food webs in many Antarctic ecosystems, other elements such as nitrogen and phosphorus are often in high supply, resulting in elemental ratios that differ from the theoretical proportions necessary for biological metabolism and balanced growth. Controls over the accumulation and biogeochemical cycling of nitrogen, phosphorus, and trace element constituents of salts and marine aerosols (e.g., sulfur, potassium, calcium, and sodium) are influenced by the proximity of marine sources, soil age, the amount of mineral weathering, and the ecological legacies of the landscape. High-elevation, ice-free regions in continental Antarctica are some of the oldest continually exposed surfaces on the planet with high salt concentrations from the long depositional history and negligible rates of soil leaching. Nitrate (NO_3), usually found in very low amounts in productive ecosystems, can reach concentrations as high as 3% of soil weight, resulting from low rates of atmospheric deposition over millennia and very low rates of biological cycling.

Antarctic terrestrial ecosystems maintain small amounts of organic matter, with very slow rates of biogeochemical cycling that may be sensitive to subtle shifts in climate. Biogeochemical cycling in Antarctic ecosystems is highly dependent on ecological legacies, is limited by the low biotic potential of the environment, and is constrained by the availability of liquid water. Small variations in climate from natural or anthropogenic change influence the availability of liquid water and may significantly alter the balance between physical and biological controls over the biogeochemistry of this sensitive landscape.

BIOGEOGRAPHY

Biogeography is the study of biological distributions at geographical scales. At a very simple level, biogeographical data allow us to know "what occurs where," thereby quickly becoming linked with studies of biodiversity. Descriptions of biogeography are fundamental to any attempt to understand the wider evolutionary relationships of and between the biota and biology of different regions of the Earth. Biogeographical patterns can also provide considerable insight to nonbiological disciplines, such as in the reconstruction of geological (tectonic) relationships, or of glacial history.

Biogeography clearly has a fundamental reliance on the quality of taxonomic knowledge available or, in other words, the ability to identify distinct taxonomic units. Until recent years, taxonomy was based on traditional morphological approaches to the description of species. With the advent of molecular biological approaches, and in particular the use of complex and demanding computing resources to allow the construction of molecular phylogenies, a second and parallel approach has become available to researchers. However, while the two approaches often produce similar results, this is not always the case, leading to areas of contention that are still to be resolved. Molecular phylogenetic approaches have the potential to identify speciation events in situations where morphological differentiation through traditional approaches is not possible (e.g., "cryptic speciation"), and also in the earlier stages of differentiation that must occur within a species and that underlie later speciation. Again, this has led to further and largely unresolved philosophical debate over how to define a species—not least as most classical and molecular phylogenetic studies are not linked to autecological knowledge of the living taxa concerned, while the level of differentiation (if any) required for taxonomic definition, and whether this can be generalised across species and higher taxa, is also far from clear. Molecular approaches are also starting to be applied to groups of microbiota, the dominant biota across much of Antarctica, where classical approaches are largely redundant and existing data very inadequate. Finally, the potential of "molecular clock genes" (highly conserved genes with predictable sequence-mutation rates) is starting to be applied in Antarctic studies, although here it is important to note that it is often not possible with the very limited fossil record, particularly for invertebrate and microbial groups, to provide an independent constraint on the dating of separation events.

The terrestrial biota of the Antarctic exists in a clearly defined element of the globe, more isolated (by physical scale and environmental extremes) from external contact than any other continental landmass. The study of the biogeography of Antarctic terrestrial biota provides clear potential for the identification of ancient evolutionary linkages with other Southern Hemisphere continents and of intraregional evolutionary processes, including signals of geological and glaciological history, as well as for the understanding of regional and global colonisation processes.

In Antarctica 99.5% of the continental area is covered permanently by snow or ice. Ice-free ecosystems include nunataks, cliffs, and areas exposed seasonally to snow and ice cover. Terrestrial habitats are more extensive, and their exposure is of longer duration, on the oceanic sub-Antarctic islands surrounding the continent. On the continent and Antarctic Peninsula, most ice-free areas are inevitably small in extent and isolated from their nearest neighbours by distances of tens to hundreds of kilometers. Antarctica as an entity is isolated from the other southern continents by the Drake Passage south of Tierra del Fuego (1000 km), and by 4000–5000 km from Australia and South Africa.

In the context of geological history and evolution, Antarctica was a section of the Gondwanan supercontinent. As Gondwana broke up, Antarctica's last continental links were with Australia and South America. The final loss of the Antarctic Peninsula–South America link, through the formation of the Drake Passage, took place 50–30 Ma. This event was fundamental in the climatic evolution of Antarctica, as it allowed the development of circum-Antarctic oceanic and atmospheric circulation patterns that effectively cut the continent off from lower latitudes, allowing continental cooling to commence. However, even though lying at high southern latitude throughout this period, Antarctica was not initially glaciated and fossil evidence clearly indicates a cool temperate fauna and flora closely similar to those then present in South America and Australia/

Dominant Biotic Components of Typical Ecosystems of the Three Antarctic Biogeographical Zones

Zone	Flora	Fauna	Microbiota
Sub	Low altitude/coastal: flowering plants (phanerogams), ferns, bryophytes, lichens (cryptogams); higher altitude/inland: open fellfield (similar to maritime zone); nonindigenous introductions	Arthropods (largely Insecta); micro-arthropods (Acari, Collembola); micro-invertebrates (Nematoda, Tardigrada, Rotifera); alien vertebrates and invertebrates	Various groups, poorly documented in detail
Maritime	Two flowering plants, limited distribution; closed and open fellfield cryptogam communities	Diptera very limited; micro-arthropods (Acari, Collembola); micro-invertebrates (Nematoda, Tardigrada, Rotifera)	Algal and cyanobacterial mats; foliose algae; protozoa
Continental	Bryophytes and lichens, more limited extent than in maritime zone	Micro-invertebrates; micro-arthropods (Acari, Collembola) more limited	Algal and cyanobacterial mats; protozoa; endolithic fungi, algae, cyanobacteria

Modified from Convey 2001.

New Zealand. Even after the commencement of glaciation, ice extent and distribution has varied widely over time, with evidence of warmer periods as recently as 8–10 million years ago that were again sufficient for the development of areas of cool temperate *Nothofagus* forest.

When the sub-Antarctic is included, Antarctic terrestrial environments can be characterised as including all exposed ground south of approximately 50° latitude. Not unsurprisingly in such a large area, a wide range of terrestrial ecosystems is present and several systems of classification have been proposed. In recent years, most commonly three biogeographical zones are recognized, the sub-Antarctic, maritime Antarctic, and continental (or frigid) Antarctic. The terrestrial ecosystems and climatic characteristics of the three zones are distinctively different.

The sub-Antarctic zone includes a series of isolated islands and groups lying at high latitudes in the Southern Ocean. Apart from South Georgia, Heard Island, and the McDonald Islands, these are located close to or north of the oceanic Polar Frontal Zone. The term "sub-Antarctic" has also been used in a wider sense in some publications to include some more northern island groups that are better described as "oceanic cold temperate," including the Falkland Islands, Gough Island, Île Amsterdam, and the New Zealand shelf islands. Sub-Antarctic island climates are strongly influenced by the surrounding ocean, which restricts temperature variation (mean monthly temperatures are positive for 6–12 months of the year), while the islands are generally not influenced by seasonal pack or fast ice.

The maritime Antarctic includes the western coast of the Antarctic Peninsula as far south as southern Alexander Island (around 72° S), the archipelagoes of the South Shetland, the South Orkney and South Sandwich Islands, and the isolated islands of Bouvetøya and Peter I Øy. It is important to note that the Antarctic Peninsula element, which includes neither the central mountainous spine and the eastern coastal regions nor the basal portion of the peninsula including Ellsworth Land, does not equate to the geological region of West Antarctica. Like the sub-Antarctic, the maritime region also experiences an oceanic influence on its climate, especially during the austral summer period after the loss of any winter sea ice. The South Sandwich Islands and Bouvetøya are exceptional, as they are geologically young (1- to 3-million-year-old) volcanic islands that continue to experience geothermal activity, and they possess unique biological communities associated with heated ground. Air temperatures in the maritime Antarctic are positive (but <2°C) for 1–4 months of the year, while winter mean temperatures are also buffered by the surrounding ocean, and short thaws may occur throughout the winter.

The final zone, the continental Antarctic, is by far the largest in areal extent and includes all of East (or Greater) Antarctica, the Balleny Islands, and the eastern side of the Antarctic Peninsula. Terrestrial habitats here are typically of limited extent and great isolation, and include areas of coastal exposure comparable with those of much of the maritime zone, and inland nunataks and mountain ranges. One particular exception to this generalisation is the extensive (about 4000 km^2) ice-free cold desert region of the Victoria Land Dry Valleys. Temperature regimes experienced even in coastal areas of the continental zone are more extreme, with positive mean air temperatures achieved for <1 month of the year. Inland, positive air temperatures may never be seen, while winter minima drop regularly to –60°C or below. Microhabitat temperatures (i.e., where the biota actually live) do not necessarily track air temperatures, and continental habitats with no winter snow protection are likely to be exposed directly to winter air temperature extremes. Conversely, during the short summer, even at the most southern locations with exposed ground or rock (nunataks and mountain ranges at 84–87° S), absorption of solar energy by rock and soil substrata is sufficient to lead to melting and the release of liquid water to temporary streams, pools, and lakes.

Climatic and environmental factors are important determinants of the biota that can exist in any given location. In the Antarctic, seasonal snow and ice cover, which provides a buffer to extreme low temperatures, rapid temperature fluctuation, and wind/ice abrasion, is one such factor. This affects all three zones, but is particularly significant in the maritime and continental Antarctic, where habitats may become free of snow for as little as a few weeks to months, and occasionally not at all in the continental zone. In contrast, most sub-Antarctic islands experience only intermittent snow cover. At the lower altitudes near the coast, microhabitat temperatures often remain positive or only just below the freezing point, and this is sufficient to allow continuous invertebrate activity.

Soils are another component of the environment with a potentially significant influence on levels of biodiversity achieved and on distributional limits. Most Antarctic soils are poorly developed, with low organic content. Brown soils are present only where more extensive communities of higher (flowering) plants have become established, and are thus better represented in the sub-Antarctic, with very limited occurrence in the maritime and none in the continental zones. Moss peat deposits are distributed in a similar pattern, while also a source of strong evidence

Estimates of Biodiversity of Native Terrestrial Invertebrate and Plant Taxa in the Three Antarctic Biogeographical Zones

Group	Sub-Antarctic	Maritime Antarctic	Continental Antarctic
Protozoa*	83	83	33
Rotifera*	ND	ND	13
Tardigrada	>29	26	20
Nematoda*	22	40	10
Annelida (Oligochaeta)	23	3	0
Mollusca	5	0	0
Crustacea (terrestrial)	6	0	0
Crustacea (nonmarine but including meromictic lakes)	48	11	11
Insecta			
Collembola	>100	10	10
Mallophaga	61	25	34
Diptera	44	2	0
Coleoptera	40	0	0
Arachnida			
Araneida	20	0	0
Acarina	140	36	29
Myriapoda	3	0	0
Flowering plants	60	2	0
Ferns and clubmosses	16	0	0
Mosses	250	100	25
Liverworts	85	25	1
Lichens	250	250	150
Macrofungi*	70	30	0

ND, number of representatives of group unknown.
*Large changes likely with future research due to current lack of sampling coverage, expertise, and/or synonymy.

(through radiocarbon dating) that extensive plant colonisation only occurred in the sub-Antarctic and maritime Antarctic in concert with post-Pleistocene glacial retreat. A further important factor in consideration of soil properties is the existence of widespread permafrost in the maritime and continental zones and more limited permafrost in the sub-Antarctic. This, in combination with periglacial cryoturbation processes, means that Antarctic soils are particularly unstable and mobile, affecting their availability to biota during the processes of colonisation and establishment.

Of the groups of biota represented in Antarctica, terrestrial vertebrates form an exceptionally small component in comparison with any other continental region, and the few that are found are limited to the sub-Antarctic. These are all birds (one passerine and two ducks; two scavenging sheathbills are also associated with the presence of marine mammals and birds), and there are no indigenous land mammals, reptiles, or amphibians. The sub-Antarctic in particular, but also coastal regions of the maritime and continental zones and even multiyear coastal fast ice, are home to globally significant populations of seabirds and mammals, and these can have a considerable impact on their local terrestrial habitats through manuring, aerosol transport of nutrients, and direct trampling.

At a large geographical scale and coincident with the environmental gradient of increasing severity between the sub-Antarctic and continental Antarctic, there are generally recognised gradients of decreasing biodiversity and community complexity, as well as progressive loss of evolutionarily more advanced groups. A range of "higher" arthropod groups is found in the sub-Antarctic, although even here diversity at higher taxonomic levels remains very limited—for instance, the majority of insects are drawn from Diptera (flies) and Coleoptera (beetles). Although detailed inventories for some taxonomic groups have been prepared at some sub-Antarctic islands, and it is known that diverse micro-arthropod (Acari, Collembola) and micro-invertebrate (Nematoda, Tardigrada, Rotifera) communities are present, surprisingly little research effort has been devoted to these groups across the entire zone, and little concrete information can be concluded about their biogeography.

Similarly, the sub-Antarctic flora is the richest of the three zones. Both phanerogams (flowering plants) and cryptogams (ferns, mosses, liverworts) are found, although, with a single exception on Macquarie Island, woody trees and shrubs are absent. The indigenous species have strong affinities with either southern South America or Australia/New Zealand. These floras appear to be very vulnerable to the impacts of invading or introduced nonindigenous species, most of which result from human activity. This may take the form of either grazing pressure from introduced mammals and invertebrates or direct competition and displacement by introduced weeds, and can result in the complete loss, currently at a local scale, of native plant (and, presumably, associated invertebrate) communities. On some sub-Antarctic islands the environmental conditions, including the lack of native grazers, have encouraged the development of a vegetation dominated by megaherbs (large rosette-forming plants) and tall tussock grasses.

Maritime Antarctic faunas are considerably less diverse than those of the sub-Antarctic, at both species and higher taxonomic levels. Higher insects are reduced to two chironomid midges (Diptera). The most common arthropods are mites (Acari) and springtails (Collembola). Micro-invertebrate groups are again well represented, although, as is typical of many Antarctic terrestrial biota, research coverage is very patchy and generally limited to specific sites visited by a small number of specialists. Faunal communities are species-poor—for instance, it is rare for more than about twenty species of arthropod to be known from any location, of which only a handful will be encountered in a cursory survey—but abundance or population density can be comparable to or greater than that seen in temperate ecosystems. Community trophic structure is very simple. The majority of invertebrates are thought to be microbivores and/or detritivores (although few specific feeding studies have been attempted), and predation is rare. For instance, the largest terrestrial predators in the maritime Antarctic are species of prostigmatid and mesostigmatid mite, of which at most two are present at any given location, and even these are often not obtained in many collected samples. True herbivory is unusual, possibly as a result of energetic constraints, although it is also generally the case worldwide that bryophytes and lichens (the dominant maritime Antarctic vegetation) are not selected by herbivores.

Vegetation over much of the maritime Antarctic is often described as "fellfield," with scree, boulder fields, and simple soils colonised by a range of cryptogamic vegetation (mosses, liverworts, lichens). In particularly favourable locations closed cryptogam communities are present, in some cases allowing the formation of layers of moss peat. Two higher plants, the hairgrass *Deschampsia antarctica* and the pearlwort *Colobanthus quitensis,* are also often present in these richer sites, and they are the only higher plants found on the Antarctic continent. As with the majority of the bryophytes, these two plants have South American distributions extending well outside the confines of Antarctica, in this case northwards along the Andean mountain chain. Cryptogamic vegetation is sensitive to physical disturbance, which, in the maritime Antarctic, takes the form of trampling from penguins and seals near their breeding colonies or resting sites. Here, vegetation is often either nonexistent or dominated by the foliose alga *Prasiola crispa*.

In terms of the groups represented, the terrestrial fauna of the continental Antarctic is similar to that of the maritime zone, except that the higher insects are lost, and most micro-arthropods have much more restricted distribution. Throughout most continental Antarctic terrestrial habitats, soil meiofauna are dominant. These faunal communities are recognised as amongst the simplest on the planet, with some large areas even lacking the nematode worms, a group that is otherwise ubiquitous worldwide. Even these simple communities do include predatory species of nematode or tardigrade. Likewise, continental Antarctic vegetation is similar in composition to that of the maritime zone, except that no phanerogams are present, bryophytes are much more restricted in diversity and spatial extent, and lichens become dominant.

In comparison with the level of knowledge available for macrobiota, and allowing the previously mentioned caveat of biases towards a limited number of detailed sampling areas, as well as the work of the small number of specialists, the level of biogeographical or even simply biodiversity data available for most microbial groups is minimal. Microbial autotrophs are recognised as fundamental to polar terrestrial ecosystem processes, being the primary colonists and sometimes the only biota present. Microbes such as fungi, algae, and cyanobacteria also play a central role in the stabilization of mineral soils, a key prerequisite for secondary colonization and subsequent community development involving other microbiota and macrobiota.

Microbes are found in all of the habitats also occupied by macroscopic faunal and floral communities—in or associated with soils, rocks, and vegetation. Fungi, algae, and cyanobacteria are often visible as filaments or mats, often associated with water bodies or damp soils. Microbial communities are well represented in all three zones, becoming visually more obvious as macroscopic groups decline in the maritime zone and often forming the climax community in the continental zone. However, and unlike representatives of most other groups, microbial communities are also present in cryophilic habitats such as snow (a small number of metazoans, notably tardigrades and some protozoans, are also found in communities in small melt holes, cryoconites, in glacier surfaces). Endolithic microbial communities are also found within the surface layers of rock matrix, particularly associated with certain types of sandstone and relatively clear minerals such as gypsum. The latter habitats in the cold desert environments of the continental Antarctic may represent one limit to biological existence on Earth.

At first sight, there is an extensive literature pertaining to the general subject of Antarctic terrestrial diversity and biogeography. Current estimates for levels of diversity in the major groups of animals and plants represented in the three zones are summarised in the second table in this entry. However, in attempting to identify overall biogeographical patterns and compare between the three zones, two fundamental problems remain even for the visible macroscopic groups. First, sampling coverage is poor at best and completely inadequate at worst—for all groups, many locations remain to be visited, while for some groups current knowledge relies on data from a very few or even single sites, with virtually no targeted collections or visits by trained specialists. Second, taxonomic uncertainty (e.g., synonymy, undescribed species, unrecognised cryptic speciation) is present to some extent in all groups encountered.

These factors negate any possibility, at present, of rigorous biogeographical analyses' being applied to any microbial groups. Molecular biological approaches to the taxonomy of prokaryotic and eukaryotic microbiota give the promise of an imminent acceleration in the level of data available, although in both cases only a tiny fraction of diversity (global or Antarctic) has been described, or even simply recognised, to date. These molecular approaches are expected to allow the testing of a currently popular biogeographical hypothesis in Antarctica: the "global ubiquity hypothesis" essentially postulates that, since many microbial groups are extremely effective dispersers through their small size and possession of resistance adaptations, there should be more evidence of ubiquitous microbial distributions (or, at least, dispersal) than is the case for larger organisms. As yet, the evidence available is conflicting—on the one hand, based on classical approaches, it has been suggested that many Antarctic algae and fungi represent cosmopolitan taxa, whilst on the other, recent molecular analyses indicate considerable isolation and lack of exchange between different communities in similar habitats over very large geographical transects.

In contrast with the lack of microbial data, large-scale biogeographical patterns clearly exist in at least some macrobiota. Recent analyses of patterns across the islands of the Southern Ocean, including those of the sub-Antarctic and maritime Antarctic, have identified an overriding importance of wind dispersal in linking the biotas of different island groups and the southern continents, and a range of factors (including climate, area, vegetation type, human occupancy) as having explanatory value for the richness of specific groups within a given island or island group. However, other than demonstration of the frequency of occurrence of aerial dispersal events to a single maritime site, studies of this type have yet to be extended to the mainland of the Antarctic Peninsula (i.e., the remainder of the maritime Antarctic) or the continental Antarctic.

With reference to the maritime and continental zones, contemporary thinking is undergoing some rapid development. Since the studies of J. L. Gressitt and coworkers in the 1960s, it has been recognised that elements of the Antarctic terrestrial biota can (and most likely did) have two separate origins—an ancient and relictual element that has managed to survive through the extremes of glaciation, and a more recent colonist element, likely to have arrived in the Antarctic following the ice retreat from Pleistocene glacial maxima. However, most terrestrial biota in all three zones, but especially the sub-Antarctic and maritime Antarctic, are found in coastal, low-altitude areas. They seem unlikely to have survived glaciation in these sites (which would have been overrun by ice, at least in the maritime Antarctic and on the colder sub-Antarctic islands) or on higher-altitude nunataks, and their presence has been interpreted as evidence of post-glacial colonization from refugia on Southern Ocean islands or continentals. This is problematic because, as yet, no island or continental refugia can be identified with confidence. In continental Antarctica, some nunataks and other ice-free areas are proven to have survived Pleistocene glaciation, and analyses of their faunal communities is interpreted as showing evidence for a relict fauna predating the onset of Antarctic glaciation, and even giving indicators of the breakup of Gondwana itself.

The "recent dispersal" viewpoint is also inconsistent with evidence from patterns of endemism in some groups across Antarctica. Levels of endemism differ between the major taxonomic groupings represented, from the mosses where virtually all species present in Antarctica have wider non-Antarctic distributions, to the nematode worms, where possibly none are known outside Antarctica. For some groups, such as nematodes, mites, and springtails, there is also a clear and striking lack of overlap at species level between the different zones (particularly the maritime and continental Antarctic). Using lichens as an example, it is also the case that the Antarctic continent may provide a significant source of propagules dispersing northwards to lower latitudes—approximately 40% of the lichen flora of the geologically young and geographically isolated South Sandwich Islands are identified as species otherwise known only from more southern Antarctic locations. Most recently, molecular biological techniques have been used to illustrate the process of radiation and local colonisation from a regional centre in springtails from Victoria Land (continental Antarctica), and to propose the continuous existence of ancestral lines of endemic chironomid midges (Diptera) over tens of millions of years on the western Antarctic Peninsula (maritime Antarctic) and South Georgia (sub-Antarctic).

Finally, it is rapidly becoming clear that human activities pose perhaps currently the greatest single threat to the biogeographical integrity of Antarctica. First, as noted, humans already have a direct impact on regional biogeography through the import and release (historically, often deliberate, though today largely accidental) of nonindigenous species, with the sub-Antarctic being particularly vulnerable. As yet there are few research and monitoring programmes directed towards nonindigenous species in place. Available data indicate that the establishment of visible nonindigenous species of plant and animal (vertebrate and invertebrate) is reasonably well documented, but that the same cannot be claimed for any groups of microbiota. Second, human activity is expected to have a pervasive influence on regional biota through a crucial indirect route. Anthropogenic climate change is being experienced across the planet but, in some parts of the maritime and sub-Antarctic, this is occurring at the fastest rates recorded anywhere. In a purely Antarctic context, such change may simply relax the currently extreme environmental constraints acting on the physiology and ecology of native invertebrates and plants, and in these cases it can be interpreted as advantageous in the sense of accelerating growth and the life cycle. However, contemporary climate change is also expected to lower the barriers currently facing potential colonist organisms, thereby increasing the chance of survival of long-distance transport to the region, and the likelihood of successful establishment on arrival, with or without direct human assistance.

BIOINDICATORS

Bioindication is the use of one or more species to identify, or demonstrate the impact of, a human-induced change in the abiotic or biotic environment. The species used to achieve this objective are bioindicators. Motivations for the use of bioindicators include the following: (1) species are sometimes more sensitive or informative indicators of environmental change than abiotic environmental measures; (2) in the absence of a comprehensive understanding of ecological processes and disturbance impacts, and insufficient resources to rapidly achieve such understanding, bioindicators are a practicable alternative; and (3) in the face of rapid environmental change, bioindicators are a comparatively efficient means of obtaining the information necessary for decision making. In Antarctica and the sub-Antarctic, human-induced environmental change takes the form of harvesting of marine resources; physical disturbance as a consequence of science, operational, and tourism activities; the impacts of alien species; pollution; and climate change. Thus, bioindicators have both realized and potential value to the understanding, conservation, and management of Antarctic ecosystems.

Three broad categories of bioindicator are distinguished based on clear differences in their objectives, namely environmental, ecological, and biodiversity indicators. Environmental bioindicators are used to demonstrate the existence or level of an abiotic environmental stressor, most typically a pollutant. For example, in the Antarctic, marine mollusks; plankton; kelp; lichens; bird and seal muscle, liver, and kidney tissue; and bird stomach contents, feathers, and eggs have all been shown to variously act as bioaccumulators (organisms that absorb compounds directly from the environment) of chemical, organic, and radionuclide contaminants. The presence of exploiter species (species whose presence is indicative of disturbance, such as human bacteria near sewage outlets), and morphological characteristics of marine species (such as the weight and lipid content of the food storage organ in sea stars and sea urchins) have also been shown to be indicative of organic waste pollution in Antarctica. Environmental bioindicators are therefore typically applied to demonstrate or monitor localized or point source contamination, and the measurement variable of interest is generally the physiological status of individuals, their organs, or their body tissues.

Ecological bioindicators are species or species groups that demonstrate the impact of either biotic or abiotic stressors on the biodiversity or ecology of a system. In ecological bioindication the fates of the bioindicator species are often themselves of concern, and population and community parameters are the targeted measurement variables. In Antarctica, populations of predatory marine mammals and birds have been used as ecological bioindicators to monitor the ecosystem impacts of harvesting marine resources. In particular, population parameters such as the breeding population size, breeding success, and adult body mass of penguins and seals are used as ecological bioindicators of the effect of large-scale fishing on Antarctic marine ecosystems. Changes in community measures, such as the species richness and composition of marine benthos, have also been demonstrated to be indicative of the impacts of disturbance on Antarctic biodiversity and ecology. Potential ecological bioindicators of climate change in Antarctica include activity thresholds in terrestrial microalgae; the abundance and distribution of plants; and arthropod population size, life cycle duration, geographic range, and body water status.

Finally, biodiversity indicators are higher-level taxa, such as orders, families, or classes, that are well known and therefore used as surrogates for wholesale patterns in species richness. Biodiversity indication has been little applied in Antarctica, possibly because of the low terrestrial species richness and consequently the small need to estimate patterns of biodiversity. However, in the marine environment the species richness of comparatively better-known taxa such as the Crustacea have been used to examine patterns of biodiversity across Antarctic marine subsystems. Moreover, in the more diverse sub-Antarctic, the species richness of native and alien mammals, birds, insects, and vascular plants was used to identify the set of islands that best represent sub-Antarctic biodiversity and are of the highest conservation value.

Regardless of the category of bioindication concerned, a rigorous bioindicator selection and testing process is critical. The essence of bioindication is the confidence with which a bioindicator may be used to provide an accurate reflection of environmental state. While there are some generic properties for good bioindicators, for example that they are time- and cost-effective to sample, the characteristics of a suitable bioindicator largely depend on both the category of bioindicator being selected and the case-specific bioindication objective. This objective, as well as the context within which the bioindicator is to be applied, must be clearly defined at the outset. The testing of potential bioindicators involves establishing a significant, strong, and predictable relationship between the bioindicator and biotic or abiotic stressor of interest. This is achieved by using appropriate sampling methods and standard sampling design principles. It is particularly important to be able to distinguish between natural variation and the disturbance-induced bioindicator response. This is followed by independent testing of the bioindicator within the spatial or temporal context within which it is to be applied. Repeated testing in this way results in the development of robust bioindication systems (decision-making tools for extracting environmental information and for application in monitoring and environmental-impact assessment), with quantified confidence limits for their application.

While the initial identification of suitable bioindicators and the development of bioindication systems may be costly and time-consuming, without this investment it is not possible to establish the degree of certainty necessary for the successful application of a bioindicator. Nonetheless, much data may be gathered during the process of monitoring, and monitoring is therefore used to confirm the efficacy of bioindicators as well as to refine and improve the predictability of bioindication systems. Because of the sensitivity of Antarctic and sub-Antarctic systems to environmental change, particularly climate, the region is highly suited to monitoring programmes that examine the consequences of such change. Such monitoring programmes must necessarily include bioindicators as representatives of the changes occurring. Antarctica faces continued threat from biotic and abiotic changes associated with human activities and impacts. Bioindicators are therefore an increasingly essential component of environmental assessment programs for the conservation of the continent and its surrounding islands.

BIOLOGICAL INVASIONS

Every day huge numbers of species are on the move to new localities around the world. This is of great importance, as introduced species are widely considered as one of the biggest threats to biodiversity and ecosystem functioning. For tens of millions of years Antarctica, its outlying islands, and the Southern Ocean have been isolated by "barriers": mainly surrounding deep water, the Antarctic Circumpolar Current (ACC), and the Polar Frontal Zone (PFZ). Yet as elsewhere on Earth, microbes and macro-organisms (i.e., plants and animals) have been transported into southern polar lands, lakes, and sea. The time context of this is important; organisms have, on numerous occasions, been bulldozed into small pockets of land (terrestrial species) and to the edges of the shelves (marine species) by expanding ice sheets. Such expulsions have then been followed by periods of reinvasion as the ice sheets retreat. However, until recently, colonisation of deglaciated land and ice-shelf retreat have probably been by polar species rather than those from other oceans and continents. So species have almost certainly been arriving and departing by a number of "natural" methods for millennia, but in the last ~200 years there have been a large number of invaders establishing—particularly on sub-Antarctic islands. Before human activity around the southern polar region, microbes and plant or fungus propagules would still have been arriving as airborne particles. Potential invaders amongst marine species could be carried on currents or hitchhike on floating volcanic rock (pumice from volcanism), driftwood, kelp, or megafauna (e.g., barnacles attached to fur seals). Floating rock travelled to New Zealand from the 1963 eruptions in the South Sandwich Islands and *Nothofagus* tree trunks have floated south across the PFZ to wash ashore on Antarctic shores. Additionally, there is evidence of species travelling passively into and out from Antarctica, but concern over introductions focusses on the most recent and anthropogenically mediated species transport for two reasons. First, the rate of introductions, number of mechanisms, and types of organism able to travel to Antarctica have all increased in association with humans. Second, climate change has rapidly changed, and is likely to further change, the survival and establishment prospects of invaders.

In the last 2 centuries, humans have travelled deeper and more frequently into Antarctic waters. In the last decade alone the numbers of tourists and ships travelling to the Antarctic have both quadrupled. Large numbers of propagules, such as seeds, spores, and even invertebrates, can be present on the walking boots of just one tourist. With humans have been a wave of deliberately or accidentally introduced species, including many vascular plants, worms, insects, mites, and mammals. In the sub-Antarctic islands, deliberate terrestrial introductions have included species imported for food, pleasure (pot plants), to control other introduced animals, or during scientific transplant experiments. Accidental introductions have accompanied many of those which were deliberate, but in addition have arrived on ships and aircraft as well as on human clothes. At two of the best-studied localities, Marion Island (in the Prince Edward Islands) and Îles Kerguelen, there have been 33 and 111 known terrestrial introductions. A few islands, however, remain near pristine with no nonindigenous species recorded (e.g., McDonald Islands). In fresh water, several species of salmonid fish have been introduced (particularly to Îles Kerguelen) and some crustaceans may have been, but the origin of lakes and stream biota has been little studied to date. The human link to most sub-Antarctic species introductions is reflected in the distributions and abundances of established alien plants and many insects which centre around whaling stations, research stations, and other heavily visited sites. Many invaders have persisted in the sub-Antarctic islands, and at Signy Island, in the maritime Antarctic, both an introduced midge and nematode have been established. There is little evidence to date of invaders successfully establishing on the continent of Antarctica; however, new micro-algae are persisting around Scott Base on the edge of the Ross Ice Shelf. Typically biodiversity in terrestrial systems is low so that just a few aggressive introduced species can have a dramatic influence. At Marion Island nearly 40% of the springtail community are invaders. An inevitable consequence of invaders becoming established is a "homogenisation" of faunas around the world and a loss of native biodiversity. Although many invading species are temporarily or permanently benign, some are serious competitors for food or space with native species, and others directly eat native species.

On Marion Island an intense eradication programme seems to have been successful in removing one prominent introduced predator, the cat, a species which has caused particular damage to nesting bird populations on sub-Antarctic islands. Further south, the Poa grass that invaded Deception Island was eradicated by an eruption. Further south still, on the continent, the midge, which persisted for several years in the sewer system of an Australian Antarctic research station, was finally eradicated after a deliberate campaign. Most of the terrestrial aliens identified to date have been found to be European. Only recently have scientists even started looking for invaders or mechanisms of invasion in the marine environment around Antarctica. It seems likely that marine species transport by shipping is most likely to be out of Antarctica in ballast water and in by hull fouling. This is because (1) ships travel south into the Southern Ocean after visits in temperate ports where they could easily pick up invasive species (ports are hotspots for many such species), and (2) typically after unloading in Antarctica, ships take on ballast water for the journey northward. Several invasive species (e.g., the sea squirt *Ciona intestinalis* and the bryozoan *Watersipora subtorquata*) have even been found on the hulls of ships. Marine species have been found rafting on kelp and plastic, and giant spider crabs are being discovered further and further south with each year of sampling. Nonnative marine crustaceans have been discovered—two as larvae and another as an adult—in the South Shetland Islands. There is no indication, however, that any of these has become established or even reproduced; thus, the Southern Ocean remains the only major environment on earth with no known established invaders.

Climate change is changing the context of invasions. Air, soil, and lake temperatures have all increased rapidly (more so than anywhere else except in parts of the arctic), which has drastically changed survival prospects of propagules arriving in terms of their hardiness, length of growing season, and water availability. This is most obviously demonstrated by manipulative experiments whereby small areas of land are maintained at slightly higher than ambient temperatures by positioning small translucent plastic greenhouses over them. The survival of propagules and growth of plants is remarkably different to adjacent areas and visually striking. In the marine environment sea-surface temperatures are also predicted to increase. Although the error associated with model estimates is large, values as high as ~2°C are suggested (total annual variability of sea surface temperature is <4°C at most localities and <1°C at some). Such a rise should both increase the viability of cold temperate invaders and place many native species close to functional maximum temperatures.

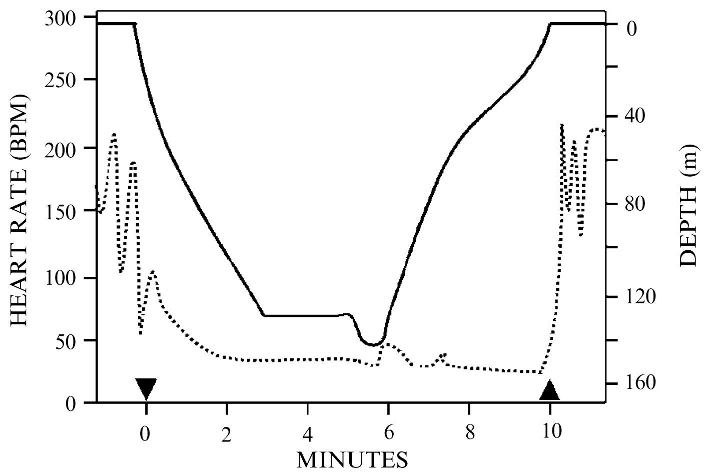
BIRDS: DIVING PHYSIOLOGY

Within the province of the Southern Ocean, there are four distinct groups of diving birds. They are penguins (family Spheniscidae); diving petrels (Pelecanoididae); petrels, shearwaters, prions, and fulmars (Procellariidae); and cormorants (Phalacrocoracidae). The most fully adapted for diving are the flightless penguins. Externally, their wings have evolved to short flippers with scale-like feathers covering the skin, and a nearly perfect hydrodynamically streamlined body. Highly modified feathers add further to the reduction of drag, in addition to waterproofing and insulation. Internally, they have exceptionally large pectoral muscles that are about 25% of the total body mass, and these same muscles have extreme concentrations of myoglobin, an oxygen-binding molecule.

Among the seventeen species of penguins the most exceptional diver, and one of the most studied with regard to diving adaptations, is the emperor penguin *(Aptenodytes forsteri)*. With an adult body mass ranging from 25 to 40 kg, it is the largest of all diving birds. With size often come greater diving capacities, and the emperor penguin holds the record for maximum diving depth (to 560 m), and also the longest dive duration for any bird (22 min). How this species responds to such extremes in breath-holding and water pressure is intriguing, and the answers will help to explain the adaptations to diving in all aquatic birds, most of which are much less suitable for study.

The close association of emperor penguins to the Antarctic sea ice, their willingness to dive under the ice, and their body size make possible an experimental procedure related to diving that would not be possible otherwise. Emperor penguins diving freely through a remote hole in the sea ice are obliged to return to the same hole to breathe and exit the water. Under these circumstances, physiological responses have been recorded with a variety of sensors attached to the penguin and connected to a submersible microprocessor. In addition, both emperor and king penguin *(A. patagonicus)* adults nurturing chicks have had similar recording devices attached when they go to sea to obtain food for their chicks. During these foraging trips they may travel several hundred kilometers before returning to the chicks.

A bird diving to depth responds to three major gas-exchange effects: (1) a cessation of an external oxygen supply resulting in hypoxia; (2) an increase in external pressure to as much as 57 atmospheres, in the case of the emperor penguin; and (3) a reduction in the insulating properties of the feathers. The results of experiments in which recorders have been attached show the responses to some of the basic effects of diving to depth. For example, as the level of hypoxia increases



The change in heart rate during the course of a dive to a depth of 130 m. The upside-down and upright solid triangles indicate the beginning and end of the dive. The solid line is the depth, and the dashed line is the heart rate. (Figure modified from P. Ponganis, unpublished data.)

during an extended dive of 10 min to a maximum depth of 130 m, the figure above shows the cardiac response. The heart rate drops from a predive hyperventilation rate of over 200 beats min^{-1} (BPM) to 50 BPM within 2 min after the start of the dive. The rate decreases a further 10 BPM after a further 2 min, where it remains until the end of the dive, 6 minutes later. Other important changes are occurring simultaneously. From the surface to about 20 m depth, the bird strokes vigorously to overcome the positive buoyancy of the air trapped in the feathers and gas contained in the internal air sacs. With increasing depth, hydrostatic compression reduces the air and gas volumes within the feathers and air sacs and the stroke frequency of the wings is reduced as the compression reduces the positive buoyancy provided by these air spaces. With this reduction in wing beat frequency, the work of swimming decreases, as does the rate of oxygen consumption from the body oxygen stores. With compression of the internal air sacs, the oxygen and nitrogen pressures increase and these gases are more readily passed to the blood, where they are transported to various parts of the body. However, the reduced heart rate modifies blood distribution, from widespread flow to all organs while the bird is at the surface to a more restricted distribution. This lessened transport of oxygen conserves some of the onboard stores, presumably for organs such as the brain that have a low tolerance to oxygen deprivation. Muscle has a high tolerance for hypoxia and also has a large amount of oxygen bound to myoglobin, which it can use internally. Simultaneously, the nitrogen level of the blood is rising, and this could be a liability if the concentrations were to reach a level that might induce a narcotic effect in the brain. Also, as the bird ascends, bubble formation in the blood and tissues might occur if nitrogen reached a high tension while the bird was at depth. Considering the debilitating effect of gas bubble formation, also called decompression sickness or "the bends," it is unlikely that diving birds are plagued by this risk. How a diving bird avoids exposing itself to high tissue nitrogen concentrations during a dive is still unknown.

Another mystery is the management of oxygen stores. Most dives are within the limits of the aerobic diving capacity that the onboard oxygen stores provide. This aerobic diving limit (ADL) can be estimated if the body oxygen stores and the diving metabolic rate are known. For the several species of penguin in which the stores and consumption rate have been estimated, it has been found that most dives are within this predicted ADL. However, many are not, and some of these dives seem to be very important to the foraging ecology of the bird. The 10-minute dive is double the predicted ADL of the emperor penguin. Dives of this duration and to even much greater depths are common, and clearly important to the bird. Possibly for some dives the ADL is extended by some altered responses to breath-holding, different from those that are more often observed for more shallow dives. For example, it has been shown that within the body there are regional differences in temperature that suggest the metabolic rate of some organs may be lowered to minimal levels during some extreme dives. Changes in buoyancy with depth may also reduce swim effort and allow the bird to glide more while descending. These and other adaptations to deep diving still need to be examined in greater detail.

BIRDS: SPECIALLY PROTECTED SPECIES

Since the signing of the Antarctic Treaty and the establishment of the Antarctic Treaty System in 1959, a high level of conservation has existed in the Antarctic region south of 60°S. The 1964 Agreed Measures for the Protection of Antarctic Fauna and Flora represented the earliest formal mechanism for the protection of native Antarctic species. Specially Protected Species were established under the Agreed Measures and presently comprise all fur seals of the genus *Arctocephalus* and Ross seals *(Ommatophoca rossii)*. No birds had been designated as Specially Protected Species as of 2005; however, discussions are underway regarding possible additions to the list.

Measures for the protection of Antarctic flora and fauna have been subject to review and improvement. The 1991 Protocol on Environmental Protection to the Antarctic Treaty (the Madrid Protocol) simplified and formalised early recommendations of the Antarctic Treaty System to bring Antarctic conservation in line with developments in international environmental law over the period 1970–1990.

Annex II of the Madrid Protocol is based largely upon the Agreed Measures, which were superseded by the Madrid Protocol when it entered into force in 1998. Annex II prevents the taking of or harmful interference with native fauna and flora unless in accordance with a permit. Permits are allowed for scientific research or educational purposes, such as the collection of specimens for museums. Permits are subject to set conditions that aim to protect the ecological integrity of the region and ensure that methods used to take native fauna cause minimal pain and suffering.

Specially Protected Species are subject to the same conditions as other native flora and fauna, but there are additional measures in place for their conservation. Specially Protected Species may only be taken if the taker is in possession of a permit for compelling scientific research. Killing Specially Protected Species is discouraged, and Treaty Parties are advised to minimise the number taken or killed to ensure the long-term survival and recovery of Specially Protected Species.

Annex II is currently under review. The Scientific Committee on Antarctic Research has been asked to advise the Committee on Environmental Protection on possible deletions/additions to Specially Protected Species; a process and criteria for Specially Protected Species listing/delisting; and practical means for their protection. The Intersessional Contact Group on the Annex II review has discussed the application of World Conservation Union (IUCN) Red List criteria to fauna and flora breeding or occurring in the Antarctic. The following table describes Antarctic birds by their conservation status.

Numerous proposed changes to Annex II are being discussed. Recommendations regarding Specially Protected Species measures currently include theautomatic listing of Endangered species; need to assess the conservation requirements of Vulnerable species; necessity for a regional assessment of the conservation requirements of Antarctic fauna and flora; development of Specially Protected Species criteria and a designation process to ensure that Specially Protected Species listings/delistings are supported by scientific evidence; taking of Specially Protected Species for compelling scientific or conservation reasons.

The Committee for Environmental Protection made recommendations at the 2005 Antarctic Treaty Consultative Meeting regarding amendments to Annex II based upon the advice obtained by the Scientific Committee on Antarctic Research and the Intersessional Contact Group.

Jane Harris

Antarctic Birds by IUCN Conservation Status

Common Name and Scientific Name	IUCN Status*
Avifauna breeding south of 60° South	
Southern giant petrel *Macronectes giganteus*	Vulnerable (VU)
Macaroni penguin *Eudyptes chrysolophus*	Vulnerable (VU)
Gentoo penguin *Pygoscelis papua*	Lower Risk/Near Threatened (NT)
Avifauna found but not breeding south of 60° South	
Amsterdam albatross *Diomedea amsterdamensis*	Critically Endangered (CE)
Northern royal albatross *Diomedea sanfordi*	Endangered (EN)
Black-browed albatross *Thalassarche melanophrys*	Endangered (EN)
Indian yellow-nosed albatross *Thalassarche carteri*	Endangered (EN)
Sooty albatross *Phoebetria fusca*	Endangered (EN)
Rockhopper penguin *Eudyptes chrysocome*	Vulnerable (VU)
Wandering albatross *Diomedea exulans*	Vulnerable (VU)
Salvin's albatross *Thalassarche salvini*	Vulnerable (VU)
Southern royal albatross *Diomedea epomophora*	Vulnerable (VU)
Grey-headed albatross *Thalassarche chrysostoma*	Vulnerable (VU)
White-chinned petrel *Procellaria aequinoctialis*	Vulnerable (VU)
Eaton's pintail *Anas eatoni*	Vulnerable (VU)

Critically Endangered: facing an extremely high risk of extinction in the wild in the immediate future. Endangered: facing a very high risk of extinction in the near future. Vulnerable: facing a high risk of extinction in the wild in the medium-term future. Lower Risk/Near Threatened: not conservation dependent but close to qualifying as vulnerable.

BISCOE, JOHN

The achievement for which John Biscoe's name will remain immortal was the third circumnavigation of Antarctica, which he accomplished in 1830–1832. During this epic, Biscoe (1794–1843) made "persistent efforts to explore" the South Sandwich Islands, discovered a new section of the continental coast, Enderby Land, and charted a significant part of the western side of Graham Land, discovering Adelaide Island and other islands in the process. He also made observations on the wildlife, air and water temperatures, the aurora, compass variations, and the winds close to the continental coast.

His two predecessors, James Cook and Fabian von Bellingshausen, commanded government expeditions, but Biscoe's was privately arranged, by the well-known London firm Enderby Brothers. They were keenly interested in exploration and the intention was that the expedition should be exploratory and scientific, albeit with the aim of covering the costs by sealing when possible. It was, in comparison with its forebears, poorly equipped. The vessels were a small "hermaphrodite brig," *Tula,* and *Lively,* which was a mere Cowes pilot cutter. With a total crew in both ships of twenty-seven men and two boys, they were wholly inadequate for such a voyage. It is a testimony to the skilled and determined seamanship of Biscoe, who travelled on *Tula,* and of Captain George Avery, of *Lively,* which was frequently separated from *Tula,* that they survived at all, let alone achieved what they did.

After service in the Royal Navy, during which he reached the rank of Acting Master, Biscoe joined the merchant navy on the peace in 1815. He had good references from the captains he had served under, and was appointed by Enderby Brothers to command the expedition even though he may never have been in command before and seems never to have visited the Southern Ocean nor to have undertaken a sealing or whaling voyage.

The expedition left London on July 10, 1830, and, after a difficult passage, which exposed the limitations of the ships, it arrived at the Falkland Islands on November 11. The ships departed on November 27, and their first achievement was to eliminate the fabled "Aurora Islands" (also searched for by James Weddell) from the chart by sailing over their position. Biscoe then reached the eastern side of the South Sandwich Islands on December 19. He spent the period from then to New Year's Day 1831 navigating through the archipelago, and often sent *Tula*'s small boats and *Lively* to examine the islands more closely. This was to no avail as far as landing places or seals were concerned, but many important observations were made, particularly relating to the islands' positions. Biscoe then headed southeast, crossing the Antarctic Circle on January 21, 1831, and reaching his farthest south, 69° S, on January 28. Further progress was blocked by pack ice, with what is now Princess Astrid Coast only 100 km away.

On February 24–25, Biscoe sighted the ice front near Tange Promontory and spent the next few weeks heading eastwards and attempting to survey the new land despite continuous gales and adverse winds and currents. He dutifully named many of the mountains after members of the Enderby family. By March, *Lively* had become separated from *Tula,* many of the sailors were sick, and the expedition was in serious difficulty: "The vessel is a complete mass of ice, only 3 of the crew who can stand" (Biscoe 1830–1833). Biscoe resolved to head for Tasmania, and *Tula* arrived at Hobart on May 9, 1831. The crew were assisted in mooring the ship by the pilot and by men from Eliza, commanded by Weddell, which was in port. Biscoe assumed that *Lively* had foundered in a storm, but when *Tula* departed in early September, much to Biscoe's surprise, it hove in sight. On separation, Avery, appreciating that his ship was in a desperate position concerning the health of the crew, had headed for Port Phillip, where they had arrived "in the very utmost state of distress" (Biscoe 1830–1833). Going ashore to secure provisions, the crew returned to discover *Lively* gone. They found the ship aground two weeks later, refloated it, and made for Hobart and the fortunate meeting with *Tula*.

Allowing time for *Lively* to be refitted, Biscoe set out again on October 8, 1831, heading for New Zealand. They attempted some sealing, on the Chatham Islands, but secured fewer than thirty skins. After eliminating the "Nimrod Islands" from the chart, again by sailing over their position, Biscoe resolved to visit the South Shetlands to undertake further sealing, but took a more southerly route than that direct to the archipelago. On February 15, 1832, land was sighted with lofty mountains. Biscoe named this Adelaide Island, after the consort of King William IV. He also observed the mountains of Bellingshausen's Alexander Island, some 160 km to the south. Biscoe examined the west coast of Graham Land as closely as circumstances permitted, discovered the Pitt Islands (now named the Biscoe Islands), and landed on what is now Anvers Island. Believing this to be the mainland, he landed and took possession of it. He was among the first to appreciate that these and his discoveries were "the headlands of a Southern Continent" (Biscoe 1830–1833).

Proceeding northwards, the ships arrived at the South Shetlands and added slightly to their meagre catch of skins and oil. It was late in the season, and by this date the seal population of the islands had effectively been destroyed. Therefore, Biscoe resolved to head for the Falklands, where both ships arrived on April 29, 1832, thus completing their circumnavigation.

Unfortunately, *Lively* was wrecked there, and Biscoe had trouble with the crew, who did not want a renewal of the voyage "for which I can hardly blame them" (Biscoe 1830–1833). He therefore headed north. There was much desertion in Brazil, and with a depleted crew *Tula* arrived in London on February 8, 1833. The voyage had been a financial disaster for the Enderby family, but they could at least bask in the glory of its achievements. These were speedily delivered to the Royal Geographical Society, and Biscoe was awarded the Society's gold medal as well as an equivalent from the French.

Biscoe returned to the sea and undertook voyages in Australian waters including a possible one to 75° S, although this must be regarded as doubtful. By the 1840s, he was seriously ill, and indeed his constitution never recovered from the damage it received on the great voyage. Charitable solicitations were made in the Tasmanian press to enable him and his family to return to England. En route he died and was buried at sea.

Biscoe's discoveries rendered more likely the existence of an Antarctic continent, and his observations of the coasts along which he travelled were, in the circumstances, very accurate. His discovery that the usual wind, close to the continent, was from south through east led him to suggest that future efforts should be from east to west. It was this seminal proposal that placed those expeditions following him most deeply in his debt.

BLACK-BROWED ALBATROSS

The black-browed albatross *(Thalassarche melanophrys)* is a medium-sized albatross weighing between 3 and 5 kg and with a wing span of over 2 m. Adults are distinguished by a white head with distinctive black brow above the eye, a bright yellow-orange bill, and an underwing pattern with a broad black leading edge. Juveniles have dark horn-coloured bills with dark tips.

In 2000, black-browed albatrosses were listed as "near-threatened," with this listing being upgraded to "vulnerable" in 2002. The conservation status of black-browed albatrosses was again upgraded in 2003 to "endangered," as it is inferred that the global population will have decreased over 50% over the three generations (65 years) on the basis of recent rates of population decreases. Black-browed albatrosses are the most widespread of all albatross species, breeding at twelve sites around the Southern Ocean. About 60% of the global population of 530,000 breeding pairs breed at the Falkland Islands. Other large populations occur at South Georgia and Chile, with the smallest populations occurring at Macquarie Island and Campbell Island.

Black-browed albatrosses breed colonially on tussock slopes or on cliff terraces. Breeding generally occurs annually, regardless of breeding success the previous season, and the breeding season extends from September to April. Eggs are laid in October and incubated for about 68 days. After hatching the parents continue to alternate the brood guard shifts for about 3 weeks. The chicks fledge about 4 months after hatching, with chicks and successful breeding adults departing the colonies in April or May.

Typically, immature birds return to the colonies at 6–7 years of age, and breeding usually begins when birds are 10 years of age. The life history of black-browed albatrosses at South Georgia is well studied, and for this population, it is the very low survival rate of juveniles that has the most influence on the population decrease.

Black-browed albatrosses occur throughout the Southern Ocean, reaching as far north as 20° S during the nonbreeding winter months, and usually between 40 and 70° S in summer. Comparison of satellite tracking information shows that black-browed albatrosses from different populations have largely mutually exclusive foraging ranges. Most breeding birds forage extensively over shelf, or shelf-break waters, in many cases close to their colonies. Some birds, however, travel considerable distances to forage and visit the Polar Front waters and waters adjacent to the Antarctic ice edge.

Black-browed albatrosses feed by both surface seizing and diving to depths of 4 m. Consistent with their variety of foraging habitats, their diet includes fish, squid, and krill and shows distinct variation with location, with more squid being consumed by birds when foraging at frontal zones or in deeper ocean water.

These birds are also energetic and consummate scavengers of bait and offal discards from fishing vessels. It is this practice of scavenging baits from longline hooks that results in the deaths of more than 300,000 seabirds, including an estimated 100,000 albatrosses and petrels, each year in both legal and illegal fishing practices. Black-browed albatrosses are among the species of albatrosses killed on longlines, and this has been identified as a key factor driving the population decreases. In the absence of the adoption of effective changes to fishing practices, it is projected that such decreases will continue into the future.

BLUE WHALE

Blue whales are of the order Cetacea, suborder Mysticeti (meaning moustache, which refers to baleen plates), family Balaenopteridae, and genus and species *Balaenoptera musculus* (Linnaeus 1758). "Balaenoptera" comes from the Latin for "winged whale," while "musculus" is latin for "muscle." Two subspecies are found in the Antarctic, the true blue whale, *B. m. musculus*, and the pygmy blue whale, *B. m. brevicauda*. The pygmy blue whale was not identified until the early 1960s. Other common names used in the past include "sulphur-bottom" and "Sibbald's rorqual."

General Appearance and Size

Blue whales are the largest animals ever to have lived. In the Southern Hemisphere, the average true blue whale female reaches about 25–26 m in length and weighs around 100–120 tonnes. Females are generally about 5% longer than males. The largest recorded blue whale measured 33.6 m, perhaps weighing as much as 190 tonnes. Pygmy blue whales are smaller, as their name implies, reaching about 22 m.

The blue whale has a large, broad head that comprises around 25% of the total body length. A head ridge runs to the paired blowholes, which are located behind a characteristically large "splash guard." The "blow" is tall (up to 12 m), dense, and broad and is helpful in identifying the species from a distance. The mottled skin can appear blue but is generally pale and dark grey. The ventral surface is lighter. Chevron-like patterns curve down and back on both sides behind blowholes. The patterns on the skin can be used to identify individuals. The dorsal fin is relatively small and is set so far back on the body that it does not become visible for some time after the head breaks the surface. Blue whales are rorquals, and have 60–88 ventral grooves that run from the lower jaw to the umbilicus and that allow the mouth to expand when feeding. They have 270–395 triangular black baleen plates hanging from the upper jaw on each side (about 1 m in length and 0.5 m at the widest part), spaced 1–3 cm apart, used in filtering krill. The bristles on the inner side are around 0.3 mm in diameter. The relatively blunt flippers reach about 15% of body length and are dark grey on top and pale underneath. The gray flukes are broad and triangular with a straight or slightly curved trailing edge and they may have variable white patches on the underside.

In Antarctic waters, all or portions of the body may have a dark yellow-green to brown sheen from the presence of diatoms, single-celled algae that attach themselves to the skin and are the origin of the common name "sulphur-bottom."

Distribution and Migration

True blue whales are found throughout the Southern Hemisphere (and indeed, the Northern Hemisphere), although densities are lower in the eastern Pacific sector. They migrate between sub-tropical breeding areas (the location of the breeding grounds is unknown) and the Antarctic feeding grounds, where they are found primarily close to the ice edge. Blue whales rarely, if ever, feed outside the Antarctic and so, in the 4–5 months (November to March) they are in the Antarctic, they must store energy in their blubber to last them for the migration to and from the breeding grounds, as well as their time on the breeding grounds. Pygmy blue whales generally do not migrate as far south as true blue whales, with most animals found north of 55° S. There are probably at least six separate populations of true blue whales in the Southern Hemisphere.

Life History and Behaviour

Blue whales can live up to 100 years old. True blue whales reach sexual maturity at around 23–24 m (females) and 22 m (males) and probably at about 8–10 years old. Pygmy blue whales reach sexual maturity at around 22 m (females) and 21 m (males). The gestation period is thought to be around 12 months; newborn calves weigh 2–3 tonnes and measure about 7 m (true) or 6.3 m (pygmy). They are weaned at about 6 months, by which time they have reached around 13 m (true) or 11 m (pygmy). There is evidence that pregnancy rates increased and animals reached sexual maturity earlier after depletion by whaling, perhaps as more food per individual became available.

Little is known about the social structure of blue whales. They are usually seen as single animals, although larger concentrations (up to fifty animals) are known in areas of high prey density (the primary prey species is Antarctic krill, *Euphausia superba*). Blue whales can engulf up to 32 m^3 of water and prey with the ventral grooves fully distended and eat up to 6 or more tonnes of krill per day. Feeding blue whales typically dive for around 8–15 minutes whilst feeding.

It is interesting that, at least in the Northern Hemisphere, blue whale/fin whale hybrids have been documented; in at least one instance the female (a fin whale) was pregnant.

Blue whales produce extremely powerful, low-frequency (17–20-Hz) sounds that may be able to travel hundreds or even thousands of kilometres. It is thought that these sounds may play an important role in communication and perhaps navigation.

Conservation/Status

Blue whales were the preferred target of commercial whalers in the Antarctic because of their large size and hence high oil yield. The populations were severely depleted but not given complete protection by the International Whaling Commission until 1966. Illegal catches by the Soviet Union (largely of pygmy blue whales) continued until the beginning of the 1970s. About 358,000 blue whales were killed south of 40° S between 1904 and 1970, with over half of these killed between 1929 and 1939.

Although still at very low levels (less than 1% of their original numbers), true blue whales are showing encouraging signs that they might be recovering at around 2–8% per year. A recent study estimated their numbers in the Antarctic to be around 1700 in 1996.

Aside from man, the main predator of blue whales is the killer whale, *Orcinus orca,* which has been known to take adults as well as calves. Some scientists have suggested that interspecific competition with Antarctic minke whales *(B. bonaerensis)* may have inhibited the recovery of blue whales. The effect of climate change on stocks of krill and hence blue whales is unknown.

BOOKS, ANTARCTIC

The literature of the Antarctic had its beginnings in 1775 with the anonymous, surreptitious publication of John Marra's *Journal of the* Resolution*'s Voyage,* a firsthand account of James Cook's second voyage rushed into press a mere six weeks after the expedition's return, eighteen months before the 1777 publication of Cook's official account, *A Voyage towards the South Pole and round the World*. During that voyage, the Antarctic continent, while remaining undiscovered, was first circumnavigated, the Antarctic Circle was crossed for the first time, and all previously known lands were proven not to be part of the great, imagined "terra australis." Explorers had been probing farther and farther south for two centuries prior to the early 1770s, but all claims concerning an Antarctic continent were either misrepresentations or speculations.

Sealers, nearly all British and American, reached the vicinity of the Antarctic Peninsula in the years 1819–1830 but few cared about publishing their observations. The history of that period has only recently been pieced together by painstaking delvings into contemporary periodicals and what survives of records, logs, and charts.

By the end of the nineteenth century, still only a handful of Antarctic expeditions had set sail with serious scientific or hydrographic objectives: those of Cook, Fabian G. von Bellingshausen, James Weddell, John Biscoe, Jules S.-C. Dumont d'Urville, Charles Wilkes, James Clark Ross, Thomas Moore, Eduard Dallmann, Carl Larsen, Henryk Johan Bull, Adrien de Gerlache, and Carsten Borchgrevink. While more and more books and papers were making their way into print by the turn of the century, most concerning these voyages, only about seventy-five freestanding works and several hundred journal articles, had appeared.

Publications concerning the Antarctic became increasingly numerous during the 1890s and the first decades of the twentieth century in parallel with the evolving Heroic Age. Publishers almost everywhere during that period were manufacturing elaborately lettered, decorated, and illustrated cloth-backed, casebound books, often with foldout plates or maps, adding substantial appeal to the volumes that document this important and exciting period of Antarctic history-making. But with the exception of occasional bestsellers, Antarctic publishing was not particularly profitable. Even so, leaders' firsthand narratives sold at least satisfactorily, and trade publishers were willing to partner with explorer–authors. Some of the best-known London publishers took on Antarctic narratives, including the firms of John Murray (Ross); Smith, Elder (Robert Falcon Scott); Hurst and Blackett (Otto Nordenskjöld); William Heinemann (Shackleton, Douglas Mawson); Hodder and Stoughton (Jean-Baptiste Charcot); and Cassell (Frank Wild, Vivian Fuchs). In a notable instance, London publisher George Newnes financed the Borchgrevink expedition in exchange for future publishing rights to the official narrative. Explorers' profits from book sales were often applied to offset expedition debts, as in the case of Shackleton's 1907–1909 and 1914–1917 expeditions. Still, editions were often small owing to limited demand, with the result that many important books are nowadays hard to come by in their original editions. For example, Ross's two-volume set *A Voyage of Discovery* and *Research in the Southern and Antarctic Regions* (1847) was a classic in its own time, but only 1500 sets were produced.

Contemporary books by expedition participants other than the leaders, with the single exception of books emanating from Scott's last expedition, had virtually no demand and were printed in miniscule quantities by small publishing houses or by the authors themselves or their descendants. Apsley Cherry-Garrard's *The Worst Journey in the World,* concerning Scott's last expedition, has rarely been out of print since its first publication in 1922, while Leonard Kristensen's *Antarctic's Reise til Sydishavet,* a substantial Norwegian account of the Bull expedition, has never been translated. With the exception of Friedrich Bidlingmaier's little book *Zu den Wundern des Südpols,* no firsthand accounts or diaries of the German expeditions led by Drygalski and Filchner other than the leaders' have been published. Even these, long available in German, only appeared in English translation for the first time in 1989 and 1994, respectively. In some instances, leaders (Wilkes, Richard E. Byrd) suppressed the publication of participants' accounts.

Scientific works, with an even more severely limited audience coupled with an inordinate cost of producing the requisite illustrations or photographs, were usually underwritten by governments or scientific institutions with the aid of subscription, the creation of a dedicated scientific institution for ardent fund raising (William Bruce), or in the extreme, by selling off some of the expedition's prized collections of biological specimens and artifacts (Mawson). Johann Reinhold Forster produced *Characteres Generum Plantarum,* the botany of Cook's second voyage, at his own expense; the penalty for his effort was a substantial personal loss. The publication of Antarctic science has always been an extreme labor of organization and funding, writing and illustration, and publication and sales.

By the early twenty-first century, freestanding publications numbered several thousand and included not only expedition prospectuses, narratives (a number of which have become classics in the world's exploration literature), science reports, cartographic and photographic works, biographies and autobiographies, diaries and logs, analytical reviews, and bibliographies, but also interpretive works including art, poetry, literary prose, plays for screen and stage, treatises on leadership, and fiction. Journal articles number in the tens of thousands. The most recent two decades in particular have witnessed an explosion of new book publishing and the reissue of the classics coincident with surging Antarctic tourism and a worldwide mania for Antarctic heroes, particularly Ernest Shackleton. This energized market has unfortunately produced many items of negligible value, but serious historians and researchers have filled many gaps in knowledge concerning the classical and heroic periods, and expedition participants' diaries and English editions of heretofore-untranslated works are being published for the first time. And with technological improvements in image transfer, a number of fine illustrated books have appeared.

To navigate the literature, several bibliographies are available, which are given in the "References and Further Reading" list at the end of this entry. The principal strength of the first four is the extensive coverage of journal articles in multiple languages. Spence is a popular short list. Renard—strictly speaking an auction catalog, but valuable as more than that—represented a leap in Antarctic bibliographical scholarship, with multiple editions of individual works and brief, informative annotations. Rosove is a comprehensive analysis of freestanding publications concerning the classical and heroic periods, with extensive annotations. In addition to these bibliographies, several major polar research institutions' catalogs are available online.

Some of the great classics of the Antarctic literature are given in the "Great Classics of Antarctic Literature" list. Without a doubt, the *ne plus ultra* of the Antarctic literature is *Aurora Australis,* an anthology of writings by members of Shackleton's British Antarctic Expedition of 1907–1909, and the first book printed and bound in Antarctica. At least sixty-five copies were extant in 2005; certainly not more than ninety to one hundred were ever produced. Printed on a small press by novices to the trade and illustrated from etched aluminum plates under the adverse conditions of the Cape Royds hut in winter, then bound in plywood boards from packing cases, leather from horse harnesses, and string, the finished books were truly a remarkable achievement. Many books were signed by expedition members or carry an interesting provenance. Over half are in institutional libraries, leaving relatively few in private hands. When a copy fleetingly appears on the market, the would-be buyer must be prepared to pay upward of £30,000. Forty years ago, £300 would have sufficed.

Great Classics of Antarctic Literature

Amundsen, Roald, Sydpolen: Den Norske Sydpolsfærd med Fram 1910–1912, Kristiania: Jacob Dybwads, 1912. Original 40 parts and publisher's 2-vol. trade edition. *The South Pole: An Account of the Norwegian Antarctic Expedition in the "Fram," 1910–1912*. London: John Murray, 1912. 2 vols. Mankind's first arrival at the South Pole.

Bellingshausen, Fabian G. von. 1831. 2 vols. and atlas. *The Voyage of Captain Bellingshausen to the Antarctic Seas 1819–1821*. London: The Hakluyt Society, 1945. 2 vols. The second Antarctic circumnavigation, with the first land discoveries south of the Antarctic Circle and first sighting of ice contiguous with the Antarctic continent.

Byrd, Richard E. *Alone*. New York: G. P. Putnam's Sons, 1938. Author's signed and trade editions. Dramatic account of Byrd's solo wintering-over at Advance Base planted in the Ross Ice Shelf in 1934.

Cherry-Garrard, Apsley. *The Worst Journey in the World: Antarctic 1910–1913*. London: Constable and Company, 1922. 2 vols. The principal account of Scott's last expedition, considered on its literary merits to be the finest polar book ever written.

Cook, Frederick A. *Through the First Antarctic Night, 1898–1899: A Narrative of the Voyage of the "Belgica" Among Newly Discovered Lands and over an Unknown Sea about the South Pole*. New York: Doubleday & McClure, 1900. Author's signed and trade editions. Chronicling mankind's first winter south of the Antarctic Circle.

Cook, James. *A Voyage Towards the South Pole and Round the World: Performed in His Majesty's Ships the* Resolution *and* Adventure, *in the Years 1772, 1773, 1774, and 1775*. London: W. Strahan & T. Cadell, 1777. The first southern high-latitude circumnavigation and crossing of the Antarctic Circle, with the first landing at South Georgia and discovery of the South Sandwich Islands.

Fuchs, Vivian E., and Edmund Hillary. *The Crossing of Antarctica: The Commonwealth Trans-Antarctic Expedition, 1955–58*. London: Cassell, 1958. The first crossing of the Antarctic continent.

Marra, John. *Journal of the* Resolution*'s Voyage, in 1772, 1773, 1774, and 1775*. London: F. Newbury, 1775. The first published firsthand account of the Antarctic polar regions.

Mill, Hugh Robert. *The Siege of the South Pole: The Story of Antarctic Exploration*. London: Alston Rivers, 1905. The great Antarctic historian's masterpiece.

Palmer, J. C. *Thulia: A Tale of the Antarctic*. New York: Samuel Colman, 1843. The first Antarctic poetry, inspired by events on the United States Exploring Expedition of 1838–1842.

Ross, James C. *A Voyage of Discovery and Research in the Southern and Antarctic Regions, During the Years 1839–1843*. London: John Murray, 1847. 2 vols. Discoveries of the Ross Sea, Victoria Land, Ross Island, and Ross Ice Shelf.

Scott, Robert F. *The Voyage of the* 'Discovery.' London: Smith, Elder, 1905. 2 vols. The leader's brilliantly written account of his 1901–1904 expedition, one of the most important expeditions of Antarctic scientific and geographical inquiry.

———. *Scott's Last Expedition*. London: Smith, Elder, 1913. 2 vols. Scott's immortal diary and writings of his second-place finish at the South Pole and fateful return, with official reports.

———. *The South Polar Times*. London: Smith, Elder, 1907 (vols. I and II), 1914 (vol. III). Writings and illustrations created during the winter months by members of Scott's two expeditions.

Shackleton, Ernest H., ed. *Aurora Australis*. Published at the winter quarters of the British Antarctic Expedition, 1907, during the winter months of April, May, June, July, 1908. First Public Edition: Alburgh, Harleston, Norfolk: Bluntisham Paradigm, 1986. An anthology by expedition members; the first book written, printed, and bound in the Antarctic.

———. *The Heart of the Antarctic: Being the Story of the British Antarctic Expedition, 1907–1909*. London: William Heinemann, 1909. 3-vol. deluxe and 2-vol. trade editions. A dramatic farthest south, along with first arrivals at the summit of Mt. Erebus and nearest the south magnetic pole.

———. *South: The Story of Shackleton's Last Expedition, 1914–1917*. London: William Heinemann, 1919. The leader's unforgettable account of the Imperial Trans-Antarctic Expedition and the Endurance.

Weddell, James. *A Voyage Toward the South Pole*. London: Longman, Rees, Orme, Brown, and Green, 1825. Discovery of the Weddell Sea and the shattering of Cook's record for a new farthest south.

BORCHGREVINK, CARSTEN E.

Determining the contributions of Carsten E. Borchgrevink (1864–1934) to polar history requires a certain degree of patience and understanding. Certain facts about the work of Borchgrevink (pronounced "BORCH-gre-vink") are beyond dispute—he participated in the Antarctic expedition of 1894–1895 and led the Southern Cross expedition of 1898–1900. Assessing what he accomplished is not as simple.

An Anglo-Norwegian who went to Australia to seek his fortune but, instead, drifted through a variety of jobs including teaching, Borchgrevink made his entrée into the polar realms when H. J. Bull (1844–1930) used his connections to Sven Foyn (1809–1895), the inventor of the whaling gun, to launch a whaling expedition in Antarctic waters south of Australia. Bull wanted to take a scientist on this voyage of the Antarctic and might have enlisted the services of William S. Bruce (1867–1921), destined to be, arguably, the finest scientist–explorer the British produced in the Heroic Era. Alas, Bruce could not arrange to meet the ship's sailing date. Borchgrevink applied for the scientist's position but was rejected; instead, still enthusiastic for the voyage, he signed on before the mast.

The journey was not commercially successful but did contain one important incident—the first popularly recognized landing on the Antarctic continent. On January 23, 1895, a small boat approached shore with Bull, the ship's captain, Leonard Kristensen, and several others including Borchgrevink, who, as the ship neared land, leaped from the boat, either to guide it to shore or to claim, as he subsequently did, that he was the first person on the last continent.

Dubious though this claim was, Borchgrevink parlayed it into a career as an Antarctic explorer. Later that year he returned to Great Britain and addressed the International Geographical Congress meeting in London and electrified his audience with his first-hand experience of having seen Antarctica. While other aspects of his presentation caused some of the geographers present to be hesitant in their appraisal of the brash young man, Borchgrevink used the same directness to appeal to Sir George Newnes, a newspaper magnate, who agreed to fund an Antarctic expedition under Borchgrevink.

That effort, the Southern Cross expedition, for good and ill, established Borchgrevink's reputation in polar annals. The Anglo-Norwegian showed great skill in assembling a crew, materials for the expedition, and his scientific staff, but proved a failure as a leader in the field. His staff's amusement at their leader's gaffes and lack of scientific expertise soon turned to outright detestation of his whole being.

What sealed Borchgrevink's reputation was his inept handling of the scientific results of the expedition. At the minimum his carelessness destroyed much of the fine work of the scientists under his leadership; at worst he might have been encouraged in his behavior by jealousy of their accomplishments. Uncovered for these actions, he chose the route of the minimally competent administrator—blaming everyone but himself for problems he had created and lashing out at those who called him to task for his behavior.

After the expedition, Borchgrevink resumed the anonymity of his pre-1894 days, only occasionally coming to the public eye. He proposed to lead an expedition to the South Pole using reindeer in 1909, and, after the tragic end of Captain Robert Falcon Scott, reported to the press that Scott had confided to him his sense that he, Scott, would not return from the Terra Nova expedition. That claim is not substantiated.

Denied official recognition of his Southern Cross accomplishments because of the enmity of those in official British geographical circles, he was ignored until, in 1930, the Royal Geographical Society awarded him the Cullinan Medal for his accomplishments. By that time, the earlier animosity of his staff had tempered sufficiently that they endorsed this award.

Borchgrevink died in Oslo in 1934, a largely forgotten figure from a distant era of polar exploration.

BOUVET DE LOZIER, JEAN-BAPTISTE

Jean-Baptiste Bouvet de Lozier was born in Paris in 1705. His father, a lawyer at the Royal Council, came from a Breton family of St. Malo. Bouvet was a learned and refined man. He studied in Paris and wrote, "having seen a map of the world, I was stunned by this immense emptiness around the southern pole that geographers fill with unknown Lands, and at once was seized with the goal of discovering them." Sent to St. Malo, he was hired by the French East India Company, where he served as a shipmaster and later as a governor until the dissolution of the company in 1763.

Bouvet took an interest in the theories of the time about the location of the Land of Gonneville, then thought to be the southern continent. Indeed, a "Mémoire touchant l'établissement d'une mission chrétienne dans le troisième monde autrement appelé la Terre australe" ("Paper on the subject of the establishment of a Christian mission in the third world also known as Southern land") had been published in 1663 by the Abbé Jean Paulmier. Claiming to be a descendant of Gonneville, Paulmier recounted Gonneville's journey to what he had named the Southern Indias in 1503–1504. Also, Etienne de Flacourt recalled in his famous *Histoire de la grande île de Madagascar* ("History of the great isle of Madagascar"), published in 1661, this "continent a few weeks away" for which "Madagascar could be used as warehouse for trade."

Thus, Captain Bouvet offered (to the directors of the India Company) to go look for the mythical Land of Gonneville. He presented three papers, in 1733, 1735, and 1737, in which he argued the practical interest for East Indian trade of setting a base in the southern sea, the geographical knowledge of the southern sea, and, lastly, the beginning of a colonial power ("a new Europe is there for whom wishes to discover it," he wrote).

The India Company agreed, and in July 1738, two frigates, *Aigle* and *Marie,* under Bouvet's command, left the harbor of Lorient. As planned, they first stopped over in Brazil. Then, moving to the latitude of Patagonia in the south Atlantic, the frigates zigzagged from west to east of the Cape's meridian, between the latitudes of 44° S and 55° S, where the probable site of the discovery was thought to be.

As early as November 26, 1738, Bouvet wrote, "a fog arose that almost never left us, it is one of the greatest obstacles... More often the two ships could not see each other within the range of a gunshot." On December 31, the cold was intense and massive ice blocks loomed up through the fog and snow: "they took all sorts of forms, of islands, fortresses, ships; they lent themselves to all mirages, and the fantastical effects these floating and translucent masses would have been much more picturesque had the sun shone its rays on them. The sea was streaked by whales, divers, penguins, and albatrosses with a heavy and powerful flight."

On January 1, 1739, through gales, rough seas, thick fog, they glimpsed "a very high land that only the fog had prevented us from seeing earlier, it seemed covered with snow and surrounded by large ice masses."

This relief was named Cape Circoncision. But until January 12, any attempt to get closer to determine whether it were a cape of a southern continent or an island, was foiled by the fog, wind, ice, and exhaustion.

"We only saw on deck but a few sea officers and a few young seamen sustained by their honor or youthful strength, though all had lost almost all of their voice."

It was then that Bouvet decided to give up. It was a failure, and the southern continent seemed to withdraw farther and farther away toward the south, in unreachable seas. However, Bouvet wrote later, "if circumstances have since prevented that I employ myself to follow this undertaking whose success could be as glorious as useful to the State, at least I have the satisfaction to have been the first to propose it this century."

Today, Circoncision Cape remains: it is the northwest end of the Norwegian possession of Bouvetøya, located at 54°26′ S, 3°24′ E. What is remarkable is that Bouvet actually happened upon this pin-head in the midst of the vast Southern Ocean. Still, it would take almost four centuries to prove that Gonneville had not landed in 1503 on Antarctic land, but on the Brazilian coast, near Porto Alegre.

Bouvet later married the daughter of an administrator of the India Company, and in 1751 was named governor of Île Bourbon (known today as Réunion), later transferring to Île de France (Mauritius), both islands at the time belonging to the India Company. As governor, he made efforts to alleviate the misery of these colonies, which had no resources. He set up a civil registry, prompted Catholic missionaries to build a school for boys, and even planned a school for girls. He built roads, researched the possibility of digging a harbor, and developed the cultivation of coffee, indigo plants, mulberry trees, and nutmeg trees. He also organized defense against possible British assaults. In 1756, Bouvet asked to go back to France, but the inhabitants of Île de France begged him on their knees not to leave yet. In 1763, as the two islands returned to the control of the government after the cessation of the India Company, Bouvet remained in Bourbon, giving away his salary to cover supply expenses.

Bouvet went back to France in December 1763 and was awarded military nobility in 1774, being praised with the comment: "He may be the greatest and most capable seaman the Company has ever had in its service." Bouvet died in 1781 at his estate of Vauréal, near Paris.

BOUVETØYA

Bouvetøya (Bouvet Island) is located at 54°26′ S, 3°24′ E in the South Atlantic Ocean and is one of the most isolated islands in the world. Due to its steep coastline, it is also one of the most inaccessible, and 93% of the surface is covered by glaciers. The island is 9.5 km long and 7 km wide and covers an area of 49 km^2. The climate is oceanic with an annual mean temperature of –1°C. Bouvetøya is usually shrouded in clouds, but the crater rim and the highest point—780 m—may be seen on rare occasions.

Bouvetøya rises from the Mid-Atlantic Ridge as a volcanic cone. The oldest basalt rocks are 1.3 Ma, while the youngest lavas are 0.1 Ma. Fumaroles are abundant.

There are no grasses or flowering plants at Bouvetøya, but there are approximately seventy species of terrestrial cryptogamic plants: mosses, liverworts, lichens, and fungi. The flora are very similar to those of other Antarctic islands farther to the west. Regarding terrestrial animals, only four species of mites and three of springtails have been recorded. The most common species are the oribatid mite *Alaskozetes antarcticus* and the collembolan *Cryptopygus antarcticus*.

The southern elephant seal and the Antarctic fur seal breed on Bouvetøya. The population of elephant seals ranges from 200 to 400 individuals. Fur seals were heavily hunted by Norwegian whalers in 1927, but to prevent eradication, further hunting was stopped. About 1200 fur seals were counted in 1928.

There are several penguin rookeries at Bouvetøya, mainly made up of chinstrap and macaroni penguins. The latter type is the most numerous. Some of the rookeries are located in the steep mountain sides of the island. A small number of Adélie penguins are also breeding, as well as eight other species of seabirds.

Due to a landslide between 1955 and 1958, a new relatively flat area was formed at the western side of the island. The Westwindstranda is approximately 1500 m long and up to 300 m wide. The highest point, called Nyrøysa, rises 33 m above sea level. Westwindstranda was quickly colonized by penguins and seals. A Russian expedition counted approximately 950 penguins in 1958, but in 1979 Norwegian scientists found that the number had increased to almost 15,000. Later, the breeding grounds were taken over by fur seals, and the number of penguins had decreased to approximately 2000 in 2001.

The population of fur seals increased from 500 in 1964 to 66,000 in 2003.

Bouvetøya was discovered in 1739 by a French expedition headed by Jean-Baptiste Bouvet de Lozier. Due to unfavorable weather conditions, no landing was made, but Bouvet believed he had discovered the unknown austral continent. The island was revisited by British and American sealers in 1808 and 1822, and the first mapping was carried out by the German Valdivia expedition in 1898. In order to establish a whaling station, Bouvetøya was visited yearly by Norwegian expeditions on board the steamer Norvegia. Due to the steep topography, the station could not be built, but the island became a Norwegian possession in 1930. In 1971 it was proclaimed a Norwegian nature reserve, by which designation the ecosystems of the island and adjoining sea are protected.

BRANSFIELD STRAIT AND SOUTH SHETLAND ISLANDS, GEOLOGY OF

Bransfield Strait is situated at the southwestern end of the Scotia Arc, a large-scale tectonic structure linking South America and the Antarctic Peninsula. It is a young (<4 million years old) basin created when the South Shetland Islands crustal microplate migrated northwest, away from the northern Antarctic Peninsula. Rifting within the continental volcanic arc represented by the South Shetland Islands and northern Antarctic Peninsula caused the movement. The active rift is bounded by normal faults to the northwest and southeast and it extends about 400 km northeast from Low Island to Clarence Island where it is terminated by major oblique cross-faults. Seismic refraction studies have shown that the basin is formed in thinned continental crust on top of about 30 km of "anomalous" crustal material. The extension is probably a result of Drake Passage oceanic crust rolling back at the South Shetland trench. The oceanic crust is probably still being consumed (subducted) beneath the islands at a very slow rate. Three major sub-basins are informally defined. The south Bransfield basin extends between Low Island and Deception Island and is the shallowest, with depths typically <1000 m. The central Bransfield basin is up to 2 km deep, about 40 km wide, and 200 km long between Deception Island and Bridgeman Island. It includes the prominent 20- by 50-km, flat-floored King George basin, a sub-basin that is also the site of high heat-flow values and hydrothermal venting. Similar vents also occur buried in the Deception Island caldera. The north Bransfield basin is the deepest and structurally most complicated, with maximum depths over 2700 m.

The seafloor of Bransfield Strait is covered by very young sediments draped over a substrate of volcanic rocks formed during the rifting process. The latter form a series of seamounts and discontinuous ridges. Together, they comprise an incipient mid-ocean ridge, which, as is unusual for mid-ocean ridges generally, is exposed subaerially at Deception and Bridgeman islands. The volcanism in Bransfield Strait started at least 0.3 Ma and continues today at Deception Island. From compositional studies of volcanic ash preserved as layers in ice caps on the South Shetland Islands and in marine sediments, it is known that at least three different volcanoes erupted in Bransfield Strait during the past few thousand years (Deception Island, Bridgeman Island, and a third presumably submarine volcano whose location is currently unknown). Deception Island has been particularly active, with multiple eruptions during the last few tens of thousands of years. The volcanic ashes were dispersed up to 800 km across the Scotia Sea and, in one case at least, as far as the South Pole (3000 km away).

Because of the setting, the volcanic rocks show some of the chemical characteristics of the older continental volcanic arc magmatism as well as features of volcanoes in oceanic basins. Smaller volcanic edifices near the northeastern end of the basin are composed of basalts with the most arc-like compositions, whereas basalts with compositions most similar to mid-ocean ridges occur toward the southwest end. The latter include a large caldera-topped seamount and, unusually, some magmas with andesite and rhyolite compositions. Bridgeman Island contains basaltic andesites and Deception Island has a broad compositional series ranging from basalts to dacites. Low-pressure fractional crystallization of olivine, spinel, and plagioclase can account for most of the compositional variations within the individual volcanoes, whereas differences between volcanoes are probably a result of different mantle sources and melting processes. There are no clear systematic volcanic and chemical variations along the basin axis, suggesting no strong support for the model of unidirectional (southwest) propagation of rifting suggested by geophysical data.

For simplicity, the geology of the South Shetland Islands can be divided into two parts: the metamorphic rocks of the Elephant and Clarence Islands Group and Smith Island, and the mainly volcanic and sedimentary rocks that form the islands from Low Island to King George Island. The metamorphic rocks were pervasively recrystallized under a variety of conditions corresponding to greenschist, albite–epidote–amphibolite, and blueschist facies. The blueschists on Smith Island were the first rocks of their type to be discovered *in situ* in Antarctica, as recently as 1975, although similar rocks were also discovered later on Elephant Island. Their particular importance is due to the unusual conditions required for their formation, corresponding to high pressures (i.e., crustal depths of about 20 km) yet low temperatures (350°C). Rare relict detrital textures, pillow lavas, and cherts are also preserved on Elephant Island, and serpentine-altered ultramafic rocks on Gibbs Island. The distinctive combination of lithologies; low temperatures and high pressures required for the metamorphism; and deformation style have been attributed to formation within an accretionary prism during subduction at the South Shetland trench (i.e., material scraped off the downgoing oceanic plate and underplated on the leading edge of the overriding continent). The metamorphism and therefore subduction probably took place around 109–101 Ma (Elephant and Clarence Islands Group) and 47 Ma (Smith Island) but there is also some evidence for much older metamorphism (at 240–280 million years). The younger ages may represent overprinting by later deformational and metamorphic events.

The oldest rocks elsewhere in the South Shetland Islands are quartz-rich sandstones of the Triassic age that were deposited 240 Ma. Although the strata are exposed only on one peninsula on Livingston Island, similar rocks form extensive outcrops in the northern Antarctic Peninsula, suggesting a formerly much wider distribution, and they may underplate most of the islands. The sequence is predominantly overturned and it may form a very large overfold. Metamorphism is only weakly developed and the original sedimentary structures are well preserved. The sediments were deposited in submarine fans along a mature continental margin, but the tectonic setting of the formation is not well known, ranging from the shallow structural levels of an accretionary prism to a fore-arc basin.

Marine sedimentary rocks on Low Island were deposited in a sedimentary basin on the ocean side of an active volcanic arc during the late Jurassic (155 Ma), which was then situated in the northern Antarctic Peninsula. However, in the earliest Cretaceous times (at about 144 Ma), the South Shetland Islands became the location for the active arc that subsequently dominated the geological development of the island group. The oldest of these arc products are associated with fossiliferous marine and nonmarine sandstones and conglomerates of the early to mid-Cretaceous age (140–100 Ma) on western Livingston Island and Snow Island. The compositions of those volcanic rocks are mainly basaltic but they also include the only rhyolites known in the islands. The South Shetland volcanism migrated northeastward with time, so that the next youngest volcanic strata occur in eastern Livingston Island, where they comprise subaerially erupted basalt–andesite volcanics around Mount Bowles, and sedimentary strata at Williams Point and Moores Peak. The Williams Point Beds were eroded from volcanic terrain and deposited in late Cretaceous (90–80 Ma) riverbeds. They contain some of the best-preserved plant fossils from Antarctica. By contrast, the Moores Peak beds formed after a major collapse of one of the Cretaceous volcanoes.

Younger volcanic strata crop out in the central and eastern islands. They range in age from the latest Cretaceous (about 80 Ma) on Robert and Greenwich islands to Palaeocene–Eocene (60–40 Ma) on King George Island. Like the earlier volcanism, they were erupted subaerially and those on King George Island also contain former lake deposits with abundant very-well-preserved plant fossils. The activity continued to be dominantly basaltic, but very thick andesite lavas with spectacular columnar jointing are particularly common in the Eocene strata. Basaltic volcanism recommenced after a 10-million-year gap but it was now located in eastern King George Island, where basalt to dacite lavas were erupted. Although mainly subaerial, they included several small volcanoes erupted into seawater with very primitive compositions. These younger rocks are also associated with sedimentary deposits related to at least three glacial periods, called the Polonez (29–26 Ma), Melville (23–22 Ma), and Legru (age uncertain) glaciations. The Polonez Glaciation is the oldest glacial period represented onshore in Antarctica. Both the Polonez and the younger Melville glacial units contain abundant marine fossils. They also contain fragments of distinctive rock types that must have travelled at least 2000 km from the likeliest source areas in the Transantarctic and Ellsworth mountains in East Antarctica. Marine siltstones and sandstones less than 20 million years in age, which occur in the Seal Islands (off the north coast of Elephant Island), are the youngest sedimentary strata in the South Shetland Islands. They may also have formed during a cold-climate period, but their precise age and origins are not yet clear.

The volcanic activity seems to have died out at around 24 Ma, but it recommenced about 1 Ma when several small ash cones were erupted on northeastern Livingston and northern Greenwich islands. Penguin Island is also part of that phase of activity although it is lava dominated and separated from the other centres by over 100 km. The island also contains a well-preserved volcanic cone, which may have been active in the last few hundred years. The origin of this final phase of volcanic activity is probably related to the regional extension associated with the rifting of Bransfield Strait, and the young volcanic centres show a variety of compositions ranging from sodium-rich alkaline magmas to island arc magmas.

Plutonic intrusions, mainly granodiorite, are also present on many of the islands. They have a range of ages that mirrors the general trend of northeasterly-younging seen in the volcanic suites. The oldest intrusion is on Low Island (120 Ma) whilst the youngest occurs on Cornwallis Island (9.5 Ma) over 400 km to the northeast. The latter is the youngest granite intrusion dated so far in Antarctica.

BRAZIL: ANTARCTIC PROGRAM

Scientific activities performed by Brazil in the Antarctic take place under the aegis of the Programa Antártico Brasileiro (PROANTAR, the Brazilian Antarctic Program). Implementation of PROANTAR is under the responsibility of the Comissão Interministerial para os Recursos do Mar (CIRM, the Interministerial Commission for Sea Resources), a federal multiministerial organization coordinated by the commander of the Brazilian Navy, Ministry of Defense (formerly Ministry of Navy). Its executive branch is the Secretaria da CIRM (SECIRM), coordinated by the Brazilian Navy.

PROANTAR was created in December 1982, 7 years after Brazil's adherence to the Antarctic Treaty (1975), when the first national scientific expedition was dispatched to the Antarctic region. A geographic survey of possible sites for installing a research station and scientific investigations in the fields of upper-atmosphere physics, biological oceanography, and meteorology took place during the summer aboard the oceanographic ships *Barão de Teffé* (Brazilian Navy) and *Prof. W. Besnard* (Universidade de São Paulo). Initiation of PROANTAR and scientific results obtained during the first Brazilian Antarctic expedition allowed Brazil to become a Consultative Party to the Antarctic Treaty in 1983 and Member of SCAR in 1984.

Until 1990, SECIRM was in charge of both conducting the Antarctic science program and supporting activities of PROANTAR. From 1991 on, the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq, National Council for Technological and Scientific Development), an agency of the Ministério da Ciência e Tecnologia (MCT, the Ministry of Science and Technology), was in charge of the scientific activities of PROANTAR. Other important components of the Brazilian Antarctic system are the Ministério das Relações Exteriores (MRE, Ministry of Foreign Relations), MCT, and Ministério do Meio Ambiente (MMA, Ministry of Environment). MRE, through its Comissão Nacional para Assuntos Antárticos (CONANTAR, National Commission for Antarctic Affairs) elaborates the Política Antártica Nacional (POLANTAR, National Antarctic Politics). The POLANTAR expresses the Brazilian national interests in the Antarctic region, the main objectives and lines of action of PROANTAR. MCT houses the Comitê Nacional de Pesquisas Antárticas (CONAPA, National Committee on Antarctic Research). CONAPA provides a link between the Brazilian Antarctic science community and the Antarctic science activities and initiatives internationally promoted and coordinated by SCAR. The MMA is responsible for the implementation of measures in the Protocol on Environmental Protection to the Antarctic Treaty with regard to Brazilian activities in the Antarctic. Scientific research within PROANTAR is performed in a decentralized way by a number of universities and research institutions (average twenty-five) from all over the country.

Supporting activities provided by SECIRM to PROANTAR include logistic operations, education in Antarctic matters (particularly with reference to environmental questions), and pre-Antarctic expedition training of scientists and supporting personnel. In association with the Fundação Universidade Federal de Rio Grande (FURG, Foundation Federal University of Rio Grande), SECIRM runs the Estação de Apoio Antártico (ESANTAR, Antarctic Supporting Station) in Rio Grande, southernmost Brazil. ESANTAR keeps and maintains Antarctic clothing, vehicles, camping gear, and other equipment utilized in annual Antarctic fieldwork. Since 1996, the oceanographic vessel *Ary Rongel* (Brazilian Navy) has been utilized for transporting PROANTAR participants and for resupplying Brazilian science facilities in Antarctica. Transportation of cargo and personnel is also provided by the Brazilian Air Force, which performs several flights year-round to the Chilean air strip at base Presidente Frei, on King George Island.

Brazilian Antarctic installations include the Estação Antártica Comandante Ferraz (EACF, Commander Ferraz Antarctic Station) and three summer refuges on Elephant Island, Nelson Island, and Fildes Peninsula, King George Island. Built in 1984 on Keller Peninsula, Admiralty Bay, King George Island, EACF became a year-round station in 1986. It can accommodate around forty-six persons in summer and twenty-two in winter.

Evaluation of projects submitted by the Brazilian scientific community to PROANTAR is made by CNPq through its Grupo de Assessoramento do PROANTAR (GA, Assessing Group) using a peer-review process, on the basis of scientific consistence, relevance to main Antarctic science questions, and quality of team. All projects are previously reviewed with regard to their possible environmental impact by the Grupo de Avaliação Ambiental (GAAm, the Environmental Evaluation Group of MCT). Approved projects are then examined for their logistical requirements by the Grupo de Operações (GO, Operations Group of SECIRM).

Prior to 2002, the scientific content of PROANTAR was made up of projects submitted by Brazilian researchers in the general fields of atmospheric sciences, life sciences, and Earth sciences, initially supported by SECIRM and later by CNPq. A major restructuring of PROANTAR scientific organization then took place as a combined initiative of MMA and CNPq. The reorganization involved the establishment of two nationwide research networks formed by numerous multidisciplinary and multi-institutional research groups with a focus on the investigation of Antarctic environmental changes.

Network 1 aims at analysing changes that may be occurring in the Antarctic Peninsula region, with regard to their possible interaction with terrestrial processes outside Antarctica, particularly those that might have an effect on the Brazilian territory. Network 2 intends to produce a detailed diagnosis of the present state of the Antarctic environment within the Antarctic Specially Managed Area Admiralty Bay, where a substantial part of the Brazilian Antarctic activities take place. Network 1 includes about sixty researchers from seven research groups. The number of scientists involved in Network 2 is around 120, representing 15 research groups. Around thirty Brazilian research institutions are presently active in PROANTAR. Scientists from sixteen international institutions collaborate with the two networks. Both networks are intended to be pluriannual activities with an initial duration of 3 years. A smaller percentage of the science budget is dedicated to supporting high-quality, innovative research projects proposed by scientists or science groups.

Scientific results of PROANTAR are published in both national and international peer-reviewed journals. Lists of publications appear annually in the Brazilian report to SCAR and may be examined in existing databases maintained by CNPq. Pesquisa Antártica Brasileira (Brazilian Antarctic Research), the PROANTAR scientific journal, is published by the Academia Brasileira de Ciências (Brazilian Academy of Sciences) on behalf of the program with the financial support of CNPq.

PROANTAR is a modestly funded Antarctic program with a total yearly budget of around 1.5 million US dollars (2001–2004). Of this amount, approximately 30% goes to science while 70% is spent on supporting activities. Research is presently funded by resources from both CNPq and MMA. Resources for supporting activities come from SECIRM.

BRITISH ANTARCTIC (*EREBUS* AND *TERROR*) EXPEDITION (1839–1843)

On June 1, 1831, James Clark Ross located the North Magnetic Pole near Cape Adelaide on the west coast of Boothia Peninsula. Hence, when the Royal Navy was persuaded to mount an expedition to carry out a series of observations at fixed stations in the Southern Hemisphere and, if possible, to locate the South Magnetic Pole, the choice of Ross, by then a captain, to lead the expedition was a natural one.

The ships allocated to the expedition were two barque-rigged bomb-vessels, HMS *Erebus* and *Terror,* 372 and 326 tons respectively. Second in command (and captain of *Terror*) was Captain Francis Crozier, who had sailed with Ross on William Edward Parry's second, third, and fourth Arctic expeditions. Surgeon on board *Erebus* was Robert McCormick, who also filled the functions of geologist and ornithologist; assistant surgeon was Joseph Dalton Hooker, who also acted as botanist. The total complement of the expedition was 126 men.

The expedition sailed from Margate Roads on September 30, 1839. Having called at Madeira, the Canary Islands, Cape Verde Islands, St. Paul Rocks, and Trindade, on January 31, 1840 they reached St. Helena, where the first magnetic station was to be established. Army officer Lieutenant Lefroy and a party were put ashore, but it was soon discovered that the island was particularly unsuitable for magnetic studies due to great anomalies produced by its volcanic rocks.

The ships put to sea again on February 9, 1840, reaching Simon's Bay near Cape Town on March 16. Lieutenant Wilmot and a party went ashore to set up a magnetic observatory, and then, on April 6, the ships put to sea again, and were soon separated in bad weather. *Erebus* sailed close past the Prince Edward Islands and then, during the period April 25–30, charted the Crozet Islands (today known as Îles Crozet), some distance from where previously plotted.

Both ships reached Kerguelen on May 5. Ten days later, they were warped to the head of Christmas Harbour, where two observatories were built on the beach—one for magnetic studies, the other for astronomical observations and pendulum studies—as well as huts for the observers. Here the ships stayed for over two months marked by foul weather with gale-force winds, rain, and snow on most days.

Putting to sea again on July 20, the ships ran eastwards to Van Diemen's Land (Tasmania) and reached Hobart on August 16 and 17. Here Ross and his officers were given a very warm welcome by the Lieutenant Governor, Sir John Franklin, who helped choose a site for the observatories; 200 convicts were assigned to dig the foundations. Leaving Lieutenant Joseph Kay and two mates to continue the observations, *Erebus* and *Terror* sailed again on November 12, 1840, bound next for the Auckland Islands; here, in Port Ross, a further set of observatories was built, and the ships stayed for a month, while the usual magnetic observations were carried out and the harbour surveyed.

On December 12, the ships put to sea again, bound next for Campbell Island, where they spent a few days. They then headed south, in search of the South Magnetic Pole. The first iceberg was seen on December 27, and the edge of the pack ice was encountered on New Year's Day, 1841, right on the Antarctic Circle. The ships entered the pack ice on January 5 and, taking advantage of leads and polynyas, worked their way south. Adélie penguins provided great entertainment; numerous seals, mainly crabeater and Weddell seals, were seen; one that was shot proved to be of a new species: a Ross seal.

By January 8, a dark water-sky was visible to the south and by the following morning they had penetrated the belt of pack ice that guards the Ross Sea almost permanently, to reach the open waters beyond, the first ships ever to do so. On the morning of January 11, an imposing range of snow-covered mountains was sighted ahead, the Admiralty Range in Victoria Land. Measurements of dip and variation revealed that the Magnetic Pole must lie more than 500 miles (800 km) to the southwest, that is, well inland and hence inaccessible by sea.

The next morning, parties from both ships, led by their captains, landed on a small island that Ross named Possession Island; here he raised the Union Jack and claimed the new lands for Queen Victoria. The ceremony was held in the middle of a noisy, smelly penguin rookery.

Pushing southward Ross passed and named two islands, Coulman Island, named after the father of Ross' fiancée, Ann, and Franklin Island, on which a landing was made. On January 27, a conspicuous, snow-covered, conical peak appeared dead ahead. Next day it was revealed to be an active volcano, emitting dense clouds of smoke and gouts of flame. It was named Mount Erebus and an adjacent, extinct volcano Mount Terror.

The ships had just passed another small island, named Beaufort Island, when a continuous, low, white line extending along the horizon was spotted ahead. As they approached it became steadily higher, until it appeared to be a continuous ice-cliff, 165–200 feet (50–60 m) high, its top absolutely level and stretching out of sight to the east. Ross named it "the Barrier"; he had discovered the front of the Ross Ice Shelf, a vast expanse of floating glacier ice filling the southern part of the Ross Sea and produced by the convergence of a large number of outlet glaciers fed from the Antarctic Ice Sheet. Its front is about 500 miles (800 km) wide, and it extends almost 600 miles (965 km) from north to south, narrowing southwards. It thus covers about 180,000 square miles (466,000 km^2), about the same area as France.

Swinging east along the Barrier, Ross traced it for a distance of some 375 miles (600 km), but found no break in it, nor any diminution in height. Finally, blocked by pack ice, on February 12 Ross started back west. Passing Mount Terror and Mount Erebus again, Ross established that they were on an island (since named Ross Island), beyond which he discovered an embayment that was named McMurdo Bay (now McMurdo Sound) after Terror's first lieutenant. Ross had hoped to find a wintering site here, but the approaches were blocked by fast ice; coasting back north along the Victoria Land coast, he was unable to find a suitable wintering site there either, so on February 26 he started back north for Hobart, arriving there on April 7, 1841.

In Hobart the ships were refitted, while the crews relaxed. The ships departed again on July 7, 1841, and reached Sydney a week later. An observatory was established on Garden Island in Sydney Harbour, and there observations were made for comparison with simultaneous observations made at Hobart. The observations completed, the ships put to sea again on August 5, bound for Bay of Islands, New Zealand, where they remained for three months while the now-standard magnetic, pendulum, and meteorological observations were made.

Erebus and *Terror* sailed again on November 23, 1841, southward bound, once again, for the Ross Sea. The first pack ice was encountered on December 16, much farther north than in the previous year. Once again they crossed the Antarctic Circle on New Year's Day. On January 19, 1842, the ships were struck by a violent gale while they were in heavy pack ice and the rudders of both ships were smashed. After this damage was repaired, they finally reached the open waters of the Ross Sea again in the early hours of February 2. The Barrier again hove into view on February 22, and the two ships swung east to trace it for some 10° of longitude farther than they had the previous year.

With new ice starting to form, Ross now headed back north. Emerging from the pack ice on March 1, he swung east, bound for Cape Horn. But there were still large numbers of icebergs, and on the night of March 12–13, while trying to avoid a large berg that had loomed out of the darkness, the two ships collided and their rigging became entangled. Ross managed to extricate himself from this predicament by backing his sails, getting some sternway on his ship, then maneuvering her through the rapidly closing gap between two other very large bergs.

The damage repaired, the ships continued to run east, passing Cape Horn, and on April 6, 1842, reached Port Louis in the Falkland Islands, where they were to spend most of the winter. Observatories were set up and the usual schedule of magnetic, pendulum, astronomical, and meteorological observations began. Both ships, in turn, were emptied of stores and equipment and were careened on the beach so that the damage to their hulls could be repaired. Leaving an officer to continue the magnetic observations at Port Louis, on September 8, 1842, the ships sailed for Cape Horn, where Ross wanted to make comparative magnetic measurements. They reached St. Martin's Cove, Hermite Island (just north of Cape Horn), on September 20. An observatory was set up and the observations continued for a month. The ships then returned to the Falklands, arriving on November 13.

A month later, on December 17, the magnetic observations at Port Louis completed, Ross put to sea, heading south once again. He planned to investigate the western shores of the Weddell Sea. Arguing that prevailing westerlies should push the pack away from the western shores, he hope to attain a higher latitude than Weddell's record of 74°15′ S.

Passing east of Clarence Island, the two ships raised Joinville Island, off the northeastern tip of the Antarctic Peninsula. Manoeuvring in thick weather, on December 31 Ross was rewarded with a fine, clear day, which found him south of Dundee Island (which he mistook for part of Joinville Island) in the wide embayment of Erebus and Terror Gulf. On January 6, 1843, Ross, Crozier, and the other officers landed on Cockburn Island and took possession of all the islands visible. Running south and west past Seymour and Snow Hill islands, by mid-month the ships were brought up by the edge of the fast ice to the south. On February 1 Ross abandoned any hope of getting farther south in this area; he got clear of the ice by February 4 and headed east along the edge of the pack. The latter began to trend southeast and, following it, Ross not only crossed the Antarctic Circle for the third time, but reached 71°30′ S before being blocked by pack ice on March 5, 1843, off the coast of Queen Maud Land.

Extricating his ships from the ice, Ross next set a course for the Cape of Good Hope. *Erebus* and *Terror* dropped anchor in Simon's Bay on April 4. Having completed the magnetic observations there, they sailed again on April 30 and having called at St. Helena, Ascension, and Rio de Janeiro, they reached Folkestone on September 4. They were paid off at Woolwich on September 23.

James Clark Ross had exceeded by an enormous margin the original aims of his expedition. Having conducted magnetic observations for varying lengths of time at nine different observatories in the high southern latitudes, he had vastly expanded the knowledge of magnetism in the Southern Hemisphere. And from his measurements of dip and variation in the Ross Sea, he had proved incontrovertibly that the South Magnetic Pole lay some five hundred miles inland from that sea. But in addition to this, Ross was the first to penetrate the ice-free waters of the Ross Sea, the first to see Mount Erebus, and the first to see and map the Great Ice Barrier or Ross Ice Shelf.

Of the published scientific results of the expedition, the most voluminous were those analysing the results of the magnetic observations, published during the period from 1843–1868, and the analysis of Hooker's botanical collections. His beautifully illustrated Flora Antarctica, a groundbreaking work, was published in two volumes. The expedition also made useful contributions in the areas of oceanography and marine biology. As the first multidisciplinary Antarctic expedition, it set a very high standard for all those that followed.

BRITISH ANTARCTIC *(NIMROD)* EXPEDITION (1907–1909)

Although attaining the North Pole had been the aim of many expeditions in previous decades, the British Antarctic Expedition of 1907 was the first to have the explicit goal of reaching the South Pole, which remained one of the last great mysteries on Earth. One should not be confused by the expedition's grand title, however; it was not a national effort, but very much the brainchild of one man—Ernest Shackleton.

Shackleton's desire to lead such an expedition came from his experiences on the British National Antarctic Expedition (1901–1904) under Robert Falcon Scott, on which he had served as third officer.

In the summer of 1902–1903, Scott, Shackleton, and surgeon Edward Wilson attained a farthest south of 82°17′ S on the Great Ice Barrier (now known as the Ross Ice Shelf). During the journey, all three suffered from scurvy, with Shackleton by far the most severely affected, which led to Scott invaliding him home against his will. Shackleton's desire to prove that he should not have been sent back early—as well as his belief that a successful attempt on the Pole could gain him fame and fortune—led him to consider commanding his own expedition, although he received little encouragement for several years.

In February 1907, a bank loan of £7000 was guaranteed for Shackleton by his employer, the Scottish industrialist William Beardmore. This allowed the explorer to move forward with his plans, which included leaving England that very year. Shackleton soon found that Scott also hoped to return to the Antarctic, and that his former commander did not want him using their previous base at Hut Point on Ross Island, nor even going near Ross Island or its adjacent McMurdo Sound. After extensive negotiations, Shackleton agreed to land instead at King Edward VII Land. This was a major concession because Ross Island abutted the Barrier and appeared, at that point, to be the start of the ideal road to the pole, whereas no one had ever landed at King Edward VII Land, hundreds of miles away from McMurdo Sound at the eastern edge of the Great Ice Barrier. While conditions to the south of it were totally unknown, it was the only other place that seemed within striking distance of the pole.

Key to Shackleton's hopes for reaching the pole were two forms of transport never before used in the Antarctic: an Arrol-Johnston motor-car given him by Beardmore (who owned the company) and Manchurian ponies. Shackleton was convinced to take ponies by Frederick Jackson, who had used them in his exploration of the Arctic archipelago of Franz Josef Land. The lack of success with dogs on Scott's expedition—caused in great part by inexperience with the animals—had left him and his former companions with little trust in them, so, although he brought a handful of dogs south, Shackleton planned to manhaul should the motor-car and ponies fail.

On August 7, 1907, the expedition ship Nimrod—a former Newfoundland sealer—departed from England, having been visited at Cowes 3 days before by King Edward VII and the Royal family. While the ship proceeded slowly to New Zealand, Shackleton remained behind to continue raising funds, major contributions already having been made by William Bell, Campbell McKellar, and the Earl of Iveagh. Significant funding also was contributed by the family of Sir Philip Brocklehurst, the 20-year-old baronet becoming the first subscribing member of an Antarctic expedition.

In December, while travelling to Lyttelton, New Zealand, to join the ship, Shackleton met with Professor Tannatt William Edgeworth David, a renowned geologist at the University of Sydney. Shackleton and David had agreed that "The Prof," as he came to be known, would accompany the expedition to Antarctica and then return north on *Nimrod,* which would winter in New Zealand, while the expedition staff remained in the Antarctic. Politically influential, David helped convince the Australian government to grant the expedition £5000, which allowed Shackleton to add one of David's former students—Douglas Mawson, a geologist at the University of Adelaide—to the shore party.

On January 1, 1908, *Nimrod* departed south, her lack of storage for coal requiring that she be towed some 1400 nautical miles (approximately 1600 statute miles or 2600 km) to the ice edge by the steel steamer Koonya. The difficulties of this effort were increased dramatically by a terrible storm that lasted for 10 days. Near the Antarctic Circle, *Nimrod* was cut loose, and moved south.

On January 23, the expedition approached the Great Ice Barrier. It soon became apparent that large sections had calved off since Scott's party had last visited the area. A new feature, which Shackleton named the Bay of Whales, had formed, and the entire episode led him to decide that setting up base on the barrier would be unsafe. They attempted to reach King Edward VII Land, but the tiny ship could not force her way through the heavy ice. After consulting with several of the shore party and Rupert England, the ship's captain, Shackleton decided the only viable way to protect his men and to keep faith with those funding and supporting the expedition was to break his promise to Scott and proceed to McMurdo Sound.

Miles of ice blocked the approach to Hut Point, however, and on February 3, Shackleton selected Cape Royds, a rocky promontory 18 miles (29 km) north on Ross Island, as his base. Here a hut was built for the fifteen men who would winter in the Antarctic, including David, who had decided to remain with the expedition and had designed for it a serious scientific program.

Unfortunately, the ice in McMurdo Sound broke up shortly after Cape Royds was occupied and *Nimrod* returned north, the open water and impassable conditions on the island itself cutting the shore party off from the road to the south until the sea froze over again the next winter.

In order to keep his men occupied and their spirits high, Shackleton decided they should make the first ascent of Mount Erebus, the active volcano on Ross Island. On March 5, a party of six left for the attempt. David, Mawson, and assistant surgeon Alastair Forbes Mackay formed the intended summit party, and expedition second-in-command Jameson Adams, surgeon Eric Marshall, and Brocklehurst comprised the support party. Adams later decided that the entire party would continue to the top. On March 10, having left Brocklehurst in his sleeping bag with frostbitten feet, the other five men reached the summit of the active crater, where they took photographs and made measurements before returning to the base.

In August, after the sea had again frozen over and the worst of the winter was past, Shackleton began sending parties south, in order to move supplies to Hut Point and to give sledging experience to his men, only two of whom—Frank Wild and Ernest Joyce—had previous Antarctic experience. Shackleton's plan entailed breaking his party into four groups, one of which would remain at Cape Royds and carry out scientific studies. Two of the other groups would make attempts on the South Pole and the South Magnetic Pole, respectively, while the third would engage in a geological field trip to the mountains west of McMurdo Sound.

Shackleton's plans for the Southern Party had been revised after they found that although they could use the motor car to positive effect on smooth sea ice; it was not suitable for the snow-covered barrier. More importantly, of the ten ponies brought south, only four were still alive: two had been put down aboard ship due to injuries, and four had died at Cape Royds due to eating corrosive materials or salt-covered sand. With only four ponies, the Southern Party was cut from six to four men. Accompanying Shackleton were Wild, Marshall, and Adams.

On October 29 the polar party headed south, each leading a pony. A five-man support group carried extra supplies before turning back on November 7. Early on, Shackleton cut the carefully planned rations, in order to extend the time away from base from 91 days to 110. The ponies quickly proved to be at a serious disadvantage in a glacial environment, needing to be protected from the cold and wind each night much more than dogs would have, and their sharp hooves and heavy bodies causing them to break through the coverings over crevasses more frequently than the men. On November 21 one of them had become so weak and inefficient he was shot. On November 26, in the middle of the barrier, they surpassed Scott's farthest south.

Two days later a second pony was put down, and on December 1 a third. Three men now hauled one sledge while Wild guided Socks, the last pony. Meanwhile, the line of the Transantarctic Mountains, which had previously paralleled their course, now curved to the east, blocking the explorers' path. In order to continue directly south and to avoid an area of the barrier that became violently disturbed with massive pressure ridges and increasing crevasses, the four men began to ascend what they called the Great Glacier (later named the Beardmore Glacier), which they hoped would take them through the mountains. On December 7, Socks fell down a crevasse, leaving them to proceed on their own.

For 3 weeks they struggled up the glacier, eventually reaching the Plateau, across which they continued, despite suffering from inadequate nutrition, high-altitude problems, extremely low temperatures, strong headwinds, and difficult sledging surfaces. By early January 1909 they realized that it was unlikely they would be able to attain the pole and return alive, but they were determined to reach within 100 miles of it. On January 9, after being kept in their tent for 2 days by a blizzard, they made a final push to 88°23′ S, only 97 geographic miles (112 statute miles or 180 km) from the pole. There Shackleton made one of his bravest decisions: turning back despite being so close to their goal. This decision allowed him to bring back all of his men alive.

The return north saw the four men repeatedly run out of food and just reach the supplies at the next depot. At one point travel was precluded altogether when all four suffered severe enteritis from eating pony meat that had gone bad. Hurrying desperately, because they were not certain if *Nimrod,* which was scheduled to return to the Antarctic from New Zealand, would wait for them beyond the end of February, Shackleton and Wild managed to reach Hut Point the night of February 28. They were picked up by the ship the next morning, and then returned to the barrier to collect Adams and Marshall, the latter of whom had collapsed.

Meanwhile, the Northern Party—consisting of David, Mawson, and Mackay—had left Cape Royds on October 5, 1908, to man-haul up the coast of Victoria Land until they could find a place to turn inland toward the South Magnetic Pole. Forced to relay their sledges because they had too many supplies to pull at one time, they made slow progress. In early November they passed over the Nordenskjöld Ice Barrier, and on December 1 they reached the massive Drygalski Ice Tongue, which took 10 days to cross. They began their ascent up a series of glaciers towards the Antarctic Plateau on December 16. Their trek inland continued for weeks, culminating on January 16, 1909, when, at 72°15′ S, 155°16′ E, they calculated they had reached the South Magnetic Pole. They then retraced their steps until blundering into a terribly crevassed and dangerous area near the base of the Larsen Glacier. They reached the coast in early February and were picked up by *Nimrod,* which had returned from New Zealand. They were almost left behind, because during a blizzard *Nimrod* passed where they were waiting, but the first mate, John King Davis, convinced the captain to go back—rather than abandoning the explorers to their fate as he intended—and they found the three men precisely where Davis had thought they might be.

Not long before, Nimrod had rescued the three members of the Western Party—Brocklehurst, Raymond Priestley, and Bertram Armytage. These three had formed part of the Southern Party's support before turning back. In December, they ascended the Ferrar Glacier, discovering defects in the maps prepared by Scott's expedition, and studying the geology of the area before returning to the coast to await the Northern Party. They were almost killed when the sea ice they were camping out on broke loose and started floating out of McMurdo Sound, but they managed to escape when it briefly brushed against the shore. After waiting for more than three weeks, they were finally picked up on January 24.

With all members safely on board, the expedition returned to New Zealand to great acclaim. While Shackleton and the members of the shore party were showered with honors, Davis, who had served as first mate throughout the expedition, successfully completed his first command by taking *Nimrod* back to England. On this voyage, Davis, who would go on to become the most experienced of all ship captains involved in Antarctic exploration, followed a far southerly route, which allowed him to prove that four sets of islands previously reported did not, in fact, exist.

The British Antarctic Expedition was very successful from both geographical and scientific standpoints. Shackleton and his companions recorded the greatest advance towards either end of the earth ever made, including beating the old farthest south record by 366 geographical miles. By pioneering the way to the central Antarctic Plateau, they proved beyond doubt the continental nature of Antarctica. They not only were the first to attain and record the nature of the far reaches of the barrier, as well as the Beardmore Glacier and the central plateau, but in doing so they opened the road that Scott would follow on his subsequent expedition.

Although the scientific contributions of David, Mawson, Priestley, and James Murray have been somewhat obscured due to those of Scott's expeditions and because of Shackleton's relative lack of interest in academic matters, large quantities of data were obtained at Cape Royds, on the ascent of Mount Erebus, the trek to the Magnetic Pole, and the Southern Party's journey. The geological surveys and studies carried out by David, Mawson, and Priestley extended and corrected the work from earlier expeditions, and the monograph on the geology of southern Victoria Land by David and Priestley remained the authoritative account for many years. Mawson also made the first serious study of the physical structure of Antarctic ice, and Murray the initial significant examinations of Antarctic freshwater biology in the lakes dotting Cape Royds.

Perhaps most importantly, the expedition introduced to the far south three men—David, Mawson, and Priestley—who would be giants in the history of Antarctic science, with Mawson leading the Australasian Antarctic Expeditions (1911–1914) and the British, Australian, New Zealand Antarctic Expedition (1929–1931). In the ensuing decades, David, Mawson, and Priestley all held major academic and administrative posts, through them serving as powerful advocates for Antarctic science, and helping establish, promote, and guide Antarctic research.

BRITISH ANTARCTIC *(SOUTHERN CROSS)* EXPEDITION (1898–1900)

In the last years of the nineteenth century, with individuals in Germany, Great Britain, and France trying to launch major national expeditions, a young interloper who was not part of the official geographical establishment persuaded a newspaper magnate, Sir George Newnes, to fund an expedition to Antarctica. The organizer, Carsten E. Borchgrevink (1864–1934), began his expedition amid a hostile environment in Great Britain led by the president of the Royal Geographical Society, Sir Clements R. Markham, whose vitriolic accusations against Borchgrevink must be understood in the context of an old man outdone by a younger and less experienced one.

Despite obvious shortcomings as a leader, Borchgrevink chose his staff wisely and produced a well-equipped expedition. The *Southern Cross* expedition sailed from London on August 28, 1898 and arrived in Tasmania in November 1898. From there, the men proceeded to Cape Adare at the northern tip of Victoria Land, a place Borchgrevink knew from a previous trip. The journey through the ice was arduous, and Captain Bernhard Jenson showed great skill in guiding his small craft through the dangerous water.

The length of time required for passing through the ice pack and the lateness of the season prevented extensive exploration by ship for other sites. The choice of Cape Adare proved to be an unfortunate one, as it did not allow easy access to other nearby areas. As a result, geographical discovery on land was limited, although the cruise during both the first and second summer afforded opportunities for geographical discovery. Still, the scientists, including Louis Bernacchi (1876–1942), Nicholai Hansen (1870–1899), and William Colbeck (1871–1930), made good use of their opportunity and produced a significant body of scientific research. *Southern Cross* departed Cape Adare to winter in Australia.

As a leader, Borchgrevink soon demonstrated his shortcomings, which were many. His lack of scientific expertise need not have been the severe disadvantage that he made it, but his overblown sense of his own scientific abilities provoked in his young scientific staff an early contempt that grew to dislike and then to hatred. Borchgrevink lacked appropriate humility and suffered, as many incompetents do, from an inability to recognize generously the quality of the work of others. Despite this, the scientists accomplished more than a year of magnetic and meteorological observations plus data on the local flora and fauna.

Borchgrevink's skills in choosing good equipment and, particularly, palatable and adequate food, meant that the health of his men remained good through the winter. An exception was Nicholai Hansen, who appears to have had preexisting health problems for which the expedition physician, Herlof Klovstad (1868–1900), was unable to find a cure. Hansen's death in October 1899 was the darkest moment in the expedition.

The wintering party lived in a prefabricated hut that, while small, was comfortable. They soon settled into a routine of scientific work. Borchgrevink's restless nature, combined with an ever-growing animosity from his staff, prompted him to make several winter sledging trips, often in the company of the two Sami that the leader had selected for the staff. These two men showed great acumen and were successful hunters.

The conditions of life together were not made easier by Borchgrevink's uneven temper and immoderate leadership. On several occasions he quarreled with his staff—even dismissing Colbeck from the expedition at one point. Still, the scientists persevered and Borchgrevink's lack of scientific leadership did not diminish the work of the expedition.

In January 1900, *Southern Cross* returned to Cape Adare, took on the wintering party, and then sailed south along the coast. The crew was as dazzled by the Ross Ice Shelf (then known as the Great Ice Barrier) as James Clark Ross' men had been 60 years earlier. Cruising along this huge wall, Borchgrevink's party came to an indentation in the ice shelf, an area subsequently known as Balloon Bight on the *Discovery* expedition. The ship established a new farthest south for a vessel, and two parties sledged out on the ice shelf. One, led by Borchgrevink, established a new farthest south. Again, as with his claim to the first on the last continent, the accomplishment had less actual import, but did give Borchgrevink a place in the annals of polar history.

The ship returned via Hobart to London in the summer of 1900. By that time, preparations for Robert Falcon Scott's British National Antarctic Expedition were well advanced, and Borchgrevink's estrangement from official geographical circles diminished the initial credit that his expedition received.

Aside from the scientific achievements, the *Southern Cross* expedition demonstrated that humans could winter on the Antarctic continent. Moreover, although subsequent expeditions did not always profit from the experience, this endeavor demonstrated the value of kayaks, skiing, and dogs as means of transport in the south polar regions and indicated that the Sami of the north could apply their polar survival expertise in Antarctica. That these lessons were not applied in subsequent Heroic Age expeditions, particularly other British ones, was less the fault of

Borchgrevink than of those in official geographical circles, who disdained learning from an outsider.

The *Southern Cross* expedition was a credible pioneering effort, successful in meeting many of its goals, and, as such, compares favorably with several other later British expeditions to 1922.

BRITISH ANTARCTIC SURVEY

The origins of the British Antarctic Survey lie in World War II as a secret Royal Naval operation known as Operation Tabarin, established to counter the potential dangers from German commerce raiders in the Southern Ocean. There was also the political context provided by the conflicting territorial claims of the UK, Argentina, and Chile to Antarctic territory.

In February 1942, Argentina had reaffirmed its claim to the sector between 25° and 68°34′ W via an expedition to Deception Island and as far south as the Argentine Islands. This sector overlapped with the British claim (published in Letters Patent in 1908) from 20° to 80° W and known as the Falkland Islands Dependencies (FID). The first step in the British response was to send HMS *Carnarvon Castle* to Deception Island and Signy Island in January 1943 to reassert the British claim. Meanwhile on 28 January 1943 the British War Cabinet approved an expedition to the FID to strengthen the British title and deny the use of harbours and stocks of oil to enemy shipping. A small military force was tasked with establishing a wintering presence on the Antarctic Peninsula under the direction of the Royal Navy, but acting on behalf of the British Colonial Office. The code name "Tabarin" came from a Parisian nightclub well known to the organisers before the war.

Fourteen volunteers were selected in great secrecy, with the only clue as to their destination being the issue of sunglasses! They mustered at Port Stanley in the Falkland Islands and set off south on 29 January 1944 in two small ships, HMS *William Scoresby* and SS *Fitzroy*. The plan was to establish wintering stations on Deception Island and in Hope Bay on Trinity Peninsula. At Deception Island the base was established in Whalers Bay. Ice conditions meant that the ships could not safely land the people and equipment in Hope Bay, so they headed south down the western coast of the Peninsula, finally choosing Port Lockroy on Wienke Island as the site for the second station.

Tabarin had an advisory committee to provide polar expertise, consisting of James Wordie, a veteran of Shackleton's Imperial Trans-Antarctic Expedition; Dr. Brian Roberts, biologist on the 1935–1937 British Graham Land Expedition; and Dr. Neil Mackintosh, Director of the Discovery Investigations. Given this membership it was natural that the opportunity for doing science under the umbrella of a military operation was recognised and seized upon from the outset.

With the end of the Second World War, administrative control of the stations was transferred to the Colonial Office in recognition of the political purpose for which they were maintained. In July 1945, the operation was renamed the Falkland Islands Dependencies Survey (quickly shortened to FIDS). Whilst FIDS primarily operated to maintain a presence to support the British territorial claim, the work on the ground was predominantly expeditionary and scientific, with programmes of geology, biology, meteorology, survey, and mapping. In 1948, the Falkland Islands Dependencies Scientific Committee was appointed to report on scientific matters to the Colonial Secretary, whilst responsibility for the administration and operation of FIDS was formally transferred to the Governor of the Falkland Islands and Dependencies. The Governor established a small team in Port Stanley to manage the operation. At the same time, "Rear Base" was set up to provide the operational head of FIDS (SECFIDS) with an office when in London. Two years later the Falkland Islands Dependencies Scientific Bureau was established in London to coordinate the exploitation of the scientific data and samples collected by FIDS, with Dr. Vivian (later Sir Vivian) Fuchs as Principal Scientific Officer.

Over the next few years the many strands of management and oversight (Colonial Office, Governor FI, SECFIDS, Bureau and Rear Base) evolved so that in 1953 the Scientific Bureau became an integral part of FIDS, with Fuchs designated as Director of FIDS Scientific Bureau, responsible to the Governor. The first 5-year scientific plan was produced by the Bureau in 1955—starting a pattern of research management that continues today. Through the latter half of the 1950s there was much discussion about consolidation and reorganisation, so that finally in 1959 it was agreed that FIDS would be run as a single organisation with a director answerable to the governor. Dr. Fuchs was confirmed as director.

FIDS marine capability greatly improved at this time with the purchase of a Norwegian vessel, the MV *Arendal* (renamed the Royal Research Ship [RRS] *Shackleton*), in 1955, and the delivery of the new purpose-built RRS *John Biscoe* (the second FIDS vessel to carry this name) in 1956.

Around this time the spectacular success of the International Geophysical Year had resulted in the negotiation of the Antarctic Treaty, which came into force in 1962. One consequence was the redesignation of the British territorial claim to be the British Antarctic Territory, and following from that the renaming of FIDS as the British Antarctic Survey (BAS) on 1 January 1962. But the old acronym did not die; it just transmogrified to become the colloquial name for successive generations of field staff collectively known as Fids (standing for foolish idiots down south—or words to that effect!). With the renaming, London Office became the headquarters of BAS.

Over the next few years Sir Vivian Fuchs attempted to assure the long-term future of BAS within the UK government administration. Things came to a head in 1965 when the Treasury moved to have BAS wound up. The consequent review committee decided that BAS should continue, but become a component body of the recently formed Natural Environment Research Council (NERC). Thus on 1 April 1967 BAS transferred from the Colonial Office (and Governor FI) to NERC with a dowry of £1 million. This amounted to about 14% of the Council's budget, roughly the same as today.

During the early years, BAS relied upon a combination of *Biscoe, Shackleton,* and chartered vessels. But 1970 saw the delivery of a new much larger purpose-built logistics vessel, RRS *Bransfield.* This vessel, together with RRS *John Biscoe,* allowed BAS to dispense with ship charter.

Though BAS was now a single scientific organisation, the scientific staff were scattered around the United Kingdom and hosted in a variety of university departments, government laboratories, and museums. The HQ occupied a small office in London with a much larger logistics and administrative operations in Port Stanley.

In June 1967, a NERC Antarctic Committee was established to provide oversight of the BAS programme. In 1970, an additional committee was established by NERC—the BAS Advisory Committee—to provide the BAS director with advice on scientific matters. The question of whether BAS should be centralised at a single site was first raised in 1970, approved by NERC in June 1972, and finally realised at its present site in Cambridge in May 1976.

Sir Vivian Fuchs retired as director in 1973, to be succeeded by Dr. Richard Laws. This marked a watershed for BAS. Sir Vivian had successfully assured BAS's future in its permanent home, but during his tenure BAS had maintained an expeditionary ethos. Dick Laws began the process of building the organisation up as an integrated multidisciplinary research institute. However, he had to struggle continually against threats to reduce the budget. Soon after he took office BAS was required by NERC to cut expenditures by around 10%. NERC proposed that Halley Station be closed and *Biscoe* sold to save funds. These suggestions were countered successfully, but the consolidation of BAS in Cambridge offered an opportunity to save through a phased close-down of Stanley Office. By 1978, BAS representation in the Falklands was reduced to just one person, Myriam Booth, who continued in that role until her retirement in 2004. Also, increased use of snowmobiles and greatly improved air support through the acquisition of two DHC-6 Twin Otters allowed geological fieldwork without requiring science personnel to winter. This in turn allowed Stonington to be closed in February 1975.

Further budgetary pressure appeared in 1979, which caused BAS to look at several options for saving money, before deciding the least bad one was to close its station at King Edward Point on South Georgia. The Foreign and Commonwealth Office (FCO) was unhappy with this because BAS staff provided the administrative presence in the territory. They therefore agreed to fund the construction and operation of a new facility at King Edward Point. This was completed and ready for occupation at the end of March 1982.

The year 1982 was fateful for BAS, but it ultimately turned out to be the start of a new golden era. The new King Edward Point facility had only been occupied for 3 days before the Argentine invasion on 3 April saw the BAS team deported from there and interned briefly in Argentina before repatriation to the UK. The main invasion of the Falkands on 2 April had severed all communications between Cambridge and the Antarctic stations as this was routed via the cable and wireless radio station in Port Stanley. Other nations quickly came to BAS's aid by providing relays, and the BAS ships headed home maintaining radio silence and staying well away from South American ports.

The successful recovery of South Georgia and the Falkands by June 1982 had an enormous impact on BAS. The Prime Minister, Margaret Thatcher, decided that it was in the UK's interest to be a major player on the geopolitical stage where South Atlantic and Antarctic matters were concerned, and that one of the routes to achieving this would be via science. She directed that the BAS operating budget be doubled and a major capital investment programme be carried out. The realisation of this directive dominated the rest of the 1980s and early 1990s for BAS. The expansion was not always a smooth process; there were interdepartmental difficulties that sometimes delayed it, and also organisational problems. But by the early 1990s, BAS had been transformed into a highly capable and professional operation second to none in the world. Major investment provided an outstanding new research vessel—RRS *James Clark Ross*—to replace *Biscoe,* a new sophisticated station at Halley, redevelopment at Rothera to provide a crushed rock runway and wharf, a four-engined DHC-7 aircraft that provided an intercontinental capability to Rothera, and a fleet of four DHC-6 Twin Otters. In addition, all ships and stations were now communicating via digital geo-stationery satellite systems and all were provided with local area networks. Finally, there was redevelopment of the BAS Cambridge site that more than doubled the accommodations and provided world-class laboratory facilities.

The 1980s saw a scientific result come out of BAS that has assured both BAS and the three authors of the paper of their place in posterity. This was the discovery by Farman, Gardiner, and Shanklin of the ozone hole over Antarctica. That single result probably justifies all the money that the UK ever spent on Antarctic research, because of the paradigm shift that it caused, not just amongst scientists and politicians, but in the awareness it gave to the person in the street of our potential as a species to wreck our environment.

Further financial difficulties were encountered in the mid-1990s because the cost of operating and maintaining the new infrastructure was greater than anticipated. This led to a comprehensive internal review of scientific aims and consequent logistics needs. As a result, Faraday station was deemed surplus to requirement and was offered to and accepted by the Republic of Ukraine, who now operate it year round. Signy Island was reduced to a small summer-only facility and the main focus for inshore biology research was moved to Rothera, where a new sophisticated laboratory facility was built—the Bonner Laboratory. In 1999, *Bransfield* was finally retired from service to be replaced by a Norwegian vessel, acquired through a Private Finance Initiative deal and renamed the RRS *Ernest Shackleton*.

Dick Laws retired in 1987, to be replaced by Dr. David Drewry, who was director until 1994, followed by Dr. Barry Heywood, and then since 1998 by Professor Chris Rapley. These individuals have had to lead BAS through a tumultuous time. The relationship between BAS and NERC has at times been quite strained, stemming primarily from the fact that after the Falklands conflict the two separate strands to the BAS mission (political presence and basic science) were more starkly defined. The new funds were "ring-fenced" so that NERC, whilst accountable, was not in control, while the FCO took a strong interest in the political element of the mission. It is only in recent years that an effective relationship has developed. This has depended on a change of view in the UK in which government now recognises its research institutes as assets to be exploited and developed, and through a very determined push by BAS to ensure that its science portfolio is consistently world class, and to demonstrate this through rigorous peer review.

From a bunch of gifted amateurs doing a bit of science on the side whilst fighting a war, BAS has developed over the past 60 years into one of the UK's premier research institutes with a world-wide reputation for excellence.

BRITISH ANTARCTIC *(TERRA NOVA)* EXPEDITION (1910–1913)

On June 15, 1910, Captain Robert Falcon Scott's expedition ship, *Terra Nova,* set sail from Cardiff, Wales, bound for Antarctica. So began one of the most momentous and dramatic of all the expeditions of the Heroic Age of polar exploration. Scott had two principal ambitions: to be the first explorer to reach the South Pole, consequently surpassing the "farthest south" reached by Ernest Shackleton on the British

Antarctic Expedition on January 9, 1909, and to collect scientific data on the biology, geology, meteorology, and geophysics of Antarctica.

When *Terra Nova* reached Melbourne, Australia, Captain Scott was astonished to receive a telegram from the Norwegian polar explorer Roald Amundsen, indicating that he had turned from his professed attempt to reach the North Pole and was now proceeding for Antarctica. Scott realised that the "race for the South Pole was now on," and that he was no longer just in a contest with a former colleague and fellow Briton, but also with a very experienced polar explorer and representative of another country. He saw that the reputation of the British Empire was at stake.

Scott had joined the ship in Simon's Town, South Africa, and was enlisting further personnel in Melbourne and in New Zealand. *Terra Nova* was a converted Dundee steam-whaler of 700 tonnes gross that had been thoroughly overhauled and refurbished in the London docks on the Thames. The vessel was already heavily laden; in addition to large quantities of coal, there was a prefabricated hut, and all the provisions for a three-year stay in Antarctica. The ship carried sledges, thirty-four dogs, three motor sledges, an observation balloon, and a range of scientific equipment. Scott had selected a ship's complement of sixty-five, the ship's officers and crew seconded mainly from the Royal Navy, and the scientific staff from both the armed forces and academic life. Scott was in overall charge, and his second-in-command Lieutenant E. R. G. R. "Teddy" Evans, at that stage the ship's captain. The other officers included Lieutenant Victor Campbell; Lieutenant Henry Robertson "Birdie" Bowers; Captain Lawrence E. G. Oates of the Inniskillig Dragoons, who had general charge of the ponies; and naval surgeons G. Murray Levick and Edward L. Atkinson. The scientific staff was led by Scott's great friend from the British National Antarctic Expedition (1901–1904) Dr. Edward Wilson, and also included George Simpson, meteorologist; Frank Debenham, Raymond Priestley, and Griffith Taylor, geologists; Denis Lillie and Edward Nelson, biologists; and Charles S. Wright, physicist. Oates (nicknamed "Titus") and Apsley Cherry-Garrard had each paid £1000 to accompany Scott; "Cherry" was appointed assistant zoologist. Only Wilson and four petty officers—Tom Crean, Edgar Evans, William Lashly, and Thomas Williamson—had been before with Scott on *Discovery* on the earlier expedition, and Teddy Evans had assisted in the relief expedition to free *Discovery* from the ice.

In New Zealand the expedition was met by Scott's wife, Kathleen, and by Oriana Wilson and Hilda Evans, who had travelled out by passenger liner. A frenzy of activity of further "getting ready" took place, and the expedition was joined by Herbert Ponting, photographer; Lieutenant Wilfred Bruce, Scott's brother-in-law; Cecil Meares, dog handler, as well as the Russian dog-driver Demetri Gerov; and by nineteen Manchurian ponies and their Russian groom, Anton Omelchenko.

Terra Nova left Port Chalmers on November 29, 1910, and almost immediately encountered the first of many trials: a force-10 gale, which threatened to capsize the overladen vessel. The ship plunged and rolled in mountainous seas, shipping much water. Ten tons of coal were thrown overboard, as well as other bulk supplies; two ponies died; and the bilge pump was choked by coal dust, so that a constant chain of buckets for bailing had to be maintained for more than a day. Eventually Lieutenant Evans cleared the pumps of coal-dust balls, sea water could be emptied from the ship, and at last, the gale subsided. On December 9, the ship reached the extensive pack ice, but it was a slow journey breaking through to the Ross Sea and an ultimate landing place. Scott's first choice—Cape Crozier on Ross Island—proved impossible, as did Hut Point, the old Discovery base, and Scott eventually selected Cape Evans, 13 miles (21 km) north of Hut Point. Valuable time had been lost through the severe storm and the long journey through the pack, so unloading had to proceed at a good pace using the dog and motor sledges, the ponies, and man-hauling to transport the store ashore. Unfortunately, the third motor sledge plunged through weak sea ice and sank to the bottom. A new base hut was erected, measuring 15 meters by 8 with a height of 5 meters in the centre. According to naval tradition, the crew were separated from the officers and scientists by a central line of packing cases with separate messing facilities. Stables were built for the ponies, accommodation for the dogs, and corners allotted to the scientific and photographic laboratories.

Scott had already decided on the composition of the scientific exploring parties, which were named the Southern, Eastern (later Northern), and Western Parties. Scott led off first with twelve men, ponies, and dogs on January 26, 1911. Their objective was to travel across the Great Ice Barrier (now known as the Ross Ice Shelf) laying caches of food, fuel, and fodder at intervals at least as far as 80° S, to be used by the Polar Party the following year. He was accompanied by Teddy Evans, Wilson, Oates, Meares, Bowers, Cherry-Garrard, Atkinson, the Norwegian ski expert Tryggve Gran, petty officers Crean, Patrick Keohane, and Robert Forde, and Demitri. The Western Party consisted of Griffith Taylor (the leader), Debenham, Wright, and Petty Officer Edgar Evans. They headed for the mountain ranges west of McMurdo Sound to examine the Dry Valleys and the Koettlitz Glacier. The Eastern Party under Campbell consisted of

Priestley, Levick, petty officers George Abbott and Frank Browning, and Able Seaman Harry Dickason. They left in *Terra Nova* for King Edward VII Land at the eastern end of the Great Ice Barrier, but could find nowhere suitable for a base camp and turned west where they might land on the barrier itself. To their astonishment they discovered *Fram* and that Amundsen had established a camp, called Framheim, at the Bay of Whales. The two vessels exchanged entertainment and pleasantries, and Campbell was impressed by Amundsen's camp, which had an extensive library, the luxury of a sauna, and special provision for 110 dogs, all located some 60 miles (100 km) closer to the South Pole than their own base.

Scott's party had difficulties with both the dogs and the ponies, and Atkinson sustained a serious foot injury. They established a cache, which they named One Ton Depot, at 79°29′ S, some 30 geographical miles (56 km) short of their original objective. On the return, a number of the ponies died, and the party was forced to remain for a month at Hut Point, before McMurdo Sound froze over enough to allow them to return to Cape Evans. During this period they were joined by the members of the Western Party. They also learned from a letter left by Campbell of the location of Amundsen's camp, but it was then too late in the year for Scott to alter his own plans for the assault on the Pole. In March they returned to Cape Evans, and the entire party settled in for the long southern winter.

The absence of the Sun during the winter months enforced a leisurely routine on all the personnel in the hut—common mealtimes, regular feeding of dogs and ponies, instrumental weather readings whatever the snow and wind conditions outside, and detailed preparations for the attempt on the Pole once the Sun was again above the horizon. Evening lectures were given by the scientists three times each week, recitals were attempted on the pianola, and Ponting's beautiful slide shows were much enjoyed. In addition, the tradition of producing *The South Polar Times,* a base magazine first put together on Scott's earlier expedition, was continued under the editorship of Cherry-Garrard.

On June 27, 1911, a mid-winter journey to Cape Crozier, on the far side of Ross Island, started in order to allow Wilson to visit a breeding colony of emperor penguins and to collect eggs and possibly embryo chicks. Wilson was joined by Cherry-Garrard and Bowers. The story of this heroic sledge journey was later immortalised in Cherry-Garrard's *The Worst Journey in the World*. The journey was fraught with difficulties—rough ice made sledging difficult as they were hauling food and equipment weighing 757 pounds (343 kg) between them, and the winter darkness hampered navigation. At times the temperature fell to –49°C, and on July 5, it reached a low of –51°C. Eventually they reached the colony, killed three penguins, and collected five eggs, two of which were smashed on the climb back to their camp. No more could be done, as a severe gale blew away their tent and the temporary canvas roof of their snow shelter. By the greatest good fortune Bowers discovered their tent a quarter of a mile away. They set out back on the return journey and arrived at Cape Evans, completely exhausted, on July 31, having covered 116 miles (187 km). It had been one of the most bitterly challenging journeys ever undertaken in Antarctica. For Captain Scott and all the others, it was a portent of the assault on the Pole, and clear evidence of the strength of members of his expedition.

On October 24, 1911, the first stage of the Southern Party was ready, comprising the motor-sledge team led by Teddy Evans, mechanic Bernard Day, Lashly, and steward F. J. Hooper. The two sledges broke down after a short crossing, but far enough to allow the following ponies a lighter load at the beginning of their journey to what was named Corner Camp. Scott set out on November 1 with ten ponies, together with Atkinson, Bowers, Cherry-Garrard, Crean, Edgar Evans, Petty Officer Patrick Keohane, Oates, Wilson, and Wright. Last came the dog drivers Meares and Demetri Gerof, with twenty-six dogs. All three groups rendezvoused at 80°32′ S on November 21.

Scott's route to the Pole was planned to cross the Great Ice Barrier via the established depots to the foot of the Beardmore Glacier and thence to climb to the Polar Plateau via the Beardmore, setting up new depots for the return journey. All the ponies were eventually killed and their meat added to the daily rations or cached, and the remaining dogs taken back by Meares and Demetri to assist with a relief party to meet Scott and the others on their return from the Pole. The ascent of the Beardmore seemed an endless grind—105 miles (169 km) rising to some 10,000 feet (3050 m) above sea level over steeply inclined, heavily crevassed hard ice, often in near-blizzard conditions. It was man-hauling on skis day after day. Although they were driven on by the prospect of their ultimate goal, the severe conditions for such a long period began to take their toll. The low temperatures, dehydration, high altitude, and incipient scurvy weakened even this group of physically strong men.

On December 21, Scott had sent back Atkinson, Cherry-Garrard, Wright, and Keohane, and on December 31, he ordered Evans' team to depot their skis and to continue on foot. This instruction seems strange in retrospect, and, without any reason given by Scott in his diaries, inexplicable. On January 3, 1912, Scott made another unfathomable decision, to increase the number of the polar party from an original four to five, by including Bowers, a tireless and strong man-hauler. This made the tent more crowded and required an increase in the daily food allocation, requiring, therefore, the repacking of stores. In addition, Bowers no longer had his skis, and had to trudge along on foot. But he was a fifth man to help in pulling the sledge. The final polar party consisted of Scott, Wilson, Bowers, Oates, and Petty Officer Evans, representing the lower deck. The others, Teddy Evans, Crean, and Lashly were dispatched back to Cape Evans. In great hardship they reached the Great Ice Barrier, where Evans was found to be suffering from acute scurvy. He managed, with help, to come close to Corner Camp but could go no farther. Lashly stayed with him, and Crean went alone to raise help from Atkinson and Demetri, who were at Hut Point. Evans was shipped back on Terra Nova to New Zealand, where he recovered. Crean and Lashly were awarded the Albert Medal for their bravery.

Meanwhile Scott's party sledged onwards across the Polar Plateau until January 16, when Scott wrote, "The worst has happened." In the distance they could see the outline of a pole, flying a black flag. They feared they had been beaten by Roald Amundsen, and in the nearby tent was a message from Amundsen, and a letter to be sent to the king of Norway. Amundsen, with his fellow Norwegians Olav Bjaaland, Helmer Hanssen, Sverre Hassel, and Oscar Wisting, had attained the pole on December 15, 1911. They had travelled with dog teams from the Bay of Whales, by a new route across the barrier and up the Axel Heiberg Glacier.

Scott made careful observations to confirm the position of the pole, and wrote in his diary the most often-quoted, poignant, and heartfelt cry of any polar explorer: "Great God! This is an awful place, and terrible enough for us to have laboured to it without the reward of priority." In utter despair, the party took photographs of themselves at the pole, and on January 18 started back. "Now for the run home, and a desperate struggle," Scott wrote.

Scott and his companions now had to contemplate their own return. They were dispirited in the extreme, suffering from frostbite and malnutrition; Wilson had an injured leg, Evans' cut hand was not healing, and Oates had a gangrenous foot. At first travel was smooth and rapid, and Scott called a halt on February 8 and 9 to collect some 16 kg of rock and fossil samples, but as they reached the lower Beardmore it was clear that Evans could no longer share the sledge hauling. His harness was taken off, but he fell farther behind and collapsed and died on February 17. As they crossed the Barrier, they hit particularly bad weather and their progress was slowed. Oates was in a bad way with his foot and on March 16 left the tent to make the ultimate sacrifice. His statement "I am just going outside, and may be some time" is one of the most famous in the history of polar exploration. He was never seen again.

The party continued on slowly, but when they were only 11 miles (18 km) from One Ton Depot, they were imprisoned in their tent whilst an exceptionally fierce blizzard blew for some 10 days. There, Scott wrote numerous letters and made his last entry in his diary, dated March 29, 1912. It is likely that the three remaining men—Scott, Wilson, and Bowers—died around that date.

Meanwhile a second Western Party had gone back into the areas west of McMurdo Sound, again led by Taylor, and this time including Debenham, Gran, and Forde. They were picked up in February 1912 by *Terra Nova,* which also collected many of the other expedition members from Cape Evans and returned north to New Zealand, not knowing what had happened to Scott and his party.

At Cape Evans, Atkinson, the senior officer with the disability of Evans, took command. He sent Cherry-Garrard and Demetri south to meet the Polar Party, but a blizzard struck when they reached One Ton Depot, and the two men were not able to travel farther south, ultimately heading back north on March 10. With the departure of *Terra Nova,* the thirteen remaining members of the expedition grew more and more apprehensive about the Polar Party. Then winter set in, and it became apparent that Scott and his companions would not return. On Midwinter Day, June 22, Atkinson discussed their future activities; all agreed it was essential to search the barrier as soon as possible. Accordingly, three search parties had left by October 30, and on November 12 Wright spotted something in the distance. It was a tent, and within they discovered the bodies of Scott, Bowers, and Wilson. The diaries were removed, the tent collapsed, and over it they built a cairn atop of which was a simple cross.

In January 1913, *Terra Nova* returned under the command of Teddy Evans and picked up the remaining men of the expedition, including the members of the Northern Party, who had joined their colleagues at Cape Evans in November 1912.

BRITISH ANTARCTIC *(TERRA NOVA)* EXPEDITION, NORTHERN PARTY

One of the basic plans for Robert Falcon Scott's British Antarctic expedition in *Terra Nova* was to have two supplementary parties to the main geographical one that would head towards the South Pole. One of these, the Western Party, would travel into the mountains west of McMurdo Sound and engage in scientific studies. The other, under the command of Lieutenant Victor Lindsey Arbuthnot Campbell, was to carry out scientific work in King Edward VII Land, east of the Great Ice Barrier (now known as the Ross Ice Shelf). It was known as the Eastern Party and sailed from the new base at Cape Evans in February 1911 in *Terra Nova*. Unable to reach King Edward VII Land, the party tried to find a suitable landing base on the barrier itself. But, upon reaching the Bay of Whales, they found Norwegian explorer Roald Amundsen and his party to have established a base there. With no other suitable anchorage, the ship returned first to Cape Evans and thence north to Victoria Land, where Campbell's party of six—now renamed the Northern Party—was landed at Cape Adare. With the help of the crew of *Terra Nova,* they put up a new hut to winter in and also rebuilt the old huts from Carsten E. Borchgrevink's *Southern Cross* expedition. The ship then sailed for New Zealand.

Along with Campbell, who had been nicknamed "the wicked mate" for his strict naval discipline, were naval surgeon Murray Levick, geologist Raymond Priestley, and three seamen, petty officers George Abbott and Frank Browning, and Able Seaman Harry Dickason. They were about to endure conditions as cruel as Scott's own party had endured. The small group began a disciplined routine of observations into the zoology, geology, and meteorology of the nearby area, and Abbott acted as carpenter and Dickason as cook. They were virtually trapped at Cape Adare for the austral winter, although they did engage in several sledging trips that were disappointing in their results. The men anxiously awaited the return of *Terra Nova,* which arrived on January 4, 1912. Campbell and his party quickly embarked and were taken south to Terra Nova Bay, where they disembarked at Evans Coves on January 8 with just six weeks' sledging rations. Having completed scientific work around Mount Melbourne, they waited to be picked up by *Terra Nova* on February 17. However, the ship did not arrive, although it made repeated attempts to break through pack ice some 30 miles (48 km) out. Campbell realised that they were required to spend another winter in this desolate spot. Their tents had been damaged in a gale and there was no other possibility of a shelter than digging a cave in the snow and ice. A drift was found on the eponymous "Inexpressible Island," and an underground "igloo" was prepared. It was just 12 feet by 9 (3.7 x 2.7 m) in dimension with the ceiling so low that no one could stand upright. The floor was covered by old tent cloths laid over dried seaweed, gravel, and pebbles; some insulation was obtained by forming the cave walls of 12-inch (30-cm) snow blocks. Two door frames were made from biscuit boxes, and the entrance was covered by a sealskin curtain. To one side was a foul latrine. In this confined space the six men cooked, ate, slept, and lived out their days and nights with only a few novels, a Bible, and Priestley's journal for reading matter. Food was obtained by killing seals and penguins stored in a small cache within the cave interior so that preparation consisted of laboriously carving the frozen flesh with hammer and chisel into pieces small enough to place on the primus stove. The blubber lamps gave barely any illumination while smoking so much that it was not long before the cave walls and the explorers' clothing, bodies, and hair were permeated with it. Priestley guarded the few remaining rations they had brought with them, and distributed tiny amounts on a regular basis.

They became gradually weaker through lack of exercise and the debilitating diet; ultimately the entire party had severe enteritis. On September 30, 1912, Campbell decided they must attempt the 200-geographical-mile (370-km) haul back to Cape Evans. Browning and Dickason were too weak to pull a sledge along the sea ice, but on October 29, at Cape Roberts, a food cache was found that had been left the previous year by the Western Party.

Here were biscuits, raisins, tea, butter, lard, and cocoa, and a change of clothing. It was like a wondrous feast to men deprived of food for so long.

Sufficiently revived to continue their journey, they pressed on with a new vigour and reached an empty Hut Point on November 6. Atkinson had left a message for the captain of *Terra Nova,* from which they learned of the fate of Scott and his comrades. The next day they reached Cape Evans to find another hut unoccupied but soon were welcomed by geologist Frank Debenham and the new cook, W. W. Archer. They heard that the others had gone south, as a search party, to look for evidence of the tragedy.

Campbell was promoted to Commander for his leadership of the Northern Party. After serving in World War I, he settled to live in Newfoundland for the rest of his life.

BRITISH GRAHAM LAND EXPEDITION (1934–1937)

The British Graham Land Expedition (BGLE) was launched in 1934 on a budget of £20,000, which included a grant of £10,000 from the then British Colonial Office, with the rest raised from public subscription. The expedition was highly cost-effective both in the fields of land exploration and of scientific work in biology, geology, and meteorology.

The expedition was led by the Australian John Riddoch Rymill (1905–1968), who had cut his teeth in polar work in the harsh school of East Greenland under the leadership of H. G. (Gino) Watkins on the British Arctic Air Route Expedition, 1930–1931 (BAARE). Watkins had next planned to lead a trans-Antarctic expedition, but, since funds were not available, he returned to East Greenland with a four-man party in 1932, with Rymill as his second-in-command. Following Watkins' tragic death by drowning while sealing from his kayak in August 1932, Rymill took over the leadership of the party, which carried out useful survey and meteorological work.

Rymill now took up the Antarctic challenge, but was persuaded by advisors in London to lead a survey and scientific expedition to Graham Land, the northern part of the Antarctic Peninsula, lying to the south of the Falkland Islands.

There were sixteen members of the expedition, four of whom were seconded on full pay from the Royal Navy and two from the Army. The expedition ship was the three-masted topsail sailing schooner of 130 tons, named *Penola* after Rymill's family station in South Australia. In command of Penola was Lieutenant Robert Edward Dudley Ryder, RN (1908–1986). With little fanfare, *Penola* sailed from the port of London on September 10, 1934, with Ryder appalled by the sloppiness of his mainly university crewmen. Ryder demanded things be in very "ship-shape" fashion, but eventually an understanding was reached, with Ryder relaxing a little and the civilians raising their standards drastically.

Rymill was a born leader of men. He stood 6'4″, of magnificent physique with immensely broad shoulders. His personality and bearing, and his schooling under Watkins, were such that his tactful suggestions passed for orders. This is the ideal form of leadership on a civilian operation with modest numbers. Withal he was an expert dog-driver and skier, an experienced air pilot, and a competent surveyor.

Most members of the BGLE would have stood out in any company. Ryder was an able marine surveyor whose surveys of harbors off the west coast of Graham Land are still used on British Admiralty charts. The first mate of *Penola* was James Hamilton Martin (1900–1940), an outstanding seaman who, after service as an officer in the Grenadier Guards near the end of World War I, indulged his passion for sailing, including as a seaman and then as boatswain in RRS *Discovery* on the British Australian New Zealand Antarctic Research Expedition, 1929–1931, for which he was awarded the Polar Medal in bronze.

The expedition doctor was Surgeon Lieutenant Edward William Bingham (1901–1993), who had previously served on the BAARE. A number of other members of the expedition also had previous polar experience. From the BAARE there were Wilfred Edward Hampton (1907–1994), experienced pilot and engineer of the BGLE's light aircraft, and Alfred Stephenson (1908–1999), expedition chief surveyor. From expeditions to Svalbard there were Colin

Bertram (1911–2001), the seal specialist; Launcelot Fleming (1906–1990), the expedition geologist and chaplain, jocularly called the "Bishop of the Antarctic"; and Brian Burley Roberts (1912–1978), the expedition ornithologist. The youngest member of the expedition was Duncan Carse (1913–2004), who, at the age of 21, transferred from RRS *Discovery II* to *Penola* as a deckhand (later radio operator) in the Falkland Islands.

At Port Stanley, in the Falkland Islands, *Penola* underwent refitting before sailing on January 7, 1935, for Port Lockroy, Wienckle Island, where the expedition's aircraft (a single-engine de Havilland Fox Moth), the heaviest of the stores, and the dogs for sledging had been dropped off by *Discovery II*. Due to engine problems, they were not able to take the ship much farther into the ice, so they wintered at the Argentine Islands, building a two-story living hut with an attached airplane hangar, and allowing *Penola* to freeze in for the winter.

Throughout 1935, the expedition members explored, surveyed, and charted the area; made scientific observations and built up collections; and raised and trained the dogs. Early in 1936, *Penola* sailed to Deception Island, and on her return the base was moved farther south, to Marguerite Bay. Here a party of nine men and ninety-three dogs was left for a second winter while the ship returned to the Falkland Islands.

Extensive surveying was planned from the new base, beginning with an aerial reconnaissance program. Then, following winter depot-laying sledge journeys, a large program of exploration was carried out, examining the fjord system of Marguerite Bay, the plateau of central Graham Land, and the areas surrounding George VI Sound, a large channel separating Alexander Island and the Antarctic Peninsula. In early 1937, Penola returned to pick up the shore party and pack up the southern base.

The expedition returned to England in 1937 with no fanfare at all, because clouds of war were gathering in Europe and because the excellent organization of the expedition precluded the disaster and loss of life that attract publicity. The BGLE brought back a rich harvest of scientific results in the fields of survey, geology, and biology. Above all it established that the Antarctic Peninsula is in fact a peninsula and not an archipelago, as postulated by Sir Hubert Wilkins on his flight southwards from Dundee Island in 1929, and by Lincoln Ellsworth. The BGLE also established the insularity of Alexander Island as separated from the Antarctic Peninsula by the wide channel of King George VI Sound.

All members of the BGLE received the Polar Medal in Silver with Antarctic clasp 1935–1936, or second clasps to Polar Medals already held, and all are commemorated in place names on or off the west coast of Graham Land. Several of them went on to establish international reputations. Ryder was awarded the Victoria Cross "for valour" as commander of the Royal Naval force in the raid on St. Nazaire in 1942. He retired from the Royal Navy as a captain in 1950 to become a Conservative Member of Parliament.

After service in World War II, Bingham was appointed the third field commander of the Falkland Islands Dependencies Survey (now British Antarctic Survey), and established its farthest south-base at Marguerite Bay on the west coast of Graham Land. Fleming became director of the Scott Polar Research Institute (SPRI) before becoming Bishop of Portsmouth, then Bishop of Norwich, and finally Dean of Windsor and confidant of HM Queen Elizabeth II. Bertram succeeded Fleming as the director of SPRI. Roberts later became head of the Polar Regions Section of the Foreign and Commonwealth Office, where he played a leading role in Antarctic affairs internationally, including the development of the Antarctic Treaty. And Carse led a series of expeditions, 1951–1957, to map South Georgia. The map he produced was of great value in the Falkland Islands conflict of 1982.

BRITISH IMPERIAL EXPEDITION (1920–1922)

This expedition was originally conceived by its leader John Lachlan Cope in 1919 as involving up to fifty people, making it one of the largest planned until that date. In fact, it eventually became the smallest ever to winter in Antarctica, consisting of just two men—Thomas Wyatt Bagshawe, a 19-year-old geologist, and Maxime Charles Lester, a 22-year-old Royal Naval Reserve lieutenant with some surveying experience—who spent a year, from January 1921, at Waterboat Point on the northwest coast of Graham Land, Antarctic Peninsula.

The first, most grandiloquent plan drawn up by Cope, who had served as surgeon and biologist of the Ross Sea party of Ernest Shackleton's 1914–1917 Imperial Trans-Antarctic Expedition, included the circumnavigation of Antarctica from a base in the Ross Sea using Scott's old ship *Terra Nova,* the first flight over the South Pole, and an extension of the survey of the west coast of the Weddell Sea beyond the limit reached by Otto Nordenskjold's 1901–1903 Swedish South Polar Expedition, to join up with the discoveries of William Speirs Bruce, Wilhelm Filchner, and Shackleton on the south and east coasts. A more modest proposal, without the circumnavigation, but still including a plan to take twelve war surplus planes to the Ross Sea and fly them to the South Pole, attracted the interest of Hubert Wilkins, an experienced aviator who had spent four years in the Arctic with Vilhjalmur Stefansson's 1913–1918 expedition.

However, Cope failed to find financial backing even for this reduced objective, and so was forced to abandon the planes, retaining only the third component, a dog sledge journey south from Snow Hill Island along the western and southern shores of the Weddell Sea. Even so, the expedition could not afford its own ship, and had to rely on whaling ships operating in the Peninsula area for transport.

The four members of the expedition, with rather meagre supplies and only eight dogs, finally met at Deception Island on Christmas Eve 1920, intending to find a whaler to take them to Hope Bay on the tip of the Antarctic Peninsula, from where they would make their way by lifeboat to Snow Hill Island. However, Hope Bay was inaccessible due to ice, and the whaler deposited them on January 12, 1921 on a tiny point at the northern entrance to Paradise Bay on the Danco Coast, at 64°48′ S, 62°43′ W. Still, they hoped to be able to reach the Weddell Sea coast and follow their original plan, but it soon became obvious there was no way across the mountainous spine of the peninsula. With the third and final component of the expedition at a dead end, Cope and Wilkins opted to return home by whaling ship, but the two younger men volunteered to stay for the winter; they had come to sample the Antarctic, and they were not going back until they had done so. Before his hurried departure on March 3, 1921, Cope agreed to try and find a ship to relieve the pair next year; failing that (as indeed turned out to be the case), the whaler captain agreed to take them home at the end of the following season.

Left to their own devices, Bagshawe and Lester made their home in a stranded waterboat, 30 feet (9 m) long by 10 feet (3 m) wide, after which the Point was named. With their only tools—a saw, two geological hammers, a chisel, and some pocket knives—and with nails "every shape other than straight" extracted from packing cases, they extended the boat with canvas and boards lined with spare eiderdowns to provide a tiny "lounge" and kitchen. Despite ingenious improvisation—using sealskin for door hinges‘ making a shovel from a kerosene tin, candlesticks from cigarette tins, and an oven from a biscuit tin—their living conditions were squalid in the extreme. Their cramped quarters leaked in the frequent icy rain, their stove made from an old oil drum either refused to light or smoked them out, and their diet consisted almost entirely of seals and penguins, which at least helped them to avoid scurvy. By July 1921, they had made the best they could of their situation, with such civilised comforts as a linen tablecloth for meals and a gramophone for musical evenings. With only candlelight, they could not read in the evenings, and had no communication with the outside world at all. Their isolation was increased by the confines of their location, surrounded by water on three sides and a 100-foot (35-m) glacier wall on the fourth. With limited equipment and manpower they could not venture far along the coast on the unreliable sea ice, nor could they use the dogs in the rough terrain inland. The longest expedition they managed was 6 miles south along the edge of the glacier, a 12-hour return trip on August 24.

Nonetheless they completed a substantial scientific program. Throughout the year they maintained a two-hourly meteorological log, using a screen built by the whaling ship's carpenter, with a homemade wind vane on top, compiling the first complete annual record of weather conditions in the region. In addition, Bagshawe collected geological and biological specimens, and kept a daily ice log, while from October 30 for 30 days they kept an hourly tidal log, taking alternate 6-hour watches at the tide gauge, a calibrated half oar attached to a boulder-filled wooden barrel. Their greatest interest, however, was in the Adélie and gentoo penguins that nested nearby; Bagshawe made extensive notes on their behaviour, to the point of identifying individuals by name, and, on leaving, he found he missed his friends very much. Unfortunately, this work was not published until 1939, as appendices to Bagshawe's narrative of the expedition. As pioneers of such research in this region of Antarctica, their results would have been helpful to their successors, just as they found the reports of Jean-Baptiste Charcot's two earlier expeditions.

When Captain Andersen in the whaler Svend Foyn finally came to take them home on January 13, 1921, after a year and a day at Waterboat Point, they both "felt miserable as we watched the hut disappear from sight...it was to us a haven of comfort" and Bagshawe summed up his experience as one of "sheer delight" (Bagshawe 1939).

In a fitting tribute to the two members of this bizarre expedition, Frank Debenham, first director of the Scott Polar Research Institute, commented, "Never were there such devoted scientists...these two young men possessed that quality so annoying to the great Napoleon, of not having the sense to know when they were defeated" (Bagshawe 1939).

BRITISH NATIONAL ANTARCTIC *(DISCOVERY)* EXPEDITION (1901–1904)

The British National Antarctic Expedition, Robert Falcon Scott's (1868–1912) first expedition, was one of the most important endeavors of the Heroic Age and introduced several of the great figures to the Antarctic regions. The effort set the stage for British involvement in the period until 1922, including offering insight into the tragic events of the second Scott expedition. The scientific results mark it as one of the most productive of the early-twentieth-century expeditions.

The *Discovery* expedition, as it was also known, owed its existence to the strong will of a single person. Sir Clements R. Markham (1830–1916) was determined to combine two of his great loves—polar exploration and the Royal Navy—to create the crowning achievement of his term as president of the Royal Geographical Society (RGS). He hoped to send forth a national Antarctic expedition that would revive the adventurous spirit of his fellow countrymen and place Great Britain once more at the forefront of scientific exploration. Virtually from the moment of his election as president, he used the RGS as a vehicle to carry out his plan.

At first his efforts at private funding were met with indifference. He subsequently attempted to get the British government to underwrite the cost but found no support in that arena. Eventually he combined his efforts with the Royal Society, and together they campaigned to launch the endeavor. The breakthrough Markham had hoped for came in March 1899 when Llewellyn Longstaff offered the RGS a £25,000 contribution. This donation finally allowed the two royal societies to petition the government and acquire sufficient funding for the voyage.

Markham was determined to have a purpose-built ship and discounted the evidence that a whaling vessel would have been sufficient for the task. Thus, *Discovery* was constructed in Dundee, Scotland (where it has now returned as a major tourist attraction), and launched in March 1901. The vessel was not without its problems. Throughout the first voyage the ship was slower than expected and was plagued by a series of leaks.

Sir Clements also selected the commander of the expedition, a young naval lieutenant, Robert Falcon Scott. Controversy still exists regarding the means by which the appointment took place, whether Scott or Markham took the lead in bringing about the decision. The choice of Scott was not without opposition from elements within the Royal Navy. A few years earlier, Markham had suggested the qualifications for an ideal leader for this kind of endeavor. Although

Scott did not really match that profile, once Sir Clements made his mind up, he was tenacious in his defense of Scott, who was subsequently approved by the committee that oversaw the direction of the expedition.

Moreover, prior to sailing, a huge controversy erupted, which in the short run allowed Markham to triumph, but in the longer term may have had unfortunate consequences. J. W. Gregory (1864–1932) had been chosen as the scientific director of the expedition, and once his appointment was secured, he attempted to ensure he would have control of all scientific work. In general, he found support from the Royal Society. Together they preferred an expedition that placed science above adventure or geographical discovery. Not so Markham, who, as a consummate committeeman, finagled the situation and succeeded in establishing that the captain of the ship, Scott, would be in absolute command. The men of the Royal Society were miffed and lived to see a degree of revenge meted out against the president of the RGS. For his part, Gregory found the newly established conditions intolerable and resigned. George Murray (1858–1911) became the temporary scientific leader, but in the end Scott essentially performed those duties himself. Although it was not part of the reason he was chosen to command, Scott made a good scientific leader.

However, as Peter-Noel Webb has pointed out, Gregory's loss might be greater than some historians have noted, for his knowledge and expertise might have enhanced the results of the expedition, particularly in the eventual development of the theory of plate tectonics.

Among those chosen as members of the professional staff and ship's complement were young obscure men who subsequently became among the great figures in polar history. Edward Wilson (1872–1912), a young physician only recently back from tuberculosis treatment in Switzerland, could not pass the physical examination. But Scott had been so impressed with Wilson that he insisted he be appointed. Ernest Shackleton (1874–1922) had fortunate personal connections to the Longstaff family and secured a place, while another financial backer recommended Albert Armitage (1864–1943), who served as the pilot and second-in-command. Tom Crean (1877–1938), Bill Lashly (1868–1940), and Ernest Joyce (1875–1940) each made a first trip to the Antarctic on this voyage. The scientific staff, meanwhile, was enriched by Louis Bernacchi (1876–1942), who had served on the *Southern Cross* expedition and who along with Armitage and surgeon Reginald Koettlitz (1861–1916) was among the three who had previous polar experience.

Preparations completed, *Discovery* sailed from England in July 1901 and proceeded to Christchurch, New Zealand, via Cape Town. The ship did not live up to expectations in terms of sailing ability and coal consumption, but more annoying was the constant leaking. At Cape Town it got a substantial refitting at the cost of the Royal Navy, which lent every assistance to Scott and his men. Departing South Africa, Scott opted to skip a previously scheduled stop in Melbourne and proceed directly to New Zealand.

As was the case with other British Antarctic expeditions of this period, the people of New Zealand proved gracious hosts. The time ashore there was not only a welcome respite to the men but also a time to make the ship ready for the voyage south. *Discovery* was put in dry-dock to stop the leaking, but subsequent sailing indicated that the problem remained. Physicist Louis Bernacchi joined the staff at this time, as did another great figure in polar history when Crean was added to the roster. Throughout the stay the scientists continued their work and made arrangements to coordinate experiments that would take place in both New Zealand and the Antarctic.

Regrettably the departure was marred by tragedy as a sailor fell to his death from the top of the mast as the ship was departing Lyttelton, an accident that bears an uncanny parallel to one on Jean Charcot's (1867–1936) first expedition.

The journey to the Ross Sea was accomplished without undue difficulty, and a stop was made at Cape Adare, where Bernacchi was able to visit his former quarters from the *Southern Cross* expedition. Scott took his ship to Ross Island and then out along the Ross Ice Shelf, known at the time as the Great Ice Barrier. Pushing eastward the explorers reached the end of the Ross Ice Shelf and spied new territory, King Edward VII Land, one of the most significant geographical discoveries of the voyage. Turning westward again, at an inlet in the wall of ice, the men landed and launched a balloon to give them a better view of the area. The balloon proved to be of limited use, and, after several men went aloft, the experiment was not repeated.

Scott took his ship back to McMurdo to a place known now as Hut Point and there prepared his ship to be frozen in for the winter. On shore the men erected a hut (still standing), which served as a storage and work area for the expedition. The remainder of the fall was spent establishing the scientific work and in several short forays.

The first attempt at sledging showed the degree to which the party was less prepared than it might have been. What would later be considered a short and not-terribly-difficult sojourn was made, but when the men returned, they were exhausted and spoke of how arduous the journey had been. This experience should be kept in mind when assessing later journeys when the men were hardened to the life of man-hauling in the Antarctic.

One party was sent to Cape Crozier in early March 1902 to leave a message as agreed before departing from England. Scott had planned to lead this group himself but a skiing injury made that impossible. The party encountered difficulties, and Lieutenant Charles Royds, who was in charge of the group in place of the injured Scott, decided to send Lieutenant Michael Barne back with a party of bluejackets. On their return, this party became separated into two teams, and one of the sailors, George Vince, died in an accident. Others might well have died, had Frank Wild (1874–1939) not led the remainder of his group back to the safety of the ship.

From the moment they arrived at Hut Point, the scientists launched their research programs, and these continued throughout the winter. For the entire party, the coming of winter was a mixture of excitement with concern about surviving the long polar night. *Discovery* was locked into the ice 500 miles (800 km) farther south than any previous group, and surviving the winter was not a guaranteed outcome. April 1902 saw the disappearance of the sun and onset of real winter.

A regular routine was maintained throughout the dark months with a fairly light workload for the men, while the officers and scientists were kept busy with a variety of tasks. In effect, Scott became his own scientific director and proved a very good one, showing considerable interest in the scientific work and keeping a light hand on the direction of the research.

A strict class structure was maintained. Officers and men had separate quarters and different food, tobacco, and work assignments. For the purpose of the trip, the scientists were considered officers and gentlemen.

Diversions were an important part of these months, with regular lectures, musical programs (including some vaudevillian efforts), and the publication of a literary magazine, *The South Polar Times*. Such journals were a staple of nineteenth-century British Arctic expeditions. This writing effort is an example of how Markham transmitted to these voyages many of the experiences of those previous endeavors. Furthermore, their literary skills showed the degree of influence that the educational reforms of late-nineteenth-century Great Britain had had on the working classes. Both the officers and the men contributed to this periodical, which was edited by Shackleton, who showed the same flair with this as he had with his other work on the expedition. Wilson contributed exquisite drawings, and the single copy of the work was read first by Scott and then aloud to everyone else. After the voyage, a limited edition of the magazine was published; it commands a hefty price today.

The ship contained a fine library, and the tastes of both the wardroom and the mess deck were satisfied. The winter passed without serious mishap, although several times men were lost for periods of time trying to maneuver near the ship in bad weather.

Spring officially began with the departure of a sledging party from the base in early September 1902, and the summer of 1902–1903 contained a full program of activities. The first few sojourns demonstrated that the men had much to learn about sledging and that their management of the dogs lacked expertise.

At one point, with many of the ship's company, including Scott, out on sledging trips, Armitage's party returned with some of his men suffering from scurvy. This one opportunity for leadership showed Armitage to good advantage. He took immediate and decisive efforts to attack the problem, including a private and direct conversation with the cook, who had previously shown no inclination or ability to prepare seal, a principal source of fresh food in the region. Regrettably, that conversation was not recorded, but after it, the cook demonstrated great skill and enthusiasm in his preparation of seal. A further crisis was averted.

The principal effort that summer was an attempt on the South Pole. Scott had no real expectation of reaching ninety degrees south, but was determined to make a credible effort. Taking with him Wilson and Shackleton, the three men plodded south, using a combination of dogs and man-hauling for transport. The dogs quickly showed signs of illness and almost certainly were done in by the food they were fed. Their poor performance, combined with Markham's insistence that man-hauling was "the true British way," established in Scott's mind that dogs were not the answer to travel in Antarctica. Once the dogs had all died, the trio continued on their own.

Scott was determined to do his duty, which in this case was to proceed south until the last day of 1902. The appearance of scurvy in the three men did not deter him, as he pressed on until 31 December, when the party reached 82°17′ S before turning back. En route north, all three men were severely affected by the disease, but Shackleton was, by far, the most greatly weakened. Shackleton coughed blood, had difficulty in breathing, and showed a steady deterioration of strength. At one point, Wilson believed that his companion would die. However, when they turned north, with the wind at their back, they rigged a sail for the sledge, and Shackleton was able to ride for a short while on the sledge, having by that time been relieved by Scott of man-hauling. When the trio arrived back at Hut Point, all were played out and required bed-rest to recover.

When Scott returned, he found that the relief ship *Morning* had arrived under the command of William Colbeck (1871–1930), of *Southern Cross* experience. This relief had long been part of Markham's plans, although he had not been terribly open about it when he had promoted the expedition. The ice had not broken up, and *Discovery* was held fast, 10 miles (16 km) from open water. Although Scott continued to hope that warm weather in the late summer might free his ship, it remained imprisoned for another winter.

When the relief ship departed, several men were sent back to England, including Shackleton. H. R. Mill (1861–1950), the great polar historian, saw this decision as the defining moment in Shackleton's life. Some authors have seen Shackleton's dismissal as being based on Scott's jealousy or fear of being outshone by his third lieutenant. Scott's relationship with Armitage and the offer to let the latter return with the relief ship would seem to support this thesis. While untoward motivations may have played a part, Scott's decision to send invalid Shackleton home was largely based on Scott's (mistaken) belief that Shackleton lacked both the stamina and the pluck for polar work.

The second winter passed in much the same manner as the first, although the men were no longer as taken with the novelty of their surroundings as they had been the previous year. Bernacchi took over the editing of *The South Polar Times,* and another series of the magazine enlivened the darkness.

During the third summer season, Armitage was excluded from the important sledging work and left to direct the freeing of the ship from the ice by cutting a channel through the ice. Such a project was hopeless. Important sledging work was, however, accomplished. Royds led a party to Cape Crozier to investigate the emperor penguin rookery there. Perhaps most important was the trip that Scott made accompanied by Lashly and Evans to the Polar Plateau in Victoria Land. The insight that Scott gained into the psyche of two of the finest bluejackets of the Royal Navy broadened his view of his men more than all of his previous naval experience. Lashly's coolness in a disaster saved the lives of his two companions and added to his reputation as one of the great minor figures of the Heroic Age.

While the relief brought by *Morning* in 1903 was not necessary for the survival of the men, back in England, Markham insisted on a second relief effort. His attempts to raise by subscription funding for a second relief expedition were insufficient. Regrettably, Markham overplayed his hand, and, in language more histrionic than accurate, berated the government for not coming to the rescue of Scott's men. Prompted by backstairs actions on the part of some members of the Royal Society, the government of Prime Minister A. J. Balfour responded, but in a way quite unintended by Markham. The government agreed to rescue Scott, but demanded that Sir Clements surrender all control or influence over the relief.

The government then launched a hugely overpriced and perhaps overdone rescue attempt that involved two ships and two superb captains, Colbeck again, and Henry McKay, an Arctic veteran of formidable reputation. *Morning* was used again, and the government quickly refitted and towed to New Zealand a sturdy whaler, *Terra Nova*.

The rescuers arrived at McMurdo Sound to find that 18 miles (29 km) of ice separated them from *Discovery*. All attempts to cut a path through to Scott's ship had proven impossible. As the ice began to break up, McKay smashed his ship into the wall of ice to break through. Until virtually the last moment, it appeared that the effort would be fruitless, but suddenly the crashing efforts of McKay, combined with explosives and the help of nature, freed *Discovery*. The three vessels floated together in a little pool of water off Hut Point.

Although *Discovery* ran hard aground shortly after being liberated, the three ships departed McMurdo Sound and returned to New Zealand, although they did not travel together because of the different sailing abilities of the vessels.

The British National Antarctic Expedition was one of the most important expeditions of the Heroic Age, and its scientific accomplishments indicate that this voyage was a first-rate effort. The eleven volumes of scientific results attest to the contributions made by Scott's men and compare favorably with other contemporaneous efforts. Scott proved a fine scientific leader, and this voyage introduced to the Antarctic men whose names live on in legend in the annals of polar history: Scott, Wilson, Shackleton, Wild, Crean, and Lashly. But for other later circumstances, men like Armitage and Skelton might similarly be enshrined. The shortcomings of this endeavor owe much to the influence of Markham and his incorrect belief that nineteenth-century British Arctic methods were the standard of behavior and could not be improved upon. For many of those things for which critics blame Scott, the faulted behavior can usually be traced to Markham. For a pioneering effort, the officer and men of *Discovery* had every reason to feel proud of what they accomplished.

BRITISH, AUSTRALIAN, NEW ZEALAND ANTARCTIC RESEARCH EXPEDITION (BANZARE) (1929–1931)

On July 3, 1925, Australian Prime Minister Stanley Melbourne Bruce saw a delegation from the Australian National Research Council (ANRC), which urged that Australia should act, in concert with Britain, to secure for Australia the administration of Antarctica between 90° and 160° E, using as part justification the geographical results of the Australasian Antarctic Expedition (AAE, 1911–1914). Bruce said that the government would pursue these ends through appropriate channels. The following year, the Imperial Conference of Commonwealth countries, meeting in London, considered the question, listing areas of Antarctica within the "Australian quadrant" (from 45° to 160° E) that might be annexed on the basis of nineteenth-century British sightings or exploration by expeditions under Douglas Mawson and Robert Falcon Scott, including Enderby Land (45°–53° E), Kemp Land (58°–60° E), Queen Mary Land (86°–101° E), Wilkes Land (131°–135° E), King George V Land (142°–153° E), and Oates Land (157°–159° E). Although the Conference advocated further exploration and research in these regions, no schemes to plant the flag and read proclamations were mooted.

With Australian government approval, the ANRC set up an Antarctic Committee, which included, besides Mawson and John King Davis (captain of the expedition ship *Aurora* during the AAE), prominent scientists and government representatives, with power to act and advise. It was proposed to use Scott's old ship, *Discovery,* undertaking landings and flag-raisings along indicated parts of the Australian quadrant on the assumption that these would subsequently be placed under Australian control. They advocated a second season in the Antarctic if necessary, a scientific program, and use of a ship-based seaplane. The Australian government gave the go-ahead on October 11, 1928. Funding came largely from private sources: £20,000 from chocolate millionaire Sir Macpherson Robertson (or Mac-Robertson), \$40,000 (£8500) from Randolph Hearst for the American press rights, and smaller amounts from other quarters. The Australian government provided £14,000 and the government of New Zealand £2500. Thus, *Discovery* to one side, the British, Australia, New Zealand Antarctic Research Expedition (BANZARE) received more support from the United States than from Britain. Mawson set up a London Committee and oversaw the ordering of equipment and provisions. The British lent *Discovery* for two seasons.

A barque with auxiliary steam engine, *Discovery* rolled badly and required 50 tons of coal to be kept as ballast, limiting the steaming range. A second problem was the command structure, decided upon by the Australian Committee guided by Mawson: Mawson as expedition commander, and Davis as second-in-command and master of the ship only when Mawson was not on board, since it was a ship expedition. Thus, while Davis was the captain, he did not command. He merely had a veto power over Mawson's instructions if he thought those instructions endangered the ship. This led to much squabbling during the first season (summer 1929–1930) and to Davis' refusal to continue for the second season (summer 1930–1931).

Mawson knew that Norwegians under Hjalmar Riiser-Larsen on *Norvegia* intended to make landings and claim territories in the general area of Enderby Land and Kemp Land. For this reason, he started from Cape Town rather than from an Australian port. *Discovery* left Cape Town on October 19, 1929, heading southeast. After securing botanical and geological collections at Îles Crozet, they proceeded to Îles Kerguelen, where they made scientific observations and collections while the long job of recoaling was carried out. It can be argued that Mawson wasted time at Îles Crozet. Prime Minister Bruce's secret instructions of September 12, 1929 stressed planting the flag and reading the proclamation of annexation. Economic and scientific goals were to be secondary. Yet even so they did not make directly for Antarctica but for Heard Island, where they spent 9 days inspecting flora and fauna, surveying, dredging for marine life, and collecting geological specimens. Making southeast from Heard Island on December 4, *Discovery* pioneered the echo-sounding of the long undersea ridge running from Kerguelen past Heard Island to Gaussberg in Antarctica (the Banzare Rise).

Attempts to reach Enderby Land were thwarted by heavy pack ice. Arguments flared between Mawson and Davis over ways to get around or through it. These arguments were noticed by the other members of the expedition, who included the photographer Frank Hurley and a range of scientists. The Gipsy Moth biplane, equipped with floats, was set up and flying by December 31, but no land was clearly discerned until a flight on January 5, 1930, with Mawson in the forward (passenger) seat. This flight gave him his first extensive sighting of what he would name Mac.Robertson Land. They sailed on westward past Kemp Land (unseen) towards Enderby Land, learning by wireless cable that the Norwegians had claimed territory there the previous month. Later, in the interests of British–Norwegian relations, Mawson was allowed to claim the Enderby Land and Kemp Land coasts, although he had not landed there. The closest they came to Enderby Land was a small island in sight of it, named Proclamation Island, on the peak of which Mawson claimed for the Empire full sovereignty of Enderby Land, Kemp Land, and Mac. Robertson Land (47–73° E). On January 14, they met *Norvegia,* which carried two seaplanes and had had more success. During the following days there were additional flights from *Discovery,* this time over the continent, and more land was claimed (around Cape Ann), but coal was running low and on January 26 they headed north.

The second BANZARE cruise achieved greater results. *Discovery* was now captained by K. N. MacKenzie. On November 22, 1930, they set out from Hobart (Tasmania), proceeding via Macquarie Island to Cape Denison in Antarctica (the main base during the AAE), thence westwards, charting the coast of Adélie Land and discerning during flights in the Moth what Mawson named Banzare Land and Sabrina Land (January 1931). Early February saw them off the coasts of what Mawson named Princess Elizabeth Land and, farther west, Mac.Robertson Land (these discerned from the air). Conditions this year permitted the ship to come closer to the land. New features were charted, known features charted more accurately, new mountain ranges observed, and landings made on the mainland on February 13 and 18 (at Scullin Monolith and Cape Bruce). With coal reserves low, the ship then proceeded for Australia across the Banzare Rise, the cruise ending at Hobart on March 19, 1931. Its extensive discoveries and claims, augmenting the superb geographical achievements of the AAE, provided the grounds for the Australian Antarctic Acceptance Act of 1933. This became law in 1936, establishing (with British agreement) the Australian Antarctic Territory, that vast slice of the Antarctic "cake" running from 45° to 160° E, with the sole exception of the French Terre Adélie.

As a result of the oceanographic program, a continuous undersea land-platform around a third of Antarctica was clearly demonstrated, establishing the continuity of land of continental dimensions beneath the ice plateau, in contradistinction to a series of islands cemented by the polar ice cap. This left unresolved whether there were not two continents beneath the ice, riven by a channel from the Weddell Sea to the Ross Sea, a question then being answered by the work of Richard E. Byrd.

BRUCE, WILLIAM SPEIRS

Regarded as the principal Scottish polar explorer, William Speirs Bruce was, in fact, born on August 1, 1867, at 43 Kensington Gardens Square in the Paddington district of London. He moved to Scotland to attend a summer school in natural history organised by the University of Edinburgh in 1885, and there came into contact with many of its natural scientists. He decided then to withdraw from his intended course of study in medicine at University College, London, and transferred his allegiance to Edinburgh, its city and its academic life. From this time he maintained Scotland as his adopted home, and gradually became a fervent Scottish nationalist. He did have strong family links with Scotland; although his mother, Mary Lloyd, came from Wales, his father, Samuel Noble Bruce, had a long line of Scottish ancestry. William Bruce's grandmother was Charity Isbister from the Orkney Islands, and his paternal grandfather, the Rev. William Bruce, was born in Glasgow in 1799 and became a preacher in the newly formed Swedeborgian church, taking a ministry in Dundee before moving to Hatton Garden in London. The future polar explorer's middle name, Speirs, derived from another Scottish relative, and it has given rise to some confusion in spelling, being often misspelled as "Spiers" or "Spears."

Bruce was the fourth child in a middle-class family of eight children and had one younger brother. His birth certificate shows his father as a surgeon, but he was, in reality, a physician conducting a general practice in one of the wealthiest parts of London. The family later moved nearby to Holland Park, 18 Royal Crescent, and lived there for many years. Bruce grew up in a prosperous Victorian family with a retinue of servants, a coachman, and nursemaids. He was educated privately at home and was frequently taken by his nursemaid to nearby Kensington Gardens and the Museum of Natural History. His father attributed William's love of natural history to these events. It was a beginning, but his truly formative influences would come later in Edinburgh.

Bruce's education was continued at a progressive boarding school, Norfolk County School, North Elmham. He continued his studies of natural history where he would undoubtedly have come into contact with the new ideas of Charles Darwin, for the famous *Origin of Species* had been published in 1859. In 1886, he attended two summer schools in Edinburgh. The summer schools took place at the Royal Scottish Marine Station, Granton, close to the Firth of Forth, making use of a canal barge, *Elizabeth,* affectionately known as The Ark, for laboratory classes. Here he came into contact with the eminent environmentalist and teacher of the holistic method Patrick Geddes.

At the University of Edinburgh, Bruce had classes with such illuminati as professors P. G. Tait, John Arthur Thomson, Sir John Young Buchanan, and Sir William Turner. He learned the rudiments of anatomy, physiology, biology, and zoology. At Granton, he also came into contact with the prestigious zoologist Sir John Murray, who had been on the *Challenger* Expedition, the first of the major scientific expeditions to sail around the world. Murray was editing the Challenger Reports, and Bruce was enrolled to help, on weekends, in their compilation. Bruce was gaining an enviable training in natural history, oceanography, and exploration from the finest group of experts in Britain of the time. In addition to these natural philosophers, Bruce formed an association and friendship with other environmentalists: Sir Alexander Buchan, a pioneer meteorologist, and Hugh Robert Mill, librarian of the Royal Geographical Society of London.

In 1892, Bruce saw an opportunity to explore the Antarctic and enlisted as surgeon on Balaena, one of the fleet of the Dundee Whaling Expedition, bound for the Southern Ocean, to search for the Greenland or "right" whale. He took with him a small collection of scientific instruments to record the weather and the nature of the sea waters. Although the expedition was a failure in sighting whales and the science was less than adequate, it gave Bruce a taste for polar regions: "I am burning to be off again anywhere, but particularly to the far South where I believe there is a vast sphere for research," he wrote to Mill on his return in 1893. He abandoned his university studies and was offered a post, by Alexander Buchan, as assistant superintendent of the new Ben Nevis weather station.

Bruce's acquaintance with the Arctic came through his friendship with Mill, who first recommended Bruce in June 1896 for the post of naturalist on the Jackson-Harmsworth expedition to Franz Josef Land. On this expedition, Bruce met Albert Armitage and Reginald Koettlitz, both of whom were later to participate in the British National Antarctic Expedition (1901–1904), and, to his amazement and delight, the Norwegian explorer Fridtjof Nansen. In 1898, Bruce sailed again as naturalist to the Arctic, this time with the industrialist Andrew Coats aboard his steam yacht *Blencathra,* bound for Novaya Zemlya. The ship returned to Tromsø, where Bruce met Prince Albert of Monaco aboard his fine oceanographic research vessel Princesse Alice. Bruce was invited to accompany the Prince to Spitsbergen waters and to spend the winter of 1898–1899 in Monaco continuing his work as naturalist.

On returning to England Bruce looked repeatedly to the Antarctic for further research; he was possibly the best-qualified polar scientist in Britain at the time. Accordingly, he applied to join Robert Falcon Scott's expedition aboard *Discovery,* but Clements Markham, who was recruiting for the expedition, delayed so long in his reply that Bruce decided to put together an expedition of his own, and to make it exclusively

Scottish. This became the Scottish National Antarctic Expedition, 1902–1904, and Bruce's prime claim to fame as a polar explorer. On leaving the South Orkneys he left behind a scientific station that has become the oldest to survive in the whole of Antarctica.

In 1901, Bruce married Jessie Mackenzie, daughter of Alexander of Tain Easter Ross, and their first child, Eillium Alastair, was born in April 1902, and a daughter, Sheila Mackenzie Bruce, in 1909. The family lived in Joppa, close to Edinburgh, where William Bruce could continue his professional life. He established the Scottish Oceanographical Laboratory in 1906, which housed his vast collection of polar exhibits, but he was forced to close it in 1919 due to a shortage of funds. In 1909, he initiated the Scottish Spitsbergen Syndicate as a mineral prospecting company, and he returned there for several summers, but without any economic mining taking place. By 1920, he was failing in health, and he died in Edinburgh on October 28, 1921. By his express wish, his ashes were carried to Antarctic waters and scattered outside the harbour of Grytviken, South Georgia.

BULGARIA: ANTARCTIC PROGRAM

Bulgaria started its polar activities in Antarctica in 1967–1969, when Bulgarian meteorologists took part in the XIII Soviet Antarctic Expedition. In the austral summer season of 1987–1988 six Bulgarian scientists participated in joint projects with the British Antarctic Survey and the Soviet Antarctic and Arctic Research Institute. This Bulgarian programme was aimed at gathering valuable experience both in carrying out scientific research and the organization of the logistics in Antarctica. During this Antarctic season a refuge was established on Livingston Island (South Shetland Islands) on a spot located on the northeast side of the South Bay.

In the period between 1993 and 2005, Bulgaria organized twelve successive Antarctic campaigns. A summer base named "St. Kliment Ohridski" was established to accommodate a staff of fifteen. The base is functioning thanks to the logistic support and valuable help of the Spanish Polar Institutions. The Bulgarian and Spanish polar researchers work in close collaboration.

Organization and Scientific Activities

The Bulgarian Antarctic Institute is the national operator of Bulgarian Antarctic activities. The Institute organizes annual Antarctic campaigns and operates the Bulgarian Antarctic base, St. Kliment Ohridski. The Bulgarian Government is represented on the Executive Council of the Institute by a Vice-Minister of Foreign Affairs. Antarctic activities are planned by the Executive Council on recommendation by the Scientific Board of the Institute. The National Antarctic Programme is guided and financed predominantly by the Ministry of Foreign Affairs and partly by the Ministry of Education and Science and the Ministry of Ecology and Waters. Bulgarian Antarctic activities are under the aegis of the President of the Republic of Bulgaria.

The scientific part of the programme is implemented by scientific teams, provided with contracts, approved by the Antarctic expert commission at the Ministry of Education and Science. The main scientific topics include earth sciences, such as geology, geophysics, physics, glaciology, geomorphology, meteorology, and cartography; life sciences, such as zoology, botany, and ecology; and human medicine. Research work is implemented by means of 3-year projects undertaken by university-based or academic scientists. Emphasis is given to a multidisciplinary approach towards understanding the patterns and processes in main polar natural systems and their evolution.

The activities under the biological research programme have focused on the study of the biological diversity of the main habitats on Livingston Island. A number of plant and animal species and their communities have been described. The diversity of protozoa, diatoms and other algae, soil nematodes, and freshwater and interstitial crustaceans has been studied. Eight new species for the flora and fauna of the world have already been described and more are being studied. Communities of diatom algae, protozoa, and nematode tropic groups have been studied and patterns of their distribution among Antarctic habitats have been described. Penguin genetics and molecular biology are also studied as a tool for addressing questions of their systematic adaptation. The results of the Bulgarian biological research programme are published in the Series "Bulgarian Antarctic Research—Life Sciences."

The further development of Bulgarian biological studies in the Antarctic will include investigations into the structure and functioning of Antarctic terrestrial ecosystems and environmental monitoring based on heavy metal content in lichens and penguin feathers. A special project will be started to study the role of solar ultraviolet light as the prime ecological factor in the formation of cell lethality and mutagenic and carcinogenic effects together with their different protecting mechanisms including DNA-repair systems, antioxidant enzymes, and related proteins.

The main objective of the geological research projects will be to explain the stratigraphy and tectonics of the Mesozoic turbidity successions and the petrology of the subductional plutons and to draw up a new model of tectonic–magmatic history of the South Shetland Islands. The first find of macrofossil, the age-diagnostic Upper Tithonian ammonite reported from the Miers Bluff Formation of the Bulgarian scientists, will change the ideas about the geological evolution of the South Shetland Islands and Antarctic Peninsula during the Mesozoic. The further development of the Bulgarian geological studies will include detailed geological mapping in a scale of 1:5000, paleontological searches for macrofossils and microfossils, and paleoenvironmental interpretations.

The main trends of the glaciological and meteorological studies are to design drills and equipment used in vertical and horizontal drilling; to investigate the microclimate phenomena related to complex orography, glaciers, and proximately the ocean; and to automate the meteorological monitoring in order to collect data, necessary for the glaciological and biological observations. Dating of the ice layers of the Hurd Peninsula glaciers and analysis of the elements and isotopes of ice samples are among the expected results.

Bulgarian Station St. Kliment Ohridski

The summer-only station St. Kliment Ochridski is located at 68°38′ S, 60°21′ W on a small saddle on Hurd Peninsula, 150 metres behind South Bay, Livingston Island. The Spanish station Juan Carlos I lies 1.7 km to the southwest. Opened in 1988, the station is administered by the Bulgarian Antarctic Institute and financed by the Ministry of Foreign Affairs.

The station's seven buildings are located on a ridge 20 m above the beach. The original station living hut of 3.5 x 6 m was built in 1988 and is steel-framed and clad in sandwich panel, providing great thermal efficiency. It is now used as the communications centre and also has overflow accommodation for five. Adjacent to this is a 2.5- x 4-m wooden-clad container used as a store for food, emergency equipment, and other supplies. Two portable arch-frame "Weatherhaven" shelters of 8 x 4 m and 4 x 2 m respectively house an inflatable rubber boat and associated gear, and provide potential extra accommodation. The main station building is of sandwich-panel construction clad with prefabricated concrete panels, and is approximately 12 x 5 m, with food storage in a rock-walled subfloor area. This building includes a sizeable kitchen/dining area, bathroom, clinic, and two bedrooms of four bunks apiece with some limited desk space. Power generators are housed in a steel-framed and metal-clad shelter of 4 x 6 m, to the south of the main building. A small A-frame shelter that serves as a chapel in summer and a snowmobile store in winter is located 300 m behind the station.

BYRD, RICHARD E.

Richard E. Byrd was the pivotal figure in the twentieth century for the United States in Antarctica. Byrd organized, led, or shared the leadership of five expeditions to Antarctica. Before his death in 1957, some even referred to Byrd as the "Mayor of Antarctica" because of his stature and influence over US efforts in the continent.

Early Life

Born in Winchester, Va., on October 25, 1888, Richard Evelyn Byrd traced his ancestral roots to one of the founding and prominent families in the state. His father and namesake was an attorney in

Winchester, served as a prosecuting attorney for 20 years, and became speaker of the house in the state assembly. The explorer's brother, Harry, added to the political luster of the family, first as governor and then as a United States senator. Access to prominent people in government and in society gave Byrd a significant advantage in his career as an explorer.

Byrd moved to a career as an explorer gradually. Travel interested him first. At the age of 12, he traveled alone around the world, after visiting a family associate in the Philippines. Opportunities to see the world and be a leader drew Byrd to a career in the US Navy. In 1908, he won an appointment to the United States Naval Academy in Annapolis, Md., from which he graduated in 1912.

As a junior officer in the Navy, Byrd had difficulty standing for long watches at sea, due to injuries in football and gymnastics, which had weakened his right foot. While serving on the USS *Wyoming,* he fell through an open hatch and reinjured his foot, forcing surgery and rehabilitation. After duty on the presidential yacht *Mayflower,* Byrd retired from active duty.

World War I restarted Byrd's career and turned his attention to aviation. Called to active duty, he ran the naval militia of Rhode Island in 1916. Having proven his leadership abilities, Byrd earned a transfer to Washington, D.C., first at the Bureau of Naval Personnel and then at the Commission on Training Camps in 1917. With the support of the secretary of the Commission, Byrd won an appointment as a naval aviation cadet at Pensacola Naval Air Station. After earning his wings, he continued as an instructor. Byrd's interest in airplanes focused on the navigational challenges of long-distance flight. He became expert in the use of the bubble sextant and wind-drift indicator as tools of aerial navigation. In 1917 he proposed to fly airplanes—flying boats—from Halifax, where he was stationed, to Europe rather than transport them on ships. In 1919, Byrd helped to plan the successful trans-Atlantic crossing by NC-4 flying boats.

Opportunities and accomplishments over Arctic ice and Atlantic water set the stage for Byrd's work in Antarctica. In 1925, Byrd had charge of the US Navy's flying boats on the private expedition to Greenland commanded by the veteran explorer Donald McMillan. That expedition was the first to use the Bumstead Sun Compass in aerial navigation and short-wave radio for communication. Unfortunately, the expedition did not have enough favorable weather for Byrd to try to fly across Greenland to the North Pole.

In 1926, Byrd's flight to the North Pole provided the accomplishment that launched his career in Antarctica. The well-connected Byrd asked financial support from Henry Ford, John D. Rockefeller, and others. In addition, he arranged well-paid contracts with news and film media. Finally, Byrd had enough money to buy a used but well-tested airplane—a three-engine Fokker that he named in honor of donor Edsel Ford's daughter Josephine. He leased a surplus ship, *Chantier,* to carry him, his plane, and his expedition members to Spitsbergen. There, Byrd faced Roald Amundsen, who had been planning an airship attempt. With help from Bernt Balchen, a member of Amundsen's expedition, Byrd as navigator, and pilot Floyd Bennett, whom Byrd had met in Pensacola, they took off before Amundsen. During the flight, the plane developed an oil leak but, according to Byrd, the two persevered until they reached the North Pole on May 9, 1926.

Critics of Byrd have doubted his accomplishment of the North Pole. They point to the duration of the flight and question that the plane had the speed to reach the objective in the time before he returned. Byrd's notebook of the flight contains erasures, still legible, that skeptics consider important. Nevertheless, Byrd's claim of the North Pole made him a national hero. The US Congress awarded him the Medal of Honor and promoted him to commander. New York City threw him a ticker-tape parade. A businessman and philanthropist, Henry Wanamaker, offered Byrd a plane and financial support to be the first to fly to France. In 1927, another ticker-tape parade followed when Byrd became the third after Charles Lindbergh to fly from the United States to Europe.

Byrd and Antarctica

Buoyed by his accomplishments, Byrd turned to the Antarctic as the theater of his ambitions. As he explained in his book *Skyward,* one of the principal reasons for going to Antarctica was to add to the knowledge of aviation by testing people and airplanes in hostile environments: "Spectacular flights accelerate progress, for when the flight is decided upon, the necessity in some cases produces inventions and developments which, in the ordinary course of events, would tend to be very slow and uncertain" (*Skyward* 297).

Byrd was an unusual explorer. Not an able skier, he excelled as a planner, organizer, and publicist. His expeditions to Antarctica were the largest of the time. Apart from the basic supplies of food, clothing, and shelter, each used airplanes, multiple ships, motorized transport, and radio equipment. Each included distinguished scientists and programs of investigation in such fields as meteorology, geology, and biology, which entailed added equipment and supplies.

Constant publicity helped to stoke public interest, raise enough money to pay the debts of one expedition, and sow the seeds of the next. Byrd gave much attention to publicists and to providing the news media with good stories. His first expeditions included professional writers and a film crew from Paramount. Byrd himself was photogenic, and each expedition offered drama as well as accomplishment. The most dramatic moment of the first expedition was the flight over the South Pole. In the second, during which the US Congress promoted him to Rear Admiral, Byrd almost died of carbon monoxide poisoning in an isolated hut during the winter.

His last three expeditions also applied modern technology to geographical exploration and scientific investigation, but they were different in funding and purpose. After returning from Antarctica in 1935, Byrd began raising money privately for another expedition. However, the financial depression in the United States had worsened and raising money privately proved too difficult. International tensions provided another opportunity for exploration in Antarctica. Concerned about the claims of other nations to Antarctica, President Franklin D. Roosevelt, whom Byrd had befriended years before, created an interagency task force, the United States Antarctic Service. Its purpose was to set up and keep two scientific bases in Antarctica. Leadership of the enterprise went to Byrd, who added the funds he had raised. Although Byrd organized the effort successfully, it ended prematurely in 1941 because of World War II.

Following the war, Byrd returned to Antarctica in 1947 during Operation High Jump. Byrd had the title of Officer-in-Charge and had leadership of the scientific program. However, Rear Admiral Richard Cruzen had command of the 4700 naval and marine personnel and 13 ships involved. It succeeded in mapping roughly 1.5 million square miles of Antarctica. The brief duration of High Jump, which did not winter in Antarctica, severely limited scientific work. An important purpose of the expedition was to test the equipment and expertise of the US Navy.

Byrd was not an active military officer or an official, but he continued to play an important role in the government-funded expeditions of the US in Antarctica. After efforts to lead another Operation High Jump failed, Byrd continued to push for further exploration and scientific investigation of Antarctica. When the United States decided to take part in the International Geophysical Year of 1957, Byrd became involved in the planning. In 1955, the 67-year-old Byrd received appointment, without salary, as Officer in Charge, US Antarctic Programs. He was to be "the senior US representative charged with effective monitorship over those political, scientific, legislative, and operational activities which comprise the total US Antarctic Program." Byrd's last visit to Antarctica in 1955 was to plan the bases necessary for the scientists. He died 2 years later on March 11, 1957.

Byrd's career in Antarctica left many legacies. Apart from places named by and for him, his expeditions are the basis of potential US claims to the continent. He also developed further the application of modern technologies to exploration in Antarctica. Although he was not the first to use airplanes, radios, or trucks in Antarctica, his expeditions proved their usefulness there. Finally, the scientists who accompanied Byrd not only made important discoveries but also educated and inspired generations of future scientists. They advanced knowledge of the Earth's ecological forces and worked to keep Antarctica a laboratory for science.

C

CAMPBELL ISLANDS

The Campbell Islands group, situated at latitude 52°33′30″ S, some 700 km south of the South Island of New Zealand, comprises the main Campbell Island (11,268 ha) and several islets, principally Dent Island (23 ha) and Jacquemart Island (19 ha). The islands are the dissected remnant of a Miocene shield volcano (6–11 million years old), rising to 569 m at Mt. Honey. Wave erosion has removed the volcano's western flank, leaving an unbroken line of cliffs. Pleistocene-age glaciers have carved cirques, U-shaped valleys, and fiords, the largest of which is Perseverance Harbour. Peat blankets the landscape and is prone to landsliding.

The climate is cool (mean annual temperature of 6°C), cloudy, windy, and wet (annual rainfall 1400 mm) with about 325 rain days during the year. Winter snowfall is usually light and transient.

There are 218 species of vascular plants. Grassland, mainly of *Poa litorosa* and *Chionochloa antarctica,* predominates. Following removal of sheep and cattle, there has been remarkable regrowth of megaherbs, including all three species of *Pleurophyllum—P. speciosum, P. criniferum,* and *P. hooker*—together with two large carrot relatives, *Anisotome latifolia* and *A. antipoda,* and the Macquarie Island cabbage, *Stilbocarpa polaris.* The unpalatable lily *Bulbinella rossii* forms extensive meadows. On moorland above 300 m are two endemic forget-me-nots, *Myosotis antarctica* and *M. capitata*. A gentian, *Gentiana antarctica,* and rosette daisy, *Damnamenia vernicosa,* occur, the former endemic to Campbell Island, the latter found also at the Auckland Islands. A coastal fringe of shrubland extends to about 180 m in altitude, with *Dracophyllum longifolium* and *D. scoparium* forming a dwarf forest about 3–5 m tall, and *Coprosma* and *Myrsine* also present. Some 81 species of introduced plants have been recorded, *Poa annua* being especially widespread.

The islands are a major global centre of albatross diversity, with six breeding species: the endemic Campbell Island *(Thalassarche impavida)* (26,000 pairs), grey-headed, black-browed, southern royal (14,000 pairs), Antipodean *(Diomedea antipodensis),* and light-mantled sooty albatross. The islands are the main breeding ground for the rare yellow-eyed penguin *(Megandyptes antipodes)* (500–600 pairs), while eastern rockhopper penguins *(Eudyptes chrysocome filholi)* are abundant but recently have reduced markedly in numbers to around 50,000 pairs. Several species of petrel breed, especially on predator-free islets, together with an estimated 1000 endemic Campbell Island shags *(Leucocarbo campbelli)*. Important among the land birds are the flightless Campbell Island teal *(Anas nesiotis),* one of the world's rarest ducks, which was rediscovered on Dent Island in 1975; the Campbell Island snipe (*Coenocorypha* undescribed sp), discovered on Jacquemart Island in 1997; and the New Zealand pipit *(Anthus novaeseelandiae)*.

The New Zealand (Hooker's) sea lion, New Zealand fur seal, and southern elephant seal breed in small numbers, and southern right whales congregate for mating. A massive poisoning campaign in 2001 may have eradicated the Norway rat and cats, the last of the introduced mammalian predators.

Campbell Island was discovered by sealers in 1806, and seals were decimated by the 1830s. Shore-based whaling continued until 1916. Sheep farming commenced in 1895 but terminated in 1931, with the last feral sheep eliminated in 1992. A wartime coast-watching station, occupied from 1941 to 1945, was subsequently used as a meteorological station, which was replaced in 1958 and closed in 1995. Sporadic scientific and conservation expeditions occur and small numbers of seaborne tourists visit each year under strict supervision. Campbell Island is a nature reserve and World Heritage site.

CANADA: ANTARCTIC PROGRAM

Canadian participation in Antarctic research started when Hugh Blackwall Evans was a member of the Southern Cross expedition, the first to spend a winter on the Antarctic continent in 1899, and the involvement has continued for over a century. Canada adhered to the Antarctic Treaty as a nonconsultative party in 1988, and subsequently ratified the Convention on the Conservation of Antarctic Marine Living Resources, the Convention on the Conservation of Antarctic Seals and, in 2003, the Protocol on Environmental Protection to the Antarctic Treaty. Environment Canada administers the Canadian legislation that implements the Environmental Protocol.

Organization of a coordinated Canadian approach to Antarctic science started in the early 1990s after an initiative of the Canadian Polar Commission (CPC) (www.polarcom.gc.ca). As a result, Canada joined the Scientific Committee on Antarctic Research (SCAR) in 1994 with the CPC as the adhering body. Canada became a Full Member in 1998 and established the Canadian Committee for Antarctic Research (CCAR) as the national committee for SCAR. Canada is also a member of the Council of Managers of National Antarctic Programs (COMNAP) through Natural Resources Canada's Polar Continental Shelf Project (http://polar.nrcan.gc.ca).

Canada does not have, nor does it plan to establish, an Antarctic base of its own, but seeks instead to use available space at existing facilities. This is aimed at reducing both cost and environmental impacts and recognizes that new satellite and remote sensing technology, increases in sample and data sharing and computer modelling projects make field programs less important than in the past.

A number of Canadian scientists, mainly faculty members from universities, and scientists from government laboratories participate in Antarctic research (see *Canadians in Antarctic research 2002–2004,* www.polarcom.gc.ca/antarctic/documents). The report also lists the contributions to Antarctic science they made during the same period. Canada does not have a separately funded and managed national Antarctic program as many other nations, but efforts are underway (as of fall 2004) to establish a Canadian Antarctic Research Program. In the meantime, the scientific effort is loosely coordinated through CCAR as the national committee for SCAR.

Research funding comes mainly from the granting councils (e.g., the Natural Science and Engineering Research Council [NSERC] and the Social Sciences and Humanities Research Council [SSHRC]) for university faculty and students and from government departments (for government scientists). Polar Continental Shelf Project operates the Canadian Arctic/Antarctic Exchange Program that promotes scientific exchanges between Canadian scientists and their Antarctic colleagues (http://polar.nrcan.gc.ca/pcs_whatwedo/index_e.aspx?ArticleID=657).

Based largely on experiences gained in Arctic Canada, a variety of Canadian companies provide goods and services to Antarctic operations of many nations. Examples are air services (e.g., by Kenn Borek Ltd.), prefabricated buildings, camping equipment and cold weather clothing. The Canadian RADARSAT satellite provided imagery for the construction of a detailed mosaic map of the continent. Since the early 1990s Canadian tour companies have regularly organized ship-based tours to the Antarctic Peninsula area.

CAPE PETREL

The Cape petrel (*Daption capense,* a member of the family Procellariidae, order Procellariiformes) is a widely distributed petrel of the Southern Ocean. It is a member of the fulmarine petrel complex, which also includes Antarctic petrels, snow petrels, northern and southern giant petrels, and northern and southern fulmars.

The name of the genus *Daption* is actually an anagram of *pintado,* the Spanish word for "painted," a description first ascribed to the bird by early sailors in the Southern Hemisphere. The species is named after the locality where it was first described, the Cape of Good Hope. It is still occasionally called Cape pigeon, a reference to the bird's stocky build and habit of seizing individual food items like a pigeon pecking at grain. In Spanish, it is known as *petrel moteado,* meaning "spotted petrel."

Cape petrels have a distinctive appearance, with their strikingly checkered and mottled black and white upperparts and black head, bill, and feet, contrasting strongly with primarily white underparts. Males and females do not differ in plumage, although males are slightly larger in size (males weigh approximately 470 g and females approximately 445 g).

Cape petrels are loosely colonial breeders with a wide, circumpolar distribution. There are two recognized subspecies, *D. capense capense* and *D. capense australe*. The considerably more abundant nominate subspecies, *D. capense capense,* is concentrated in the Scotia Sea and sub-Antarctic, although it also breeds in the high Antarctic on peri-Antarctic islands. *D. capense australe* has a small population restricted to the sub-Antarctic islands south of New Zealand. Colony size ranges from a few scattered pairs to thousands of pairs.

The world population is considered stable and secure, with a crude global estimate of approximately one million birds. Due to its large global population, broad distribution, and generally remote and inaccessible breeding colonies, there are few conservation concerns for the species.

The timing of the breeding season events is consistent from one season to the next. Arrival at the colonies typically begins in mid to late October and is followed by egg laying in late November to early December. Chicks hatch in early to mid-January with fledglings departing at the end of February to early March. Like all procellariiform seabirds, Cape petrels are obligate single egg layers. Thus, they cannot lay a replacement if the original egg is lost. Cape petrels are considered annual breeders, although in certain years high numbers of birds forgo breeding, presumably due to poor body condition of prospective breeders.

Cape petrels nest in a variety of open habitat types, from flat and sloping ground to cliff ledges. Nests are either bare with collections of small stones, or shallow scrapes where soil substrate is available. Individuals tend to return to the same nest site year after year to breed with the same mate. The species is highly monogamous, with approximately 75%–85% of individuals breeding with the same mate as the previous year. Birds change mates because of a series of breeding failures in previous years or loss or delayed arrival of their mate. Cape petrels, like other petrels, are strongly philopatric, meaning that young birds typically return to their natal (birth) colony or one nearby to establish a nest and begin breeding.

There is little variation in laying date among years, and the timing of breeding is generally highly synchronized, presumably due to the limited window of opportunity for breeding (discussed later). Both parents share incubation duties and the care and feeding of the nestling. At the nest, both adults and nestlings employ an effective defense mechanism: they are accurate marksmen that can spit stomach oil up to 2 m away to dissuade potential predators, principally skuas *Catharacta* spp.

Procellariiform seabirds typically grow considerably more slowly than predicted for other birds of the same size. Interestingly, the fulmarine petrels, including Cape petrels, exhibit a compressed breeding season relative to other birds in the order, meaning that both their incubation and nestling periods are shorter (approximately 50% shorter than predicted). It is believed that this pattern is an adaptation for breeding in the short, high-latitude summers where there is limited time in which food is highly abundant and environmental conditions are appropriate for breeding. Although chicks grow twice as fast as predicted, their general pattern of growth is similar to that of other petrels; chicks typically reach a peak mass that may exceed 150% of adult mass, followed by mass recession until fledging.

Survival rates are lowest for fledglings but subsequently increase for birds that survive their first year of life. The few estimates of adult survival that exist for this species suggest that annual adult mortality rates are approximately 5%, resulting in a life expectancy of over 20 years. Age at first breeding is variable but averages 6 years.

Like other petrels, Cape petrels are opportunistic foragers. Their diet consists primarily of euphausiids (krill), fish, squid, and carrion, especially seal and whale carcasses. During the breeding season, krill frequently dominate the diet; in the Antarctic, numbers of Cape petrels at sea are positively related to krill density. Cape petrels employ a variety of surface feeding techniques to capture prey, including surface seizing and scavenging. Occasionally, Cape petrels make shallow surface dives to approximately 1 m to pursue prey items. Cape petrels are also habitual ship followers, foraging on discarded scraps and offal in addition to prey items carried to the surface by propellers. Evidence suggests that Cape petrels may use their well-developed olfactory abilities to help locate food patches. Foraging trips during the chick-rearing period usually range from 2 to 5 days in length.

When breeding, birds are restricted to foraging in the surrounding inshore and shelf waters within a few hundred kilometers of colonies. Outside of the breeding season, birds are highly dispersive, spending most of their life on the open ocean.

At the conclusion of the breeding season in late February and early March, Cape petrels begin to migrate northward. This migration is extensive, frequently extending up to 15°–20° S. Along the west coast of South America, high numbers of Cape petrels range up the Humboldt Current to the subtropics and occasionally as far as the tropics, with vagrants rarely reaching the Northern Hemisphere.

CARBON CYCLE

The carbon cycle is defined as the flow of carbon through the atmosphere, the ocean, organisms and organic sediments and sedimentary rock. As in all seas, the marine carbon cycle in the Southern Ocean is regulated by (1) the transfer efficiency of carbon dioxide (CO_2) between atmosphere and the ocean, (2) the solubility (thermodynamic) pump, and (3) the biological pump. A fourth pump, the carbonate (alkalinity) pump, is presumably of restricted importance south of the Polar Front due to the scarcity of calcifying organisms. There is particular interest at present in understanding the sinks where CO_2 is sequestered and how long it remains there.

Like other gases, CO_2 flows from high to low partial pressure (p). Whereas mean pCO_2 in the atmosphere has increased from ~360 to ~380 ppm in the past 40 years, it ranges from 150–200 ppm in the surface layer of polar seas to 500–550 ppm in the surface layer of tropical seas. This is a consequence of strong biological pumping and upwelling of CO_2-rich water. Generally, the concentration of CO_2 is higher in deep water than near the surface. Because of the comparatively small variation in atmospheric pCO_2, exchange of CO_2 between the atmosphere and the ocean is almost entirely caused by the pCO_2 variation in the surface ocean on decadal time scales.

Because the transfer efficiency of CO_2 (and gases in general) between the atmosphere and the ocean not only is proportional to the magnitude of the gradient and but also critically dependent on strong wind, the exchange of CO_2 between the atmosphere and the ocean along the roaring forties north and south of the Polar Front is presumably efficient. Realistic modeling of the wind-dependent transfer of CO_2, however, is paramount because otherwise predictions of the size of carbon sinks and sources can easily err by a factor of 1.5–2.

Present estimates indicate that the Southern Ocean is the primary sink for anthropogenic CO_2 (CO_2 supplied on top of a calculated flux of nonanthropogenic CO_2), amounting to ~2 petagrams (1 Pg = 1 gigaton) of carbon per year, which is a little above a quarter of the global anthropogenic supply. Because of small convection depth (<1000 m), however, the anthropogenic CO_2 is not stored in the deep Southern Ocean. Instead it is transported northwards towards the tropical seas with

Antarctic Intermediate Water that is formed near the Polar Front. The concentration of anthropogenic CO_2 in the Southern Ocean is the lowest in any ocean, <20 mol m^{-2} as opposed to 30–50 mol m^{-2} between 30° and 50° S and >50 mol m^{-2} in the North Atlantic.

The solubility carbon pump is based on the fact that cold water can hold more of free CO_2 in solution than warm water at the same partial pressure, ~4% more per centigrade of temperature decrease. The solubility pump is therefore most important in surface currents that are cooled while flowing polewards. The sequestration of CO_2 in the Southern Hemisphere therefore takes place mainly between the tropics and the Polar Front. The area south of the Polar Front is characterized by upwelling of cold North Atlantic Deep Water and, near the Antarctic continent, by formation of bottom water. These water types do not warm or cool significantly while moving vertically. With almost no biological activity in the winter, large stretches of the Southern Ocean are likely to be neutral or, perhaps, a weak CO_2 source.

The biological carbon pump is based on sequestration of CO_2 by photosynthetic plankton (phytoplankton). This lowers pCO_2 in the euphotic (well lit) zone and therefore increases the gradient in pCO_2. Given strong wind, this promotes draw-down of CO_2 or weakening of outgassing from the ocean.

A large part of the carbon sequestered by photosynthesis is grazed and broken down by oxic respiration in a matter of days by heterotrophic plankton, including microbial heterotrophs within the euphotic zone. This returns sequestered CO_2 to the water. The remaining part sinks (export production) and is subject to the same breakdown processes. Less than 3% of the sinking particulate matter will reach the seabed of the deep ocean (>3500 m depth) and take part in the formation of sediments. CO_2 arising from respiration in the upper 1000 m of the water column is likely to reach the upper ocean within a year or less.

Biological carbon pumping is to a great extent regulated by the same factors that regulate primary production; that is, presence/absence of sea ice, vertical mixing, grazing and the availability of micronutrients and macronutrients. A phytoplankton bloom in Antarctic waters typically represents 10–25 mmol m^{-3} of particulate organic carbon (POC), yet higher values can be observed in the marginal ice zone. Enhanced phytoplankton biomass is also typical around islands. The predominant phytoplankton are diatoms and the prymnesiophyte *Phaeocystis antarctica,* of which aggregates of the latter sink particularly rapidly. *P. antarctica* seems to be prominent in the Ross Sea, where it is competitive when the depth of mixing is 80–100 m; diatoms seem to be favoured by stratified water. At present the knowledge of growth strategies of different phytoplankton is very limited due to a lack of experimental research.

Following the phytoplankton blooms near the Polar Front and in the marginal ice zone, vast stretches of the surface water of the deep Southern Ocean enters a high-nitrogen, low-chlorophyll (HNLC) state. This state is characterized by strong iron and grazing control of the growth rate and the phytoplankton biomass, respectively, as verified by several field experiments since the early 1990s. This and limitation by light leave about half of the macronutrients in the water after the blooms have concluded. Iron is needed for nitrate uptake and in the electron transport chain of mitochondria, and therefore lack of iron retards nitrate and carbon uptake. Silicate uptake in diatoms, however, is not affected, and therefore iron-deficient diatoms can be heavily silicified, which in turn leads to rapid sinking. This may explain why bottom sediments in the low-productive HNLC regions are abnormally rich in diatomaceous silicate ("opal").

Estimates of the annual primary production in the Southern Ocean are uncertain and ranges from 1.0 to 3.6 Pg C (average, 2.3 Pg C), which corresponds to 28–100 g C m^{-2} (average, 65). This is a little higher than the regional uptake of anthropogenic carbon. The bulk of the annual primary production, 0.78–3.2 g C, takes place in the permanently open water, mainly the Polar Front zone. The marginal ice zone contributes 0.14–0.38 Pg C and the ice-covered zone, 0.036 Pg carbon. The total annual primary production south of the Polar Front corresponds to 26–90 g C m^{-2}, clearly lower than the average for the global ocean, ~110 g C m^{-2}.

Annual export production of POC south of 50° S is ~1 Pg C (~10% of the global export production) and between 30° and 50° S, the sub-Antarctic zone, ~2 Pg C. The highest vertical carbon flux south of 50° S, 30 g C m^{-2}, is observed in the Polar Front zone, and the lowest, 5–10 g C m^{-2}, is in the ice-covered parts of the Ross and Weddell Seas. The distribution of export production is therefore closely related to the distribution of primary production. Export of dissolved organic carbon (DOC; actually soluble and semisoluble) in the upper 100 m is ~0.4 Pg C, decreasing to ~0.1 Pg C at 500 m depth and <0.1 Pg C at >3500 m depth, corresponding to 40%–50% of the vertical POC flux.

The vast area of HNLC waters in the Southern Ocean has suggested the idea of enhancing biological carbon pumping by fertilizing these waters with iron. To succeed, such fertilization should generate blooms of fast-sinking diatoms, which have high iron requirements. The C:Fe ratio of such diatoms is <850 (w/w). Sequestering 1 Pg of carbon, about one-eighth of the annual anthropogenic carbon supply, would therefore require dumping of >0.0032 Pg of iron II sulfate into the HNLC-regions of the Southern Ocean (~32 thousand 10,000-ton shiploads) during the course of 3–4 months. To ensure that 1 Pg of carbon reaches deeper than 1000 m, the project had to be sized for sequestration of 10 Pg carbon. Worse, if coccolithophorid blooms arise, calcification, which produces CO_2 can neutralize the photosynthetic sequestration of CO_2. In any case, sequestering 10 Pg of carbon by means of iron fertilization is likely to sequester ~1.8 Pg of nitrate-nitrogen, which is about half of the nitrate pool in the upper 500 m of the HNLC regions of the Southern Ocean, and a similar amount of silicate. Thus, the same amount will be lost from the nutrient transport with Antarctic Intermediate Water towards the tropical zone. As a consequence, marine bioproduction and carbon pumping in the tropical zone would decrease strongly, yielding a net change in global carbon pumping close to zero. And the ecological consequences of the gross redistribution of bioproduction from the tropical zone to the Southern Ocean would be enormous.

Recent models of the carbon cycle in the Southern Ocean south of the Polar Front indicate annual sequestration of ~0.47 Pg C, with interannual variability ±0.2 Pg C, largely related to the El Niño Southern Oscillation-linked Antarctic Circumpolar Wave. Future increase in atmospheric CO_2 may strengthen the role of the Southern Ocean as a carbon sink; on the other hand, this may be counteracted by stratification of the upper 500 m if the temperature of the upper Southern Ocean increases.

CARTOGRAPHY AND CHARTING

Mapping Antarctica is especially challenging: It is remote and permanently covered in ice, and its hostile terrain and polar climate hamper the collection of data. Because it is also a dynamic continent, with glaciers advancing or retreating and huge icebergs (up to 95 miles in length) calving from ice shelves, maps need to be revised regularly.

For early cartographers, the size and shape of the continent were mere speculation. Depicted on a world map of 1531 as a hypothetical southern continent (Terra Australis), which extended as far north as Tierra del Fuego, its true extent was gradually revealed by exploration over the ensuing four centuries. Its known limits were reduced when several of the sub-Antarctic islands were first sighted, probably during the seventeenth century (e.g., Île Amsterdam in 1623, South Georgia in 1675), and when the Antarctic Circle was crossed by James Cook in 1773. Subsequent ship-borne exploration, mostly searching for new sealing and whaling grounds, led to the discovery of the South Shetland Islands in 1819 and Antarctica in 1820. Seasonal and permanent floating ice around Antarctica hindered access by ship and it was the twentieth century before extensive inland travel began, with Robert Scott's first expedition of 1901. The first systematic aerial photography was acquired in 1928–1929 by the Wilkins-Hearst Antarctic Expedition, and by the 1960s most of Antarctica's coast and hinterland had been visited or photographed from the air. However, the launch of the US Landsat satellites in the 1970s had the most significant influence on Antarctic cartography, providing an accurate overview of large parts of the continent for the first time.

Although charts were prepared by the early explorers, many in-shore waters were still poorly charted, even uncharted, in the late 1940s when systematic surveys, using echo-sounders, began. On land, several national mapping agencies had published reconnaissance maps by the 1950s but, after the International Geophysical Year (IGY; 1957–1958), Geographic Location and Number of Maps and Data, at Different Scales, Used to Prepare the SCAR Antarctic Digital Database*

Scale	Country of origin	Geographic location	Number
1:200,000	Russia	Marie Byrd Land	2
	UK	Theron Mountains, Coats Land	2
1:250,000	Australia	Bunger Hills, East Antarctica	1
	Japan	Eastern Dronning Maud Land	2

1:3,000,000	UK	Part of interior of continent	2
1:5,000,000	USA	Ronne Ice Shelf	1

*Versions 1.0–3.0. Additions released as Version 4.0 were derived from digital data only and are not recorded here.

increased scientific activity required more accurate maps and charts. Australia, Japan, New Zealand, Norway, Russia, the United Kingdom (UK), and the United States (US) undertook systematic mapping for their scientific programs; all, except Russia and the US, limited map production to specific sectors, representing their territorial claims. Other countries (e.g., China, Germany, Poland, and Spain) mapped only their research areas and scientific stations. Through the Scientific Committee on Antarctic Research (SCAR), international agreement was reached in 1961 on standard symbols, projections, and scales to use on Antarctic maps, and to avoid duplication of effort by freely exchanging information. Mapping sub-Antarctic islands is the responsibility of their claimant nation.

Initially, Antarctica's hostile environment and lack of exposed rock for establishing ground control (only 0.33% of its surface is exposed rock) made systematic surveys difficult to achieve. In 1943, the British began making local surveys from scientific stations, with an astrofix as origin, using triangulation/trilateration techniques supported by exploratory sledge-wheel and compass traverses (a bicycle wheel with cyclometer towed behind a dog-sledge measured distances and a prismatic compass gave azimuth and bearings). When reconnaissance surveying ended in the Antarctic Peninsula in the 1970s, electromagnetic distance measuring devices were being used and a US/UK control network of Doppler satellite positions had been established. Vertical aerial photography of northern Antarctic Peninsula, acquired by the Falkland Islands and Dependencies Aerial Survey Expedition, 1955–1957, contributed to the British mapping program.

The US produced reconnaissance maps of East Antarctica in 1947 and in 1959 began publishing 1:250,000 scale maps of the Transantarctic Mountains and parts of West Antarctica. Those maps and a series of 1:500,000 scale hill-shaded sketch maps, begun in 1963, were compiled from ground survey and tri-camera aerial photography (three cameras, operated simultaneously, with one vertical and two pointing obliquely sideways). After IGY, Australia mapped much of the East Antarctic coast at 1:1,000,000, revising its maps using Russian space photography from the Kosmos satellite, launched in 1966. Russia produced 1:1,000,000 maps of the Antarctic coast and areas of rock outcrop, and other maps at a range of scales, including an Antarctic atlas, published in 1966.

In spite of the huge effort expended on data collection, insufficient ground control hampered the preparation of conventional maps, even at 1:250,000 scale, and, in the mid-1970s, satellite image maps became standard. Map coverage was still poor in

1989 when the UK initiated a project to digitize Antarctic maps; this became the international Antarctic Digital Database (ADD) under SCAR in 1990. The ADD is a seamless digital map prepared from sources at a range of scales, the largest scale with significant coverage (20%) of the continent being 1:250,000 maps of coastal regions, mountainous areas, and large areas of exposed rock (e.g., Transantarctic Mountains); smaller-scale maps were used to complete the database. The ADD was published on CD-ROM in 1993 and new versions have been released on the Internet since 1998.

Global positioning system satellites (GPS) were launched in the late 1980s and, for the first time, ground control could be achieved in Antarctica without people needing to remain on station, in uncomfortable conditions, for long periods. SCAR organized several international GPS campaigns in Antarctica, providing accurate geographic coordinates for a network of sites. Nations also undertook local GPS surveys to improve control for their modern mapping programs (e.g., producing large-scale maps 1:1000–1:50,000 of areas of special significance, such as scientific stations). A number of cooperative mapping programs developed in the 1990s through international agreements.

Higher-resolution satellite imagery (better than 10 m on the ground), and the use of digital cameras linked to GPS systems for aerial photography, have improved the quality and coverage of Antarctic maps. Digital cartography and Geographic Information Systems (GIS) now underpin many logistic and scientific programs in the Antarctic, including geological and thematic mapping, and coastal-change studies. The primary geographic source for continent-wide GIS applications is the ADD, a composite of information obtained over several decades. In 1997, the Canadian–US Radarsat Antarctic Mapping Mission acquired imagery of the entire continent within a month and produced the first high-resolution image mosaic of Antarctica in near real-time—the true shape of Antarctica's coastline was finally revealed at the end of the twentieth century.

CETACEANS, SMALL: OVERVIEW

The diversity of small cetaceans in the Antarctic is low relative to temperate and tropical regions. The dolphin family, Delphinidae, is represented by three species—hourglass dolphin *(Lagenorhynchus cruciger),* long-finned pilot whale *(Globicephala melas),* and killer whale *(Orcinus orca)*. Only one species of porpoise (family Phocoenidae)—the spectacled porpoise *(Phocoena dioptrica)*—is found in the Antarctic. Four additional delphiniid species—southern right whale dolphin *(Lissodelphis peronii),* dusky dolphin *(Lagenorhychus obscurus),* Peale's dolphin *(Lagenorhychus australis),* and Commerson's dolphin *(Cephalorhynchus commersonii)*—are normally found in sub-Antarctic waters but occasionally enter Antarctic waters.

A physical barrier for most dolphins and porpoises moving into the Antarctic is the Polar Front. The hourglass dolphin and spectacled porpoise are the small cetaceans that regularly inhabit the Antarctic zone south of the Polar Front. The larger delphinids include the killer whale and the pilot whale and both occur north and south of the Polar Front. The killer whale is the only delphinid that occurs in the pack ice.

Other dolphin species spend time in sub-Antarctic waters close to the Polar Front and cross it intermittently. Of these, the southern right whale dolphin is pelagic and has a circumpolar distribution. The dusky dolphin, Peale's dolphin, and Commerson's dolphin are all found closer to shore in varying degrees, near the southern continents and around sub-Antarctic islands.

Most small cetaceans in the Antarctic and sub-Antarctic zones feed relatively near the surface (within 200 m) on a variety of fish, squid, and crustaceans. An exception is the long-finned pilot whale, which feeds predominately in deeper waters on squid.

Unlike many of the larger cetacean species, small cetaceans were not subject to whaling in the eighteenth and nineteenth centuries. In current times, small cetaceans inhabiting coastal waters are susceptible as bycatch in fishing nets. Localized, directed takes of dusky dolphin, Peale's dolphin, and southern right whale dolphin have been reported. Generally, the conservation status of small cetaceans in the Antarctic and sub-Antarctic are not known.

Hourglass Dolphin

This small, robust dolphin is boldly patterned with a white hourglass pattern on its side set against a black body. The large dorsal fin has a flattened-hook appearance in adult males. The hourglass dolphin is a fast, splashy swimmer. The average group size is 4–7 dolphins. They are often seen in association with fin whales or other large baleen whales, and feeding in large aggregations of seabirds.

The hourglass dolphin has a circumpolar distribution, in pelagic waters and around oceanic islands situated near the Polar Front. A circumpolar population estimate of 140,000 was based on surveys south of the Polar Front. The population likely exceeds this estimate since the dolphin's range extends to 45° S.

Long-Finned Pilot Whale

There are two species of pilot whales, long-finned and short-finned, but only the long-finned are found in the Antarctic region. Long-finned pilot whales in the Antarctic are accorded subspecies status, *G. m. edwardii.*

The long-finned pilot whale has a long and robust body with a prominent, bulbous melon. It is almost entirely black. It is a sexually dimorphic species: The males are longer and have an extremely large and broad-based dorsal fin. Pilot whales have a matrilineal social structure similar to that of killer whales. Groups typically consist of 20–90 whales. They are gregarious and are often observed in mixed species assemblages with hourglass or southern right whale dolphins. Pilot whales are deep-divers (500–600 m) that feed on squid and occasionally fish.

The long-finned pilot whale has a circumpolar distribution and is most frequently sighted near the Polar Front. It is common around Chatham Island where there have been mass strandings. A population of 200,000 has been estimated for whales south of the Polar Front.

Spectacled Porpoise

The spectacled porpoise is small with a distinctive color pattern. The upper body is black and sharply demarcated on the longitudinal axis from the white lower body. This species is sexually dimorphic: Adult males have a much larger dorsal fin than adult females. The common name refers to a contrasting black and white eye ring visible in most adults. Spectacled porpoises are usually observed slow-rolling at the surface, and they are shy around vessels. Most groups are small, consisting of 1–3 individuals.

Sightings of spectacled porpoise are rare but widely distributed, indicating a possible circumpolar distribution. They are found in the open ocean as well as around sub-Antarctic islands. They are difficult to observe at sea except in good weather, so they may be more common than sightings would indicate. There is no population estimate for this species.

Southern Right Whale Dolphin

The southern right whale dolphin is one of an antitropical species pair: It has a close relative in the North Pacific, the northern right whale dolphin *(Lissodelphis borealis)*. The southern right whale dolphin is long and slender and possesses a striking black and white color pattern. The most notable aspect of its external morphology, however, is the complete absence of a dorsal fin. The southern right whale dolphin is a fast swimmer, often porpoising high out of the water. Group size ranges in the hundreds, sometimes as many as a thousand. It is frequently seen in association with other species such as the long-finned pilot whale and dusky dolphin.

The southern right whale dolphin most commonly inhabits deep water in the sub-Antarctic zone. It is also seen around Chatham Island and the Falkland Islands. There is no population estimate for this species.

Dusky Dolphin and Peale's Dolphin

These robust dolphins are similar in appearance, with complex color patterns of black, grey, and white, and a prominent dorsal fin. The dusky dolphin has the broader range of the two species, with an irregular distribution in continental shelf waters and around sub-Antarctic islands. It is acrobatic and gregarious, and commonly seen in groups of one hundred or more. Peale's dolphin, by contrast, usually occurs in small groups of two to seven. Its distribution is associated with kelp beds and with fast-flowing channel waters.

Commerson's Dolphin

The Commerson's dolphin is one of four species in the genus Cephalorhynchus that all have localized distributions in southerly, coastal waters. The Commerson's dolphin is the most wide-ranging species in this category. It is frequently sighted at sea by those departing on ships from South America to Antarctica.

CHALLENGER EXPEDITION (1872–1876)

Although in scale it was reminiscent of the great voyages of circumnavigation of an earlier era, the *Challenger* expedition was designed not to discover new lands but to explore the depths of the sea. This was a relatively new area of scientific research—now known as oceanography—that had developed rapidly during the previous quarter century. Voyages of discovery between 1750 and 1850 had made great progress both in exploring and in the scientific study of hitherto unexplored portions of the globe, but limitations in the resources available to them meant that in some respects they were only partially successful. One such area was the scientific study of the sea, and another the geographical exploration of the polar regions, but by the 1870s new ideas and technologies encouraged new approaches. Although the main objectives of HMS *Challenger*'s voyage of 1872–1876 were scientific, her officers were experienced naval surveyors, and among its subsidiary aims was an exploratory southern detour during the passage between the Cape of Good Hope and Australia. After visiting Îles Kerguelen, the *Challenger* crossed the Antarctic Circle early in 1874. Heavy pack ice prevented a landfall but the expedition spent a fortnight in high southern latitudes.

The *Challenger* was the first British naval vessel to visit Antarctic waters since Sir James Clark Ross's expedition in the 1840s. As well as magnetic observations, Ross had also carried out pioneering oceanographic research. However, the procedures involved were still at an early stage of development and errors in his painstaking observations reduced their usefulness. By the 1870s, huge strides had been made in the theory and techniques of deep-sea observation.

The *Challenger* expedition originated from an initiative by two British biologists, William Benjamin Carpenter and Charles Wyville Thomson. They realized that experience gained by surveyors during two decades of laying submarine telegraph cables, together with the introduction of steam power, had opened up new opportunities for deep-sea investigation. On dredging cruises made in HMSS *Lightning* and *Porcupine* between 1868 and 1870, they discovered living creatures well below the supposed 300 fathoms limit of life. On the basis of the associated sea-temperature observations, Carpenter also proposed the existence of a general oceanic circulation governed by density differences. When his ideas met with a critical reception in some quarters he proposed a grand voyage of oceanic discovery to sample the life of the deep sea on a wider scale, and also to collect data supporting his theory.

Carpenter was successful in winning public as well as scientific support for this enterprise, and the *Challenger,* a steam-assisted screw corvette, sailed in December 1872. Its captain was George Strong Nares, a veteran of the Franklin searches of the 1850s, and Thomson headed a team of civilian scientists. After a year working in the Atlantic, the vessel arrived at Cape Town late in 1873. The scientific programme involved routines of deep sounding and dredging, together with observations of the physical and chemical properties of sea water, but other work was also undertaken, and during the next leg of the cruise Nares had orders to head into the Southern Ocean and if possible locate land sighted by the American expedition under Lieutenant Charles Wilkes in 1840.

After visiting the Prince Edward Islands and sighting Îles Crozets, where adverse weather conditions prevented landing, *Challenger* reached Kerguelen in early January 1874 and spent three weeks completing the survey of the island. Continuing south, they visited Heard Island, which with Îles Crozets was being considered as base for a Transit of Venus expedition later that year (which ultimately went to Kerguelen). On February 16, 1874, *Challenger* became the first steam vessel to cross the Antarctic Circle before encountering pack ice in latitude 66°40′ S, longitude 78° E. The weather being fine, Nares skirted the pack eastwards, in the hope of sighting Wilkes' Termination Land. However on February 24, conditions deteriorated and after sustaining minor damage in collision with an iceberg *Challenger* turned north, towards Australasia and the Pacific.

Although *Challenger* spent a relatively short time in Antarctic waters and never sighted the continent, the expedition contributed to the renewal of interest in Antarctic exploration and provided valuable new scientific information about the area. The scientists and surveyors added to knowledge of sub-Antarctic islands and Antarctic sea ice and meteorology and pioneered modern oceanographic investigation of the region. John Murray found that "diatom ooze," the seafloor sediment prevailing in high southern latitudes, consisted principally of the microscopic skeletal remains of single-celled algae inhabiting the surface waters of the region. At this point in the voyage, *Challenger* was equipped only with maximum and minimum thermometers so that a temperature inversion in the surface layers, where cold but fresh melt water had accumulated, prevented bottom-water measurements but the fine weather experienced near the ice edge enabled the chemist J. Y. Buchanan to make valuable observations of the properties of seawater and sea ice. Trawling yielded in excess of 400 living species in southern waters, most of them new to science, while deep-sea soundings gave the first reliable indications of oceanic depths along the vessel's track, including one of 1300 fathoms (approximately 3000 metres) only a few miles from the land reported by Wilkes. Dredging operations also brought up pieces of rock from the sea bed, some of which were not of basalt, like the oceanic islands but granite and other rock types typical of a continental landmass. It was assumed that these had been deposited by icebergs and that their presence, together with that of large tabular bergs, was evidence that land with a covering ice sheet, similar to that discovered by Ross on the far side of the Pole, lay farther to the south.

John Murray subsequently campaigned for a British Antarctic expedition to explore the region more fully. However, disagreement between scientists and geographers over the relative importance of exploration and scientific research meant that it was W.S. Bruce and the Scottish National Antarctic Expedition, and expeditions from other nations, that were most effective in continuing Southern Ocean research in the early twentieth century.

CHANTICLEER EXPEDITION (1828–1831)

The voyage of HMS *Chanticleer,* a gun brig of 237 tons, was first proposed by the Board of Longitude in 1826. The instructions were subsequently drawn up by the Royal Society. The purposes of the voyage were to ascertain the true figure of the Earth by a series of pendulum experiments, mainly in the Southern Hemisphere, to determine the longitudes of various ports, and to undertake observations of meteorology, magnetism, ocean currents, and other items of importance to nautical science.

Captain Henry Foster, FRS, was appointed to the command. He had been awarded the Copley Medal of the Royal Society for his work as astronomer during Sir William Edward Parry's third Arctic voyage of 1824–1825 and had earlier carried out pendulum experiments in South America and Greenland. He was one of the ablest scientific officers in the Royal Navy and his death by drowning in the River Chagres, Central America, towards the end of the expedition in February 1831, was a great loss. A particularly fine memorial to Foster can be found in the parish church of Woodplumpton, near Preston, where his grieving father was rector. The command of *Chanticleer* was subsequently taken over by First Lieutenant H. T. (later Sir Horatio) Austin, who had been in HMS *Fury* in 1824–1825 and was later commodore of the Franklin search squadron, 1850–1851, both voyages to the Arctic.

One of the most notable features of the voyage of *Chanticleer* was the series of observations made on Deception Island in the South Shetland Islands, which had been discovered only 10 years previously. Second Lieutenant E. N. Kendall, who had traveled with Sir John Franklin, surveyed the island. His chart was published to accompany his account in the *Journal of the Royal Geographical Society*. The flooded volcanic crater of the island is named Port Foster for the expedition's commanding officer. The only full, published narrative was that by the surgeon, W. H. B. Bentley, who had been directed to preserve specimens in zoology, mineralogy, and geology.

Chanticleer was specially equipped, and a range of expensive scientific instruments was supplied. According to A. G. E. Jones, Webster had earlier corresponded with the Admiralty about a method of preserving meat, and the ship carried a large supply of Donkin's preserved meat, a relatively early use of such provisions. However, a short allowance of food resulted in the consumption of more than 7000 penguins at Deception Island.

The extensive results of the observations from *Chanticleer* were drawn up by Francis Baily, president of the Royal Astronomical Society, and published at the expense of the Admiralty in 1834.

CHARCOT, JEAN-BAPTISTE

When Jean-Baptiste Étienne Auguste Charcot was born in Neuilly-sur-Seine on July 15, 1867, there was little reason to think that he would become one of France's greatest polar explorers and scientists. His father was a renowned neurologist and head of the Salpêtrière neurological hospital, and he was insistent that his son follow in his footsteps as a medical doctor. Despite from a young age being enamoured of ships and the sea, and dreaming of joining the French navy, Charcot nevertheless followed his father's wishes and eventually qualified as a doctor in 1895.

The year Charcot completed his medical training, his mother died, two years after his father had, leaving the young man extremely wealthy. Charcot immediately changed his medical pursuits to bacteriology, and in 1897 he essentially abandoned medicine altogether. In the meantime, he had become a competent mariner, purchasing a series of progressively larger yachts, each named *Pourquoi Pas?* He had also joined the elite social set in France: His wife was a granddaughter of Victor Hugo; through her Charcot was also related to Edouard Lockroy, the Minister of the Navy; his sister's husband was the proprietor of the powerful newspaper *Le Matin;* and a half sister was married to P-M-R. Waldeck-Rousseau, who was prime minister of France from 1899 to 1902.

In the years around the turn of the century, Charcot made a series of ever-longer cruises, sailing to England, then around Ireland, then to the Shetland Islands and the Faeroes, concurrently engaging in scientific work. In 1902, in the ship *Rose-marine,* Charcot sailed to Iceland, the Faeroes, and Jan Mayen, immediately falling in love with the Arctic, where he would return many times. Upon his return, he commissioned his own 250-ton vessel, constructed to the highest of standards for scientific research, able to winter in the polar regions, and taking advantage of the knowledge gained by his new associate Adrien de Gerlache, who had led the Antarctic expedition in *Belgica,* the first to winter in the Antarctic. The costs of the new ship—named *Français*—were so high, however, that even Charcot's fortune proved insufficient, so that he eventually installed an underpowered 125-hp engine, which would later prove problematic in the Antarctic.

Charcot planned for his first cruise in *Français* to be to the high Arctic, but news of the efforts to relieve the Swedish expedition under Otto Nordensjöld helped change his mind and turn him toward the area of the Antarctic Peninsula, where his first expedition (1903–1905) explored and conducted scientific observations. At the end of the expedition, Charcot sold *Français,* which had been damaged, to the Argentine government and returned to France to find himself, with the help of publicity from *Le Matin,* a national hero. His wife divorced him on the grounds of him having deserted her to go to the Antarctic, but he soon remarried. In addition to press support, he now had government sponsorship, which allowed him to build a new, larger, more powerful ship—which he again named *Pourquoi Pas?*—and to lead another expedition to the Antarctic Peninsula region (1908–1910).

In 1911, Douglas Mawson unsuccessfully tried to purchase *Pourquoi Pas?* for his Australasian Antarctic expedition, but instead the ship was designated as a French marine research laboratory, of which Charcot was appointed director. In the next two years Charcot made two voyages to Jan Mayen, and then during the First World War he commanded "Q-ships," which were designed to destroy German submarines.

After the war, Charcot began a series of yearly cruises in *Pourquoi Pas?,* spending about three months each year in the Arctic, North Atlantic, or Bay of Biscay. He first visited Greenland in 1925, and thereafter spent much time exploring the East Greenland coast, and helped establish the French research station at Scoresby Sund for the International Polar Year (1932–1933). In 1928, he searched the edge of the ice pack for Roald Amundsen, who had himself disappeared while searching for the members of Umberto Nobile's expedition on the dirigible *Italia*.

On September 16, 1936, leaving Iceland for France (after having been to East Greenland), *Pourquoi Pas?* was caught in a violent storm and foundered on the rocks off Aftanes. Charcot and all but one member of the crew were lost. He was later honoured with a national memorial ceremony attended by the President of France.

CHEMICAL OCEANOGRAPHY OF THE SOUTHERN OCEAN

The chemistry of the waters of the Southern Ocean is determined by two dominant factors. The first is the physical chemistry of the system (that is, the chemistry determined by Gas Laws, solubility of ions, etc., as well as the interaction with physical oceanographic features such as density-driven currents, air-sea exchange, etc.), and the second is the influence of biological processes. Chemical forms discussed herein include dissolved gases (oxygen and carbon dioxide), macronutrients (nitrate, phosphate, silicic acid), micronutrients (iron), and dissolved organic matter.

The concentration of gases in Antarctic waters is largely a function of their solubility, which in turn is determined at equilibrium by their partial pressure (the percentage in air by volume) and temperature. Oxygen and carbon dioxide are more soluble at low temperatures, so that surface waters of the Southern Ocean have higher concentrations than in temperate or tropical regions. Both are also influenced by phytoplankton (single-celled photosynthetic organisms), which add O_2 during growth (and remove CO_2), and in subeuphotic (dimly lit) waters, oxygen is used by microbial respiration (which generates carbon dioxide). Phytoplankton also remove nutrients along with CO_2, and they are regenerated in deeper waters as well. Thus biological processes couple gases and nutrients in both space and time. Therefore, a typical vertical profile of oxygen would have high concentrations at the surface (often at or above saturation), reduced levels from c. 200–1000 m, and slightly increased concentrations to the bottom. Carbon dioxide concentrations would be the inverse of the oxygen levels. Suboxic and anoxic conditions are extremely rare in Antarctic waters.

Exchanges of gases also occur between the ocean and atmosphere, and their magnitudes are determined by the gradients between the two. Because atmospheric carbon dioxide concentrations are increasing due to anthropogenic effects, the Southern Ocean (south of 50° S) as a whole has become a sink for CO_2; that is, there is a flux of CO_2 from the atmosphere to the ocean. This has been determined through the use of global climate models because observations cannot be taken simultaneously throughout the entire Southern Ocean. The models converge on the magnitude of the sink, and also show that the size of this sink has increased in the past 25 years. Predictions suggest this trend, along with the increasing concentrations of atmospheric CO_2, will continue in the next century (Caldeira and Duffy 2000).

Ice can greatly restrict the exchange of gases with the atmosphere. For example, in the Ross Sea carbon dioxide accumulates under the sea ice during winter (when no photosynthesis occurs and respiration continues at low rates), and late winter CO_2 concentrations (that is, total inorganic carbon concentrations) exceed those of seawater in equilibrium with the atmosphere by at least 100 μatm. Equilibrium conditions (c. 373 μatm) are approached in non-ice-covered regions.

Substantial regional differences in dissolved oxygen levels occur. For example, oxygen concentrations at 100 m near 65° S can exceed 8 mL L^{-1} in the Southeast Pacific, but are <5 mL L^{-1} north of George V Land (Gordon and Molinelli 1982; Orsi and Whitworth 2005). In waters 2500 m deep, oxygen concentrations are all greater than 4 mL L^{-1}. Waters farther south generally contain more oxygen than those in the north (50° S) by about 1 mL L^{-1} due to the colder temperatures and greater solubility near the continent.

Macronutrients, such as nitrate (NO_3), phosphate (PO_4), and silicic acid ($Si(OH)_4$), are required for the growth of phytoplankton, and therefore are part of the biogeochemical cycling of organic matter in the ocean (as are oxygen and carbon dioxide). Nutrients are incorporated and chemically reduced by phytoplankton into body tissues in the euphotic zone, where they ultimately are eaten or sink. The generation, transformation, and unidirectional transport of organic matter from the surface by oceanic biota to depth is called the biological pump. In deeper waters other organisms use this material as food, and in that process elements are recycled back into the original (oxidized) form. Therefore nitrate and other macronutrients have similar profiles; that is, reduced concentrations at the surface, increasing levels below the euphotic zone, and nearly constant concentrations below some 500–1000 m.

Surface waters in the Southern Ocean exhibit extreme seasonality due to the seasonal changes in solar input (which in turn controls ice formation). Gas concentrations and nutrients also show marked seasonal differences (Gordon and Molinelli 1982). For much of the year when biological processes occur at low rates, nutrient concentrations are at their seasonal maxima; conversely, during the short but intense growing season in austral summer, nutrient concentrations reach their minima. Surface nitrate concentrations are high, largely because of the continuous upwelling of deep water at the Antarctic Divergence. Concentrations range from 20–30 μM (1 μM = 10^{-6} moles per liter of seawater, with a mole of any substance being its mass numerically equal to its molecular weight in grams), and only in restricted areas are the levels reduced to <5 μM. A small north-south gradient in NO_3 concentration also occurs between the Antarctic Divergence and Convergence, where concentrations drop to c. 12 μM.

Phosphate concentrations mirror those of nitrate, with maximum concentrations in deep waters being >2.25 μM. Surface concentrations can drop below 1.0 μM. The ratio of nitrate:phosphate in the Southern Ocean is 15.9, similar to that of the entire ocean. Geographic variations are less pronounced than those of nitrate. Silicic acid concentrations (also known as silicate) are among the highest in the world's oceans, and at 3000 m can exceed 150 μM south of Africa. Surface values range from near zero to >90 μM. The extremely low values occur in areas near the Polar Front after the seasonal phytoplankton bloom and reflect a very strong north-south gradient between the Polar Front and the Antarctic Divergence in $Si(OH)_4$ concentrations. South of the divergence values tend to be more constant, except in regions where extensive silicic acid removal by diatoms (a type of phytoplankton) occurs.

All nutrients, after incorporation into phytoplankton cells, must be regenerated and remineralized in the water column. In the case of nitrate, it is reduced upon uptake by phytoplankton and is often released in dissolved form as ammonium by heterotrophic organisms. NH_4 in turn must be oxidized to nitrate by bacteria; therefore, because all of these transformations are biologically mediated, rates of nitrate remineralization are controlled by biological processes. In contrast, the uptake of $Si(OH)_4$ is biologically mediated, but its remineralization is largely controlled by chemical processes and is more independent of biological transformations. In cold waters, biogenic silica is transformed to dissolved silicate more slowly than nitrogen is remineralized (relative to warmer waters), producing some uncoupling between the elemental cycles and vertical distributions in the water column.

Dissolved organic matter (DOM) is a generic chemical group that includes a wide variety of organic compounds (amino acids, lipids, nucleic acids, humic and fulvic acids, polysaccharides, etc.). Each class and compound is biologically and/or chemically oxidized at different rates, and so the composition of bulk DOM varies with depth. Indeed, chemical techniques for the separation and identification of classes of organic compounds in seawater are time consuming and often very difficult analytically, so a clear appreciation of the dynamics of individual compounds is lacking. DOM consists of compounds that include dissolved organic carbon (DOC) as well as those with dissolved organic nitrogen (DON). Each component is measured in a very different manner, and most measurements are available for DOC.

DOM exhibits vertical profiles that are the inverse of those of nutrients, because the source of DOM is biological (photosynthesis, generation during feeding, cellular breakage, etc.). That is, DOM is higher in the euphotic zone and decreases to a low and constant level below c. 300 m. Deep-water values of DOC are c. 42 μM, and horizontal variations occur and are a function of the age of the water (older waters, such as those in the deep Pacific, have lower DOM values). Ratios of DOC:DON in the euphotic zone are about 6, and those in deeper waters near 12. Ranges of DOC in surface waters of the Southern Ocean are from 45–120 μM, with higher values in the regions with extensive biological activity.

Extensive research has been conducted to assess the distributions and effects of dissolved iron. This is in large part in recognition that iron is a major determinant of the nature and extent of phytoplankton growth, which in turn limits energy transformations within food webs. Many uncertainties remain (e.g., the use of organically bound iron by phytoplankton, the oxidation by light of reduced iron, recycling of iron in the euphotic zone), but we have broad outlines of the distribution of iron and its importance to phytoplankton. Iron occurs in the ocean in extremely low concentrations—from 0.05 to 3 nM (1 nM = 10^{-9} moles per liter seawater; 1 μM is 1000 times more concentrated than 1 nM). At such low concentrations, extreme care must be taken to sample water using fastidiously trace-metal-clean techniques to prevent contamination prior to measurement. Surface variations in iron concentrations occur, but due to the relatively limited number of reliable measurements in the Southern Ocean, it is at present difficult to quantify the range of values. Higher levels of iron (>3 nM) are found near islands and coasts, and in waters that have had recent contact with sediments. Ice can also be a source of iron, as Fe accumulates at extremely low rates from dust during the austral winter and is released into the ocean upon melting. Phytoplankton growth reduces iron concentrations to undetectable levels in spring and summer.

There has been a suggestion to fertilize the Southern Ocean with iron to stimulate phytoplankton removal of nutrients and CO_2, with the ultimate goal to reduce the rate of carbon dioxide accumulation in the atmosphere. Small (15 × 15 km) iron fertilization experiments have been conducted in the Southern Ocean (and elsewhere), and all have shown a notable increase in phytoplankton and removal of carbon. It is far less certain how much of this cellular material is exported to depth and permanently removed from the surface. Much concern about the environmental impacts of this carbon reduction scheme has been expressed (for example, creating anoxic zones at depth; disruption of extant food webs; stimulation of nuisance species; harming of non-Antarctic waters), and it presently remains unfeasible to fertilize the waters of the Antarctic to significantly impact atmospheric CO_2 concentrations.

CHILE: ANTARCTIC INSTITUTE

The Antarctic Institute of Chile is a state agency within the Ministry of Foreign Affairs. It was founded in Santiago on February 28, 1964, by presidential Decree No 103. Ambassador Raul Juliet proposed this initiative to the Senate Committee on Foreign Affairs (Chilean Parliament) during the hearings for a law (Arts. 4, 5, 6) to reorganize the Ministry of Foreign Affairs. At the time the minister of Foreign Affairs was Carlos Martínez Sotomayor, serving in the government of President Jorge Alessandri. The political and economic scenario of the early 1960s in Chile did not allow an independent specific law to create a new government agency, which would certainly have an impact on the national budget and number of state employees.

Chile made an Antarctic territorial claim in 1940. On July 23, 1958, the minister of Foreign Affairs, Alberto Sepulveda, called the attention of the Chilean Antarctic Council to the need to create the Antarctic Institute, as requested by Lucia Ramírez and Germán Carrasco of the Section Antarctic Affairs of the Ministry. Since 1946, Chile had organized thirteen annual Antarctic expeditions, and had built three stations, two on the South Shetland Islands and one on the Antarctic Peninsula. Later, in December 1958, Chile signed the Antarctic Treaty in Washington, D.C., becoming one of the twelve founder nations.

The law describes the functions of the new Institute as the national government agency in charge of the planning, orientation, and coordination of all scientific and technological Chilean Antarctic activities.

Presently the Institute has five sections: Scientific, Logistics, Outreach, Finances, and Administrative all under one director and a deputy director. Last year the Institute headquarters were moved from Santiago to Punta Arenas, following a government decision within the framework of a general plan of decentralization of the state agencies. The Scientific Council and the Financial Committee of the Council for Antarctic Policy assist the director of the Institute on the preparation of scientific programs and budgetary matters.

The Scientific Section is in charge of organizing the national scientific contest. This is open to all qualified scientists, mainly from Chilean universities; specialists from Chile and other Antarctic nations referee proposals. A Scientific Board ranks the projects, based on scientific merit and feasibility, and makes a proposal to the director. Then the annual expedition is planned and a timetable is produced in collaboration with the Logistics and Finances sections.

The head of this section also supervises all scientific publications acting as managing editor of "Serie Científica del Instituto Antártico Chileno," sending all papers to peer reviewers.

The Logistics Section organizes the annual scientific expedition providing assistance, supplies, equipment and transport to all scientists. The Navy and the Air Force at the request of the Institute do transport. It builds and maintains six summer stations, four on the South Shetland Islands and two on the Antarctic Peninsula. The largest one is Prof. Escudero on Fildes Peninsula, King George Island, with laboratory space for ten scientists and the support staff.

The Outreach Section prepares, edits, and publishes a Bulletin and a Scientific Series and several occasional publications on Antarctic science and Antarctic Treaty matters. This section also organizes the annual instruction courses for all participants on Chilean Antarctic activities and supervises the Institute Library. Contents of these courses include science, research, law, and policy such as the Antarctic Treaty, Protocol on Environmental Protection to the Antarctic Treaty, and the Convention on the Conservation of Antarctic Marine Living Resources. This section organizes and promotes the delivery and dissemination of the scientific results through conferences, exhibitions, and events for students and general public. The Institute Library houses a unique collection of books on early Antarctic exploration and history of the development of Antarctic policy, as well as scientific periodicals to support research. It also holds a large collection of maps and navigation charts published by Antarctic Treaty nations.

The Finances Section prepares the annual budget and handles all expenditures related to research, publications, and expeditions. The Administration section deals with personnel, buildings, vehicles, and routine maintenance and inventories.

In the development of scientific research the Institute frequently collaborates with its homologue institutions and universities. For example, since 1990 it has had a program on permanent satellital observations of the continent with the German Spatial Agency (Deutsches Zentrum für Luft und Raumfart).

Since its inception, the Institute has organized and sponsored forty-one Antarctic expeditions, financed more than 420 scientific projects, and published fifty annual issues of the Scientific Series, twenty-five annual issues of the Bulletin, and more than twenty occasional publications and reports. It has sponsored many workshops and scientific meetings including four annual Antarctic Research Congresses.

The Institute is also the headquarters of the National Committee on Antarctic Research, a subsidiary body of the Scientific Committee on Antarctic Research (SCAR), under the aegis of the International Council of Scientific Unions (ICSU). Its members are distinguished Chilean Antarctic scientists. The main functions of this Chilean Committee are to assist the government and the Institute on Antarctic science matters including the preparation of scientific Antarctic programs. The Chilean Committee also acts as a liaison with the international scientific community and its members attend the biannual meetings of SCAR.

The Institute provides technical and scientific assistance to the Department of the Environment of the Ministry of Foreign Affairs. The Institute's director chairs the National Board of Antarctic Affairs, which deals with policy making and planning the Chilean Antarctic activities and participation in Antarctic International fora.

CHILEAN SKUA

The total population of Chilean skuas *Catharacta chilensis* is unknown, but appears to be several thousand birds. There is no information available on population trends or changes in the extent of the breeding range but there appears to have been a decrease in recent years. Breeding populations of Chilean skuas are present on the coasts of southern South America, from Chile (Concepción) and southern Argentina to Tierra del Fuego. At sea, birds have been observed as far north as Peru (14° S) and on the Atlantic coast to 22° S and eastward to the Falkland Islands. In recent years, increasing numbers of Chilean skua-like birds have been observed on the South Shetland Islands and the tip of the Antarctic Peninsula.

Chilean skuas are coastal and marine birds and occur predominantly in South American channels and straits. The breeding grounds are mainly on islands and remote mainland coastal areas. The Chilean skuas disperse northwards after breeding. The wintering grounds are mainly along the coasts of Chile and Argentina, extending north to south Peru and possibly east to West Falkland Islands. Migration to Peru has been observed in April.

There are no data on the longevity for this species. Chilean skuas breed annually, returning to the breeding areas in October/November. Chilean skuas breed in colonies, sometimes in high densities. Egg laying (normally two eggs, sometimes one) begins in November. The nest scrape is lined with dead grass. Unlike other skuas, adults show very little aggression against people entering the breeding territories. The chicks hatch after 28 to 32 days.

Very little is known about the food of Chilean skuas. They are predators of chicks and eggs of seabirds, but also feed on invertebrates during low tide and from rubbish dumps near towns. They are known to steal food from other birds (kleptoparasitism), to feed on the shore among kelp gulls *Larus dominicanus,* and to follow fishing boats.

At Puerto Deseado, Argentina, a mixed-species colony of Chilean and Falkland skuas *(Catharacta antarctica antarctica)* has been found in which there are also hybrids of these two species. Some skua specimens with the coloration pattern of a Chilean skua have been observed at King George Island and at the tip of the Antarctic Peninsula. On King George I, a hybrid between a South Polar and a Chilean skua has been breeding successfully with a South Polar skua *Catharacta maccormicki* for at least 12 years. In this bird, the forehead, crown, eye region until the gular stripe, and wing coverts are dark brown. Its chin and throat are orange, and the nape and back of the neck are largely pale. The mantle, foreneck and flanks appear brown-and-white spotted, contrary to the orange-and-brown spotted breast, belly and ventral region. A remarkable feature is the narrow closed orange band of its underwing coverts. The bill and legs are black. A chick of this pair was found dead in the North Atlantic Ocean.

CHINA: ANTARCTIC PROGRAM

The purpose of the Chinese National Antarctic Research Expeditions (CHINARE) is to get a better understanding of the Antarctic and its role in the global climate system and the Earth system, and to make contributions to the peaceful use of Antarctica for humankind.

The Chinese Arctic and Antarctic Administration (CAA), part of the State Oceanic Administration (SOA) in Beijing, is the lead government office responsible for the organization, coordination, and management of the national Arctic and Antarctic planning. Its responsibilities include drawing up an integrated national polar research strategy and policy to guide China's polar research activities; developing a five-year plan to implement the national policy and updating the plan annually; coordinating the yearly national polar research expedition, including logistics; promoting interagency coordination of polar research programs, including logistical planning and data sharing; and coordinating and promoting cooperative polar research programs with other countries and international organizations.

The Polar Research Institute of China (PRIC) in Shanghai is the domestic base for CHINARE and is in charge of running and managing the icebreaker M/V *Xuelong,* Chinese Antarctic Great Wall Station, and Zhongshan Station and servicing logistical needs of CHINARE. PRIC is also the polar research center of China. Regarding science, PRIC is responsible for conducting national polar research expeditions. Its current research fields include glaciology, biology, ecology, upper-atmospheric physics, and marine sciences. It carries out international cooperation and academic exchange activities. It has founded several important laboratories for ultralow temperature experiments, clean analysis, polar biological experiments, ionosphere analysis, aurora and magnetosphere analysis, and marine environment numerical modeling. Scientific data and a great number of samples and specimens of polar meteorites, ice cores, and microorganism isolates collected by all Chinese Antarctic and Arctic expeditions are preserved in PRIC.

Financial support for management and field operations is from government funding. The State Ministry on Science and Technology and the National Natural Science Foundation of China as well as some nongovernmental agencies support the scientific research funding, to which scientists from all scientific fields of any research organizations and universities in China may submit proposals. Those successful can take part in the CHINARE field investigations as an additional part of the national research program.

Chinese Antarctic research—started by collaboration with foreign countries such as Australia, Japan, Argentina, Chile, New Zealand, the United Kingdom, and the United States from 1979 to 1984—has developed greatly. As of 2005, four national five-year programs have been successfully carried out. The First Chinese National Antarctic Research Expedition (CHINARE-1) was dispatched in late 1984 and completed the establishment of Great Wall Station on King George Island, South Shetland Islands (62°12′59″ S, 58°57′52″ W). It was opened on February 20, 1985, and has been a year-round station since its establishment. The station is equipped with vehicles, office building, kitchen, living quarters, clinic/recreation/sports building, weather building, comprehensive observatory building, storehouse, electrical power house, and science building for field sampling and research on sea-ice satellite remote sensing, biology, geology, and environmental study and for routine observations of geomagnetic survey, upper-atmosphere physics, whistle sound, and earthquakes.

In early 1989, CHINARE-5 established the second year-round base—Zhongshan Station at the Larsemann Hills in the Elizabeth Land, East Antarctica (69°22′24″ S, 76°22′40″ E). It opened on February 26, 1989, and has been run as a year-round research station since. It is equipped with heavy snow vehicles for inland traverses and a variety of buildings for office work, living, science, power, storage, communications, weather observation, and medical services. The major scientific activities at the station are glaciology, upper-atmosphere physics, atmospheric science, climate change, sea-ice satellite remote sensing, geology, environment, earth science, and marine science in the Prydz Bay and its adjacent region of the deep ocean.

Twenty-one CHINARE voyages have been carried out to resupply and change over personnel for the two Antarctic stations. These voyages included eighteen marine science cruises, implementing the national marine research programs in physical and chemical oceanography, marine biology, geochemistry, and sea/air/ice interactions in the Southern Ocean. These were carried out by the research vessels *Xiangyang Hong No. 10* (1984–1985), the ice-strengthened vessel *Jidi* (1987–1993), and the icebreaker M/V *Xuelong* (1994–present). Two cruises to the Pacific sector of the Arctic Ocean were successfully completed by the ice-breaker M/V *Xuelong* in 1999 and 2002.

Four inland traverses to Dome A, the highest position on the Antarctic ice sheet, and two geological surveys to the Grove Mountains from Zhongshan Station have been carried out in the past seven years. In 2004–2005, the fourth traverse team arrived at the top of Dome A and a series of investigations and samplings were carried out over 13 days, gaining information in preparation for the establishment of a Dome A station by 2010. The traverse lasted 63 days.

Current ship-based research emphasizes: physical oceanography, marine chemistry and carbon cycling, Antarctic krill, polar microbiological studies on features, processes and adaptation, marine CO_2 and aerosol, and sea-ice processes. Station-based research emphasizes space environmental monitoring and dynamic processes in the cusp region, the recent processes of snow and ice, mass balance and historical climate record in the ice sheet of East Antarctica, ice sheet/ice shelf/ocean interactions, sea ice and climate, the process of climate variability in the Antarctic region and its impact on climate change, geology of the Larsemann Hills and Grove Mountains, historical climate record of ecosystem and process in the ice free areas of Antarctica, shifts of penguin populations with respect to environmental change, meteorology and atmospheric science, geodesy and geographic information, meteorites of the Grove Mountains, and Antarctic environmental monitoring and data information integration systems.

China has been publishing a quarterly, *Chinese Journal of Polar Science,* in both Chinese and English since 1988. The National Polar Archive was established in 1990.

CHINSTRAP PENGUIN

Chinstrap penguins *(Pygoscelis antarctica)* belong to the group of Pygoscelid penguins together with Adélie penguins *(P. adeliae)* and gentoo penguins *(P. papua)*. They breed south of the Antarctic Convergence, mainly on the Antarctic Peninsula south to Anvers Island (64° S) and on the islands of the Atlantic sector of the Southern Ocean (South Shetland Islands, South Orkney Islands, South Sandwich Islands, Bouvetøya, South Georgia). Small colonies in anomalous locations have been found on the Balleny Islands, north of the Ross Sea in the Pacific Ocean sector, while attempts at breeding have been recorded on Cape Horn in South America. Its populations are stable or increasing at present, with estimates running in the millions of pairs. They are by far the most abundant penguins in the Scotia Arc, consuming around 90% of all the krill harvested by all land-based predators in the South Shetland Islands. They breed in colonies ranging from a few pairs to hundreds of thousands. They weigh around 4 kg and show the typical black and white plumage of penguins with a diagnostic thin black line running under the chin. Males are slightly larger than females and have a stouter bill. The maximum dive depth recorded is 100 m, but most dives reach less than 50 m in depth, with a mean dive duration of 90 s. Diving effort is concentrated around midnight and noon. The diet consists mainly of krill, although in certain areas also includes myctophid fish.

Chinstrap penguins breed during the short Antarctic summer on steep slopes and rocky outcrops, which are the first areas freed of snow in the spring. Two eggs are normally laid after a short phase of territory occupation, courtship, and mating. Monogamous pair-bonds may last several years, with 80% of individuals pairing with the same partner in successive seasons. Site fidelity is higher for males, with 90% returning to the same nest site in successive seasons (80% for females). No extra-pair paternity has been detected through DNA-fingerprinting in chinstrap penguins. Nests are mounds of pebbles, which reduce the risk of flooding of nest contents by melt water.

During the 1-month incubation period, both parents take shifts at covering the eggs and maintain the nest by collecting new stones. Predation of eggs by skuas is higher in small colonies, while competition for scarce pebbles leading to fights is higher in large colonies. Siblings hatch with on average one day difference, although hatching asynchrony may be as high as 4 days. Chicks hatched late in the season have poorer survival prospects and grow slower than early-hatched chicks. This seasonal trend is related to a reduced disposition to invest by parents as the season progresses. Late-breeding individuals seem to have a poorer health status than early breeders. Chicks are guarded by one of the parents for several weeks, parents taking shifts at the nest and foraging at sea. The amount of food demanded by chicks increases until both parents must forage daily to satisfy this need. At this point, chicks are left alone in loose aggregations, traditionally called crèches but more appropriately referred to as brood amalgamations. These aggregations help to protect chicks from skua predation by collective defence and spreading of risks. The age at which chicks are left unguarded depends on brood size (single chicks are left at greater ages) and parental condition, and is very variable (20–40 days). Chicks left unguarded at earlier ages experience higher mortality risks.

During the postguard phase, parents arrive at colonies only to feed the chicks, which they attract to the nest site by calling. Parent-offspring recognition occurs apparently strictly by sound. When chicks arrive at the nest site, they are led into so-called feeding chases by the parent running away. These chases manage to separate the two competing chicks, which are fed singly at leisure by the parent by regurgitation. Parents are aggressive towards unrelated chicks during visits and there is no collective antipredator defence of chick aggregations by adults. When chicks are 50–60 days old, parents stop provisioning them, forcing them to go to sea and to an independent life. Late-hatched chicks are left unprovisioned at earlier ages. The first days of independent life are marked by a high mortality, presumably due to problems in finding food and intense predation, mainly by leopard seals *Hydrurga leptonyx*. Structurally larger chicks, which have a higher body condition, are also the ones with a higher probability of surviving this crucial period. Parents in energy balance provisioning grown chicks require 1.7 kg of krill daily to sustain their energy requirements (6000 kJ), while each chick of 40 days would consume 0.5 kg of krill daily. Diurnal foraging trips may cover up to 8–10 h, while in some areas the overnight foraging trips may last almost 24 h.

After breeding, adults spend several weeks foraging intensely at sea to accumulate fat reserves amounting to several kg. These reserves are needed for the moulting fast period, when they renew their whole plumage during a period of two weeks when they cannot go to sea. Pairs moult together at their recent nest site. First-year birds have shorter and slighter bills than adults, and dark facial feathers. Young penguins visit breeding colonies in order to prospect for future nest sites and mates during their first years of life and are intensely attracted by chicks in aggregations, which they at times try to mount. There are reports of individuals breeding at two years of age. Young nonbreeders moult earlier than breeders and close to the breeding colonies, coinciding with the final stage of breeding. Life expectancy of chinstrap penguins is unknown, although probably similar to that of Adélie penguins. Little is known about behaviour during winter, although their movements can cover long distances. One individual was tracked during 4 months at sea during winter and reached 1600 km from the colony in which it had moulted. It spent more than 60% of its time in open water north of the edge of the pack ice. Sea-ice conditions during winter may affect mortality, as shown by a reduction in the number of breeding pairs in the subsequent spring.

CHRISTENSEN ANTARCTIC EXPEDITIONS (1927–1937)

Lars Christensen was responsible for extending and promoting Norwegian interests in the Antarctic while operating a whaling fleet in the area. Christensen's southern operations followed earlier exploratory ventures, and a period of shore-based whaling under concession in relatively restricted areas. These operations began as access to Arctic waters was being denied, when technology was allowing rapid expansion of pelagic whaling, and when the 1926 Imperial Conference was moving towards control of considerable areas of the continent. As exploratory voyages, Christensen's expeditions might be considered intermediary between private, poorly financed expeditions and those more publicly sponsored (Bogen 1957): certainly Christensen sought no support for his ventures.

Conventionally, Christensen's expeditions have been considered as a series of nine single-ship ventures, but they were often not, being integrated into more general, seasonal whaling activities involving tankers, factory ships, and catchers under his command. Here, details are summarized, with an emphasis being placed on the ships *Odd 1, Norvegia,* and *Thorshavn,* but others were involved. There are several accounts of most voyages, and repetitions have produced some conflicts of dates (and occasionally places); further, positions were not always accurate, and features were variously named. Some discrepancies of date or event are indicated, as are some instances where only one author provided specific information.

Christensen's Objectives

Christensen provided several reasons for his expeditions, considering some (like his four *Thorshavn* voyages) to combine business and science, whereas others were essentially for scientific and geographical purposes. Often avowing almost altruistic views regarding his activities, while operating commercially, Christensen wanted to enhance Norwegian whaling opportunities, and he considered that his nine expeditions were ''conceived as a Norwegian contribution'' (Christensen 1938: 4) to research and exploration. But other issues were involved. Thus, increased (in extent and area) pelagic whaling influenced all expeditions (Christensen 1938: 4), but there was also the desire to establish a Norwegian Antarctic ''inheritance'' and to ''possess supply depôts'' in unclaimed areas (Christensen 1935: 17, 31). In fact, there was a desire to invoke claims (with some emphasis on ''the whole region between Enderby and Coats Land'' (Christensen 1935: 204), to establish structures to support occupation (as on Bouvetøya, and Peter I Øy), to ''safeguard Norwegian interests'' (Christensen 1935: 222) without restrictions imposed by other nations. While meteorological and oceanographic observations were routinely made, biological and water samples obtained, and whales sought, the existence of some islands and rocks was also to be resolved. Attempts to sketch coastal areas and obtain aerial photographs were paramount at times, with a need to adequately survey newly discovered areas using modern techniques (for example, as on *Thorshavn*'s fourth voyage), all against a background of perceptions of territorial claims, intentions, and changes in Antarctic (and national) politics. The less-overt desire to examine whaling operations, to introduce new technologies, and to maintain or enhance profitability also took Christensen south.

Summary of Seasonal Activities

1926–1927

Odd 1 (156 t whale catcher; leader: Eyvind Tofte; captain: Anton A. Anderssen) undertook a short prospecting voyage from South Georgia (left January 4, 1927). They sailed from Deception Island, South Shetland Islands, on January 12 after coaling from the factory ship *Pythia*. Peter I Øy was sighted early January 17, a landing attempted, the island circumnavigated, and the ship then went south to the pack ice, returning to Deception Island on January 22.

1927–1928

Norvegia (c. 290 t wooden sealer, 350 hp engine; leader: Håkon Mosby; captain: Harald Horntvedt) went from Cape Town (November 19) to Bouvetøya (November 30), which the party annexed (December 1, involving captain and eleven crew) and then made several landings on. They obtained numerous seal skins and built a ''small house'' (Bogen 1957, quoting Horntvedt) during the month spent in the area; many whales were seen. The intended program of searching between Enderby Land and Dougherty Island (of questionable status) to the west was affected by the ship striking an underwater rock on December 3, but they continued south after ''sounding and sealing operations'' until stopped by the pack ice (January 7; Holtedahl 1931) at about 60° S. The increased leaking and a limited coal supply forced a return to Grytviken, South Georgia, which they reached on January 22. The ship docked for repairs, while the scientists continued on other ships (Holtedahl 1931).

1928–1929

The expedition was originally intended to erect a wireless station on Bouvetøya and then go east along the ice edge, but the instructions were later changed. *Norvegia* (leader: Ola Olstad; captain: Nils

Larsen) left Grytviken on November 8, and met the factory ship *Thorshammer* a month later to receive equipment and men for the proposed station. They were in the area of Bouvetøya December 16–21 (Christensen 1935), but the weather prevented the establishment of the station, although two houses were erected. They unsuccessfully searched for Thompson Island and "Chimneys" (December 21–29), and then the ship west to meet *Thorshammer* and its transport, *Thorøy,* for an exchange of material and men (on or about December 31). They bunkered alongside *Thorshammer* January 1–4, the sailed to Deception Bay, where they refueled prior to sailing for Peter I Øy (January 27, Christensen 1935). A landing was made at Peter I Øy on February 1 (Holtedahl 1931), and the next day it was annexed for Norway. Subsequently, a depot was established and local investigations were made. On February 8 the ship headed southwest, reaching about 140° W on February 20. *Norvegia* took a more northerly return route, did not find Dougherty Island, arrived back at Deception Island on March 19, and laid up at South Georgia.

1929–1930

Again it was intended that *Norvegia* would construct a building on Bouvetøya, take aerial photographs, seek whales, and investigate the coasts between Coats Land and Enderby Land and from Kemp Land to Kaiser Wilhelm's Land. Aviator Hjalmar Riiser-Larsen (leader), two planes, gear, and assistants sailed from Sandefjord on August 24 on *Thorshammer*. *Norvegia* (Nils Larsen) was around Bouvetøya October 14–21, when a depot was established. They then met *Thorshammer* to the west and received two aircraft (a monoplane and seaplane) on November 4, and equipment and crew on November 8 (Holtedahl 1931; Aagaard 1944 gives different details). The airman Finn Lützow-Holm was brought from Cape Town on *Thorøy*. *Norvegia* was off Bouvetøya November 11–14 (Holtedahl 1931 gives November 12), a hut was placed on Lars Island and oblique photographs were taken. The ship then went east along the edge of the pack ice, and began sailing south about December 1 when north of Enderby Land (Holtedahl 1931). South of 64° S, land was seen from the seaplane on December 7. Ice and weather affected the ship's movement, but land was again seen on December 22, at which point the plane landed near the coast and the men skied towards an ice-free area. A Norwegian flag was raised near the landing site and a claim made; significantly, this was well before Douglas Mawson's claim at Proclamation Island (Holtedahl, who provides many details, does not mention the ceremony). *Norvegia* then went northwest to *Thorshammer,* picked up coal, and returned to the southeast. They met Mawson on *Discovery* on January 14 and discussed their activities, following which *Norvegia* went east and *Discovery* west. New land was seen from 66°20′ S on January 15, and flown over later that day and the next. The ship affected by storms and ice conditions and sheltered with *Thorshammer* for some days before going west. They made soundings in the Gunnerus Bank on February 1, and found open water on February 16. Two days later, they saw land (Kapp Norvegia), which they overflew. Another flight on February 20 from within Selbukta allowed further sketching of Kronprincesse Märtha Kyst. *Norvegia* turned north on February 23 (Christensen 1935), and the aircraft were transferred to *Thorshammer* (Riiser-Larsen 1930; Holtedahl 1931; Bogen 1957: 63 places airmen on *Thorøy*). They refueled on March 2 and arrived at Cape Town on March 23 with 370 nautical miles (685 km) of coast charted between 43° and 45° E, and more than 200 nautical miles (370 km) to the west.

1930–1931

This voyage was to search for disputed islands, establish a house and depot on Peter I Øy, and circumnavigate the continent. Gunnar Isachsen was scheduled to lead it until Riiser-Larsen took over around Gunnerus Bank. *Norvegia* (Nils Larsen) left Cape Town on October 4, passed Bouvetøya October 14, coaled from *Thor 1* on October 17 at about 57°40′ S 0°28′ E (Isachsen 1932), and unsuccessfully searched for Truls Island. Although the ship's bridge was damaged when refueling from *Falk* in early November, it continued east, refueled from *Kosmos* near the Ross Sea in early December, and searched (December 13–17, though Isachsen 1932 gives slightly different dates) for islands that were of questionable existence. Pack ice prevented access to Peter I Øy on January 2, and the ship bunkered at Deception Bay on January 10–11. They sailed east, passing the South Sandwich Islands and discovering Maud Bank (January 30). On February 9, they met *Thorshavn* (with Riiser-Larsen, the Christensens, and the aircraft) near Gunnerus Bank. Isachsen transferred to *Thorshavn,* while Riiser-Larsen and the planes went onboard *Norvegia,* which then went southwest. Two flights (February 16–17) allowed the mapping of some 200 nautical miles (370 km) of Princesse Ragnhild Kyst (25–33° E), where a flag and documents were dropped. Two flights on February 21 and 23 found more coast before the planes returned to *Thorshammer* on February 24 (Holtedahl 1931 indicates February 25) and Riiser-Larsen joined *Truls*

(February 28). *Norvegia* then sought Pagoda Rocks without success. They reached Bouvetøya on March 8, and spent about a week there; a landing was made at Lars Island, and it was discovered that the hut there, as well as that on the main island, were gone. The expedition arrived at Cape Town in late March, having collected more than 2000 samples, made approximately 120 soundings and occupied more than fifty hydrographical stations.

Thorshavn (c. 11,000-ton tanker; used by Christensen and wife on four voyages) had left Cape Town on January 6 (with Riiser-Larsen and aircraft onboard) to examine fleet activities. They met *Ole Wegger* on January 18, and later joined the factory ships *Falk* and *Solglimt* for oil transfers. They sailed south on January 31 to rendezvous with *Thorshammer* on February 1. Christensen went southwest from 66°49′ S, 75°30′ E on February 4. Using both Thorshammer and *Thorshavn,* they found Fram Bank and (with hindsight) the continent was seen. Continuing west, they joined *Norvegia* on February 9, when the planes and crew were transferred. They then turned for Cape Town, arriving there on February 19.

On February 12, Christensen instructed catcher *Torlyn* (captain Klarius Mikkelsen) to go south and explore the Lars Christensen Land coast. The catcher *Seksern* had found new land that day and was in the McKenzie Sea on February 13 when *Torlyn* reached 68°52′ S, 72°30′ E and later subsequently sighted Cape Darnley (Bjerkø Head). The next day, *Torlyn* followed the barrier northwest, and ice-free areas and mountains were noted before the ship rejoined *Thorshammer*.

1932–1933

Few Norwegian ships operated in 1931–1932, although more than 230 had the previous season. Nevertheless, Christensen decided to involve some ships that year, as he wanted to improve technology and profits, and examine the prospects of electric killing. *Thorshavn* (captain Mikkelsen) left Cape Town with the Christensens aboard on January 25, 1933, to meet *Solglimt* at about 65° S, 41° E. Riiser-Larsen, Hallvard Devold, and Olaf Kjellbotten (intending an inshore sea-ice expedition using dog sleds) were also aboard. En route, Christensen asked *Solglimt* and *Thorshammer* to search the ice edge between 44° and 55° E for potential landing sites. *Thorshavn* met *Thorshammer* on February 4, and offloading took place the next day. They made towards *Vestfold* at about 64°10′ S, 41°20′ E on February 6, and then joined *Ole Wegger,* but bad weather prevented unloading. *Thorshavn* turned south and spied Enderby Land early on February 8, although ice prevented a catcher from reaching Proclamation Island. *Thorshavn* departed *Ole Wegger* for *Vestfold* on February 10, and men, dogs, and equipment were transferred to *Thorshammer* on February 13. *Thorshavn* neared Bouvetøya on February 20, visited Gough Island and Tristan da Cuhna while returning north, and arrived at Rio de Janeiro on March 7.

Thorshammer was off Princesse Ragnhild Land on February 19, when Riiser-Larsen and others landed on the ice at 68°45′ S, 33°50′ E on March 5. An SOS was sent out on March 9 following the breakup of the ice. Although most of the dogs and much of the equipment were lost, the party itself was picked up by the catcher *Globe V,* and subsequently transferred to *Ole Wegger,* on which they arrived at Sandefjord on April 24.

1933–1934

Christensen originally intended that the third *Thorshavn* (captain Mikkelsen) voyage would be his, and the ship's, last. His plan was for it to conduct a circumnavigation, take routine observations and automatic soundings, and use a seaplane (pilot Alf Gunnerstad). *Thorshavn* left Cape Town on December 20, reached *Thorshammer* on December 27, *Solglimt* (65° S, 30° E) on January 2, *Tafelberg* on January 15, and *Ole Wegger* on January 21. Going west, they found shallow water on January 9 following which the Framnæs Mountains were observed. On January 10, accompanied by the catcher *Treern,* they spied more land from both the ship and the air, but the Douglas Islands were not found. Moving east, *Thorshavn* reached 87° E on January 17; the catcher *Ørnen III,* with a plane, entered the ice and found open water at 65°22′ S the next day. Gunnerstad and Larsen flew to 66°40′ S, and then went northwest for 18 nautical miles (33 km), finding completely ice-covered "land" (then named Princesse Astrid Land). Continuing east, with *Solglimt* and five catchers, they made efforts to determine the whaling prospects from the Ross Sea to South Shetland Islands.

Thorshavn's steering gear was severely damaged on February 3, but they turned south towards barrier nevertheless. They reached the ice edge on February 10 at 71°44′ S, 134°11′ W (farther south than any previous ship had ever been in area). The plane continued south to 72°8′ S, and the barrier was seen 35 nautical miles (65 km) away and for about 120 nautical miles (220 km). They followed the ice edge, but fog prevented them from sighting Peter I Øy. Heading north, they found Sars Bank on February 24, and reached Montevideo on February 27.

1934–1935

Thorshavn (captain Mikkelsen) met *Solglimt* on February 4, 1935, to transfer oils, but both quickly moved into the ice to avoid bad weather. The unloading finished late on February 18, following which *Thorshavn* moved south and west. Shallow soundings suggested land nearby, and the coast was seen around noon on February 19. *Thorshavn* found 5 nautical miles (9 km) of snow-free coast on February 20, and Mikkelsen, his wife Caroline, and seven crew members went ashore. They raised the Norwegian flag after a speech, installed a depot, and ate a snack at the Tryne Islands, which it was later realized was not the mainland (Bogen 1957: 85). *Thorshavn* moved south, past Vestfold Hills and Larsemann Hills. The most southerly observation was of the Caroline Mikkelsen Mountains, before the ship coasted along the barrier until stopped by the pack ice. Subsequently, the Sjøvold (Munro Kerr) Mountains were observed, prior to the ship turning west near Fram Bank. *Thorshavn* left *Ole Wegger* on March 3, having coasted along some 275 nautical miles (510 km) of "new" land and arrived at Cape Town on March 13.

1936–1937

Christensen reported extensively (and repetitively) on this, his last voyage south, which was to improve mapping of newly discovered areas. *Thorshavn* left Cape Town on December 28, 1936, with the Christensens, pilot Viggo Widerøe, wireless operator Nils Romnæs, Mikkelsen, and Nilsen, and a seaplane with extra tanks, radios, and "modern" cameras capable of taking overlapping oblique photographs. They joined *Ole Wegger* on January 14 at about 62° S, 88° E. The catcher *Firern* took the plane and crew aboard and, while *Thorshavn* exchanged oils with factory ships, went south. Sounding was carried out at Gribb Bank (61°30′ to 62°10′ S, 87°30′ to 89° E) on January 20, just before *Firern* reported progress. The catcher had been forced west by the weather, and had reached Ingrid Christensen Land after three days, following which it reached King Leopold and Queen Astrid Land. Widerøe and Romnæs photographed the West Barrier (Ice Shelf).

Shortly before meeting *Firern* in an ice harbor on January 25, *Thorshavn* discovered Four Ladies Bank in Prydz Bay. Four flights were made on January 27, from West Ice Shelf to Sandefjord Bay and over Larsemann, Ranvik, and Vestfold hills. Ingrid Christensen dropped a flag on her namesake land; two flights on January 28 then covered parts of Lars Christensen Land. Christensen and the "four ladies" landed at Scullin Monolith and left a depot early on January 30. The plane headed for Framnæs Mountains (Kemp Land) on January 31, and covered 800 km. More coast was seen and photographed on February 1, when 1400 km were flown; the coverage from the West Ice Shelf to Enderby Land had been completed. The aircraft, crew, and Mikkelsen returned to *Thorshavn,* and *Firern* joined *Ole Wegger*. Cape Ann (Enderby Land) was passed on February 2 and, from a flight on February 4, new land was seen (Prince Harald Coast) with Ingrid Christensen dropping a flag at about 69°30′ S, 36° E. This area was photographed the next day, when Princess Ragnhild Coast was also overflown. Flying on February 6, from 69°15′ S, 26° E, a long, inland mountain chain was noted. *Thorshavn* started homewards on February 7, having completed approximately 1600 km of coastal photography.

The Expeditions and Their Achievements

Christensen started exploratory ventures in Antarctic waters with *Odd 1,* a short voyage that encouraged similar activities during the next 10 years, often exploratory diversions coordinated with commercial ventures involving other ships. Christensen's ships were responsible for many soundings, discovery of banks, and the attaining of extended series of meteorological and oceanographic measures. By the end of his expeditions in 1937, he could claim (Christensen 1938: 15) the sketching of some 4000 km, of which approximately half had been photographed. Through his fleet, Christensen was able to promote Norwegian interests and prominence in Antarctica, perpetuating (if not actually establishing) national values there. But quite apart from the scientific work extensively reported in various media, a more geographical (and political) statement had been made—lands had been discovered (or rediscovered) between 75° E and 18° W (Christensen 1935: 213–214). Further, Norwegian names had been sprinkled around the coast and farther inland, and definitive map sheets had been (or would be) produced. Some (for example, Aagaard 1934) claimed that Norwegians had done more than other nations "combined" to "exploit and explore" Antarctica, and Christensen stressed national rights there, as well as commercial access to whales. While his expeditions might have been a "contribution" to knowledge, he nevertheless accepted that the "special motive" was whales (Christensen 1935: 214), which were of major importance to Norwegian local and national economies.

To support whaling, it was considered necessary to have claims to the continental mainland. Christensen ensured governmental approval to claim unoccupied "new" lands for Norway, at least for some voyages, and his activities were associated with, if not stimulated by, political change (Skagestad 1975). Undoubtedly his expeditions occasionally influenced, and were influenced by, international politics relating to the Antarctic. Thus there was, for a period, some tension with Britain, which was initially opposed to Norwegian claims. However, in time, and wanting Norwegian agreement to measures for whale conservation, Britain accepted them and Norway agreed not to advance any claims east of 45° E and west of 15° W. Hence, Riiser-Larsen's attempted claim was not followed by any governmental action by Norway, and, indeed, Mikkelsen made no such mention when ashore in the Vestfold Hills, although it was perhaps considered (Norman and others 1998). The expeditions may be considered as a progressive investigation of whaling opportunities that initially were to the west (*Odd 1,* early *Norvegia* voyages), concentrating on Bouvetøya and Peter I Øy, before a more directed exploration to the east. Circumnavigations, while associated with seeking whale prospects, may also reflect a contemporary display of a national "presence" around the continent itself. Christensen's expeditions may, therefore, be seen as playing a large role in the development of an understanding of Antarctic geography and as a factor in the development of continental geopolitics. In this regard, then, it is unnecessary to consider the importance of individual voyages; rather, the synergistic consequences of all expeditions should be accepted. His efforts may also be contrasted with the relative contemporary indifference shown by Britain, and more particularly Australia, in the mid-1930s, when there was a transfer of territorial "ownership" but little interest in sending ships south to strengthen the extensive claims.

CHRISTENSEN, LARS

The major ship owner and whaling magnate Lars Christensen was born in Framnæs (Framnes), near Sandefjord, Norway, on April 6, 1884. His father Christen and mother Augusta Frederikke were part of the local (Vestfold) establishment. Doubtless influenced by his father's maritime businesses, he attended middle school and then business colleges in Germany and Norway and worked in shipping offices in Sandefjord, England, and Germany. In 1907, Christensen visited the United States and Canada to investigate whaling, and he became involved with ship-owning and whaling ventures off the Americas and Africa while, with his brothers, becoming increasingly active in his father's company. He was vice-consul (later consul) for Denmark from 1909 onwards.

Christensen married Ingrid Dahl, daughter of Thor Dahl, another entrepreneurial ship owner and merchant, in 1910. By 1921 he was chairman of what became Thor Dahls Hvalfangerselskap A/S, a business complex that incorporated his own company. Earlier interested in the potential of waters between Enderby Land and the South Shetland Islands, Christensen's association with Antarctic whaling and exploration began in 1927 when he sent *Odd 1* west of South Georgia. He made four voyages south with his wife between 1930 and 1937, visited various ships, landed on Gough Island and Tristan da Cuhna, and circumnavigated the continent. The *Thorshavn* voyage in the 1936–1937 season, with the Christensens aboard, provided oblique photographs of eastern Antarctica taken by Viggo Widerøe and Nils Romnæs, which, with observations made from Christensen's ships, enabled production of an atlas of coastal features between 20° W and 80° E. Christensen's fleet was modern and developed around pelagic operations, with factory ships and associated catchers; soundings, oceanographic information, and meteorological data were extensively obtained on exploratory voyages. He was probably the first to consider aerial spotting of whales, carrying aircraft on some voyages and using helicopters in 1952–1953.

Changes in whaling economics and regulations, and perhaps differences with other whalers, modified Christensen's later activities. Christensen established an American cargo/passenger company in 1938 and later expanded into various shipping, nylon, and oil and gas industries. He moved to the United States in 1940 and was attached to the Norwegian embassy in Washington for some six years. Although not working directly for Nortraship during the Second World War, he was chairman of its whaling committee. Following the war, he spent time in America and Norway, but also led Thor Dahl A/S to renewed prominence in whaling.

Areas of Antarctica were discovered by his crews and claims made to Peter I Øy and Bouvetøya, quite apart from Dronning Maud Land, resulted largely from his activities, variously portrayed as purely for scientific or geographic purposes, or as combining science and business. Christensen advocated Norwegian interests and "rights" in Antarctica, seeking access to the continent and its resources. He promoted such views by, for example, diverting ships to explore, encouraging media interest, funding reports of expedition results, lecturing, and producing accounts in various languages. He established the Kommandør Chr. Christensens Hvalfangstmuseum (whaling museum) in 1917, and later sponsored other museums and sculptures in Sandefjord. Christensen's work attracted numerous national and international awards. He died in New York, on December 10, 1965, at age 81.

CIRCUMPOLAR CURRENT, ANTARCTIC

Introduction

The Antarctic Circumpolar Current (ACC) flows from west to east along a roughly 25,000 km long path circling the continent of Antarctica. In terms of transport, the ACC is the largest current in the world ocean, carrying about 135 Sverdrups (Sv, 1 Sv = 10^6 m^3 s^{-1}) through the Drake Passage. The ACC connects the ocean basins, allowing a global ocean circulation pattern to exist that strongly influences water property distributions and regional and global climate.

The Drake Passage between South America and Antarctica is the only band of latitudes in which the ocean circles the Earth, unblocked by continents. This geographical "accident" has profound implications for the global ocean circulation and climate. The ACC flows through this gap and acts to isolate

Antarctica from the warm waters to the north. The present glacial climate of Antarctica was not established until the circumpolar channel was opened by the separation of South America from Antarctica 30 Ma.

The ACC affects global, as well as Antarctic, climate. Because the major ocean basins are nearly surrounded by land except at their southern boundary, the ACC is the main means of exchange of water between the oceans. The transfer of water by the ACC smooths out differences in water properties between the basins. More importantly for climate, the ACC connects the ocean basins to form a global-scale circulation pattern known as the overturning (or thermohaline) circulation. The overturning circulation is the primary way the ocean transports heat around the globe. Without the ACC, the global system of ocean currents and heat transport, and hence climate patterns, would be very different than it is today. Southern Ocean ecology and global biogeochemical cycles are also strongly influenced by the ACC and overturning circulation.

Observations of the ACC

The existence of a moderately strong current setting ships to the east at high southern latitudes was noted by early explorers. For example, James Clark Ross found his position was consistently further east than expected based on his reckoning and concluded there must be an eastward current in the region east of Îles Kerguelen. A rapid transition from warm to cold waters as ships passed from north to south was noted by many mariners, a feature that became known as the Antarctic Convergence and which is now recognised as marking one of the current cores of the ACC.

Most of our present understanding of Southern Ocean currents is based on three major circumpolar expeditions carried out in the last century: the *Discovery II* voyages in the 1930s; the monumental decade-long survey conducted by the *Eltanin* in the 1960s and early 1970s; and the circumpolar "snapshot" obtained by the World Ocean Circulation Experiment (WOCE) in the 1990s. The atlases produced by the *Eltanin* and WOCE expeditions provide useful illustrations of many of the features described in this article (see Further Reading). The comprehensive program of measurements carried out in Drake Passage in the late 1970s and early 1980s as part of the International Southern Ocean Studies (ISOS) experiment was another major milestone in ACC research. In recent decades, satellite remote sensing and computer models of ocean circulation have provided new insights into the nature, dynamics and variability of the ACC.

Structure of the ACC

Water properties at a given depth change dramatically as the Southern Ocean is crossed from north to south. Surfaces of constant temperature, salinity, density and other properties slope upward to the south. As a result, density layers found at 3000 m depth in subtropical latitudes approach the sea surface near Antarctica.

The shoaling of density surfaces to the south is associated with the strong eastward flow of the ACC. Tilted density surfaces create pressure forces which drive ocean currents and an accompanying Coriolis force to balance the pressure force. (This balance of forces, known as geostrophy, describes the dynamics of all large-scale ocean currents.) An increase in density to the south, as found in the Southern Ocean, supports an eastward flow (relative to the sea floor), as observed in the ACC. A map of the elevation of the sea surface (dynamic height) shows how the position and intensity of the current varies along its circumpolar path. Contours of dynamic height are approximate streamlines for the flow, so the current flow is rapid in regions where the contours are closely spaced and weak in regions where the contours are widely separated.

The shoaling of temperature, salinity, and density surfaces to the south occurs in a series of steps, or rapid transitions, rather than as a uniform slope across the Southern Ocean. These rapid transitions are known as fronts. Because the strength of an ocean current is proportional to the magnitude of the density gradient, each of the fronts is associated with a maximum in velocity. Most of the flow of the ACC is concentrated in the fronts, with lower speeds observed between the fronts. The zones between the fronts also tend to coincide with regions of relatively uniform water properties at each depth. The ACC fronts, unlike many fronts at lower latitudes, extend from the sea surface to the sea floor. The current jets associated with the fronts therefore also extend throughout the water column. The mean current speeds of the ACC jets are relatively modest, typically less than 0.5 m s^{-1} (about 1 knot), with much weaker flow between the jets. However, because the current is broad and deep, it carries a very large transport.

Early studies of Southern Ocean currents were based on oceanographic surveys with widely separated stations. These low-resolution transects usually revealed a single broad front or transition between warm water to the north and cold water to the south, which became known as the Antarctic Convergence, and later the Polar Front. High-resolution sampling reveals three main ACC fronts. From north to south, these fronts are the Subantarctic Front, the Polar Front and the southern ACC front. The southern limit of the ACC domain is defined by the "southern boundary of the ACC," the southernmost streamline to pass through Drake Passage, which is also often associated with a weak front and current core.

The three main fronts of the ACC are circumpolar in extent and found on any north-south transect across the Southern Ocean. Because the fronts extend to the sea floor and the stratification in the Southern Ocean is relatively weak, the position of the fronts is strongly influenced by the bathymetry. Major ocean ridges can deflect the fronts north or south by hundreds of km (e.g., in the Pacific sector).

Between the fronts lie zones with more or less uniform physical and chemical properties (at any given depth). The Subantarctic Zone is found between the Subantarctic and Subtropical Fronts, north of the ACC. The Polar Frontal Zone lies between the Subantarctic Front and the Polar Front. The Antarctic Zone is found south of the Polar Front. Within each zone, the water properties tend to be similar at each depth and follow a similar seasonal cycle. For example, the Subantarctic Zone is characterized by very deep surface mixed layers in winter and low nutrient concentrations (close to zero for silicic acid and somewhat higher concentrations of nitrate and phosphate). The Antarctic Zone is characterized by fresh surface waters, shallow summer mixed layers and high concentrations of major nutrients like nitrate and silicic acid, but low concentrations of micronutrients like iron.

The zones delimited by the fronts of the ACC also define biogeographic zones populated by distinct species assemblages. For example, waters south of the Polar Front tend to be dominated by large phytoplankton such as diatoms (who need silicic acid) and large zooplankton, while coccolithophores and small zooplankton dominate north of the Subantarctic Front. The distribution and foraging patterns of larger animals (e.g., fish, sea birds, and marine mammals) are also influenced by the frontal structure of the ACC. In some cases, the fronts themselves tend to be associated with higher primary productivity, although the strength of this association varies with time and location. The currents of the ACC can also play a direct role in ecosystem dynamics, for example by carrying krill and larvae from the Antarctic Peninsula to South Georgia.

The ACC is not the only important current system in the Southern Ocean. A westward flow is found near the shelf break and upper continental slope along much of the continental margin of Antarctica. Within the large embayments of the Weddell and Ross Seas, clockwise-rotating (cyclonic) gyres are found. Smaller gyres exist at a number of other locations between the ACC and the coast. The ACC is not isolated from these other current systems: the northern side of the gyres essentially merges with the ACC in some regions and water masses are exchanged between the ACC system and the currents to the south.

Eddies and Variability of ACC Fronts

While the three fronts of the ACC can be identified at all longitudes around Antarctica, details of the frontal structure vary around the circumpolar path. Major fronts merge in some locations, and in others the fronts split into multiple branches that remain distinct for thousands of kilometres downstream. Satellite remote sensing and high-resolution numerical models have revealed that the ACC often consists of multiple filaments, rather than the three main fronts typically found in long-term average climatologies. However, despite the complexity of the frontal structure of the ACC, the fronts are remarkably robust features of the Southern Ocean that can be identified in any cross-ACC transect with sufficient spatial resolution.

The position of the fronts varies with time, but generally over a relatively small latitude range at any given longitude (typically ± 1 degree of latitude). The variability is larger downstream of major bathymetric features and in regions where the ACC fronts interact with the strong boundary currents of the subtropical gyres to the north (e.g., south of Africa).

The variability of the ACC fronts is driven to a large degree by dynamical instabilities of the frontal jets. The instabilities cause the fronts to meander and spawn rings and eddy motions. The ACC has some of the most vigorous eddy activity observed in the ocean. Eddies are produced when dynamical processes release some of the energy stored in the sloping of density surfaces across the ACC, converting some of the energy in the mean flow into motions that vary with time, or eddies. This process is called baroclinic instability. The eddies play a fundamental role in the dynamical balance and heat budget of the Southern Ocean, as described later.

Transport

The first robust estimates of the total transport of the ACC were made in Drake Passage in the late 1970s and early 1980s. By combining repeated measurements of the density field with direct current velocity measurements, the total transport was estimated to be 134 ± 13 Sv (the error bar corresponds to one standard deviation).

More recent estimates give similar values. However, most estimates of ACC transport have included only the baroclinic contribution, or the transport carried by currents that change with depth. The baroclinic flow can be calculated from measurements of density made from a ship (and an assumption about a reference level velocity, which for the ACC is usually taken to be zero flow at the sea floor). To measure the total transport (baroclinic plus the depth-independent or barotropic part), direct current measurements are required. To measure ocean currents with the spatial resolution and duration needed to estimate the mean transport of the ACC is a huge challenge, especially outside of the relatively narrow confines of Drake Passage, and so far has not been attempted. For this reason, most of the published estimates of ACC transport refer to the baroclinic flow. As it turns out, the Drake Passage measurements, and a more limited set of observations south of Australia, suggest that the baroclinic transport relative to the sea floor is close to the total transport. Nevertheless, the magnitude of the mean barotropic transport of the ACC remains unknown.

During the World Ocean Circulation Experiment in the 1990s, the transport through Drake Passage was estimated to be 135 ± 10 Sv, close to the estimate from the late 1970s. Because the Atlantic basin is nearly closed to the north of the Southern Ocean, the net transport between Africa and Antarctica must be very close to the Drake Passage transport (to within about 1 Sv). The transport between Australia and Antarctica must be somewhat greater, to compensate for the flow from the Pacific to the Indian Oceans through the Indonesian archipelago. Repeat transects during WOCE suggest the baroclinic transport south of Australia was 147 ± 10 Sv, roughly consistent with estimates that about 10–15 Sv flows through the Indonesian passages.

(Note that while essentially all the transport through Drake Passage is associated with the ACC, this is not the case to the south of Africa and Australia. The latter continents are sufficiently far north that currents associated with the subtropical gyre systems north of the ACC may influence the net exchange of water south of the continents. Similarly, the presence of westward currents along much of the Antarctic margin will also contribute to the net interbasin exchange. For this reason, the net transport across sections between Antarctica and either Africa or Australia is not exactly equivalent to the ACC transport, although the ACC makes by far the dominant contribution.)

As previously noted, the fronts carry most of the ACC transport, in particular the Subantarctic and Polar Fronts. The relative contribution of these two fronts to the total transport varies around the circumpolar path. For example, south of Australia the Subantarctic Front carries four times more water to the east than the Polar Front, while in Drake Passage the transport carried by the two fronts is roughly equal in magnitude.

The transport of water masses by the ACC also changes with longitude. For example, the ACC carries an excess of intermediate density water into the Atlantic through Drake Passage, which is compensated by an excess of deep water leaving the basin south of Africa. These changes in water mass transports by the ACC reflect water mass transformations in the Atlantic basin, where relatively light Antarctic Intermediate Water is converted to denser North Atlantic Deep Water.

The ACC also transports vast amounts of heat, freshwater, nutrients, carbon, and other properties between the ocean basins. Differences in the net transport of heat and freshwater between Antarctica and the other southern hemisphere continents provides an estimate of the net air-sea exchange of these properties over each ocean basin.

The transport of the ACC varies over a range of time-scales. Multiyear deployments of bottom pressure recorders in Drake Passage during the late 1970s and 1990s suggest a standard deviation in net transport of about 8–10 Sv. For periods shorter than about 6 months, most of the variability is due to changes in sea level (i.e., changes in the barotropic flow). Models and sea level measurements suggest these barotropic motions are highly correlated with changes in wind stress and tend to follow bathymetric contours (more precisely, the flow is along lines of constant planetary vorticity, where planetary vorticity is given by the Coriolis parameter (equal to twice the rotation rate of the Earth multiplied by the sin of the latitude) divided by the ocean depth). For longer periods, variations in the density field (and hence the baroclinic flow) also become important.

Dynamics and Forcing

The absence of continental barriers in the latitude band of Drake Passage makes the dynamics of the ACC distinctly different in character from those of currents at other latitudes. Simple wind-driven ocean circulation theory (the Sverdrup balance), which generally does a good job of describing the circulation of the upper ocean in basins bounded by continents, cannot be applied in the usual way in a continuous ocean channel. The dynamical balance of the ACC has therefore been a topic of great interest for many years.

The Southern Ocean has long been notorious as the home of the strongest winds, and roughest seas, on the planet. The strong westerly winds have long been believed to drive the ACC. In fact, early attempts to model the ACC transport using observed winds in an idealized channel with a flat bottom obtained extremely large transports for reasonable values of the friction parameters, suggesting the winds were more than sufficient to drive a strong ACC. And despite the absence of continental barriers, the Sverdrup theory of wind-driven currents has been applied in the Southern Ocean by assuming that relatively shallow bathymetric features act as "effective continents."

However, such calculations assume no interaction between the current and the bathymetry, which we know to be a poor assumption for the deep-reaching ACC. In addition, wind is not the only factor driving the ACC. The atmosphere also drives ocean currents by exchanging heat and freshwater with the ocean, causing the density of sea water to change. Exchange of freshwater can result from precipitation, evaporation and the freezing and melting of sea ice. Because the speed of ocean currents is proportional to the horizontal gradient of density, any process that produces horizontal density gradients will drive ocean currents. In the case of the ACC, both the strong westerly winds and the air-sea exchange of buoyancy play a part in driving the current.

The momentum supplied to the Southern Ocean by the wind needs to be compensated in some way. The question of what balances the wind forcing has been a topic of debate for many decades. Recent studies have confirmed the early hypothesis by Walter Munk and E. Palmén that interaction of the ACC with sea floor topography provides a force to balance the wind. This force, known as the bottom form stress, results when the ocean currents are organized such that there is higher pressure on one side of a ridge on the sea floor than is found on the other side. In the case of the ACC, higher pressure is generally found on the west side of topographic ridges or hills, providing a force from the solid earth to the ocean that balances the wind stress at the sea surface. While these pressure differences are too small to observe directly, realistic numerical simulations clearly show this force balance in action.

Eddies produced by dynamical instabilities of the ACC fronts play a crucial role in establishing the momentum and heat balance of the Southern Ocean. The eddies transfer momentum vertically from the sea surface to the deep ocean, helping to set up the system of deep currents that interact with bathymetry to provide the bottom form stress. At the same time, the eddies carry heat polewards across the ACC, to compensate for the heat lost to the cold atmosphere near Antarctica.

The ACC and the Overturning Circulation

The eastward flow of the ACC is dynamically linked to weaker, but important, circulations in the north-south plane. The distribution of water properties on transects across the Southern Ocean clearly reveal water masses spreading across the ACC. For example, the salinity maximum of the Lower Circumpolar Deep Water and oxygen minimum of the Upper Circumpolar Deep Water can be traced as they shoal from depths of 2000–3500 m north of the ACC to approach the sea surface south of the Polar Front. The high-oxygen, low-salinity waters formed in the Southern Ocean (Antarctic Intermediate Water and Antarctic Bottom Water) can be followed as they cross the ACC and enter the basins to the north.

These distributions reflect an ocean circulation pattern known as the overturning circulation. Deep water spreads to the south across the ACC and upwells at the sea surface. Some of the upwelled deep water is driven north beneath the westerly winds, gains heat and freshwater from the atmosphere and therefore becomes less dense, and ultimately sinks to form Antarctic Intermediate Water. Deep water that upwells further south and closer to Antarctica is converted to denser Antarctic Bottom Water and returns to the north. The result of these water mass transformations is a circulation in the north-south plane that consists of two counterrotating cells.

The overturning cells in the Southern Ocean are linked to the global overturning circulation. The Southern Ocean imports deep water from the basins to the north, and exports bottom water and intermediate water. Recent studies suggest the conversion of deep water to intermediate water in the Southern Ocean is in fact a key link in the global overturning circulation. For decades it has been assumed that the sinking of dense water in the polar regions was balanced by widespread upwelling at lower latitudes. However, measurements of mixing rates and large-scale tracer budgets suggest that mixing in the interior of the ocean is an order of magnitude too weak to support the upwelling required. The conversion of deep water to intermediate water in the Southern Ocean provides an alternative means of connecting the upper and lower limbs of the global overturning circulation.

Eddies spawned by the ACC make an important contribution to the overturning circulation. The eddies transfer mass across the Drake Passage gap, where the absence of land barriers means that there can be no net east-west pressure gradient and therefore no net north-south flow. Furthermore, the same forces that drive the overturning circulation (wind and buoyancy exchange) also drive the ACC. The west-to-east flow of the ACC and the overturning circulations cannot be understood in isolation. The two are intimately linked, and eddy fluxes, topographic interactions, and wind and buoyancy forcing are all important ingredients of the dynamical coupling between them.

Role of the ACC in the Earth's Climate System and Biogeochemical Cycles

The Southern Ocean plays a number of key roles in the earth's climate system. The ACC connects the ocean basins and allows climate anomalies to propagate and influence regional climate downstream. More importantly, without the interbasin connection provided by the ACC there could be no global-scale overturning circulation. In the absence of the ACC, the transport and storage of heat by the ocean, and hence global climate patterns, would therefore be very different than they are today.

The Southern Ocean also has a large influence on global biogeochemical cycles. Upwelling of nutrient-rich deep water south of the ACC returns nutrients to the surface layer, ultimately supporting a large fraction of global primary production. Water masses at the surface of the Southern Ocean absorb gases like oxygen and carbon dioxide from the atmosphere and transfer them to the interior of the ocean when the water masses sink. As a result of the overturning circulation, more of the carbon released by human activities is accumulating in the latitude band just north of the ACC than in any other latitude band.

Summary

The ACC is the largest current in the world ocean, carrying about 135 Sv from west to east around Antarctica. The current flow is concentrated in a number of circumpolar fronts, which extend from the sea surface to the sea floor. The fronts also mark the boundaries between zones with distinct physical, chemical and ecological characteristics. Eddies produced by dynamical instabilities of the fronts play an important part in the dynamics of the ACC. The strong eastward flow of the ACC is intimately connected to an overturning circulation made up of two counter-rotating cells. The transport and storage of heat, freshwater and carbon dioxide by the ACC and the Southern Ocean overturning circulation has a significant influence on global and regional climate.

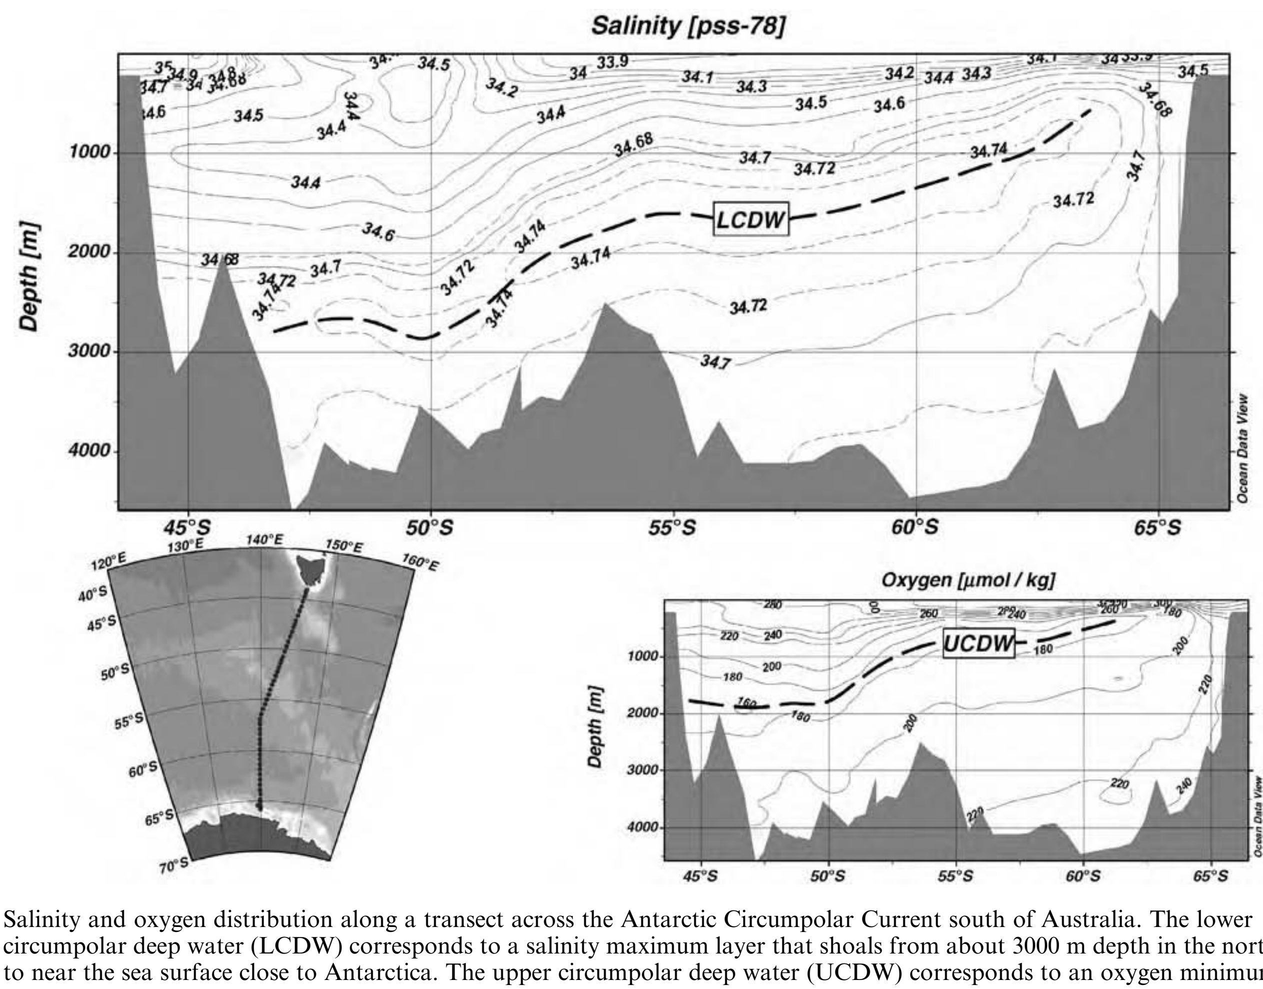
CIRCUMPOLAR DEEP WATER

Circumpolar Deep Water (CDW) occupies most of the volume of the Southern Ocean. The relatively saline CDW lies between fresher Antarctic Intermediate Water above and fresher Antarctic Bottom Water below. North of the Antarctic Circumpolar Current, the CDW is found between depths of roughly 1500 to 4000 m; south of the current, the CDW shoals to within 200 m of the sea surface beneath the fresh Antarctic Surface Water. It is common to distinguish two main types of CDW: the Lower CDW, corresponding to a salinity maximum, and the Upper CDW, corresponding to an oxygen minimum. CDW participates in an overturning circulation in the Southern Ocean which plays an influential role in the climate system.

The source of CDW is North Atlantic Deep Water exported from the Atlantic basin. North Atlantic Deep Water is formed by sinking of dense water in the Norwegian and Labrador Seas, near the northern limits of the Atlantic. The newly formed deep water is carried south in a system of deep currents along the western boundary of the Atlantic to reach the Southern Ocean. The spreading of the North Atlantic Deep Water can be traced by following a tongue of high salinity water at depths between 1500 and 3000 m. Where the North Atlantic Deep Water enters the Southern Ocean, the water mass also corresponds with a maximum in oxygen and minimum in silicate, reflecting the relatively recent formation and rapid transit of this water mass. (Most water masses are "formed" at the sea surface, where exchange with the atmosphere (e.g., of heat, freshwater and gases) produces a volume of water with certain characteristic properties. Once water sinks from the sea surface to enter the subsurface ocean, these characteristic properties can be traced over long distances, allowing circulation paths to be deduced.)

Once the North Atlantic Deep Water reaches the Southern Ocean, it turns east with the Antarctic Circumpolar Current. The salinity maximum water is known as Lower CDW once it joins the Southern



Salinity and oxygen distribution along a transect across the Antarctic Circumpolar Current south of Australia. The lower circumpolar deep water (LCDW) corresponds to a salinity maximum layer that shoals from about 3000 m depth in the north to near the sea surface close to Antarctica. The upper circumpolar deep water (UCDW) corresponds to an oxygen minimum layer that shoals from about 2000 m depth in the north to approach the sea surface on the southern side of the Antarctic Circumpolar Current.

Ocean. The salinity maximum can be followed around the entire circumpolar belt, although the high salinity is gradually eroded by mixing with surrounding fresher waters. Of the roughly $135 \times 10^6\ m^3\ s^{-1}$ of water carried through Drake Passage, approximately two thirds ($90 \times 10^6\ m^3\ s^{-1}$) is in the CDW density range.

No deep water is formed in the northern Indian and Pacific Oceans. The deep layers of these basins are supplied by water masses entering from the south, including CDW and Antarctic Bottom Water. The dense waters of southern origin enter the northern basins in a series of deep boundary currents found on the western side of the ocean basins. The northward flow near the sea floor gradually mixes with surrounding waters resulting in a decrease in salinity and density. Oxygen levels are decreased by mixing and by consumption of oxygen during the decomposition of organic matter falling from above. This altered form of CDW, which is lower in salinity, density and oxygen than its parent water mass, returns to the Southern Ocean to compensate the inflow of denser water near the sea floor. The return flow of deep water from the Indian and Pacific basins forms a distinct oxygen minimum layer in the Southern Ocean which identifies the Upper CDW.

Both the Lower and Upper CDW layers are carried east by the Antarctic Circumpolar Current. At the same time, the salinity maximum and oxygen minimum layers can be traced to the south across the Circumpolar Current. As the water masses spread to the south, they tend to rise to shallower depths, following surfaces of constant density which slope steeply across the current. The poleward movement and shoaling of the CDW is an important part of a large-scale overturning circulation in the Southern Ocean.

As the UCDW nears the sea surface, it mixes into surface waters altered by the overlying atmosphere and by precipitation, evaporation and by the melting of sea ice and glacial ice. These processes reduce the density of the surface layers, which are driven north and east beneath the westerly winds in the wind-driven Ekman layer. Ultimately the water sinks again from the sea surface and supplies the Antarctic Intermediate Water and Subantarctic Mode Water layers. The net result is that UCDW spreads poleward and upwells at high latitudes, is converted to less dense water by air-sea exchange, and is ultimately exported from the Southern Ocean as lighter mode and intermediate water. This circulation pathway is known as the upper limb of the Southern Ocean overturning circulation.

The lower limb of the Southern Ocean overturning circulation involves the Lower CDW. Part of the water that upwells is carried south beneath the easterly winds. Near the continental slope of Antarctica, the water properties are altered through mixing with colder and fresher waters to form Modified CDW, which is transformed further through complex ocean-atmosphere-ice interactions to produce dense Antarctic Bottom Water. The poleward flow of Lower CDW and compensating equatorward flow of Antarctic Bottom Water together form the lower limb of the Southern Ocean overturning circulation.

The two cells of the Southern Ocean overturning circulation strongly influence the physical, chemical, and biological distributions of the ocean. The conversion of CDW into lighter intermediate waters in the Southern Ocean is believed to be the primary way that the upper and lower branches of the global thermohaline circulation are connected. Water masses formed in the Southern Ocean as part of the overturning circulation provide oxygen to (or "ventilate") the intermediate and deep levels of the southern hemisphere oceans. The ocean uptake and storage of atmospheric carbon dioxide is regulated by the Southern Ocean overturning and the upwelling of CDW is the main source of nutrients to Southern Ocean ecosystems.

At high latitudes, the CDW often corresponds with a temperature maximum in vertical profiles, lying between the cold Antarctic Surface Water and the cold Antarctic Bottom Water. As a consequence, the CDW is sometimes referred to as Warm Deep Water, particularly in the Weddell Sea. The reservoir of heat in the CDW can have important consequences. For example, in some locations CDW can reach the continental shelf and provide sufficient heat to melt substantial amounts of ice from ice shelves and floating glacier tongues. The Weddell Polynya of the 1970s was maintained by heat supplied by the CDW, once the stratification that usually isolates the CDW from the surface layer was broken down.

CLIMATE

Introduction

Understanding the varied climates of Antarctica and the adjacent Southern Ocean has assumed great importance recently, for the following reasons:

- Southern higher latitudes are not isolated from extrapolar regions, including the Northern Hemisphere: Antarctica influences, and also responds to, climate variations elsewhere.
- The discovery of the stratospheric ozone hole, which occurs over Antarctica every austral spring, and the identification of the role of human-made chlorine compounds in ozone destruction have implications for ecosystem and human health globally.
- Polar regions likely are first indicators of contemporary climate changes potentially linked to "global warming." The Antarctic Peninsula is one of the fastest warming areas on Earth, and reduced sea ice and collapsing ice shelves have occurred in that region and elsewhere around Antarctica. Recently, the upper ocean in the Ross Sea has seen decreases in salinity.
- Cross-disciplinary studies of ecosystem variability for Antarctica and the Southern Ocean show close associations between biological activity, sea-ice conditions, and the atmospheric circulation.
- Antarctica's crucial role in past climate changes globally, as indicated in ice cores extracted from the continental ice sheet, and elsewhere, including the Northern Hemisphere.
- Antarctica's ice-free areas, notably the Dry Valleys, may be analogues for the planet Mars and are helping guide planned exploration of that planet.
- Antarctica is becoming a destination for "ecotourists" as well as scientists, and the potential environmental pressures of such activities are a growing concern. While the use of numerical models to improve weather forecasting in this region in support of human activities is critical, much understanding can be achieved with a knowledge of climatology.

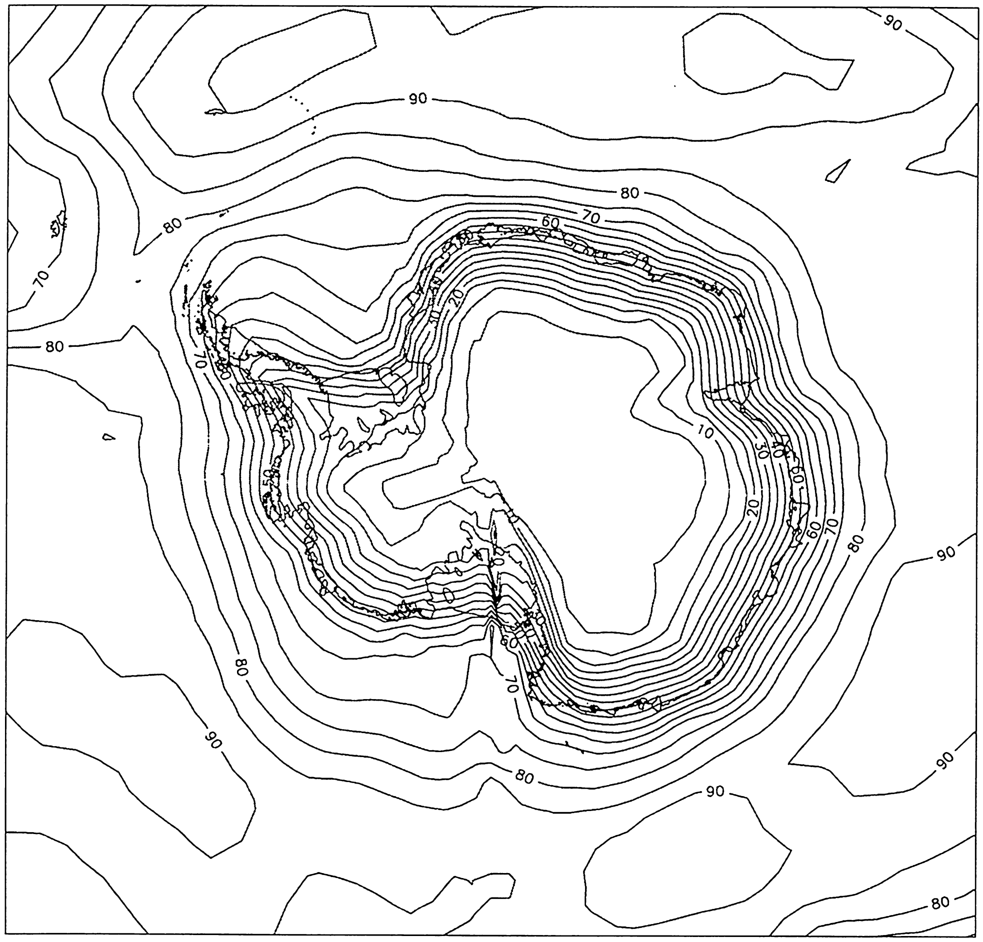
The increased need to understand Antarctic climates has been greatly assisted by advances in monitoring over the past three decades; notably the use of polar-orbiting satellites and surface-based intensive field programs such as the International Trans-Antarctic Scientific Expedition (ITASE). The latter involves drilling many shallow ice cores in transects across Antarctica to identify climate variations and changes within about the past 250 years. In addition, greater understanding has been achieved using numerical models of the atmosphere and ocean to simulate Antarctic climates and their interactions with lower latitudes.

The dominant factor in Antarctic climates is the presence of ice comprising three broad types: continental (land) ice, sea ice, and floating ice shelves. Moreover, the associated negative net radiation "balance" of southern high latitudes helps determine Antarctica's climatic relationships with extrapolar latitudes, particularly the influxes of heat and moisture due to atmospheric cyclone systems. Given the importance of the observation network to the understanding of Antarctic climates, a brief survey of the climatic database is in order.

Climatic Forcing Factors

The ice-covered South Polar region is perennially cold yet with latitudinally strong gradients of temperature and moisture (i.e., humidity, cloud cover, precipitation) located near the Antarctic coast. However, this generalization belies the regional and even local-scale climates that occur, in association with spatial variations in surface energy balance related to different ice types. These Antarctic climates result from combinations of the following physical geographic factors:

1. Elevation. The interior ice sheet of East Antarctica has altitudes of 3000–4000 m, which lowers temperatures and increases dryness (i.e., low humidity, lack of clouds) relative to locations



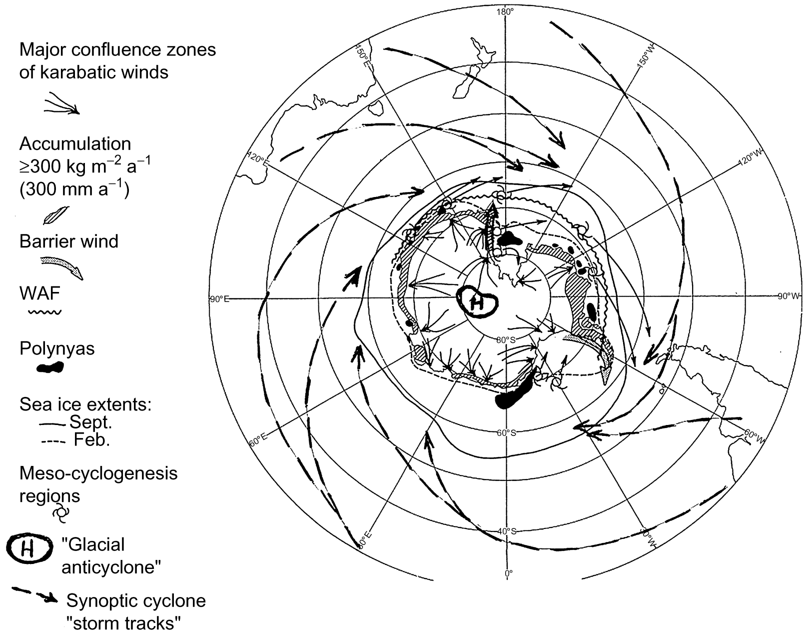
Summer mean cloud amount (%) for Antarctica and adjacent regions of the Southern Ocean, based on data from the International Satellite Cloud Climatology Project. (From Turner and Pendlebury 2004.)

closer to mean sea level (MSL), such as the lower altitudes of West Antarctica and the continent's coastal margins. Thus, the map of mean near-surface air temperature (Ta) closely resembles that of the ice-sheet topography.

2. Latitude location with respect to the prevailing patterns of atmospheric circulation. These are the westerly winds of sub-Antarctic latitudes and "polar easterlies" over the bulk of the continent and which contain, respectively, the mobile frontal cyclones entering the Seasonal Sea Ice Zone (SSIZ) from extrapolar latitudes, and the cold-cored high pressure over the continental interior.
3. The presence and extent of open water (e.g., the ice-free Southern Ocean versus polynyas—nonlinearly shaped—and leads—linearly shaped—contained within sea ice), and the presence and depth of snow on sea ice. Longitudinally, this is evident as relatively mild conditions in the western Antarctic Peninsula versus the frigid ice-covered areas of the Weddell and Ross Seas.
4. Season, particularly the change between open water and ice-cover that occurs every autumn and winter in the SSIZ, and the dominant half-yearly "cycle" of atmospheric pressure, wind speed and precipitation, or Semi-Annual Oscillation (SAO).

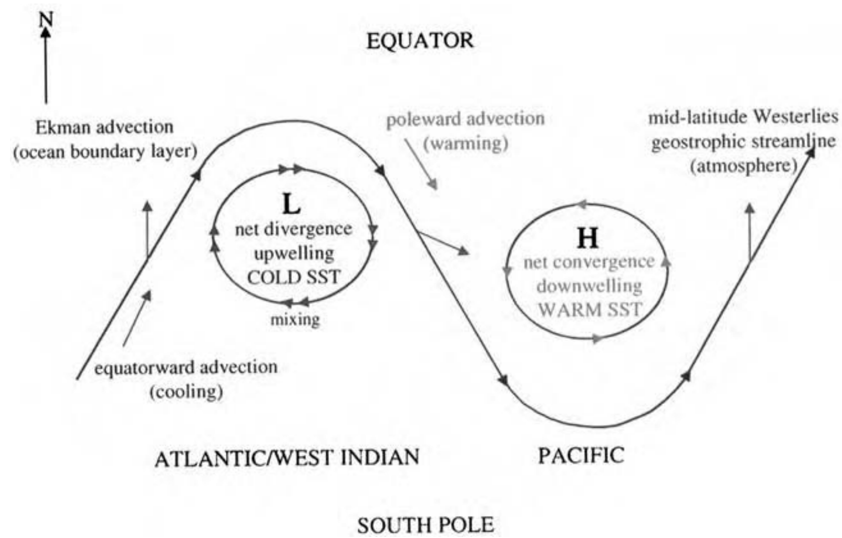
The exact roles of these physical geographic factors in Antarctica's climates, and their mutual interactions, now are discussed. Most of these factors contrast markedly with those responsible for Arctic climates.

- The South Pole is located within a continent, isolating the interior of Antarctica from heat and moisture sources located equatorwards. Thus, Antarctica is the perennial source region of the coldest and driest air on Earth, although this air modifies significantly upon leaving the continent.



Schematic representation of dominant features of the climate of Antarctica and the Southern Ocean, as compiled from various sources. (Adapted from Carleton 1992.) In addition to the sources listed in Carleton, this adaptation includes information from Carrasco et al. 2003 and Simmonds et al. 2003.

- The higher elevations of the ice sheet (“pole of inaccessibility”) are asymmetrical with respect to the South Pole location. Accordingly, the Southern Hemisphere’s cold source is displaced away from the pole towards the Indian Ocean and southwest South Pacific sectors. Similarly, the time-averaged patterns of Ta, sea surface temperature (SST), sea-ice extent near the time of maximum extent, and the troposphere’s geopotential height fields, are displaced towards those areas as a wavenumber one pattern. Modeling indicates that the off-pole location of the highest part of Antarctica explains the large interannual variability of MSL pressure (MSLP) in the Amundsen Sea area.
- Although the ice sheet topographic gradient is relatively slight over much of the interior, it increases sharply closer to the continental margin. This shape promotes radial gravity-induced drainage of cold air, or katabatic winds, that accelerate towards sea level. Conversely, over the interior, winds are relatively light.
- The occurrence of summer when Earth is closest to the Sun in late December and early January provides a short austral summer yet with some of the highest top-of-the-atmosphere (TOA) insolation values on Earth. In combination with the very high reflectivity, or albedo, of the surface, very little insolation is absorbed by the surface to either heat the air or melt snow and ice.
- The sea ice undergoes a large seasonal variation from a minimum in February/March (3×10^6 km^2 area) to a maximum in September/October (20×10^6 km^2). This change virtually doubles the size of the continent, and strongly influences the surface radiation and energy budgets, the upper-ocean temperature and salinity structure, and the receipt of moisture as snowfall at the Antarctic coastline. The regional ice conditions (e.g., the ice latitude extent, ice-water concentration) show a negative relationship to the annually averaged Ta. Similarly, multiyear trends in annual mean temperatures at coastal Antarctic stations are inversely correlated to those of sea-ice extent in broadly similar longitudes, although on a year-by-year basis the relationship is less clear.
- The circumpolar Southern Ocean mediates the interactions of heat, salt, and momentum between high and lower latitudes, including the formation and melting of sea ice. Moreover, the near-surface climates of coastal areas are modified by their proximity to the Southern Ocean relative to the continental interior. Major embayments are sites of floating ice shelves, derived from the continental ice, and are sources of large tabular icebergs that tend to move away from the continent and slowly melt, thereby affecting extrapolar latitudes. The ice shelves help buttress the continental ice sheet; they are particularly sensitive to changes in Ta and the thermal



Schematic showing the interaction between a standing wave couplet (i.e., trough, ridge) and sea surface temperature (SST) anomalies for the Southern Ocean. The waveform is a geostrophic streamline describing the surface high and low in the mean sea level pressure. Deflection of the winds to the left (secondary arrows) is the result of the Coriolis Force, which induces upwelling west (east) of the trough (ridge), but downwelling east (west) of the trough (ridge). (From Milliff et al., 1999.)

characteristics of the water circulating beneath them, influencing upper ocean physical characteristics and sea-ice conditions.

- Although both polar regions are characterized by net radiation deficits at the surface and in the atmosphere, which necessitates the advection of heat into the region from lower latitudes, Antarctica presents a strongly zonal (i.e., latitudinally symmetric) profile to ocean latitudes located to the north that is interrupted only in the Antarctic Peninsula. This geographic zonality has important additional consequences for the climates of southern high latitudes, as follows:

1. The zonal westerly winds attain high speeds at Earth's surface (e.g., "Roaring Forties," "Screaming Sixties"). Aloft, the westerlies undergo only limited annual variation in strength contrasted with their interannual variability, and also the semiannual signal (i.e., SAO). The SAO involves zonal pressure/height and associated wind changes between Antarctica and middle latitudes, peaking over the sub-Antarctic and coastal East Antarctica.
2. In the upper ocean, the zonal circulation reaches a maximum westerly speed in the Antarctic Circumpolar Current (ACC). The ACC position, which shows a close association with the highest seafloor topography, strongly influences the sea-ice spatial configuration near the time of maximum ice extent (springtime).
3. The atmospheric Rossby waves typically have lower amplitudes than their counterparts in the Arctic, and are more barotropic (i.e., the time-averaged ridges and troughs in the pressure/height and temperature fields more or less coincide). This characteristic limits the ability of "standing eddies" to transport much sensible heat into the Antarctic, in contrast with their counterparts in northern high latitudes.
4. As a consequence of the previous factor, frontal cyclones traveling within the westerlies (i.e., "transient eddies") transport most of the sensible heat to Antarctica. Moreover, the flux of moisture to the continent, and snowfall receipts in coastal and near-coastal areas, are strongly influenced by the passage of cyclones.
5. Because of the lack of heat transported by atmospheric standing eddies, the upper ocean participates in the meridional transport of heat via interactions with the frontal cyclones: southerly (northerly) winds occur on the western (eastern) sides of low pressure systems, which induce divergence (convergence) of air in the low-level wind field and upwelling of cold water (downwelling of warm water). When maintained in similar longitudes on monthly and longer time scales, these ocean-atmosphere interactions result in increased salinity west of persistent cyclone high-frequency areas, and decreased salinity east of the cyclone waves. Such an association also is evident in the suite of

anomalies characteristic of the subdecadal scale Antarctic Circumpolar Wave (ACW).
6. The dominant mode of interannual climate variability over Antarctica and the Southern Ocean, or "Antarctic Oscillation" (AAO), is strongly zonal. It involves an antiphase association of the anomalies of pressure/height, temperature, and zonal winds between middle and high latitudes, such that a positive (negative) phase is associated with enhanced (reduced) westerlies over the sub-Antarctic. Other patterns of climate interannual variability, including the Antarctic teleconnections to El Niño Southern Oscillation (ENSO), have associated atmospheric anomalies that are aligned more meridionally.

Climate Broad Types of Antarctica

Given the previous physical geographic and climate forcing factors one can identify, at a minimum, the following four broad regional surface climates in the Antarctic, with subdivisions of these types also possible:

- The SSIZ, extending equatorwards from near the Antarctic coastline to around 55°–60° S at the time of maximum extent. This is a cloudy and stormy zone dominated by the seasonal change from open water to sea-ice cover, and back again. Particularly in East Antarctica, it is possible to identify an innermost (outermost) zone of ice concentration.
- The floating ice shelves, particularly within the Ross Sea and Weddell Sea, comprise a transitional climate type between the southern SSIZ and the continental climates because of the sea water circulating beneath them.
- The western Antarctic Peninsula. Because of the Antarctic Peninsula's extension into sub-Antarctic latitudes, the westerly winds impinging upon the spine of higher topography result in a more marine climate than that to the east (Weddell Sea). However, there are large interannual variations in climate in the western Antarctic Peninsula, especially in winter, which accompany fluctuations in the intensity of the Amundsen Sea mean low pressure system (ASL) and associated sea-ice conditions.
- Continental climates are the coldest and driest, and dominate the ice-covered land surfaces. Regional-scale differences in the severity of continental climates occur due to elevation (cf. East Antarctica and West Antarctica), the exposure to synoptic cyclones that import heat and moisture (cf. the Pacific and Atlantic sides of West Antarctica), and slope/latitude (cf. coastal and interior regions of East Antarctica). Also, the interannual variability of temperature and precipitation tends to be smallest (greatest) in interior East Antarctica (the Pacific side of West Antarctica).

Climatic Consequences of the Net Radiation Deficit

The negative net radiation balance on the Antarctic ice sheet results from the high surface albedo, a loss of longwave radiation, and a highly transmissive atmosphere. For Antarctica's climates, a number of consequences arise from the net radiation deficit, notably the following:

- The Surface-Based Inversion Layer
- The Katabatic Winds
- Oceanic Processes

The katabatic winds are important for upper-ocean processes near the coast, especially in winter. These include the opening of shore leads and "latent heat" polynyas, and new sea-ice production as a result of the very low temperatures. The increased evaporation within coastal polynyas and low-ice concentration areas increases the upper-ocean salinity and, hence, the production of bottom water close to Antarctica. Changes in Antarctic deep water production may feature in long-term climate changes on global scales. For large "sensible heat" polynyas, particularly that which dominated the sea-ice regime of the Weddell Sea during the 1970s, the frequencies of cold-air mesoscale cyclones (i.e., "polar lows") increased around the polynya.

- The Kernlose (Coreless) Winter
- The Semi-Annual Oscillation (SAO)
- Cyclonic Activity and the Poleward Advection of Heat

Because the downward flux of sensible heat (Q_H) from the temperature inversion to the ice sheet is insufficient to balance the energy budget, a net inflow of energy to Antarctica occurs mostly as Q_H advected by the traveling synoptic-scale frontal cyclones. The majority of these cyclones originate in middle latitudes, with each successive stage of development (i.e., open wave → maturity → occlusion or dissipation) occurring closer to Antarctica, in the aggregate. The poleward transport of eddy sensible heat and momentum show a close association with the stages of cyclone development: the poleward heat flux decreases as cyclones evolve from the open-wave to dissipation stages; however, the momentum flux is strongly poleward in the wave stage (i.e., a positively tilted trough) but equatorwards in the dissipation stage (i.e., negatively tilted trough). Thus, the convergence of eddy momentum is strongest, on average, between about latitudes 55° to 65° S. The zone of maximum cyclonic activity is located to the north of the Antarctic Circumpolar Trough (ACT, the circumpolar belt of low pressure), which is demarcated in the MSLP data.

Mean and Variability Patterns of Climate Parameters

Air Temperature

Over the highest elevations of East Antarctica, winter surface temperatures average –60°C to –70°C, or "cold pole." Temperatures are not much warmer in summer (~ –30°C), largely because of the high surface albedo. The ability of milder air masses to penetrate into West Antarctica from the Pacific Ocean ahead of frontal systems, results from the generally low elevations of this part of the ice sheet. In most seasons, the Antarctic Peninsula exhibits an out-of-phase association of temperature anomalies with those on the Antarctic mainland and, in turn, these show relationships to atmospheric circulation. A latitudinal strong gradient of temperature exists along the western Antarctic Peninsula and also for circumpolar stations south of the ACC (60° to 70° S). For the latter zone in winter, the gradient is around 1°C/1° latitude, compared with about 0.6°C/1° latitude for 30° to 60° S, and there are associated strong gradients of SST.

Considerable interannual variability of temperature occurs in the Antarctic Peninsula, of which a substantial portion is related to ENSO. Thus, winter temperatures in the Antarctic Peninsula show associations with the intensity of the Amundsen Sea mean low (ASL) pressure system, which comprises part of the Pacific South America (PSA) atmospheric circulation pattern. When the ASL is strong (weak), typically during a La Niña (El Niño) event, the western Antarctic Peninsula experiences enhanced northerly (southerly) winds and, accordingly, higher (lower) temperatures. As a consequence of the changed temperature advection patterns in the atmosphere, along with the SST anomalies, the sea ice west of the Antarctic Peninsula retreats poleward (advances equatorwards) for a strong (weak) ASL. On the ice sheet, a portion of the interannual variability of surface temperatures is related to ENSO, although this signal varies regionally. Temperature anomalies over most of the continent tend to be negative in the year of an El Niño.

Cloud Cover

A consequence of the decrease in Ta with increasing latitude is a decrease in the atmosphere's ability to hold water vapor, evident as low values of absolute humidity and precipitable water over the ice sheet. Accordingly, cloud cover is at a minimum over the interior higher-elevation areas of East Antarctica, especially in winter: the air subsides and the clouds that do occur consist mostly of cirrus. Conversely, cloud amounts are at a maximum (80%–100%) over the ocean within the SSIZ, resulting from convergence and ascent of air in cyclone systems. Along the Antarctic coastline between these two regions there is maximum variability in cloud cover that results from the passage of synoptic systems and their associated shifts in meridional winds.

Increasingly, attention is being paid to clouds in the stratosphere (i.e., Polar Stratospheric Clouds: PSCs). In addition to their influence on the radiation budget, the frequency and spatial distribution of these clouds is important for rates of ozone destruction because they provide sites for chlorine compounds to become active.

Precipitation

Over much of the ice sheet, the very low humidity values and tendency for air to subside and diverge means that Antarctic precipitation values are low (or "polar desert"). Because direct measurements of snowfall in the Antarctic are unreliable, indirect methods (e.g., moisture budget/mass balance) mostly have been favoured. Recently, the application of mesoscale models to Antarctica yield higher resolution precipitation mean values and temporal trends. On the high plateau, mean annual precipitation is less than about 2 cm yr^{-1} water equivalent. Although the dominant precipitation type is snowfall, clear-sky precipitation ("diamond dust," wind-redistributed snow) contributes substantially to the ice sheet mass balance over interior regions. Along the Antarctic coastline, especially the western Antarctic Peninsula, snowfall amounts are higher by at least two orders of magnitude. Occasionally, mixed precipitation and rain occur in these regions. In the Pacific sector of West Antarctica, relatively few snowstorms dominate the annual snowfall regime, in association with frontal cyclones. Interseasonally, there is an SAO signal in precipitation amounts, especially for coastal Antarctica, that is associated with the latitude variations in the axis of greatest cyclonic activity. Similarly, the high interannual variability of precipitation at coastal stations results from fluctuations in cyclonic activity, at least a part of which is ENSO-related.

Surface Winds

The basic zonal conceptual model of the near-surface wind field over southern higher latitudes (i.e., westerlies, polar easterlies) is complicated by (1) the high elevations of the ice sheet, which induce persistent radial drainage of cold air (katabatic winds) over the continent; and (2) the presence of significant topography, particularly the mountains of the Antarctic Peninsula and the Transantarctic Mountains, which help produce so-called barrier winds over western sides of the major embayments (i.e., Weddell Sea, Ross Sea).

Flow over the continent. The radial airflow over the ice sheet follows the topography, as seen in the close alignment of snow sastrugi with the katabatic winds. Katabatic winds are important for redistributing snow on the ice sheet, or carrying it off continent, thereby influencing the mass balance. Satellite thermal infrared (IR) images frequently reveal dark plumes emanating from airstream confluence areas around Antarctica associated with the katabatic winds. The warmer radiant temperatures of the plumes likely result from combinations of turbulence, suspended snow, and the compressional warming of sinking air. By contrast, synoptic episodes of high winds from the east or northeast occur as intense depressions impinge upon the coast from the northwest.

Intraseasonally, periods of stronger (weaker) katabatic winds seem to be associated with a shallower (deeper) polar vortex. Accordingly, fluctuations in katabatic winds (e.g., the frequency variations of satellite-detected thermal plumes) have associated distinct large-scale patterns of pressure and height anomalies. A similarity in the temporal scales of katabatic wind fluctuations and the so-called intraseasonal, or "30° to 60-day oscillation," may indicate a physical link between southern high and lower latitudes, at least in the Indian Ocean sector.

Barrier winds. On the western sides of the Weddell and Ross seas, strong and persistent southwest to southerly winds comprise a so-called barrier wind. The barrier wind is explained from thermal wind principles: very cold and stable air over the ice shelf moves westward and is dammed up against the coastline. The very strong temperature gradient that is induced results in southerly flow along the eastern side of the barrier (i.e., the colder air is located on the right). Recent field experiments in the western Weddell Sea suggest a low-level jet structure to the barrier wind when strong surface-based temperature inversions occur.

Barrier winds can be enhanced by synoptic flow when low pressure is located to the eastward or northeastward. The barrier wind combines with the upper-ocean cyclonic gyre to advect sea ice and icebergs equatorward, particularly in the Weddell Sea. This process increases the temperature meridional gradient between the eastern and western Antarctic Peninsula, and ensures that lower temperatures occur, on average, in the southern South Atlantic compared with similar latitudes in the South Pacific.

Mean Sea Level Pressure (MSLP) and Geopotential Heights

Reducing Antarctic surface pressures to mean sea level results in a "glacial anticyclone." However, the high elevations of the ice sheet make this feature somewhat unrealistic, as they extend into the cold-cored circumpolar vortex of low pressure/height. Bordering the continent, the ACT of low pressure comprises the zone of dissipation and stagnation of frontal cyclones that have immigrated from lower latitudes. The time-averaged ACT comprises several well-defined centers of low pressure near the Ross and Weddell seas, and also off Wilkes Land in East Antarctica. It exhibits limited variations in latitude location and intensity between the extreme seasons, but maximum variability occurs in association with the SAO: closer to Antarctica in the equinoctial months, and further equatorward in the solstitial months.

Interannually, there is considerable variability of the MSLP field associated with the ACT, some of which is ENSO-related. In particular, the ASL comprises a "pole of maximum variability" in the SLP field. When the ASL is weaker, often in El Niño years, an intensified low may appear to the westward in longitudes of the Ross Sea.

The meridional strong gradients of temperature evident near the surface relax, on average, in the free atmosphere: contrasting radiation and energy budgets associated with continental ice, sea ice, and ice-free ocean, diminish with altitude. The tropospheric circulation over higher southern latitudes is dominated all year by the circumpolar westerly vortex of low-amplitude wave number one. In contrast, a three-wave pattern is prominent on synoptic time scales, and also during periods of blocking. It comprises troughs over the three major ocean basins, with cyclogenesis and satellite-viewed cloud axes located just to the eastward, and ridges located upstream over Australia, southern Africa and South America.

Winds in the Free Atmosphere

The Southern Hemisphere westerlies comprise the "flywheel" of the atmospheric general circulation, and exhibit little seasonal variation. Over the South Pacific Ocean, ENSO dominates the interannual variability of wind speed in the mid to upper troposphere, as manifest by an out-of-phase association between subtropical and middle to higher latitudes, or "split flow." Thus, in this sector at least, the subtropical jet stream, or STJ (polar front jet stream, or PFJ) tends to be stronger (weaker) during El Niño (La Niña) events. There is evidence that the opposite pattern of tropospheric westerly wind speeds occurs in the South Atlantic; that is, an enhanced STJ there when the South Pacific STJ is weaker, and vice versa.

Synoptic Climatology

The climatology (i.e., mean and variability patterns) of weather systems in the Antarctic involves three main types of system, as follows:

- Synoptic-scale frontal cyclones, originating mostly over lower latitudes;
- Mesoscale cyclones developing in cold-air outbreaks ("polar lows," cold-air mesocyclones) over higher latitudes;
- High pressure ridges interrupting the time-averaged ACT.

Synoptic Cyclone Activity

Synoptic cyclones are significant for coastal Antarctica because of the clouds, precipitation, and strong winds typically associated with these systems on their forward (i.e., eastern, southeastern) side. There, warm air overruns colder air near Earth's surface. However, the influence of these cyclones also is felt in the continental interior, especially West Antarctica, where relatively low ice-sheet elevations permit easier transit of cyclones. Satellite-based studies indicate that cyclogenesis (i.e., the formation of new cyclones) and reintensification of older systems is more common around Antarctica than previously believed. This includes synoptic-scale "bomb" events (i.e., explosively deepening cyclones) that bring extreme weather to coastal Antarctica.

Climatologies of synoptic cyclones over southern higher latitudes have been developed from tracking the associated cloud vortices evident on satellite imagery, and applying cyclone-tracking automated programs to longer-term digital series (e.g., reanalyses) of MSLP. These separate approaches broadly confirm one another in terms of extratropical cyclone frequency mean and variability patterns. Specifically, cyclones develop preferentially over middle latitudes of the ocean basins; South Atlantic, Indian Ocean, and South Pacific. As cyclones mature and intensify, they move to the southeast along well-defined climatic "storm tracks," until merging in the ACT at around 60° S. These storm tracks fluctuate interannually in association with climatic teleconnections such as ENSO, particularly in the Pacific sector of West Antarctica. Cyclonic activity tends to increase (decrease) just west of the Antarctic Peninsula during El Niño (La Niña) events, although this relationship is not unique.

Cold-Air Mesocyclones and "Polar Lows"

The scale of synoptic weather charts and lack of data at mesoscales over the Southern Ocean long precluded an accurate inventory of mesocyclones in the Antarctic and sub-Antarctic. However, polar-orbiter satellite imagery permits the detection and characterization of these systems from their associated smaller-scale cloud vortices. Because mesocyclones develop in cold-air surges, they tend to move to the east and northeast after initiation; away from the continent. Accordingly, the Drake Passage comprises a favored mesocyclone track, enhancing this area's long-held reputation for storminess. Mesocyclones occur preferentially within two main zones of the Antarctic and sub-Antarctic: the SSIZ, especially near the ice-ocean edge; and close to the continental margin, particularly the confluence areas of katabatic winds.

"Synoptic climatologies" of cold-air mesocyclones have been developed for the following areas: the Ross Sea and Ross Ice Shelf, Marie Byrd Land and Siple Coast, the Bellingshausen and Amundsen seas, and the Weddell Sea. These regional preferred locations manifest the dominant physical processes associated with mesocyclogenesis in Antarctica: respectively, baroclinity in the atmospheric boundary layer, associated with strong horizontal gradients of temperature and moisture that result from differential energy fluxes between ice and water; and "column stretching" of air as it descends the ice sheet (i.e., increasing positive vorticity). The latter process sometimes is enhanced by strong latent heating from shore polynyas. The AWS pressure data have indicated mesocyclones developing on parts of the ice sheet and ice shelves that lack a significant cloud vortex. The latter results from combinations of the very dry air, and the difficulty in separating clouds from the ice surface in remotely sensed data.

Mesocyclone climatic variability is both interseasonal, in association with the SAO, and interannual, with an ENSO signature. The SAO is evident from increased frequencies of mesocyclones over the sub-Antarctic in March and September, relative to ocean areas further north. Interannually, an association with ENSO has been identified for the Ross Sea and Bellingshausen-Amundsen sector for the consecutive winters of 1988 (following an El Niño) and 1989 (following a La Niña). Mesocyclone activity was more frequent in the Ross Sea sector in 1988, and more frequent in the Bellingshausen-Amundsen sector in 1989. These variations are consistent with the shifts in atmospheric long waves, patterns of SST anomaly, and sea-ice extent, although additional years should be studied to fully elucidate these polar low relationships.

High Pressure Ridges

The dominance of cyclonic activity in the sub-Antarctic means that high pressure ridging from higher latitudes typically is transient and relatively weak. It is most evident on synoptic (daily) time scales, when the circulation can be much more meridional than that portrayed in time-averaged maps of MSLP. However, anticyclonicity that is sustained over a number of days can occur in association with ridges extending poleward, in the following preferred longitudes: 0° to 15° E, 50° to 60° E, and 140° to 150° E, with weaker ridging at 70° to 90° W. Blocking episodes in longitudes of eastern Australia and the Tasman Sea can deliver significant precipitation to East Antarctica. They are frequent during El Niño events.

Modes of Sea Ice—Atmosphere Coupled Variability

Antarctic sea ice interacts with the overlying atmosphere to manifest circulation variability on temporal scales ranging from the daily through interannual to decadal. Geographically dependent patterns of coupled sea ice—atmospheric circulation variability result from radiative, thermodynamical (e.g., layer thickness) and dynamical (near-surface wind field) processes linking the ice and the air. In particular, ice extent in the Ross and Weddell varies out of phase.

Synoptic interactions occur on daily to weekly time scales and regional to sector spatial scales. They involve the sea-ice edge and encroaching cyclone systems. For example, examination of early satellite passive microwave temporal data showed wavelike features in the Antarctic ice edge ascribed to the effects of synoptic systems. More recent analyses using scatterometer and other data confirm the role of frontal cyclones in the patterns of ice advance and retreat and also ice concentration, including polynyas. Moreover, patterns of cyclonic activity that are sustained on climatic scales (e.g., as "storm tracks" >10 days) similarly are evident in sea-ice extent and concentration regional patterns.

On the forward (i.e., eastern) side of a low, northerly winds advect mild air and cause the ice edge to retreat southward and ice concentrations to increase due to convergence and compaction of the ice. On the back (i.e., western) side of a low, cold-air advection from the south enhances the ice advance through a combination of freeze-up and wind drift of ice towards lower latitudes.

There is no clear statistical association between the zonally averaged Antarctic sea-ice extent and storm tracks, however the changed sea-ice conditions induced by synoptic cyclones can increase cold-air mesocyclogenesis to the westward near the ice edge. Although blocking in the sub-Antarctic climatologically is weaker and of shorter duration than in the Northern Hemisphere it has associated signatures in the regional sea-ice patterns. Blocking leads to regional ice retreat towards the continent and enhanced fluxes of heat from the ocean into the atmosphere. Accordingly, such episodes may intensify storminess in the region once the blocking ridge has broken down.

Monthly to seasonal interactions appear in their coupled wave-number patterns: the locations of anomalous troughs (ridges) in the tropospheric height field tend to coincide with the longitudes of greater (reduced) ice extent. This relationship occurs because cold air advection in the troughs is associated with ice advance, and warm advection and ice retreat occurs in the ridges. Similarly, winters having greater (reduced) sea-ice extent tend to coincide with stronger (weaker) zonal westerlies in the sub-Antarctic, at least, in longitudes of the Ross Sea. This relationship likely comes about because stronger westerlies encourage divergence of the pack, which leads to ice growth through a combination of freezing and equatorward ice advection. There is evidence that an equatorward-displaced sea-ice edge strengthens the latitudinal temperature gradient, further intensifying the zonal westerly wind index.

The dominant SAO of MSLP, height and tropospheric winds is linked to the zonal patterns of ice advance and retreat occurring via the shifts in latitude location of the ACT between equinoctial and solstitial months. Because the ACT represents a tropospheric shear zone between the westerlies (polar easterlies) located to the north (south), its location with respect to the SSIZ influences the ice-edge latitude and ice-water concentration during the year, as follows. In early autumn, the ACT is located equatorwards of the sea ice: ice growth occurs as temperatures fall but is relatively gradual because of compaction due to easterly winds. Ice growth is more rapid after the ice edge moves north of the ACT in late March, and continues through winter because of subfreezing temperatures and the ice divergence induced by westerly winds. In late spring, there is a relatively rapid retreat of the ice through a combination of rising temperatures (i.e., enhances melting) and the northward movement of the ACT (i.e., ice is compacted due to convergence induced by easterly winds).

Interannual Coupled Variations between the sea ice and atmosphere mostly are linked to the dominant circulation teleconnection patterns; notably, ENSO and the Pacific-South America (PSA) pattern. Although details of these teleconnections are given elsewhere in this Encyclopedia, their general associations with Antarctic sea-ice variability are provided here.

The Trans-Polar Index, ENSO, and Antarctic Dipole:

Early studies of the variability patterns of Southern Hemisphere atmospheric circulation from Principal Components Analysis (PCA) showed an out-of-phase relationship of pressure/height between Australia/New Zealand and South America. This teleconnection pattern is described by a Trans-Polar Index (TPI), representing the difference in MSLP monthly anomalies between Hobart and Stanley. Positive (negative) values of the index correspond to an enhanced ridge (trough) in the Australian sector, and an enhanced trough (ridge) over southern South America. Comparisons of TPI with the long-term sea-ice record for Orcadas show a significant association between the two variables: years of more extensive or later clearance of the ice accompany an enhanced trough over the region and greater incidence of southerly winds, and vice versa. Often, the anomalous trough (ridge) in the Weddell Sea sector accompanies an El Niño (La Niña) event. Moreover, ENSO typically has associated sea-ice conditions that are out of phase between the Amundsen-Bellingshausen seas and Weddell Sea. These sea-ice contrasting anomalies across the Antarctic Peninsula also are evident in MSLP and temperature, and statistically are linked to larger-scale variations in SST and surface air temperature in the tropical Pacific and even globally. Accordingly, this Antarctic Dipole Index (ADP) correlates well with the Antarctic sea-ice edge in the Pacific and South Atlantic sectors.

The Antarctic Oscillation (AAO)

The dominant mode of interannual climate variability in the Southern Hemisphere extratropics, or Antarctic Oscillation (AAO)—also known as Southern Annular Mode (SAM) and Zonally Varying Mode—has an association with the zonally averaged sea-ice conditions in the Antarctic: ice is more (less) extensive for stronger (weaker) westerlies. Although this association is consistent with that found regionally and on shorter time scales, there may be a seasonal dependence.

Decade-Scale Coupled Variations—The Antarctic Circumpolar Wave (ACW)

Decadal-scale coupled atmosphere—upper ocean variations, including sea-ice conditions, mostly are connected with the Antarctic Circumpolar Wave (ACW). The ACW evidently is of extratropical origin and, in its purest form, is a wave number 2 pattern of alternating anomalies of high and low atmospheric pressure. In the upper ocean, anomalies of downwelling, reduced salinity and less extensive sea ice result from enhanced northerly winds east of the centers of negative pressure/height anomalies. East of positive SLP/height anomalies (i.e., high pressure ridges), anomalous upwelling, increased salinity and more extensive sea ice accompany the greater frequency of southerly winds. ACW coupled anomalies propagate eastwards in the ACC for a complete circuit of Antarctica in about 8 years, or 4 years per wave. They are most coherent in the Indian Ocean, South Pacific, and southwest Atlantic, where they may help reinforce—and be reinforced by—the anomalies connected with ENSO. However, the ACW expression is not stable even for the contemporary period; thus, the relationships with sea-ice regimes also are expected to vary. Interestingly, an ACW is evident in long-term ice core data from Dronning Maud Land.

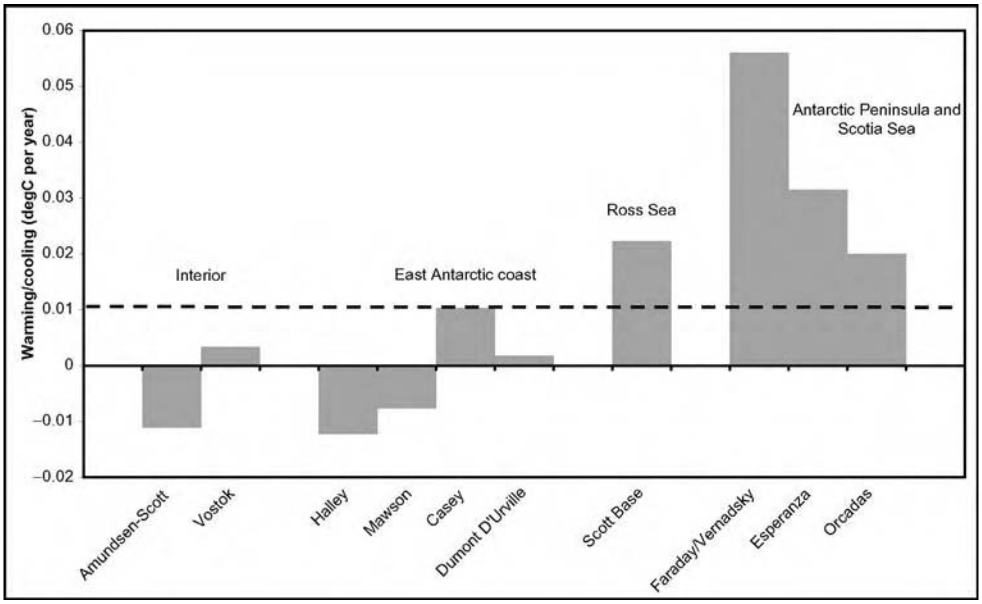
CLIMATE CHANGE

Observations of Recent Climate Change

While the observations made by early expeditions to Antarctica provided a valuable insight into the mean climate of the region, systematic study of the variability of climate at high southern latitudes had to await the establishment of permanent observatories, where long-term climate records could be gathered. The longest such record by far comes from Orcadas station in the South Orkney Islands, established by the Scottish National Antarctic Expedition in 1903 and maintained by the government of Argentina since 1904. A number of stations in the Antarctic Peninsula have unbroken climate records starting in the late 1940s or early 1950s but the majority of records from continental Antarctica start during the International Geophysical Year of 1957/1958. Most of these records are from coastal Antarctica. The only long records from the high plateau of East Antarctica are those from South Pole (Amundsen-Scott) and Vostok stations. The deployment of automatic weather stations and exploitation of remotely sensed data have provided information on year-to-year climate variations in parts of Antarctica remote from the permanent observatories. However, records from these sources are generally too short to provide much useful indication of any long-term changes that may be occurring. A recent development that has proved to be of great value for Antarctic climate studies has been the production of long series of atmospheric reanalyses by the US National Centers for Environmental Prediction and by the European Centre for Medium-range Weather Forecasts. Based around the computer models that are routinely used for numerical weather



Long-term annual mean temperature trends at selected Antarctic stations, grouped by region. All stations shown have records extending back to at least 1958. The record for Orcadas starts in 1903. The horizontal broken line shows the average warming trend for the Southern Hemisphere as a whole over the period from 1951 to 2000.

prediction, the atmospheric reanalyses make use of all available in situ and remotely sensed data to provide a detailed three-dimensional picture of the structure and circulation of the global atmosphere. The reanalyses extend back over 40 or more years but are of questionable accuracy in high southern latitudes before the early 1970s, when satellite data first became available to supplement the sparse observing network over Antarctica and the Southern Ocean.

Analysis of surface temperature records across the Antarctic reveals a complex pattern of variation and change. Around the coast of East Antarctica station records display a mixed pattern of warming and cooling trends. However, none of these trends are statistically significant given the relatively high level of interannual variability apparent in the records. On the East Antarctic Plateau, the record from the South Pole shows cooling in all seasons (statistically significant in the annual mean), while the Vostok record shows little overall change in annual mean temperature. Only in the Antarctic Peninsula is a spatially coherent temperature trend seen. Here, all long-term station records show a significant warming trend in annual average temperatures. The most rapid warming has occurred on the west coast of the peninsula. Annual mean temperatures at Faraday/Vernadsky station have risen by 2.9°C over 1950–1999. This is one of the largest temperature increases seen anywhere on Earth over this period. Warming during the winter (June–August) months (5.5°C over 1950–1999) has made the biggest contribution to the annual mean warming trend at Faraday/Vernadsky but even the smaller warming during summer (December–February, 1.2°C over 1950–1999) is significantly greater than that seen in other parts of Antarctica or across the Southern Hemisphere as a whole. Winter temperatures on the west coast of the peninsula are strongly anticorrelated with the extent of sea ice in the Bellingshausen Sea just west of the peninsula. When the ice edge here is anomalously far north, winter temperatures are below normal and vice versa. As the prevailing winds in the peninsula sector are from the northwest, the sea-ice cover in the Bellingshausen Sea determines how much heat these winds pick up from the ocean. Sea ice thus exerts a strong control on west peninsula temperatures, and the complex interactions between atmosphere, ocean and ice explain much of the climate sensitivity of this region. The Bellingshausen Sea is one of the few sectors of the Antarctic in which sea-ice cover has been observed to decline over recent years and this decline may have contributed to the rapid warming of the west peninsula region during winter.

Effects of Recent Climate Change

The rapid warming of the Antarctic Peninsula has driven significant change in the physical and living environment. In the northern and western parts of the peninsula, mean summer temperatures are close to freezing so even a small temperature increase can greatly increase the number of days on which temperatures rise above freezing and thus cause glaciers, ice caps and ice shelves to melt more rapidly. On the west coast of the peninsula, the area of the Wordie Ice Shelf has decreased from around 2000 km^2 in 1966 to around 500 km^2 in 1992. A similar pattern of ice shelf disintegration has occurred on the eastern side of the peninsula. During the austral summer of 1994–1995, the Larsen-A ice shelf and the small ice shelf in Prince Gustav Channel disintegrated rapidly. The latter event made James Ross Island a true island for the first time since its discovery in 1842, suggesting that recent climate change in the peninsula is exceptional in the context of the historical record. Further south, the Larsen-B ice shelf started retreating in 1998 and underwent a final spectacular collapse in February 2002. While the exact mechanisms responsible for these dramatic changes are still a matter of some debate, it is almost certain that the observed atmospheric warming is the underlying cause. The warming has also driven other slower changes in the glacial environment of the Antarctic Peninsula including the retreat of small ice caps on low-lying islands and a reduction in the area of perennial snowcover in the coastal regions. While less dramatic than the rapid collapse of the ice shelves, these changes have provided increased opportunity for colonisation by plants. The amount of Antarctic hair grass *(Deschampsia antarctica)* on the Argentine Islands increased twenty-five-fold between 1964 and 1990. There have also been large shifts in the marine ecosystem associated with the reduction in sea-ice cover in the Bellingshausen Sea that has accompanied the warming of the peninsula. Numbers of Adélie penguins, a species associated with the sea-ice edge, have declined significantly while populations of chinstrap and gentoo penguins, which feed in open water, have increased.

Outside the Antarctic Peninsula, Antarctic climate has been relatively stable over the period of the instrumental record and the impacts of any changes and variations have been correspondingly smaller. Summer temperatures over the major ice shelves (Ross and Filchner-Ronne) have remained well below freezing, protecting them from the changes seen in the warmer environment of the peninsula. Certain Antarctic environments appear to be particularly sensitive to climate change. For example, the thickness of perennial ice cover on lakes in the McMurdo Dry Valleys appears to have varied considerably in response to variations in regional temperature and precipitation.

Atmospheric Circulation Variability

Studies using atmospheric reanalyses have demonstrated that much Antarctic climate variability is associated with hemispheric-scale patterns (or "modes") of atmospheric circulation variability. The Pacific–South American (PSA) mode is a pattern that links atmospheric conditions over the tropical Pacific with those over the Amundsen and Bellingshausen Seas. This pattern is often particularly strong during El Niño warm events (periods of anomalously warm sea surface temperature in the tropical central Pacific). During an El Niño warm event, atmospheric pressure over the Amundsen and Bellingshausen seas is often anomalously high, leading to a reduction in the strength of the prevailing northwesterly winds along the west coast of the peninsula. El Niño warm events are thus generally associated with colder than average temperatures in this region, with anomalously extensive sea ice. The opposite phase of El Niño (sometimes referred to as La Niña, in which sea surface temperatures in the tropical central Pacific are anomalously cool) often generates an opposite response—anomalously low pressures over the Amundsen and Bellingshausen seas, leading to warmer than average temperatures on the peninsula. Atmospheric circulation changes associated with variations in the PSA pattern also cause significant changes in the rate of snowfall over parts of West Antarctica. It is thus becoming clear that some of the variability observed in Antarctic climate may be attributed to changes in the climate system remote from Antarctica.

While the PSA pattern impacts principally on the climate of the Antarctic Peninsula and West Antarctica, the Southern Hemisphere Annular Mode (SAM, sometimes also called the Antarctic Oscillation, AAO) influences climate throughout high southern latitudes. The SAM is characterised by synchronous atmospheric pressure variations of opposite signs in high- and midlatitudes of the Southern Hemisphere. These cause strengthening or weakening of the circumpolar westerly winds that blow around Antarctica. Variability associated with the SAM occurs on timescales from weeks to decades and explains much of the variation in the circulation of the Southern Hemisphere atmosphere. The high index (strong westerlies) phase of the SAM is associated with anomalously warm conditions over the Antarctic Peninsula and anomalously cool conditions over much of the rest of Antarctica. An opposite response is seen when the SAM is in its negative phase (weak westerlies). Variations in the SAM also generate variability in the Southern Ocean, since the westerly winds are the principal driving force for the Antarctic Circumpolar Current. Observations suggest that the SAM has tended towards a more positive phase since the mid-1960s, leading to a 15%–20% strengthening of the circumpolar westerly winds over this period. This trend in the SAM is consistent with the pattern of temperature change seen over this period—warming in the Antarctic Peninsula and cooling over the East Antarctic Plateau. There is still debate over what has caused the trend in the SAM. Experiments with global climate models suggest that increases in greenhouse gasses, such as carbon dioxide, as a result of human activity, will lead to a strengthening of the circumpolar westerlies. However, the phase of the SAM appears to be influenced by a number of other factors, including levels of ozone in the stratosphere. Depletion of stratospheric ozone since the early 1970s (the "Antarctic ozone hole") may also have contributed to the observed trend in the phase of the SAM.

Future Antarctic Climates

There are considerable uncertainties associated with predictions of future climates. A range of climate models may predict different responses to the same changes in forcing as a result of their representing key processes in different ways. Furthermore, there is a large range of plausible future scenarios for changes in the levels of atmospheric greenhouse gases and other forcing factors. Even at a global level, these two sets of uncertainties combine to give a wide range of plausible future climates while, on the scale of a region such as Antarctica, the uncertainties are even higher. The Intergovernmental Panel on Climate Change (IPCC) has compared predictions of future climate across a range of models and emission scenarios. This exercise suggests that global annual average temperature in 2100 is likely to be between 1.4°C and 5.8°C above its 1990 value. Most models used by the IPCC also predict that temperature changes over Antarctica will be larger than the change in the global mean. Temperature changes of this magnitude will have significant impact in regions such as the Antarctic Peninsula and parts of the sea-ice zone where mean temperatures are currently close to freezing. However, over much of the continent, where mean temperatures are well below freezing even in summer, this warming will have little impact on the cryosphere. The IPCC models also suggest that precipitation over Antarctica will increase by 5% to 20% over the period 1990–2100 as a result of a more intense hydrological cycle in a warmer climate. The increased accumulation of snow over the interior of the Antarctic ice sheets is likely to more than offset any loss of ice due to increased melting in the coastal regions, leading to a small growth in the mass of the ice sheets over this period. This growth in the Antarctic ice sheets over the coming century will act to reduce the expected rise in global sea level resulting from thermal expansion of the oceans and increased melting of ice caps and glaciers elsewhere.

Experiments with a number of climate models suggest that, in association with the predicted warming over the coming century, there will also be a significant strengthening of the circumpolar westerly winds over the Southern Ocean. An increase in the strength of the westerlies will cause important change in the Southern Ocean, including an acceleration of the Antarctic Circumpolar Current, deepening of the ocean mixed layer and changes in the way that water masses are exchanged between the Southern Ocean and the rest of the global ocean. These changes will undoubtedly have important consequences for marine ecosystems in the Southern Ocean and for the global ocean circulation, but these remain to be properly quantified.

CLIMATE CHANGE BIOLOGY

Climate change biology is the study of the effect of the rate and magnitude of global climate change on living organisms, from cells to ecosystems. Identifying biological responses to climate change involves establishing (1) the likely effects of these changes on species; (2) the capacity and mechanisms by which species respond; and (3) impacts on species interactions and ecosystem processes. Climate change biology in Antarctica is considered particularly important because of the rapid rates of climate change in polar regions, and the sensitivity of communities living at the physiological limits of life-supporting conditions.

Current and predicted climate changes are inconsistent across Antarctica, but include general warming of atmospheric and marine temperatures. Precipitation patterns are changing with an average increase in rainfall on the Antarctic Peninsula and a decline at several sub-Antarctic sites. El Niño Southern Oscillation events, which have significant impacts on the ecology of parts of Antarctica, remain highly unpredictable. Ultraviolet B radiation has increased as a consequence of the spring ozone hole. The direct impact of increased CO_2 on Antarctic ecology is considered to be comparatively limited. However, extremes, daily and annual ranges, rates of change, and the predictability of climate variables are biologically highly significant. The microclimatic conditions to which organisms are exposed, particularly in terrestrial environments, are in some cases also more extreme than coarse climatological readings show. Climate change effects will also differ between Antarctic biogeographical zones, and marine, freshwater, and terrestrial habitats.

Individual species respond differently to climate change; some may benefit while for others the consequences will be negative. All species have both optimal and threshold abiotic environmental limits, some fairly narrow and others broad, beyond which they perform poorly or are unable to survive. Antarctic marine benthic species, for example, have narrow temperature limits, and many are unable to survive temperature increases of even 1°C–2°C. Species responses to suboptimal or sublethal climatic conditions include either adaptation to changing local conditions or tracking optimal climate conditions by a shift in range distribution. Alternatively, local declines in population abundance may result in eventual extinction. Climate may alter, either directly or indirectly, the morphology, physiology, life history, phenology, behaviour, interactions, population dynamics, distribution, and geographic range size of species. At present we have only a fragmentary understanding of the direct, indirect, and interactive effects of different parameters of climate change on species, communities, and ecosystems. This is as true in Antarctica as it is elsewhere. Nonetheless, the fact that climate change is responsible for certain observed phenological, distributional and abundance changes in species is certain.

Antarctic terrestrial fauna and flora are well adapted to survive freezing and subzero temperatures. However, because they evolved under warmer temperatures and more intense ultraviolet radiation conditions, it has been predicted that they will respond positively to projected changes. In terrestrial habitats, climate amelioration (warming, longer growing seasons, and increased water availability) is considered to result in a general, additive increase in the abundance and distribution of plant and animal species, with a slow poleward shift in more temperate conditions and associated ecosystems. As a consequence, Antarctic terrestrial communities will become more productive and more complex. The extreme isolation of much of the Antarctic territory will retard this process. Nonetheless, colonization rates of exotic species in the sub-Antarctic have increased as a consequence of human activity, and milder climates will facilitate the successful establishment and spread of exotic species. Exotic species are also often very responsive to warming and may benefit more from climate amelioration than native species, with potentially significant consequences for the composition and diversity of Antarctic communities.

Retreating glaciers as a consequence of regional warming will result in the expansion of area available to permafrost-associated plant communities. However, changing freeze-thaw cycles may have negative consequences for some soil-dwelling species. Antarctic invertebrates tend to have flexible life histories, and warming will increase metabolic and development rates resulting in shorter generation times, greater abundances, and possibly species range expansion. Significant population expansion has been recorded for the two vascular plant species on continental Antarctica. However, some arthropods are sensitive to drying and a positive population response to warming may be curtailed in regions experiencing a reduction in rainfall. The availability of liquid water is generally more limiting than temperature to many Antarctic microbes, plants, and invertebrates.

Higher temperatures and ice reduction will bring about long-term changes in the physical oceanography and ecology of marine Antarctica. The distribution of sea ice, altered by both warming and cooling, plays an extremely important role in the ecology of the southern ocean. There is a close association between the marginal ice zone and phytoplankton blooms. Changes in the area and latitude of this zone, as well as in ice thickness and light penetration of the water column, alter patterns of primary productivity. Primary productivity in the southern ocean is a major driver of the distribution, reproductive success and population size of primary (such as krill and some fish species) and secondary consumers (birds, predatory fish, and marine mammals).

Ultraviolet B radiation is biologically harmful, and although species responses differ, it inhibits photosynthesis in many autotrophs (algae, cyanobacteria, lichens, bryophytes, and flowering plants). The long-term ecological impact of the increase of UV-B radiation in Antarctica remains uncertain, with only some studies showing a reduction in marine primary productivity, associated with a change in phytoplankton size and community structure. Should the net effect of high UV-B radiation in Antarctica be negative, the results will be far reaching because phytoplankton forms the basis of the marine food web. The interaction between solar radiation and ice extent may also be important, with a reduction in sea ice resulting in increased exposure of marine autotrophs to UV-B radiation. Terrestrial lichens, algae, and vascular plants are considered to be comparatively less susceptible to high UV-B radiation, although increased UV radiation has been associated with reduced growth rate and morphological changes in Antarctic flowering plants.

In summary, major uncertainties remain about the nature, speed, and distribution of climate changes across Antarctica. This makes the widespread prediction of biological responses difficult. Results from single species and single climate change parameter studies must be interpreted with caution, because of the potentially overriding synergistic effects of adaptation, trophic dynamics, and biogeochemical cycling. Nonetheless, there is hard evidence for biological responses to climate change in the region. Therefore, ongoing monitoring of key biotic and abiotic indicators is critical to the management of the consequences of climate change in Antarctica.

CLIMATE MODELLING

In many branches of physical sciences understanding the properties and behaviour of systems can be greatly helped by assembling physical models and subjecting these to a range of external forcings of interest. For example, discerning the flow of air and the dispersal of pollutants around cities has in the past been greatly assisted by making physical models of such cities and placing them in wind tunnels. Using the appropriate array of sensors one can then determine the flow patterns and trajectories associated with mean conditions over the city. In the wind tunnel one can also determine the sensitivity of the circulation to, for example, the addition of structures, changes in mean wind speed, changes in the "roughness" of the surface, and low-level vertical stability.

Powerful as this approach is, there are clearly limitations to its applicability to studying global climate and in particular the climate of the Antarctic region. Modern climatology shows that climate must be seen in a global context. The environment of no part of the world can be considered in isolation, and the many regional manifestations of climate must be considered against the background of the largest-scale processes and connections. It is obviously a very challenging problem to represent with a physical model in the laboratory a sphere to which an ocean, atmosphere, cryosphere and biosphere are held in place by gravity! To add to the complexity, the sphere itself is rotating. It is well understood how the rotation of a planet affects its climates, and any such model would have to include this effect. One can readily see that the construction of physical models of a given system is not always a sensible, easy, or even possible way to proceed.

An alternative approach is through the use of *numerical modelling*. Numerical climate models are based on the fundamental laws of physics which govern the physical and chemical properties of all the relevant media, or a simplification of these. Climate scientists use a broad hierarchy of models from the very simplest (for example a model which shows only how the global average surface temperature changes in response to changes in the output of the Sun) to the most complex "General Circulation Models" (GCMs). The simpler models have the advantage of allowing a ready comprehension of the behaviour of the climate system, but have the disadvantage that they are capable of representing the physics only in a reduced or simplified form. By contrast, though many GCMs are now run on PCs or clusters of PCs, GCMs have the drawback that they require massive computer resources (indeed stretching those to their limit), but they encapsulate our best and most comprehensive understanding of the laws of physics. The use of a range of models of different complexities is an invaluable aid in studying climate. We here address climate modelling undertaken with GCMs.

The fundamental equations upon which GCMs are built include Newton's Second Law (which describes how atmospheric wind, ocean currents and glacial ice flow respond to the variety of forces acting on them), the continuity equation (which says that mass must be conserved), and the thermodynamic equation (which tells how the temperature in the atmosphere or ocean will change). In addition, there are basic physical principles which determine the distribution of water vapour in the atmosphere and salt in the ocean and the consequences of those distributions (e.g., precipitation and ocean water mass formation). Depending on the purpose to which a model may be designed, it may also incorporate mathematical equations which represent, for instance, the creation and destruction of stratospheric ozone and the three-dimensional structure of isotopes in the ocean.

The mathematical (differential) equations previously outlined are nonlinear and very complex and cannot be solved with standard mathematical techniques. For this reason they can only effectively be solved on a computer. The first challenge that arises in obtaining such a numerical solution is that the equations are applicable in *continuous* space, whereas computers have a *finite* (albeit large) capacity. One of the consequences of this is that the equations must be solved at a grid of points (or boxes) which are separated by finite distances. Typically the "grid spacing" used in the atmospheric component of global climate models is of the order of about 150 km in the horizontal and a few hundred meters in the vertical. Because neighbouring regions in the atmosphere and ocean communicate with each other, this *discretization* of space means that the horizontal and vertical transmission of information is somewhat distorted. (This distortion is reduced as the grid spacings are decreased. As computers become more powerful they are able to handle higher resolution, and hence can represent the media under consideration with more degrees of freedom.)

From these comments it will be appreciated that the mathematical equations solved in models tell how rapidly the model variables *change* as a response to the disposition of the atmosphere or ocean at a given time. This means that the *time* dimension is as important as the *space* dimensions in understanding weather and climate. Hence, just as three-dimensional space must be approximated in the computer by spatial boxes, so too must time be broken up into small chunks (or "time steps"). The fundamental equations are used to show how, from the global distribution of the basic meteorological and oceanic variables at a given instant, these variables will change over a time step (which is usually of the order of 10 minutes). All the variables are then updated, and the procedure repeated for a second time step, and so on. Hence, running a GCM is a "time marching problem" and such a model would be run for a simulated time which is applicable to the problem being addressed. For example, if one were making predictions of El Niño a model may be run for three years, whereas if it was desired to obtain an outlook on how the deep ocean would respond to increasing concentrations of atmospheric carbon dioxide a simulation of many thousands of years would be appropriate.

Given the immense demands placed on computer capacity by climate models, it is not surprising that the evolution of the climate modelling discipline has matched that of the digital computer. The development of the atmospheric component of the discipline could be thought to start with the work of Smagorinsky (1963) and is now a mature discipline.

There are many processes in the climate system which are poorly understood or which, while of central importance, act on space scales smaller than the grid boxes discussed above. Atmospheric convection is one such process. The typical scale of individual convective cells in the atmosphere is 1–10 km, a scale much smaller than the individual boxes. The effect of convection cannot be ignored, however, because convective overturning is responsible for much of the vertical redistribution of atmospheric heat and moisture. Hence, though they act on a small scale, convective cells have a very significant impact of the large-scale atmospheric and oceanic structure. One of the major challenges in developing and using climate models is to represent the net effect of various small-scale processes. This is the "parameterization" problem whereby the statistical effect of features which cannot be modeled explicitly are represented in terms of what is known (i.e., the large scale distribution of the relevant variables).

Climate models are an invaluable tool in understanding and diagnosing climate behaviour. Before their output can be used with confidence it must be shown that they are capable of reproducing the means and variabilities which are displayed by the real climate. Accordingly, there are many programs directed at verifying the outputs of models. The process of verification is not as easy as it may at first appear. This, in part, is due to the fact that the limited number of climate records provide only an imperfect estimate of the "true" long-term climate structure. For example, a comprehensive picture of the three-dimensional structure of the atmosphere is available for only the last 50 years or so, and the spatial and temporal monitoring of the deep ocean is even less comprehensive. In addition, quality observations of many climate variables are very difficult to obtain (for example, the distribution of precipitation over the Southern Ocean), and hence it is not always clear against what "truth" the models should be appraised.

Most climate models in use are able to simulate present climate with commendable accuracy. As they provide a four-dimensional picture of climate their output may be used to explore the complex relations between climate parameters in locations where the relevant data are difficult or impossible to obtain. One of the other main uses of climate models is in exploring the sensitivity and stability of climate to a range of forcings, both internal or external. In particular, such models may be used to reconstruct climates during periods of interest in the past (for example, the Last Glacial Maximum or the warm period during the mid-Cretaceous) and are able to serve as a framework in which limited amounts of paleoclimate information (e.g., tree rings, pollen distributions, gases in ice cores, isotopes in foraminifera) can be integrated to form a complete picture of conditions at the time. Reliable models are also able to provide forecasts of how future climates may respond to changes in "greenhouse" gases such as carbon dioxide and methane. This use is particularly valuable considering that it is generally recognized that human activities are now modifying climate. Given the immense complexity of the climate system, climate models present the only physically consistent tool with which such scenarios can be assembled.

One of the huge challenges in modelling the climate system (and the Antarctic component of it) is that its numerous components have very different timescales. The time required for equilibration (i.e., the time needed to adjust to a new forcing), differs for the various components. The equilibration times for atmospheric process can be as short as 1 day or less, while those in the deep ocean, the glaciers, and ice sheets are of the order of hundreds of years and longer. Climate studies with models can take the form of "snapshots," where one may consider, say, the deep ocean as unchanging and be interested in how the atmosphere and surface ocean may respond on the short time-scale to some imposed forcing. However, it will not be able to give a perspective on long-term changes. The very slow response of ice masses and the deep ocean means that a fully coupled system takes a great deal of time to come into balance with the forcing, and it is important to have an appreciation of these timescales when one is interpreting the simulations of climate models.

While GCMs are global in compass it is important to realize that if their output in the Antarctic region is to be studied such models must incorporate the processes that are of consequence to that environment. The Antarctic region has some very special characteristics which result from the complex interaction between the atmosphere, ocean, sea ice, ice shelves, and the ice cap. One of these is associated with the height of the Antarctic ice cap which rises to in excess of 4 km. This massif has a significant effect on the atmospheric circulation and must be incorporated correctly into models. In addition, the surface over the continent has a strong temperature inversion much of the time and reaches its strongest in the interior in winter, when the surface temperature is more than 25°C lower than the atmospheric temperature a few hundred meters above the surface. These inversions coupled with the steep Antarctic orography give rise to the very strong downslope (or "katabatic") winds that are a persistent feature of much of the atmospheric climate on coastal Antarctica. Careful attention must be devoted to the representations of the interaction between the atmosphere and the sloping ice surface in models if these effects are to be simulated.

The amount and distribution of sea ice around Antarctica is a key determinant of how the ocean and atmosphere interact. This seasonality of this distribution depends critically on the horizontal transports of ice induced by the mechanical stresses exerted by the atmosphere on the top side of the ice and by the ocean on the bottom. Of similar importance in determining the configuration of ice are the heat fluxes from the atmosphere and ocean. Antarctic sea ice does not assume the form of a spatially continuous blanket of ice. It is subject to many stresses including those associated with the very intense depressions which are found off the Antarctic coast. In addition, the presence of strong and persistent winds over the Southern Ocean means that extreme wave conditions occur at high southern latitudes, and the Southern Ocean is consistently the roughest ocean on Earth. These very active wave fields, in turn, can influence ice conditions far into the pack and can even break up solid ice fields. In addition, the tidal activity in the region is responsible for further stress on the thin skin of ice.

In response to these forcings the sea ice continually fractures. When fractures (or "leads") occur, huge amounts of heat and water vapor are transported from the now exposed (relatively) warm water to the cold atmosphere above. These losses from the ocean encourages rapid refreezing and formation of sea ice. Hence part of the characteristics of the sea ice is the balance of the processes which cause fracturing and refreezing. The net result is that the mean concentration of sea ice is quite low near the ice edge (e.g., 50%), and may still exhibit significant percentages of open water of about 5% in the interior part of the pack. Because of the very large difference between the atmospheric and oceanic temperatures in the sea-ice domain, even small amounts of open water can dramatically affect the interaction between the ocean and atmosphere. State-of-the-art climate models predict the distribution of ice concentration, and can hence represent these physical associations.

Sophisticated GCMs also include predictions of sea-ice thickness. It should be pointed out that when sea ice forms, salt is leached out of the ice and in turn forms a very dense layer just below the ice. This dense layer descends the continental slope and drops into the abyssal waters. This sequence is a major component in the formation of Antarctic Bottom Water, which is a cold dense layer that is found at the bottom of much of the world's oceans, and gives the global ocean many of its special properties. The appropriate representation of these complex processes is critical if the climate of the ocean is to be represented accurately.

The cryosphere is involved in other aspects of climate in the Antarctic region, and one of these is associated with the many ice shelves distributed around the periphery of the continent. Ice shelves are made up of ice which is floating on the ocean's surface, but which is attached (or grounded) to the continent, or fed by processes which are occurring on the continent. As distinct from sea ice (which has a typical thickness in the Antarctic of 2–3 meters) the major ice shelves typically have a thickness of a few hundred meters at their front, and can reach thicknesses of up to 1 km near the coast. Their thickness is so great as to prevent, as distinct from sea ice, any interaction between the atmosphere and ocean. However, their presence significantly affects the local environment. The more comprehensive climate models include representations of these features. Considerable interest centres on their future stability. Numerical models explain how the stresses on ice streams and ice shelves lead to crevassing on the upper surface of the shelves. Any surface meltwater can lead to the downward propagation of these crevasses and a weakening of the entire shelf. The rapid disintegrations of the Larsen A ice shelf (on the eastern side of the Antarctic Peninsula) in the summer of 1995 and of the northern part of Larsen B in summer 2002 were reflections of their weakness. The contents of sea floor sediments indicate that these regions has not been ice free for at least the last few thousand years. Summer surface temperatures in the vicinity have shown a clear warming trend, and the two years referred to above had unusual temperatures of above 0°C. It is believed that the melt waters caused by these above-freezing temperatures were sufficient to trigger the disintegrations. There is also evidence of warm water intrusion at the base of the shelves at the time of the breakup. Comprehensive climate models include representations of the ice shelves and it can be seen as important that this matrix of processes be included in our best models if they are to provide guidance on future changes in this highly complex system.

Another fundamental constituent of the climate system in the Antarctic region is the Antarctic Circumpolar Current (ACC) and the small scale variability it exhibits. The ACC is unique (and of considerable relevance to the disposition of global climate) in that it connects the world's three major ocean basins and that its strong currents extend almost all the way down to the ocean floor. The types of mixing processes occurring in this environment must be properly represented for models to be able to simulate these characteristics. Of importance too is that the oceanic component of models be "eddy resolving." In the global atmosphere the most important scales (the "synoptic scale") are of the order of 1000 km and greater, while in the ocean this scale is much smaller (about 50 km). To represent fully the important transfers that these systems bring about, the model resolution in the ocean should be finer than that discussed above for the atmosphere. It is believed that these small scale eddies play a very significant role in determining the structure of the ACC and of the ocean climate in the Antarctic region.

CLIMATE OSCILLATIONS

Variability in the extratropical circulation of the Southern Hemisphere strongly affects the near surface climate of Antarctica. This is especially true for winter when horizontal and vertical temperature gradients are at their largest; under these conditions, small circulation changes can cause significant temperature changes. A good example is the interaction of the atmosphere with the sea ice edge; sea ice effectively insulates the atmosphere from the relatively warm sea, thereby enabling low air temperatures over the sea ice. If the large-scale circulation is directed off the sea ice, these low temperatures can be maintained and advection of the cold air over the open sea will enhance the formation of new sea ice. When the large-scale circulation is directed from open water towards the sea ice, the opposite will happen.

Climate oscillations (often called climate "modes") are defined and detected as dominant coherent patterns of variability in the large-scale atmospheric circulation. Only recently, several new Southern Hemisphere climate modes have been (re-) discovered or (re-) defined, some of them having a distinct influence on Antarctic near-surface climate. The three most-studied climate modes occurring at high southern latitudes are the Southern Annular Mode (SAM), the Semiannual Oscillation (SAO) and the Antarctic Circumpolar Wave (ACW). These are described in more detail below:

The Southern Annular Mode (SAM), or Antarctic Oscillation, is the Southern Hemisphere counterpart to the Northern Annular Mode (NAM, also known as the Arctic Oscillation). The SAM and NAM describe the temporal strengthening and weakening of the circumpolar westerly winds (polar vortex). Repeated model studies suggest that the SAM and NAM owe their existence to atmospheric processes (i.e., they do not result primarily from ocean-atmosphere interactions). This is confirmed by their typical tropospheric timescale of variability of about 10 days. Moreover, the NAM and SAM are *standing modes* (i.e., they do not travel like the Antarctic Circumpolar Wave) and are called annular (ringlike) or high-latitude modes because their structure extends all the way to the poles and is roughly symmetric around it. Up to now, there is no clear consensus regarding the process that govern the existence of annular modes, apart from the general idea that annular-mode like variability requires wave-induced momentum transport. Another recent observation is that the typical period of variability in the stratosphere is much longer than in the troposphere, and that stratospheric anomalies of annular mode like character propagate downward to the troposphere reaching the surface with a time lag of about 2 months.

Since the 1970s, the SAM (like the NAM) has increasingly been in its positive phase, indicating stronger than average circumpolar westerly winds. In the Northern Hemisphere, this has led to mild winters in Europe and northern Asia. The response in Antarctica has been more complex: East Antarctica has cooled, because a strong and annular vortex decreases air exchange with lower latitudes. It also weakens the katabatic circulation over the East Antarctic ice sheet, which results in decreased downward mixing of warm air and further cooling at the surface. On the other hand, the Antarctic Peninsula and the Weddell Sea experience significant warming when the SAM is in its positive phase. This appears to be a combined result of decreased sea ice cover in the Bellingshausen Sea and weaker cold air advection from the Filchner-Ronne Ice Shelf. This persistent positive phase of the SAM has been tentatively ascribed to springtime ozone loss in the lower stratosphere (the ozone hole); as ozone is depleted, there is less absorption of solar radiation and the lower stratosphere cools which results in anomalously strong westerly winds. However, the greatest change in the SAM has taken place in summer, while the ozone hole is most pronounced in the Antarctic spring. Model studies have also suggested that increased greenhouse gas concentrations would lead to a strengthening of the SAM.

The Semiannual Oscillation (SAO) is the twice-yearly contraction and expansion of the circumpolar pressure trough (CPT). The CPT is a belt of low surface pressure surrounding Antarctica that is dominantly present in climatologies of Southern Hemisphere surface pressure. It owes its existence to midlatitude cyclones that usually end their southeastward journey close to the Antarctic coast in the so-called depression graveyards. These cyclones are best developed in the equinoctial months March and September, when the north-south tropospheric temperature gradients between 50° and 60° S are largest in response to the maximum latitudinal gradient in insolation. This results in a CPT that is deeper and located farther southward in the equinoctial months, while it is less deep and located farther to the north in the months of the summer and winter solstices (January and June). The twice-yearly migration of the CPT between these extreme states constitutes the SAO.

The SAO is driven by solar radiation and therefore has a very stable phase. It strongly influences the climate of coastal Antarctica; at latitudes around 65° S, the half-yearly wave dominates the annual cycle of surface pressure, cloudiness, precipitation and near-surface wind speed, with peaks in March and September. The effect of the SAO on Antarctic temperature is generally more hidden, because summer-winter differences dominate the seasonal cycle of temperature. In conjunction with pressure rises over the three midlatitude continents, the expansion of the CPT in June amplifies the wave-3 pattern in the circulation around Antarctica, increasing air exchange with lower latitudes. In those parts of Antarctica that are situated in the poleward branch of circulation anomalies, this causes a significant reduction or even reversal of the seasonal cooling, with midwinter months June and July often being warmer than those of late spring and early autumn. Admiral Byrd of the US Navy first noted this phenomenon in 1934, when he stayed in a winter base in the interior of the Ross Ice Shelf (described in his epic novel *Alone*).

In contrast to its constant phase, the amplitude of the SAO shows large interannual and decadal variability. A weakening of the SAO since the mid-1970s has led to midwinter cooling in those parts of Antarctica that are most affected by the expansion phase of the SAO. It has been suggested that the SAO has varied in recent decades in opposite phase with the SAM, but evidence remains inconclusive. A significant effect of the SAO does not show up in the climatologies of the Northern Hemisphere; here, the thermal response of the continents to the summer-winter insolation cycle dominate the annual cycle of surface pressure.

The Antarctic Circumpolar Wave (ACW), discovered in 1996, is a climate signal in the ocean–atmosphere system in the Southern Ocean. Unlike the SAM, the ACW represents more of an oceanic feature that strongly influences the atmosphere. It is characterized by a persistent phase relationship between warm (cool) sea surface temperature, negative/positive sea ice anomalies and poleward (equatorward) surface wind anomalies. The ACW has a wave number of two (i.e., there are two large regions of relatively warm water, each 3000 to 6000 km across, separated by two equally large patches of cold water). This pattern propagates eastward at an average speed of 6–8 cm per second, taking approximately 8 years to circle the globe. From a fixed standpoint the ACW-related anomalies thus recur every 4 years.

The amplitude of the ACW is highest between 50° and 60° S, and as such its impact on Antarctic climate is limited to the coastal regions. The strength and pattern of the ACW varies with time (e.g., it was weak during the mid-1990s). Conflicting views exist on how these waves are triggered and maintained. One theory is that the ACW is remotely teleconnected to tropical ENSO events (El Niño Southern Oscillation), while another theory states that the ACW is a self-sustained eastward propagating wave generated locally by an ocean-atmosphere coupling mechanism. Finally, it could be a combination of these two mechanisms. As a persistent mode of variability, the ACW is somewhat out of favour these days; although it was clearly present from about 1985 to 1995, it has not been detected in data before or since, so it could well have been a one-off event when other cycles or forcings came into phase.

Assigning a hierarchy of importance for Antarctic climate to the oscillations described above is not possible without taking into account the time and spatial scale of the selected data. If we regard the period with good data coverage (mid-1950s to present) and the area between 20° S and 90° S, the SAM is the most energetic climate oscillation, followed by the ACW. If only the Southern Ocean is considered (20° S to 60° S), the ACW dominates. Spectra of the amplitude time series for the area between 20° S and 90° S show that for oscillations with a period smaller than 1.5 years the AAO explains five times more variance than the ACW, while the opposite is true for periods longer than about 3 years. For periods in between, both modes explain about an equal amount of variance. The observational time series in the high southern latitudes are often too short (<50 years) to make any firm statements about decadal climate variability.

Detecting and analyzing modes of variability in Antarctic climate requires a multitude of statistical techniques applied to time series of three-dimensional fields of atmospheric variables. The only way to obtain these data is through so-called reanalysis projects, in which state-of-the-art numerical weather prediction models are combined with an as complete as possible compilation of observational data. The most widely used reanalyses data sets have been computed by the National Center for Environmental Prediction and National Center for Atmospheric Research (NCEP/NCAR), both in the USA, and the European Centre for Medium Range Weather Forecasts (ECMWF). All reanalyses data sets have known problems and inaccuracies, but these generally do not prohibit the detection and quantitative analysis of the large-scale coherent structures described here.

The pronounced warming in the Antarctic Peninsula region of about 1°C per decade during the last 30 years has led to catastrophic disintegration of several of the northerly ice shelves. Sediment cores from the ocean floor show that these ice shelves had been stable for at least several thousands of years, and their breakup has been interpreted as the first clear sign of anthropogenic climate change in Antarctica. Unfortunately, the simultaneous reports about East Antarctic cooling and Antarctic Peninsula warming in high-impact journals have led to much confusion in the media and the public's perception of climate change in Antarctica. With our knowledge of Antarctic climate quickly increasing, climate scientists are now faced with the challenge to distinguish between natural and human-induced climate variability in Antarctica and to report this to the public in a consistent manner.

CLOTHING

Effective clothing is critical for human survival in Antarctica. Antarctic garments at the start of the twentieth century were made from natural fibres such as cotton, wool, and leather. Burberry gabardine was found to be a useful material for making windproof oversuits that were also lightweight and waterproof and provided mobility in the cold. Gabardine was the preferred choice for most expeditions at the time including the Australasian Antarctic Expedition of 1911–1914 led by Sir Douglas Mawson. This expedition established a base at Cape Denison in Commonwealth Bay, one of the windiest places on Earth where gales can reach 200 mph (322 kph). To work outside, the men had Burberry gabardine helmets and blouses that could be worn as one piece to try to prevent blowing snow from getting underneath. Wolfskin mitts were worn as gauntlets over their Burberry jacket sleeves, and crampons—metal "claws"—were fitted onto the bottom of their finnesko (reindeer skin) boots.

Although designed to insulate, provide mobility, and be windproof, these materials did not allow perspiration to escape from the body or enable the wearer to remove or add insulating layers easily. Gloves and mittens were so cumbersome that it was difficult to make adjustments to clothing and equipment without exposing skin to the elements. These factors contributed to the death of Captain Robert Falcon Scott's party on their return from the attainment of the South Pole in 1912. Unable to adjust their insulating layers under their gabardine suits, their clothing became wet with sweat during the day from the exertion of hauling sledges across the ice. As the moisture froze, the garments ceased to provide insulation. The success of Captain Roald Amundsen, who reached the pole first on 15 December 1911 and returned safely, has been attributed to his expedition's better organisation and preparation. Unlike the British party, the Norwegians wore wolfskin suits, adapted from Inuit clothing, under their gabardine outer layers. Amundsen had also learned from the Inuit that wearing clothing loosely could reduce sweating.

For polar clothing to work effectively it must:

- Keep the body warm, particularly the extremities such as the head, hands, and feet
- Allow the wearer to move freely
- Allow perspiration to disperse away from the body, and
- Be easy to add or remove in response to the environment and the activity of the wearer.

The layer method of dressing is the most effective over a wide range of conditions; the sub-Antarctic is cool and wet whilst the Antarctic continent is dry and very cold. In most circumstances, several layers of lightweight clothes are better than one or two layers of thick, heavy clothes. The layers provide greater flexibility and ventilation while the trapped air acts simultaneously as good insulation against the cold.

The real change in Antarctic clothing occurred in the 1970s, with the appearance of new synthetic materials with water-resistant characteristics such as polypropylene and polytetrafluoroethylene (PTFE). PTFE is a membrane that is both waterproof and breathable due to tiny pores in its structure. The pores are small enough to block water droplets but large enough to allow water vapour molecules from body moisture to escape. Modern polar clothing is now chosen from a wide range of artificial and natural fabrics.

Three main layers are used in polar dressing:

The foundation layer is the layer next to the skin and often referred to as "thermal underwear." Modern garments are generally made from synthetic fibres such as polypropylene. Soft, lightweight, and comfortable, it wicks perspiration away from the skin, retains insulating properties when wet, and dries quickly. Fine wool garments are now being used more as they do not smell as polypropylene does after a few days in the field.

The insulating layer is provided by garments worn over the base layer and can be adjusted to match environmental conditions. Draw cords, collars, and zippers enable the wearer to adjust ventilation according to their activity level. Traditionally, wool and cotton were used but these are now supplemented or substituted with modern materials such as polypropylene "fleece." Although wool is a breathable insulator, polypropylene fibres can be used to weave fabrics that are lighter and more compressible.

The outer layer is most important because it protects the body from the elements. The greater the wind speed, the faster the body loses heat, so the outer layer must at least be windproof while still letting perspiration escape. On the Antarctic continent, where conditions are very cold and dry, these garments do not have to be additionally waterproof. Tightly woven cotton such as ventile, which was developed during the Second World War, is still used because it remains supple at low temperatures and is durable. Natural down, the insulating underfeathers of waterbirds, is also highly effective in dry areas when built into jackets ("parkas"). The feathers trap air, providing a warm, insulating layer without adding too much weight.

On the northern Antarctic Peninsula and sub-Antarctic islands, where weather conditions can be wet, cotton and down would lose their insulating properties. They are substituted for with waterproof and windproof outer garments made from PTFE.

The body naturally constricts blood flow to fingers and toes in response to cold, so these parts are most susceptible to cold-related injuries such as frostnip and frostbite.

Footwear epitomises the variety of Antarctic activities and conditions. Plastic, double-insulated mountaineering boots are used for skiing and mountaineering. Knee-length "mukluks" provide very high thermal insulation in a layered range of materials that are efficient only when used on cold dry snow and that require drying out overnight, often in the apex of a tent. Thigh-length waders have been used on ships and on some Antarctic Peninsula ice shelves in deep, wet, soft snow in the austral summer. Gumboots and Sorrels are also worn in warmer and snow-free conditions.

Socks made with wool or with a high wool content are still used and woven using a loop stitch, which is warm, is effective at moving moisture away from the skin, and provides cushioning.

Gloves also vary with environmental conditions and work undertaken. Leather work gloves may be used on research stations. In the field, thin woollen or polypropylene gloves under windproof polypropylene/PTFE overmittens enable the wearer to retain dexterity without exposing skin to the cold. Fleece-lined gloves can be waterproofed with the plastic polyvinyl chloride (PVC), for working with wildlife or fresh/sea water. Freezer gloves with or without polypro gloves are also sometimes used (e.g., for driving zodiacs).

Headwear can be made of natural or synthetic materials and generally consists of a hat, balaclava or face mask, and a neck tube. In extremely cold environments, hats made with natural fur are effective, though fur lining is not very effective in wet conditions. Glacier goggles or sunglasses are used to protect eyes from blowing snow and glare (albedo), which without protection can lead to snow blindness.

Modern Antarctic research stations and ships are well insulated with 24-hour power enabling personnel to work or relax indoors in casual clothing such as jeans and sweatshirts. In laboratories, kitchens and plant rooms, appropriate safety clothing is worn. External doors usually open into a heated room where boots and outer layer clothing or insulated overalls are kept for outside work.

Antarctic programmes often discuss clothing development issues with vendors, but most items are mass-produced and publicly available. Experienced staff test new products in Antarctica and personnel on research stations provide feedback on their clothing and equipment.

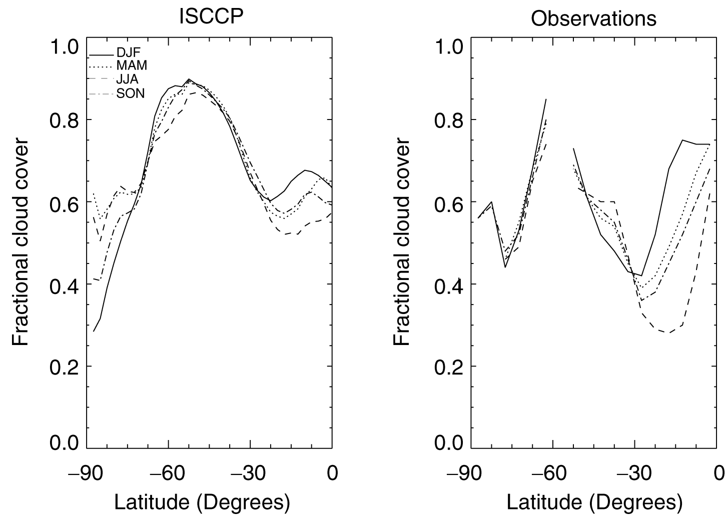
CLOUDS

Cloud Cover

The cloud cover over the oceans that surround the Antarctic continent between 45° and 60° S is generally high, the average being close to 90% in all seasons. Towards the interior of the continent the cloud cover drops to nearer 50%. The latitudinal variations in cloud cover are similar between the two plots, with a maximum in the amount of cloud close to the coast of the Antarctic continent at around 55°–60° S. However the coastal maximum extends further north in the satellite observations to around 45° S. Over the oceans that surround Antarctica there are very few synoptic observations and in this area the satellite observations are likely to be more accurate. In the coastal area, stratocumulus is the predominant cloud type while further inland more high cloud is found.

Ground-based observations of cloud amount and height are particularly difficult to make in the Antarctic environment. Flat featureless expanses of ice make the estimation of height difficult at many surface stations, and during the polar night human observers at all stations find cloud observations difficult. There are also problems with satellite observations of clouds over a snow and ice surface. During the polar day the satellite instruments must distinguish between clouds and a snow surface of similar temperature and albedo,



Zonally averaged total cloud amount from ISCCP satellite retrievals and surface observations for the four seasons.

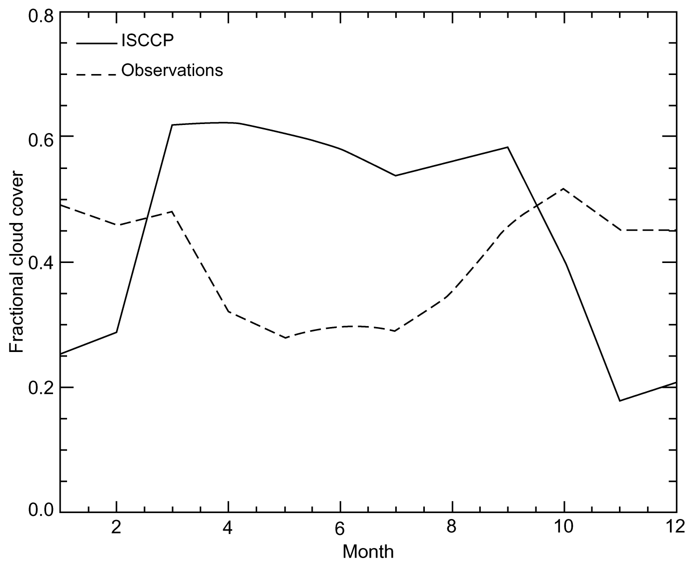
while during the polar night the persistent near-surface temperature inversion raises the temperature of some of the clouds above the surface temperature, making them easier to detect. The surface visual observations of the clouds are likely to be better during the day when the clouds are better illuminated. This means that the average total cloud amount over the polar plateau is around 50%–60%, and probably does not vary much between summer and winter. This also illustrates the problems with observing clouds over the Antarctic.

Microphysical Properties

A few *in situ* measurements have been made in Antarctic clouds and these together with ground-based instrumentation give some information on microphysical properties of Antarctic clouds. These observations have been taken for relatively short periods (one year or less) at a relatively small number of stations, and some care must be taken in extrapolating theses results to the whole of the Antarctic.

Measurements taken at Palmer Station on the western coast of the Antarctic Peninsula indicate that the aerosol concentrations in the coastal regions are lower than in any other maritime region. The long distance between Antarctica and the closest continent mean that the transport of anthropogenic aerosols is minimised. However, measurements on or close to the ground at high altitude coastal sites near the Antarctic Peninsula of ice nuclei revealed concentrations that were orders of magnitude greater than would be expected at midlatitudes. Ice nuclei numbers as high as 2000 L^{-1} were measured with an ice nuclei counter on the Bryan coast at the base of the peninsula. At the same time large numbers of ice crystals (up to 100 L^{-1}) were recorded. Also high numbers of ice crystals have been recorded on the Avery Plateau high on the spine of the Antarctic Peninsula. These measurements of ice nuclei and ice crystals were measured very close to the ground and may not be representative of higher in the atmosphere. Clouds measured from Palmer station had an optical depth of around 7 with a liquid water content of 0.06–0.18 gm^{-3}. The distribution of droplet effective radius measured at Palmer station had a peak at around 5–10 μm.

Measurements at the South Pole using an infrared Fourier transform interferometer revealed clouds that were optically thinner than those found near the coast with optical depths of less than 1. Although the clouds on the polar plateau were optically thin they were often up to 3 km in depth. A bimodal distribution on cloud height is found with peaks in cloud base height close to the ground and at around 2.5 km. The droplet effective radius had a median value of 15.2 μm, but tended to be smaller during the winter. The same pattern was observed in falling snow crystals, with smaller crystals being observed during the winter. During the winter all clouds at the South Pole are likely to be made up solely of ice crystals, although the total ice content is small (a maximum of 0.006 gm^{-3}) compared to midlatitude clouds and to the amount of liquid water found in Antarctic coastal clouds. However, direct sampling of summer cloud particles at the South Pole has found several examples of clouds consisting almost entirely of water droplets at a temperature of –25°C to –35°C.



Monthly total cloud amount at the South Pole from ISCCP satellite retrievals and surface observations.

Clouds and Climate

Clouds play a major role in forcing the climate system as they have a major effect on the radiation balance of the atmosphere. In Antarctica the phase (whether it is composed of ice particles, water droplets, or both) can make a large change to the radiation balance. Modelling studies have shown that changing the phase of Antarctic clouds can have a global effect. However, the present knowledge of microphysical properties of Antarctic clouds makes the parameterisation of these clouds in models difficult. For example, clouds made up exclusively of water droplets have been reported at the South Pole while at the coast, at higher temperatures, clouds consisting totally of ice particles are found (see previous discussion). More work needs to be carried out on the climatology of the microphysical properties of Antarctic clouds, but fortunately the latest generation of space-borne active instruments, such as lidars, hold the promise of producing such climatologies.

Clouds in the Upper Atmosphere

The clouds discussed so far are those occurring in the troposphere; however there are clouds that occur above the tropopause in the stratosphere and mesosphere. In the stratosphere polar stratospheric clouds (PSCs) can form when the temperature falls below 195 K, which can happen during the Antarctic winter. Two types of PSCs can form; type 1 are believed to be formed out of a mixture of nitric acid and water, while type 2 PSCs are less common and are formed of water ice crystals at a lower temperature (188 K). PSCs play a major role in the formation of the Antarctic ozone hole. PSCs are often called mother-of-pearl or nacreous clouds and can be observed from many sites in Antarctica during winter and spring. PSCs may appear similar to cirrus during the day but at sunset all the colours of the rainbow appear.

Polar mesospheric clouds, or noctilucent clouds, form higher in the atmosphere, in the mesosphere at around 85 km. These clouds are sometimes observed illuminated just after sunset.

COAL, OIL, AND GAS

Terra Australis Incognita was a canvas for human wishes, but the fantasies of lush forests, exotic tribes, and fantastic beasts fell to real exploration. Only the supposed mineral wealth of the continent remained, fuelled by a desire to see Eldorado in every unexplored space. Most contemporary comment on the energy mineral potential of the continent has changed little from those old cartographers, with no real basis in scientific reality. The potential for energy minerals (coal, oil, and gas) in Antarctica is extremely low.

Coal, oil, and gas are found on every continent, so it is reasonable to expect that they could be found in Antarctica. However, two areas are debated: the extent of any such deposits, and whether or not anyone has a serious intention to explore for and ultimately exploit them. There was a similar debate on Antarctic minerals, especially during the Convention on the Regulation of Antarctic Mineral Resource Activities (CRAMRA) negotiations. Most of the debate was ill informed, misusing the terms "reserves" and "resources" (Willan et al. 1990).

Of the three sources of mineral energy, coal deposits are easiest to find, to be defined by size and quality, and to exploit. Frank Wild and Ernest Shackleton found the first coal in Antarctica at the head of the Beardmore Glacier (Shackleton 1909). This discovery had enormous significance, as clear evidence that Antarctica had not always been a frozen continent. Subsequent expeditions to the Transantarctic Mountains in the Ross Sea sector confirmed that coal of Permian age (laid down about 255–245 Ma) was present throughout the range. There were also some thinner coals of Triassic age (about 220–230 million years old). The first serious suggestion for mining this came in an exchange of letters in *Time* magazine in July–August 1939. The last piece of the jigsaw was the discovery of coal in the Theron Mountains by Vivian Fuchs in 1956 (Fuchs and Hillary 1958) and in the Amery Oasis area of the Prince Charles Mountains by geologists of the Australian Antarctic Division in the mid-1950s (McLoughlin and Drinnan 1997).

All Antarctic coal lies in a narrow belt between the Weddell and Ross seas and in an isolated patch in East Antarctica; all is of Permo-Triassic age. What is more interesting is what is missing: there are no coals of Carboniferous age (which are the most important worldwide), and none of Cretaceous or Jurassic age (as in the other Gondwana continents). Why? In part, the answer is past climate; Antarctica has been in high latitudes for most of the past 300 million years, and was glaciated during the Carboniferous age. Tectonics are also important. Most of the Cretaceous basins lie within the Pacific margin active belt: sedimentation rates are high and there was much volcanism, preventing coal formation (Macdonald and Francis 1990). The only Cretaceous coals are rare, thin (a few centimetres thick), and discontinuous.

The only Antarctic coals that could be considered exploitable are Permian. Rose and McElroy (1987) showed that they had a high ash and mineral content, and many seams had been metamorphosed by the extensive magmatic intrusions of the Jurassic Ferrar dolerites. Because of the flat-lying stratigraphy of the Transantarctic Mountians, most of the outcrops of Permian coal are at altitudes above 2500 m. These factors, coupled with remoteness of most of the outcrop, and the very large stocks remaining elsewhere in the world, make it impossible to contemplate anyone ever exploiting Antarctic coal, even if they were free to do so.

The case of oil and gas is much simpler: none has ever been found, and beyond desktop studies, there has been no serious attempt to look for hydrocarbons. There are four ways to conduct petroleum exploration; all concentrate exclusively on the sedimentary basins where oil and gas are found. First, look for oil seeps at the surface. This is the way that most of the world's major petroleum provinces, including the Alaskan North Slope, came to the attention of the oil industry. No seeps have been found in Antarctica. Second, calculate the volume of sediment in Antarctic sedimentary basins and multiply that by a worldwide "finding factor" (volume of recoverable hydrocarbons per km^3 of sedimentary rock). St. John (1986) used this approach to suggest that there were potentially 106 billion barrels of oil recoverable in Antarctica (approximately twice the ultimate recovery from the North Sea). This is the highest figure ever suggested for the petroleum potential of Antarctica, and is greatly exaggerated, as the finding factor is skewed by highly productive regions of the Northern Hemisphere. Third, consider the geological evidence for the various elements of the petroleum system: source, maturation, reservoir, seal, and trap. This focuses attention on the Ross and Weddell seas, which are the only areas where basins are extensive enough to host large accumulations of oil or gas. Macdonald et al. (1988) and Macdonald and Butterworth (1990) used this approach to consider the basins around the Antarctic Peninsula; they concluded that there was some petroleum potential in the Larsen Basin, east of the peninsula, but that it was not high. Fourth, go and look for suitable traps with seismic surveys, then drill them. This is a very expensive process: seismic lines are spaced 500 m apart and surveys cost many millions of dollars; wells penetrate to depths of 2–3.5 km and cost tens of millions of dollars. As far as can be ascertained, all seismic surveys conducted offshore Antarctica have been for scientific purposes; the most detailed has a mean line spacing of more than 5 km. The deepest series of boreholes (MSSTS, CIROS, Cape Roberts) have an aggregate depth of only 1500 m (Davey et al. 2001).

In conclusion: No serious oil or gas exploration has been conducted around the continent; likely areas are restricted to the Ross and Weddell embayments; the petroleum potential is unproven (but likely to be low). Coupled with the difficulties of working in the harsh environment, it is unlikely that any exploration will occur in the future.

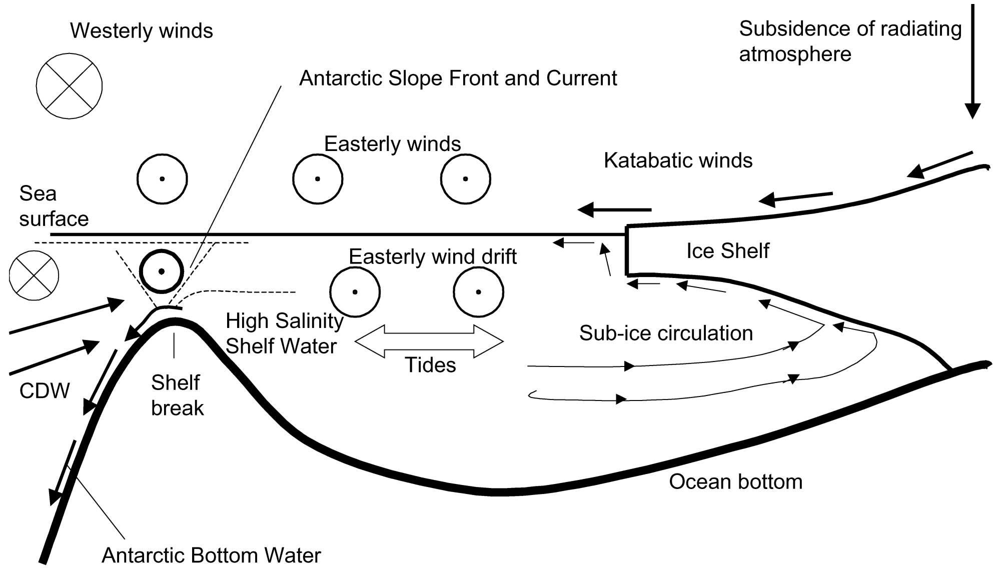
COASTAL OCEAN CURRENTS

The coastal current system around Antarctica is controlled by the interactions with the Antarctic Circumpolar Current (ACC) in deep water to the north, the bottom topography of the coastal region, and the atmosphere—the local winds and the massive seasonal variation in surface heat flux. Antarctica has a long coastline, and the observations of its coastal and regional currents are sparse, mostly confined to summer except for a few long-term moorings, and concentrated in particular areas such as the Ross and Weddell seas. Many regional anomalies, known and unknown, are omitted from this overall picture.

Like most other coastlines, Antarctica has a continental shelf and continental slope, bordering the deep Southern Ocean. However, the continental shelf is much deeper (400–600 m) here than in most other oceans (<100 m), and in many places it deepens toward the coastline, with a sill of about 450 m depth at its outer edge (the shelf break). This unusual depth is attributed to the weight of ice on the continent, depressing the ground beneath. Further offshore, the continental slope to the deep ocean is steepest in the upper 2 km, with typical slopes of 3°–6°, similar to those seen around other continents. Smaller-scale variations on this general topographic pattern include banks and troughs on the shelf, and submarine canyons on the slope and rise, which can help to drain dense fluid from depressions on the shelf out to the deep sea.

North of the continental slope, although it is a notoriously stormy environment, the average wind and its stress on the ocean are eastward. This implies that transport in the surface "Ekman" layer is predominantly toward the north. To conserve mass, the column of ocean water below the Ekman layer rises as it moves southward. This Circumpolar Deep Water (CDW) has been in the deep ocean for a long time (~1000 years), and is relatively warm, salty, low in oxygen, and rich in nutrients compared with the Antarctic coastal environment.

The coastal wind system is quite different from that over the deep ocean. The persistent clear sky over higher ice sheet elevations means that the local atmosphere continuously loses heat by radiation, causing it to steadily subside to the surface. This cold air drains off the elevated continent in all directions in a boundary layer ~200 m thick, in a flow known as a katabatic



Schematic of a north–south vertical section showing some of the aspects of Antarctic coastal currents described. Dashed lines denote isopycnals, and arrows denote wind and current direction. (CDW, Circumpolar Deep Water.)

wind. As this cold flow approaches the coast, the topographic gradient steepens, wind speed increases, and the airflow is channelled preferentially into valleys where speeds of over 200 m sec^{-1} are not uncommon—the strongest winds on Earth. This process continues throughout the year, but is strongest in winter. On reaching a level surface over the ice or water this cold dense airstream thickens and decreases in speed, often through the mechanism of a hydraulic jump. Where topographic channelling is not important, as at low levels over the continental shelf, northward moving air is directed toward the west by the Coriolis force.

At upper levels in the troposphere the wind is predominantly toward the east, circling the Antarctic continent. The two main embayments, the Weddell and Ross seas, are sheltered from this westerly wind stream by the mountains of the Antarctic Peninsula and Victoria Land. These barriers direct the main topographic air streams around them to the north, where each flow separates from the barrier, leaving a large recirculating clockwise eddy in the lee. The wind stress associated with each of these eddies then drives a corresponding clockwise oceanic gyre in the Weddell and Ross Sea basins. These gyres dominate the mean circulation in each basin and have diameters on the order of 2000 km, although the Weddell Gyre is elongated towards the northeast, extending as far as 30° E. Surface current speeds in these gyres are of the of order 10 cm sec^{-1}. At deeper levels in the Weddell Sea, two smaller gyres are evident, one on each side of 15° W. There is also some evidence that the circulation in the Ross Sea below the mixed layer is also made up of three smaller gyres. A wind-generated gyre is also expected in the Prydz Bay region, but it would likely be weaker and on a smaller scale than those in the Weddell and Ross seas.

Air draining off the continent is considerably colder than the surrounding ocean, particularly in winter. In consequence, the ocean loses heat to the atmosphere and freezes to form pack ice. This causes an enormous seasonal variation in the extent of pack ice, which retreats to somewhere near the edge of the continental shelf in summer, reaching a minimum in February. It then extends rapidly northward in autumn and winter due to the decreasing temperature, particularly in the Weddell Sea, usually reaching a maximum extent and thickness in September. The associated surface cooling causes the water over the shelf to be well mixed, particularly in coastal regions where the katabatic winds are strong, generating open areas with little or no ice (such areas are termed "polynyas"). Such regions act as continuous sources of dense salty water because of brine rejection from the continuously forming sea ice. This environment is also affected by CDW that is modified by mixing with Antarctic Surface Water. These and other water masses are identifiable by temperature and salinity characteristics, but the overall seawater density variations over the shelf remain weak.

Wind-driven currents over the continental shelf are thus expected to be largely barotropic, meaning they do not vary much in the vertical, have a simple structure, and are not particularly strong. The prevailing easterly winds produce the observed westward "East Wind Drift" that is prevalent around most of the continent and turns northward along the western coasts of the Ross and Weddell seas. The southward Ekman transport due to this wind tends to cause downwelling at the coast, which also helps to keep the shelf water homogeneous. The East Wind Drift is weaker in winter, when the ice cover resists wind-driven motion. Between the coastal easterly wind regime with southward transport and the ACC to the north with northward transport lies a broad region of surface divergence. This is the main driver for the rising of CDW over the slope and onto the shelf at most longitudes.

In most coastal environments around the world, the main currents are situated over the continental slope. A westward "Polar Slope Current" has been observed in the lower part of the water column north of the South Shetland Islands near the tip of the Antarctic Peninsula, and at several other locations along the continental margin. The natural horizontal scale for deep water currents—the Rossby deformation radius $R_0 = NH/f$, where H is the vertical scale ($\leq$depth of ocean), N the buoyancy frequency of the density stratification, and f is the magnitude of the Coriolis frequency—is only about 12 km in these polar latitudes because of the weak density stratification and large f. Hence there may be significant motion over the slope on these relatively small scales near the bottom or near the surface, including eddies. Tidal currents are strong at a few locations, particularly near the continental shelf break in the Ross Sea and near the Ronne Ice Shelf front.

Near the edge of the continental shelf, CDW over the slope meets the generally denser shelf waters at what has been called the Antarctic Slope Front. The shelf waters have been affected by surface cooling and the addition of brine from sea-ice formation and, along with shallower, fresher source waters, set up a westward "geostrophic" current along the shelf break. This semipermanent feature is narrow, with a typical width <50 km and current speeds of order 10–30 cm sec^{-1}, with little or no signal in the surface layer. The Antarctic Slope Front appears to be present at most longitudes, but is weak or absent from the Drake Passage to 130° W, that is, in the Amundsen and Bellingshausen seas west of the Antarctic Peninsula. Along the shelf break across the Weddell and Ross seas, this front develops a V-shaped profile, a feature that becomes progressively stronger from east to west across each sea. In this flow the isopycnals (lines of equal density) are depressed downward over the shelf break, and current transport is mainly in the relatively fresh water inside the V.

Antarctic Bottom Water is produced by the mixing of dense, cold, high-salinity shelf waters; CDW; and fresher water near the shelf break at the base of the V along the Antarctic Slope Front. This mixing process produces denser water than in the deep Southern Ocean to the north, and it descends the continental slope in substantial quantities. This process is best documented in the Weddell and Ross seas, but also occurs seaward of the Adelie Depression near 145° E, and possibly to a lesser extent in Prydz Bay. In the Weddell and Ross seas, this dense water is formed during most of the year, and may descend the slope as intermittent plumes or as a broad continuous sheet. Water mainly leaks out of the Adelie Depression through submarine canyons. The bottom boundary layer thickness and current dynamics are controlled by a combination of buoyancy, bottom drag, bottom slope, and flow rate. In many regions, details of the bottom topography are not yet well known because of the nearly continuous ice cover, making it difficult to assess the role of bottom roughness, from minor rills to major canyons, in the current structure.

A different type of current is the circulation driven by melting underneath the ice shelves. At most longitudes around the continent, ice is slowly pushed off the land, forming ice shelves hundreds of metres thick that float on the water, extending seaward from the grounding line for distances ranging from tens to thousands of kilometers. Warm salty CDW and cold salty shelf waters flow southward at depth, and melt some of the undersides of the ice shelves, producing cooler, fresher, more buoyant water that rises up along the sloping bottoms of the ice shelves. Although the magnitude of these circulations may be measured in Sverdrups (10^6 m^3 sec^{-1}), the inflowing and outflowing currents only average a few cm sec^{-1}. Also associated with melting and upwelling is a relatively narrow (<20 km) and strong surface current that tracks portions of the coastline. The continuity of this coastal current, in effect an intensified east wind drift, is unknown, but speeds of 20 to >50 cm/sec have been estimated at some locations.

COLD HARDINESS

Cold hardiness is the ability of animals and plants to survive subzero temperatures. Subzero temperatures can damage organisms through direct mechanical injury via the formation of internal ice, as well as through conformational changes in membranes and proteins. Antarctic marine and terrestrial organisms must survive very different thermal regimes, and thus have different strategies to survive low temperatures. Internal ice formation is the key issue for any Antarctic organism, which may tolerate the formation of ice in the tissues (freeze tolerance) or avoid the formation of ice altogether (freeze avoidance). Freeze-avoiding species can supercool (keep body fluids liquid at temperatures below the melting point) by the production of antifreezes (any substance which acts to prevent ice formation) and/or by neutralising ice nucleators (any substance that provides a substrate for ice formation). Ice crystals are the best possible nucleator, although other crystals, proteins and some microorganisms also nucleate ice effectively. Antifreezes may act colligatively (in proportion to their concentration, for example salts or sugars) or noncolligatively (out of proportion to their concentration, for example, antifreeze proteins that act directly on ice crystal growth).

Antarctic marine animals inhabit a thermally stable environment—in the presence of sea ice, seawater may be a constant –1.86°C. The intertidal limpet *Patinigera polaris* is exposed to air temperatures which are much lower than seawater temperatures. This freeze-avoiding species relies upon a thick layer of mucus to prevent nucleation by the surrounding ice. By contrast, the blood of most Antarctic fishes is less concentrated than seawater. Fishes risk freezing at ambient subzero seawater temperatures, particularly because of the presence of small ice crystals, both in the water column and in their food. In most species, nucleation by ice crystals is prevented by the production of one or more antifreeze proteins (AFPs). AFPs are present in the tissues, circulate in the blood and are secreted into the gut to act directly on small ice crystals, preventing their growth and the consequent freezing of the fish.

By contrast with marine environments, temperatures in terrestrial environments, and more specifically the surface microhabitats occupied by organisms, may span more than 60°C, with daily fluctuations of more than 30°C caused by solar radiation. Semiaquatic, freshwater species, like nematodes and tardigrades, which live in freshwater streamlets, and semiterrestrial larvae of the wingless midge *Belgica antarctica* must therefore survive an environment surrounded by ice. *B. antarctica* survives these conditions by being freeze tolerant—it can survive the formation of ice inside its body compartments. *Panagrolaimus davidi,* an Antarctic nematode worm from Ross Island, takes this a step further by tolerating the formation of ice within its cells. However, *P. davidi* and many other small semiaquatic organisms are also likely to utilise cryoprotective dehydration, whereby water is lost to ice in the environment, slowly desiccating the animal and removing all freezable water.

Cold hardiness in terrestrial animals has been best studied in the Collembola (springtails) and mites, collectively known as microarthropods. These organisms all utilise a strategy of freeze avoidance—maintenance of liquid body fluids at temperatures well below that at which freezing would occur in most organisms—and consistently die upon freezing. This latter phenomenon has allowed their cold tolerance to be readily measured using thermocouples to detect the latent heat of crystallisation, and therefore freezing events. These freezing temperatures (termed Supercooling Points, SCPs) are examined as population distributions, giving a snapshot of the distribution of cold tolerance in the population. Springtime SCPs as low as –39°C have been recorded in the springtail *Gomphiocephalus hodgsoni* on Ross Island. Low SCPs are made possible by a combination of the animals' small size (most are less than 2 mm long), carbohydrate cryoprotectants (sugar alcohols like glycerol, which act both as an antifreeze and to protect membranes and proteins from conformational changes), and antifreeze proteins, which not only prevent ice nucleation as in fishes but also serve to stabilise the body fluids against spontaneous freezing at very low temperatures.

Compared with animals, the cold hardiness of plants is a less unique feature of the Antarctic biota. Mosses and lichens have a cosmopolitan distribution, and the latter are able to survive temperatures much lower than those ever experienced in the real world. Mosses, lichens, and algae comprise the most southerly recorded living communities, suggesting that exposed rock and liquid water are the main limiting factors for these organisms. Of the vascular plant flora, the freeze-tolerant hairgrass *Deschampsia antarctica* is the more cold hardy, with an LT50 (the temperature at which 50% of the plants die) in the region of –10.4°C in summer and –26.6°C in winter. The pearlwort *Colobanthus quitensis* avoids freezing, but can survive only to c. –9.6°C, and possibly relies on the insulating effects of snow to survive the winter in its maritime Antarctic habitat.

Current cold hardiness research on Antarctic fishes is focussed on understanding the nature of production, distribution, and action of antifreeze proteins within the body, and these proteins are finding biotechnological applications, particularly in the frozen products industry. Research on mite and springtail cold tolerance is leading to a much better understanding of how cold hardiness may be manipulated over short periods of time. At present, nematode cold hardiness research seeks to determine the relative importance of freezing tolerance and cryoprotective dehydration, and to identify specific proteins associated with the survival of intracellular ice formation.

COLONIZATION

Antarctica has not always been the cold and poor biological environment that we observe today. Presence of coal and fossils of plants suggest that a temperate climate allowed the growth of luxuriant vegetation in the past. However, the subsequent total breakup of the Gondwana, when Australia and the new Antarctic continent parted 65 Ma, was the signal of the strong isolation of this region. For the past 35 million years, this isolation has been reinforced by the Antarctic Circumpolar Current, which acts as a strong barrier, limiting the exchange of marine fauna and flora. During the Quaternary era, the climate was driven by solar (Milankovitch) cycles, and the continental ice sheet fluctuated in cover. Refugia for various organisms probably existed during each glacial maximum, but it is likely that new taxa were introduced into Antarctica during cycles of ice sheet and oceanic front movement.

As a result, the Antarctic fauna and flora exhibit typical features such as low species richness, a strong latitudinal gradient from the cool sub-Antarctic islands to the extremely severe environment on the continent, specific morphological and physiological adaptations, and disharmony of terrestrial food webs, dominated by decomposers with few herbivores and nearly no carnivores. For example, the terrestrial and limnetic Antarctic ecosystems are devoid of native fish, amphibians, reptiles, and herbivorous mammals.

The high rate of endemism in some groups suggests that isolation was a major factor responsible for Antarctic and sub-Antarctic biodiversity: this is clearly demonstrated in some animal taxa such as the Collembola and Coleoptera. By contrast, recent biogeographic studies, based on molecular estimates and accurate paleogeographic reconstructions, indicate that dispersal may have been more important than traditionally assumed. For instance, the dominant pattern in plants is better explained by dispersal than by the vicariant isolation of areas.

A common idea is that Antarctica remains one of the most pristine regions in the world, being exceptionally well protected against the dangers of invasion by alien species because its isolation, the low level of human activity, and its extreme environments should prevent the establishment of new species. However, the biota of most sub-Antarctic islands and some maritime and continental Antarctic ice-free areas include alien taxa. Opportunities for alien invasion have been restricted to the last two centuries, commencing with historical sealing and whaling industries and extending to the research, commercial, and tourist activities of modern times. Introduction of species by human visitors has been facilitated by the low species richness and absence of many functional groups that make islands, and the islandlike exposed land of Antarctica, more susceptible to alien invasion.

Several stages are necessary for successful colonisation: (1) long-distance transport from source populations, including the stochastic aspect of arrival at a suitable colonisation location at a suitable time of year, (2) survival after arrival, and (3) establishment of a long-term reproducing population. Today, despite the strong isolation of sub-Antarctic and

Antarctic territories, the most critical point is not the arrival but the survival and establishment of invaders. Many examples demonstrate the role of humans in the introduction of alien species. Historically, research stations and exploring expeditions have imported a range of mammals and birds for logistic (dogs, ponies), food (pigs, hens), or companionship (cats) purposes, but such activities are no longer permitted on the continent under the terms of the Protocol on Environmental Protection to the Antarctic Treaty. Other taxa have been introduced accidentally (rats, mice, plants). Most alien plants introduced to the sub-Antarctic are European and usually show a large ecological range. Many alien invertebrates and birds are also of European origin, although now cosmopolitan. This is partly because colonization by humans in the Antarctic was largely from Europe. Many of the alien invertebrates recorded as being established on sub-Antarctic islands and found in maritime and continental Antarctic research stations are known to have been imported amongst food and other stores. More generally, many species introduced to the region have been imported with live vegetation, litter, or soil. Human activity in Antarctica has also been identified as a potential source of disease in wildlife by translocating pathogens. For example, avian paramyxoviruses and antibodies to Newcastle Disease have been found in Macquarie Island royal penguins *(Eudyptes chrysolophus)*. Even in the marine environment, a recent survey reported the discovery of the majid spider crab *Hyas araneus* in the Antarctic Peninsula marine waters. This North Atlantic species is the only record of a nonindigenous marine species in Antarctic seas. It may have arrived in Antarctica via ships' sea chests or ballast water.

The increasing number of visitors in Antarctica is also responsible for a greater flux of alien propagules. The number of scientists working on the continent remains fairly stable but the number of ships and tourists increases each year, leading to greater chances of introductions. Tourists are also disproportionately attracted to sites of high diversity, which vary as tourist trends and fashion change.

In addition to the use of ships for transport to Antarctic locations, several national operators and a small number of nongovernmental organisations use air transport. This gives faster and more efficient exchange of personnel and equipment but also allows rapid transfer of propagules, allowing even short-lived life stages to arrive alive.

Climatic amelioration is also likely to enhance the ability of both natural long-distance colonists (especially those with long-surviving propagules) and human-assisted aliens to become established, particularly in the subantarctic. For example, a recent study relating the occurrence of the cosmopolitan necrophagous fly, *Calliphora vicina,* with available meteorological data (1951–2001) at Îles Kerguelen, revealed that establishment of the fly was possible only after the early 1980s and that its continued absence in West Kerguelen is explained by the current climatic conditions there.

The increase in the human activity in Antarctica will likely increase the number and range of taxa arriving in the region, and the ameliorating climate in some areas, such as the Antarctic Peninsula and the sub-Antarctic islands, will most likely increase the probability of survival and establishment of new taxa. In consequences, substantial modifications of Antarctic biodiversity can be expected.

COMMONWEALTH TRANS-ANTARCTIC EXPEDITION (1955–1958)

Tentbound due to a blizzard in 1949, Dr. Vivian Fuchs and Dr. Ray Adie conceived the idea of a crossing of the Antarctic continent. Ernest Shackleton had hoped to accomplish it in 1914, but failed. Further discussion in 1950 by Fuchs and James Wordie, who had been Shackleton's chief of scientific staff, led in 1953 to Sir Miles Clifford (governor of the Falkland Islands) asking Fuchs to produce a plan for the crossing. Eighty copies of the original proposal were circulated, which included the following details:

1. The planned route must begin and end in the Falkland Islands Dependencies (later renamed British Antarctic Territory) and the Ross Dependency.
2. The traverse must pass through the South Pole.
3. Assistance could be expected from Commonwealth countries—the United Kingdom, New Zealand, Australia, and South Africa.
4. The expedition must include nationals of all the participating countries.
5. Logistic factors must be sufficiently flexible to ensure a high safety factor.
6. The scientific programme must be sufficient to justify the project.

A high safety factor was desirable to counter the initial resistance to the proposal from certain quarters against the risks of possible failure. The planned route was from the Weddell Sea to the Ross Sea via the South Pole. The plans for the International Geophysical Year (IGY) (1957–1958) had not been made known and neither were those for a US base at the South Pole.

After crossing the Weddell Sea pack ice, the advance party would build Shackleton Base near Vahsel Bay. The advance party would winter over, initiate scientific programming, consolidate the base and travel inland. The next year, the crossing party would arrive, winter over, and establish a small inland base, South Ice. This would function as a winter station and a depot for the crossing party. The Ross Sea exit was known, and if vehicles failed at the head of the Ferrar Glacier, the crossing party could dog sledge or man-haul from the Antarctic Plateau down to the Ross Sea. A single-engine aircraft would cross the continent and then could act as an additional safety factor. A mainly New Zealand party under Sir Edmund Hillary would build a reception station named Scott Base. Air reconnaissance and dog sledging would lay depots up to 700 miles from Scott Base.

All parties would carry out programmes of physiology, geology, geophysics, meteorology, glaciology, exploration, and survey. The Ross Sea party was to survey the western sides of the mountains discovered by Scott and Shackleton. The crossing party would make a gravity and seismic traverse measuring ice thickness.

Being a private expedition necessitated fund-raising and assistance with equipment. Fuchs arranged for heavyweight committees. In London, the twenty-three-member General Committee and eleven-member Committee of Management were both chaired by Marshal of the Royal Air Force Sir John Slessor, and Fuchs was a member. In Wellington, the seven-member Executive Committee had the Hon. C. M. Bowden as chair, A. S. Helm as secretary, and Hillary as a member.

On February 17, 1955, Sir Winston Churchill announced an HMG grant of £100,000, which was followed by a total of £87,000 from New Zealand, South Africa, and Australia. This left a shortfall of some £313,000 to be found from sponsorship from industry, institutions, sale of a book, media, and film rights and contributions from schools.

Staffing was not a problem as some 2000 applications were received. Eight men were appointed for the advance party. Twelve men were selected for the crossing party (including four from the advance party) and four RAF staff for support and for making a transcontinental flight. The crossing party included a New Zealander, an Australian, and a South African. The New Zealand party was staffed with fifteen men and three RNZAF men. In addition, five IGY staff were attached to Scott Base under the administrative responsibility of Hillary. The complement of dogs was twenty-four for Shackleton Base and sixty for Scott Base.

Snow vehicles were improving. The US military and some private expeditions were using ex-wartime petrol Weasel vehicles (the British North Greenland Expedition and the Norwegian-British-Swedish Expedition, 1949–1952). The US military was also using heavy diesel Caterpillar D4–D8 tractors. The TAE transport and engineer officer was empowered to research the field, and with assistance from the Pentagon visited US operations in Greenland. A decision was taken against crevasse-detection equipment (which later proved ineffective in Operation Deepfreeze I) and against heavy diesels for reasons of cost and high risk for an unknown route. Lighter petrol vehicles called SnoCats were found in Greenland but were initially unserviceable; however, inspection showed that with care and modification the risks of SnoCats could be reduced, and they provided a strong competitor for the Weasel.

A decision was made that two vehicles should complete the journey. Engines would be allowed to cold soak—cold starting to be available from –60°F using preheaters and within 40 minutes, or from –40°F without preheating. Achievable speed should be a mean of 20 miles per day in the unknown terrain and short Antarctic summer, and the vehicle would need to haul a heavy load over hard ice, sastrugi, and soft snow. To meet this plan some 340 hours of cold chamber tests and field trials in Norway were carried out and modifications made to all transport (Fuchs and Hillary 1958: 300–320). It was decided for financial and logistical reasons to increase the towed load for SnoCats to 2 × 2 1/2 tons (twice the common amount).

Shackleton Base was supplied with four SnoCats, four Weasels, two Ferguson TE20 tractors, and one Muskeg. Scott Base was supplied with five Ferguson TE20 tractors, and two Weasels were borrowed later from the US Navy. British Petroleum provided research facilities and all fuels and lubricants for ships, aircraft, and snow transport. Lucas provided cold chamber testing and batteries, Smiths the rewiring of the vehicles, BOC the welding gas, and Massey Ferguson the tractors. Many others provided free goods and services.

Operations

Her Majesty the Queen visited the ship, and on November 14, 1955, MV *Theron* (849 tons, 1310 hp), captained by Harald Maro, left London for the Weddell Sea. They met the pack ice on December 22 at 63°50′ S, 30°20′ W. It was not until January 23 that *Theron* sailed back to the edge of the heavy pack ice, having been beset for a month, drifting north and west. Ice damage to the rudder forced Maro to bend it straight by reversing hard into the ice. It appears that for 1955–1956 *Theron* should have entered the pack some 10° to 15° farther to the east before sailing south to reach the narrow open water along the coast. MV *Tottan* (Royal Society) did sail farther east and established Halley Bay station at 75°36′ S, 26°45′ W. *Theron* visited Halley and a TAE Auster flight showed that the area was unsuitable for inland vehicle travel. Hence *Theron* continued and Shackleton Base was finally established on the Filchner Ice Shelf at 77°59′20″ S, 37°09′20″ W, and unloading began on January 30.

On February 1, a gale from the north caused *Theron* to leave her moorings, and five men were left on the shelf ice until the following day. On February 8, the sea was freezing and rafting, and Maro and Fuchs decided that it was time for *Theron* to leave. The eight-man advance party (led by K.V. Blaiklock) was left without an erected hut. Despite criticism from "the inexperienced," the decision to leave proved wise and *Theron* escaped, enabling the TAE to proceed.

The advance party had a harsh experience, sleeping in tents, with a 21′ × 9′ × 8′ SnoCat serving as a kitchen/living room for eight months. On cooking duty for four days in turn, each man slept in the crate and dried out bedding and clothing. A severe blizzard ended on March 26 and it was found that bay ice had broken away, with the serious loss of stores and equipment. They had food for three years but only three gallons of fuel per day. On April 20, when the Sun set for four months, they continued outdoor construction work using Tilley lamps, May was the coldest month (average –35°F) and included a ten-day blizzard. The first radio contact was with a Falkland Islands Dependency Survey (FIDS) base, 12 weeks after *Theron*'s departure. August 2 was the coldest day at –63°F. On October 29, first voice contact was made with BBC London. In November a depot was established 50 miles south, and in December a 360-mile dog sledge journey made Mount Faraway in the Theron mountains (named for the ship). Under extreme conditions, the advance party had completed their tasks, with a base hut virtually constructed, a reconnaissance journey made to the south, and a meteorology programme initiated.

On November 14, 1956, the jointly chartered MV *Magga Dan* (1850 tons, 2020 hp), captained by Hans Christian Petersen, left London, calling at Halley Bay. Unloading at Shackleton Base began on January 14, and the Halley Bay advance party, who were returning to the UK, assisted unloading, and the ship left on January 28.

Otter flights on January 13, 20, 22, and 30 discovered the Slessor Glacier, Recovery Glacier, and the Shackleton Range. A landing was made in the Theron mountains, geological specimens obtained, and a tentative inland route proposed.

Between February 4 and March 26, 1957, some 20 Otter flights established South Ice at 81°56′59″ S, 28°51′40″ W. Three men led by Hal Lister wintered at the station at 4430 feet (where the lowest temperature was recorded at –74°F) and established a programme of meteorology and glaciology.

Meanwhile, the Ross Sea party, comprising 13 New Zealanders, two Englishmen, and three RNZAF men left Wellington in HMR *Endeavour* in December 1956 and arrived on January 4, 1957, to find the planned base site and the Ferrar Glacier route unsuitable. The alternative site chosen was Pram Point, Ross Island. Scott Base was constructed quickly, using an imported construction team, prefabricated section buildings, and a site on rock. On January 18, the Beaver flew the length of the Skelton Glacier. Two dog teams were flown to the Skelton Inlet and reached the Antarctic Plateau in 10 days. A third dog team travelled to the Skelton via White Island and Minna Bluff, and so the route to the plateau was proven quickly for dog teams. In March, Hillary made a 100-mile trip to Cape Crozier to prove his tractors. On October 14, Hillary's party, with three Fergusons and one Weasel, left Scott Base. On December 17, they arrived at Depot 700 following the dog-sledged route, thus proving it for their tractors.

On October 8, South Ice was relieved by air, and one SnoCat and three Weasels (driven by Fuchs, engineer D. L. Pratt, engineer D. E. L. Homard, and seismologist J. G. Pratt) set out to prove a route to South Ice. An air camp was established giving access to the Shackleton range. Two dog sledge units were flown in for survey towards the east, to flag a vehicle route up the ice wall, and for geological work.

Severe crevassing was experienced on the shelf ice, on Recovery Glacier, and south of the glacier toward the Whichaway Nunataks. Manual probing for crevasses was effective but slow. Crevasse crossing required care, and was akin to a tank crossing a minefield, except that one went down instead of up. Factors affecting snow bridge safety were the estimated strength, static and dynamic load imposed, and attrition caused by other vehicles. The greatest risk was not necessarily to the lead vehicle. The traverse of 400 miles lasted 37 days and was completed by the SnoCat and one Weasel on November 19. The pathfinders were flown back to Shackleton Base in two and a half hours. It was a close call when vibration from the two vehicles caused vast 40 × 12 foot holes to blow on either side of the vehicles. The route had proved to be marginally practicable, but by that time there was no alternative.

On November 24, the crossing party finally left Shackleton Base with three SnoCats, one Muskeg, and two Weasels. A dead reckoning traverse with astronomical control was kept. Severe crevassing was met near the Grand Chasm, and one SnoCat was almost lost. It took seven days to travel 22 miles. Poor visibility at Recovery Glacier slowed progress, but the crevasses at the foot of the Nunataks were perhaps the most dangerous. Five hours were required for a second SnoCat recovery, and a Weasel was almost lost.

The 566-mile trip from South Ice to the South Pole was made between December 25 and January 19. The two dog teams surveyed ahead, building cairns every five miles, and met no crevasses. However, several extensive belts of sastrugi up to four feet tall severely stressed the vehicles and sledges.

Meanwhile, the RAF team closed Shackleton Base and flew to South Ice on December 27. Two days later the Otter left for Scott Base, but thick cloud and rime icing forced a return from 87°40′ S. Fortunately, visibility improved to 300 feet, and the Otter pilot followed vehicle tracks into South Ice. To enable refuelling, J. Lassiter (US Ellsworth base) flew two drums from Shackleton Base to South Ice. On January 6, the Otter—the first single-engine aircraft to cross the continent—was successfully flown by John Lewis and Gorodon Haslop in turn from South Ice to Scott Base, 1430 miles in 11 hours. The aircraft could now act as a backup from Scott Base.

The temperature began dropping and the US station at the South Pole was closing down its outside access for the winter. The media had invented the idea of a Fuchs versus Hillary "race." This showed a lack of comprehension about the purpose of TAE. The US base and Hillary were nervous about the weather, and Hillary did not want to winter again at Scott Base. He had extended his tractor journey from Depot 700 to the Pole and arrived with three MF tractors that, although modified, were not suitable for load-hauling in the soft snow of the 10,000-foot-high plateau. The conditions resulted in the tractors being roped together and some of the tents, tools, and food being jettisoned in order to proceed. They arrived with only half a drum of fuel and were totally dependent upon the US South Pole base. The cable from Hillary to Fuchs suggesting that Fuchs stop at the Pole, fly home, and continue the following year caused much world press comment. This was particularly the case when Fuchs declined and explained the crossing party could operate to –60°F and, if necessary, would winter at Scott Base if they should miss *Endeavour*'s return to New Zealand.

Between 24 January and 7 February, Fuchs' party crossed the 520 miles from the South Pole to Depot 700. During his tractor traverse, Hillary had not made a survey of the section, although his party had built cairns in crevassed areas. However, Fuchs' party could not see any of the cairns or the track marks from Hillary's previous crossing. The last 60 miles contained a crevassed belt with some immense crevasses, but fortunately they were well-bridged, and the team progressed safely, with the daily mileage actually improving, as the dogs had been evacuated by the US Navy.

From 10 to 23 February, Fuchs's party crossed from Depot 700 to Plateau Depot, a distance of 445 miles. Hillary joined the crossing party, and his knowledge of the area, the route, and where his tractor marks were to be found proved very valuable, enabling them to make good mileage despite poor visibility. Severe whiteout entailed military-style driving, using hand-placed marker flags.

The 284 miles between Plateau Depot and Scott Base were covered in seven days. Blaiklock and Stephenson were flown out for special duties in Scott Base. The Skelton Glacier produced variable surfaces from hard snow to blue ice and some soft snow patches. Some heavy crevassing was met, but much time was saved since the Ross Sea party had carefully marked a reasonably safe route. Once on the Ross Ice Shelf, the 180 miles to Scott Base were easily travelled, with the best day's run being 75 miles. The 99-day, 2158-mile traverse from Shackleton to Scott Base was completed on March 2, 1958.

The scientific results were recorded in fifteen Trans-Antarctic Expedition reports. A seismic profile of the crossing was obtained by firing charges at some 30-mile intervals, together with more frequent gravity readings as raw gravity. Shackleton Base tides were calculated using a gravimeter. Glaciological studies investigated solid precipitation and drift snow, and snowfall was deduced from combined snow and drift measurement. Geological studies in the Therons and Whichaways found dolerite intrusions in the Beacon System, confirming their presence across the continent from Dronning Maud Land to Victoria Land. The fossil flora confirmed Gondwana affinities. Specimens measured for their palaeomagnetic directions supported the hypothesis of continental drift.

On the Ross Sea side, extensive geological mapping in the previously unexplored regions confirmed details of the Gondwana fossil floras and recognised some of the earliest deposits from the most recent ice age.

In 1957–1958 outstanding exploration survey work was achieved by the three dog sledge parties from Scott Base and the dog sledge parties from Shackleton Base. Physiological research was made into energy balance, acclimatisation to cold in humans, and aspects of the advance party. Engineering studies were conducted into snow friction, engine performances, fuels and lubricants, and metallurgical analysis of materials.

The success of the expedition enriched the knowledge of Antarctica, and, coupled with the outstanding dedication of the leader and the teams, fully justified the industrial, academic, and Commonwealth governments' sponsorship.

CONSERVATION

Often described as the last and greatest wilderness on Earth, the Antarctic is the only continent without any indigenous human population. Its remarkable and unique features began to be recognised a century ago but it is only in more recent decades that there has been sufficient data available to identify conservation objectives. The significance of Antarctica in understanding the way in which the Earth functions as a system is now clear and underlines the importance of keeping it as unspoilt as possible.

With less than 0.4% of its land area free of snow and ice, and its distance from the other continental land masses, the potential for colonisation of Antarctica by flora and fauna has been very limited. Although the sea around Antarctica is cold and periodically covered by pack ice, it harbours a much higher diversity than on land and in benthic communities rivals coral reefs for biodiversity. Many of the species involved are unique, both physiologically and evolutionarily. Some groups, such as penguins and seals, have large populations of a few species, and the marine food chain on which all life depends appears significantly simpler than elsewhere in the global oceans.

Although the Antarctic Treaty does not specifically address any particular conservation activities, Article IX requires Contracting Parties to develop recommendations on the "preservation and conservation of living resources in Antarctica." The use of the term "resources" rather than native species, habitats or ecosystems was indicative of the mind-set at the time the treaty was negotiated. The only previous international conservation instrument that concerned Antarctic species was the International Whaling Convention (1947), which was concerned entirely with the management of what was then a major commercial resource.

In general terms there are two conceptual approaches to conservation. One is general defining principles to provide protection from damaging effects of present or future activities. The second is more specific and deals with the management of specific activities to limit or mitigate damage. Underlying both is the concept that the Antarctic needs to be protected and managed for the benefit of all humankind. These approaches were defined soon after the treaty was concluded, and the general approach to Antarctic conservation can be considered as largely precautionary, with the parties attempting to regulate activities before damage occurs rather than after impacts have been noted.

Soon after the first meeting of the treaty parties (I ATCM), the scientific community recognised the immediate need for formal conservation objectives. At III ATCM in 1964, a proposal from the Scientific Committee on Antarctic Research (SCAR) was accepted and the Agreed Measures for the Conservation of Antarctic Flora and Fauna set out the first detailed conservation principles for Antarctica. The Agreed Measures prohibited citizens of a treaty party from killing, capturing, or molesting without a permit any mammal or bird native to the Antarctic. In addition they allowed for the designation of Specially Protected Species, but failed to define the criteria for designation. Participating governments were required to take appropriate measures to minimise harmful interference with native mammals or birds. Harmful interference was defined as allowing dogs to run free, flying aircraft or driving vehicles so as unnecessarily to disturb bird and seal concentrations, using explosives or firearms close to such concentrations, or disturbing the animals during the breeding season by persistent attentions from persons on foot. Habitat protection for areas of outstanding scientific interest was established by means of Specially Protected Areas (SPAs).

In 1966, the first fifteen SPAs were declared, and the Ross Seal and fur seals were scheduled as Specially Protected Species. At this stage it had been assumed that the Agreed Measures could be applied only to land areas and ice shelves south of 60° S, based on the way they were linked to the geographical coverage outlined in Article VI of the treaty and on international high seas rights. However, many parties saw this as too restrictive and by 1975 the Consultative Parties had reinterpreted the measures to allow the designation of limited marine SPAs.

Collecting specimens or entering SPAs required a permit issued by an "appropriate authority" under the Agreed Measures. There was no specific indication that permits issued by one government must be recognised by every other one, but that is the practice that was adopted. Parties soon recognised that there were limitations to the SPA concept. It appeared it could not be applied to nonbiological sites, there were no specific management plans or individual rules on entry, and since the sites had to be exceptional there was no way to apply the concept of protection to sites being used for scientific research and monitoring. To address this last point the proposal for Sites of Special Scientific Interest (SSSI) was introduced at VIII ATCM to allow research areas to be protected. These sites were required to have management plans and maps and had to be designated for a finite period since it was implicit that once the research or monitoring was completed the designation should be withdrawn. This designation could also be applied to nonbiological sites and was quickly used to protect Arrival Heights, Ross Island, as a site for atmospheric research. Although it has always been possible to apply both designations to protect sites of geological interest, this has only been infrequently used. The most recent analysis of Antarctic Specially Protected Areas, in 2005, showed that there were sixty-two sites protecting 1780 km^2 of sea and 960 km^2 of land. This represents less than 0.008% of the total Antarctic Treaty area. There is also a very unequal distribution both geographically and biologically of the sites.

After this initial codification of procedures the treaty parties began to develop a broad range of legal instruments for conservation and environmental management. The next major instrument was also motivated by the precautionary principle. Exploratory voyages to assess the potential for commercial harvesting of crabeater seals had alarmed SCAR and many treaty parties, who decided to develop a new instrument that would allow more rigorous control and oversight over all Antarctic seals. In 1972, the Convention on the Conservation of Antarctic Seals established several new principles for Antarctica. It explicitly recognized that marine resources could be subject to sustainable harvesting within an agreed international management framework. The convention not only defines total allowable catch (no more than 10% of the population) but also establishes that measures limiting species, sex, age or size, methods of sealing, and areas or periods closed to sealing ("seal reserves") can be specified to protect the stock. Inspection of activities as well as mandatory catch returns to SCAR were also established. SCAR is specifically required to provide scientific assessments on the effects of sealing on stocks to allow treaty parties to actively manage the commercial activity. Since the convention was adopted there has been no attempt to start commercial sealing.

More ambitious was the next conservation instrument. Increasing levels of fishing in the Southern Ocean by the Soviet Union, Poland, and several other countries during the late 1960s and 1970s began to alarm marine scientists. The secrecy inherent in all Soviet and East European activities at the time of the Cold War meant that there were inadequate data available to document the extent of the catches, but trawler fleets on station in the Southern Ocean year-round were certainly suggestive of large catches. As it was already suspected that fish grow only very slowly in the cold water there was a real threat of serious depletion. In addition there appeared to be a growing commercial interest in krill. The key role of krill in the Southern Ocean food web meant that overfishing would have damaging effects on whales, seals, and birds. In particular, since the International Whaling Commission had recognised that catastrophic overfishing of all species of large whales could only be addressed by a complete moratorium on whaling to allow stocks to recover, it was felt that any large scale krill fishery might seriously impair the recovery of whale populations. In addition IWC had earlier created whale reserves to limit harvesting of particular species. To attempt to manage all marine living resources on a sustainable basis, the treaty parties signed the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) in 1980 and it entered into force in 1982. It had three especially novel features. First, its boundary was not politically determined at 60° S as per the Antarctic Treaty but at the biological boundary of the Antarctic Polar Front. Second, the management objective was to protect the integrity of the marine ecosystem rather than manage each species stock independently. This was a revolutionary approach to fisheries management and was the most developed move towards marine sustainability anywhere in the world. And third, decisions were taken by consensus, which was a lesson learnt from the IWC where majority voting had introduced bitter disagreements between countries.

Adequate management of a major industry such as fishing requires good catch data, a clear understanding of the life cycles of the target species and their relationships with the surrounding food web and a monitoring programme to ensure that the catch quotas really are set to have no lasting effect on ecosystem structure and function. Its management regime for sustainability is thus implicitly a major force for marine conservation in the Southern Ocean. CCAMLR has an annual meeting of those countries that have ratified it during which the national representatives are informed by previous discussions in a scientific committee. There is an international secretariat in Hobart, Tasmania, to manage the data, an inspection system for the fishery vessels, a catch certification scheme to allow all catches to be traceable when sold, and long-term international monitoring of the effects of fishing on key elements of the marine ecosystem at sites around the Antarctic. In addition there are a variety of mitigation measures to avoid unwanted bycatch of both birds and marine species and areas can be closed to fishing, effectively providing temporary marine reserves. This system should provide all the elements required for sustainable management, but unregulated pirate fishing of some stocks (especially Patagonian toothfish) is destroying the legitimate licensed fishery and undermining all conservation efforts.

Mineral resources are not mentioned anywhere in the Antarctic Treaty as they were seen as too contentious an issue for discussion when the original text was being negotiated. In 1970, New Zealand noted the lack of any form of regulation dealing with Antarctic minerals and raised concerns that an uncontrolled scramble, if any significant deposits were found, would have very damaging effects on the environment. There was, and is, no scientific evidence to support contentions that there are economically valuable deposits either on land or under the sea, but public myths developed suggesting otherwise and the parties began to discuss the problem. By 1977, they had agreed that some form of regime for management was required. Formal negotiations began in 1982 and by 1988 agreement had been reached on the Convention on the Regulation of Antarctic Mineral Resource Activities (CRAMRA). Contrary to public (and indeed political) opinion in some countries, CRAMRA was never intended to be a regime that facilitated and promoted Antarctic mining. Instead it constitutes a mechanism for assessing the effects of proposed mineral resource activities on the environment, and determines whether they are acceptable and what will be required in terms of mitigation and remediation. The protection of the Antarctic environment is the key thread that runs through CRAMRA and since agreement to proceed is by consensus there are substantial political checks involved on precipitate or unacceptable activities. To come into force CRAMRA required ratification by all those countries that were claimant states. CRAMRA was not seen in a positive light by many environmental nongovernmental organizations, who set about establishing public opposition to ratification. Greenpeace was especially active in this. For political reasons Australia, then New Zealand, and finally France all decided not to ratify and so CRAMRA failed.

Yet all was not lost from a conservation viewpoint. A groundswell of international public concern was being orchestrated at this point by two nongovernmental organizations, Greenpeace and the Antarctic and Southern Ocean Coalition (ASOC). The NGOs saw that there was an opportunity to press for increased protection for the Antarctic environment and the treaty parties reacted swiftly to this. In the space of two years, through a series of special meetings, the parties drafted the Protocol for the Protection of the Antarctic Environment. This was an enormous step forward in that it revised and codified all the previous environmental legislation, introduced new concepts on how to achieve agreed objectives and stipulated a ban on all mining and mineral extraction for 50 years. Many of the important elements were taken from the failed CRAMRA legislation that had already been negotiated. The protocol may be reviewed after 50 years, if requested by any of the Consultative Parties.

The core concepts for the protocol were different to all previous attempts to organise conservation and environmental management. First, it covered all human activities in the treaty area, except those already covered by CCAMLR and IWC legislation. Second, it recognised the complexity and diversity of national legislatures and the need to be able to keep the environmental management processes up-to-date without requiring further primary legislation. To achieve this the protocol has a descriptive core of general principles that were assumed to have a considerable degree of permanency and form the primary legislation, followed by annexes devoted to management processes that may be enacted by executive order or a similar instrument. Whilst this was the route followed by many countries others failed to understand the practical importance of separating the two elements and turned parts or all of the annexes into primary legislation. The effect of this has been that these countries are now unwilling to agree to changes in the annexes that would both improve the use of the annexes and reflect changes in environmental best practice since they were negotiated.

The protocol establishes several new concepts and reiterates important existing ones within its general text. In some areas it is perhaps the most stringent environmental legislation on earth. In other areas, it is completely lacking. Antarctica is described as a "natural reserve devoted to peace and science." Most significantly, all activities must planned and conducted so as to limit their adverse impacts. The protocol, and indeed the text of the Antarctic Treaty itself, allows for official inspections of facilities, ships and abandoned worksites by other treaty parties. The Environmental Impact Assessment of all activities is mandatory and codified. The conservation of flora and fauna is further strengthened by the link to "associated and dependent ecosystems." Measures to prevent marine pollution were strengthened, in particular in light of the 1989 *Bahia Paraiso* pollution incident, and build upon the Special Area status accorded to the seas south of 60° S under MARPOL 73/78. Waste management was more rigorously defined. The protocol also simplified the protected areas system, distinguishing between areas set aside for conservation, research and monitoring (Antarctic Specially Protected Areas) and areas set aside for management through codes of conduct (Antarctic Specially Managed Areas). Considerable effort is being expended at present on linking the criteria for endangerment devised by IUCN and used throughout the world (except for the Antarctic) to the designation and management of the concept of Specially Protected Species in Annex II of the protocol. This requires a significantly different view of conservation (as a dynamic tool rather than a recipe for preservation) to that used previously by the parties in that species would be removed from the SPS list once they were no longer endangered.

There is also now a new liability annex to attempt to deal with environmental damage.

An important part of the protocol was the establishment of the advisory Committee for Environmental Protection at which it was intended to have scientifically informed discussions on all aspects of conservation and environmental management. It was envisaged as providing the Antarctic Treaty with a nonpolitical "environmental science committee" in the same way that the CCAMLR Commission is advised by its Scientific Committee. Whilst there has been considerable progress in this new forum with many individual conservation issues it remains more political than scientific on many subjects, delegations often lack adequately experienced scientific advisors and the major interactions are limited to a small number of countries.

In the early 1980s, Greenpeace and other NGOs mounted a campaign for the declaration of Antarctica as a World Park managed by the United Nations rather than by the Antarctic Treaty parties. Their grounds for this was the premise that the continent was the inheritance of all humankind, that such a designation and management regime was the only way to be certain of adequate conservation and rejection of commercial exploitation, and that laws made by the UN would be universally accepted to conserve the Antarctic for future generations. To attract publicity for its position Greenpeace established World Park Base on Ross Island for a 5-year period, aiming to show that scientific research and environmental responsibility could coexist in a way that they claimed was not implemented by many treaty parties. A number of countries outside the treaty that regularly raised questions of Antarctic governance and conservation at the United Nations showed considerable sympathy for this approach. Most treaty parties apparently felt that the long-term protection of the continent was better served by the efforts of those most committed to the Antarctic. In implementing CCAMLR and the Protocol for Environmental Protection, the treaty parties met virtually all the conservation and environmental management demands raised by the NGOs, including admitting them as Experts to the annual Treaty Consultative Meeting.

There have been other conservation activities outside the Antarctic Treaty. The World Conservation Union (IUCN) signed a World Conservation Strategy in 1980 with the intention of developing various regional implementations. One such was the Strategy for Antarctic Conservation, resulting from a joint initiative with SCAR over a period of 5 years, and published in 1991. Although all the Consultative Parties in 1991 were also members of IUCN, they were at that point completely occupied by the protocol and its implementation and paid little attention to the IUCN document. The twenty-first century now needs a new version of this framework, linking the elements of the protocol to conservation activities at a global scale.

The high levels of mortality in albatross and petrels linked to longline fisheries encouraged international efforts to develop a transboundary agreement for their protection and conservation anywhere in the world. The Agreement for the Conservation of Albatrosses and Petrels, a part of the Convention on the Conservation of Migratory Species of Wild Animals, entered into force in February 2004 and is now actively developing new initiatives to protect these birds and reverse the catastrophic declines in many populations.

Introduced species are a potential problem for Antarctic conservation, but there is as yet only limited evidence of the establishment of new species in either the marine or terrestrial ecosystems. A long-established patch of introduced grass on Deception Island was obliterated in the eruption in 1969 and has not reestablished. Nonnative invertebrates have been reported from Signy Island, introduced through contaminated soil used for trials of introduced plants. Flies have been reported breeding at Casey and Rothera stations, although such introductions are synanthropogenic. It seems likely that other invertebrate species will be found near other stations, for example on King George Island, where there have been numerous introductions of soil for potted plants and greenhouses. In the marine realm a recent report of male and female North Atlantic spider crabs in a site west of the Antarctic Peninsula has stimulated interest in examining possible pathways for marine introductions so that suitable monitoring and controls can be developed. Both ballast water and hull fouling are suspected as possible routes for introductions, but there is as yet only limited data. Monitoring for propagules in cargo and on clothing have shown that humans may carry a considerable number of new species into the Antarctic in the form of seeds and spores, many of which have been shown to be viable. A warming climate in the Antarctic Peninsula region makes it increasingly likely that future conditions will allow establishment of species from elsewhere and the increasing numbers of scientists, logisticians, and tourists to this region are regarded by some as providing previously unrealised opportunities for transport of seeds, spores, plant fragments, and insects.

There has been increasing concern about the possibility of introduced diseases causing major mortality in Antarctic birds and seals. As data on foraging for these species has accumulated it is clear that many species actively visit areas outside the treaty area and potentially come into contact with other species carrying a wide range of diseases. There has also been some survey work which has identified antibodies to specific diseases in Antarctic penguins. Although there have been some reports of local disease outbreaks, as yet there is no evidence that the risk of introduction of diseases likely to cause mass mortality has substantially increased. It is clear, however, that much basic information on disease in the Antarctic fauna remains to be gathered.

Several initiatives have produced guidelines or codes of conduct for sensitive sites. These provide a degree of protection for specific sites without the formality of the international declaration of a specially protected area. The most significant were the ones developed by the USA and New Zealand for the McMurdo Dry Valleys, which have since been incorporated in the Antarctic Specially Managed Area plan. These guidelines provide a sound basis for good practice in environmental management and conservation anywhere on the continent.

Environmental guidelines were developed by IAATO for all passengers going ashore and for many years have been a required basis for tourist management. The ATCM adopted these guidelines as Recommendation XVIII-1. Increasing numbers of tourists visiting a limited number of sites has induced the ATCM to begin drafting site guidelines for the most heavily visited sites. Whilst there is as yet no agreement on how to estimate carrying capacity for these sites nor, in many cases, is there clear evidence yet of significant cumulative damage, this new initiative is intended to be precautionary in nature.

The Convention on Biodiversity does not apply to the Antarctic so that its framework for managing genetic resources cannot be applied there. Treaty parties have already recognised that bioprospecting is a developing field and have noted that there are now over 300 patents arising from biochemical and genomic studies on Antarctic organisms. The relationship between these activities and conservation remains to be explored in the future.

Despite the opportunities to ensure that modern conservation in the rest of the world is reflected in Antarctic legislation the Consultative Parties have shown themselves lagging significantly behind activities elsewhere. The lack of connectivity is all the more surprising as these same countries, but through different government departments, have agreed to conservation and monitoring initiatives for their national territories which they seem unwilling to contemplate in the Antarctic. The activities at the CEP have the potential to avoid this in the future if parties can find ways to improve connectivity and consultation within countries between their departments responsible for representation at the ATCM, at CCAMLR and at general conservation and environmental treaties.

Sub-Antarctic Conservation Initiatives

The sub-Antarctic islands that ring the Antarctic continent are all nationally governed. Almost all of these islands have suffered from human impacts over the past 150 years leaving them with some potentially difficult conservation and management problems. Introduced plants and animals constitute major impacts on the native communities of many of the islands and governments are struggling at present to address these. This is a problem for many islands worldwide and has attracted the interest of the United Nations Environment Programme as a major concern for preserving global biodiversity. All of the sub-Antarctic islands, except the French ones of Îles Crozet and Îles Kerguelen, now have published environmental management plans.

The most serious problems have resulted from the introduction of rats with their impact on burrowing petrels, grazing animals and their effect on the native vegetation, and plants that out-compete native species and replace native communities. Some islands have also had problems with cats that eat birds, with mice, and with introduced invertebrates that damage native plants or consume native invertebrates.

The most successful control measures so far have been the elimination of cats from Marion Island and the reduction in rabbit numbers on Macquarie Island. Trials to eliminate rats using baiting techniques have been successful on Île St. Paul and are underway on South Georgia and Kerguelen. There have been culls of the cattle on Île Amsterdam. On Kerguelen, trout have been introduced into some lakes and rivers on Isle Grande whilst on Marion Island the mouse population is rapidly expanding and causing impacts on the invertebrate populations.

On South Georgia the two reindeer herds have caused considerable damage to native plant communities and allowed the establishment of swards dominated by the introduced species Annual Meadow Grass *(Poa annua)*. On the Barff Peninsula the overgrazing has been extensive in several areas causing landslips. Fenced plots have demonstrated that over 25 years there is unlikely to be any reestablishment of the original plant communities on the Barff if the reindeer are removed. The Busen herd on the other hand have not yet destroyed the integrity of the native communities.

Erosion and wind-assisted loss of soil on many of the islands in the Kerguelen archipelago is a matter of considerable concern. The very extensive overgrazing, mainly by rabbits but assisted in many areas by reindeer, mouflon, and sheep, has reduced the native plant stands in many areas to a domination by *Acaena magellanica,* which is itself grazed. Grazing by the cattle on Île Amsterdam has largely destroyed the native vegetation and allowed many aliens to become established.

On Marion Island the eighteen known introduced plant species have spread considerably and now form a significant component of many communities. However, South Africa's rigorous quarantine regulations and severe limits on visits have kept the neighboring Prince Edward Island almost completely free of all introduced species, with only three species reported, two of which may have been introduced by natural vectors. A similar rigorous approach by Australia to Heard Island has also kept that island almost free of introduced species.

The special features of these sub-Antarctic islands have prompted some governments to apply for World Heritage listing for some islands. Heard Island and Macquarie Island are both now been accepted as World Heritage Sites by UNESCO.

Exploration of Antarctica has left a range of buildings and previously inhabited sites that are a substantive contribution to Antarctic history. The conservation of these sites has been undertaken in a variety of ways. The Antarctic Treaty has a conservation category for Historic Sites and Monument and now over seventy of those have been agreed and listed by the Consultative Parties. They range from rock cairns and plaques, marking previously inhabited sites, to graves and huts from earlier expeditions.

The more substantive remains of Heroic Age exploration, in particular the huts built by the expeditions lead by Carsten Borchgrevink, Robert Falcon Scott, Ernest Shackleton, and Douglas Mawson, are all now managed by specialised conservators with continuing efforts to preserve both the fabric and the contents. The New Zealand Antarctic Heritage Trust, with support from Antarctica New Zealand, has the responsibility for the Ross Island huts of Scott and Shackleton whilst Australian Antarctic Division is engaged in conservation work at Commonwealth Bay on Mawson's hut. On the Antarctic Peninsula, Argentina has worked with Sweden to preserve the remains of Otto Nordenskjold's hut on Snow Hill Island and manages the huts, magnetic observatory and graveyard left by the Scottish National Expedition on Laurie Island, South Orkney Islands. The UK Antarctic Heritage Trust, working with British Antarctic Survey, is undertaking the conservation and management of early FIDS huts at four sites—Port Lockroy, Argentine Islands, Stonington Island, and Horseshoe Island. Port Lockroy has been extensively restored to its original condition in the 1950s and now constitutes a living museum, staffed each summer to manage visits from over 10,000 tourists. The ATCM has adopted a conservation strategy for Antarctica's most significant whaling remains, on Deception Island. The USA has undertaken conservation work on the remains of the building that housed the Ronne Expedition on Stonington Island.

On the sub-Antarctic islands the relevant national authorities have made considerable efforts to conserve key sites. At South Georgia the whaling station at Grytviken has been made safe and laid out as an open air museum, whilst on Îles Kerguelen there is a continuing programme of restoration of the original buildings at Pointe Jeanne d'Arc whaling station. Many of the islands have sealing sites which are also being recorded whilst efforts are being made on Crozet to preserve a very early whaling and sealing site in Baie Americaine.

CONSERVATION OF ANTARCTIC FAUNA AND FLORA: AGREED MEASURES

History

The Agreed Measures to promote nature conservation in Antarctica were adopted by Resolutions III–VIII of the Third Antarctic Treaty Consultative Meeting (ATCM) held in Brussels in June 1964. The Antarctic Treaty Consultative Parties (ATCPs) involved were Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, South Africa, the USSR, the UK, and the US.

The first text of a "Suggested Form of Measures to promote Conservation of Nature in the Antarctic" was prepared in March 1959 by Dr. Martin W. Holdgate for the Working Group on Biology of the Scientific Committee on Antarctic Research (SCAR). A revised text was approved by the SCAR Executive in May 1961. It emphasised the scientific importance of the Antarctic flora and fauna and set out detailed proposals for a possible legal instrument.

Dr. Brian B. Roberts played a leading part in negotiating Recommendations I–VIII, adopted by the first ATCM, held in 1961. This ATCM urged governments to develop internationally agreed conservation measures, and issued interim "General Rules of Conduct for Preservation and Conservation of Living Resources in Antarctica" based on the SCAR proposals. The governments then negotiated the Agreed Measures, adopted in 1964. Pending confirmation by all ATCPs they were implemented on a voluntary basis. They became binding in 1982.

Content

The Agreed Measures applied to all land, freshwaters, and ice shelves within the Antarctic Treaty area, which was recognised as a Special Conservation Area. The detailed articles:

- Prohibited the killing, wounding, capture or molestation of all native mammals and birds except in accordance with a permit;
- Allowed governments to issue permits for the taking of specimens for research, museums, or zoos and to provide indispensable food for people or dogs;
- Provided for the designation of Specially Protected Areas and Specially Protected Species;
- Prohibited the introduction of nonindigenous plants and animals (except carefully controlled nonavian domestic species, under permit);
- Demanded strict control of potentially damaging activities such as allowing dogs to run free, flying helicopters or driving vehicles near bird and seal colonies, using explosives, or persistently disturbing wildlife in the breeding season.

Development

Following the adoption of the Agreed Measures, in November 1966, SCAR prepared a first list of fifteen proposed Specially Protected Areas (SPAs) and recommended Specially Protected status for the Ross Seal and all species of fur seals. These were adopted at the 4th ATCM in Santiago, Chile, also in November 1966. In 1972, provision was made for designating Marine Protected Areas and Sites of Special Scientific Interest (SSSI) managed for scientific research. By 1991, twenty-four SPAs, thirty-seven SSSIs, and one Specially Managed Area (SMA) had been designated (some of the original SPAs being transferred to the SSSI list).

Although a landmark statement of policy, the Agreed Measures did not have full Antarctic Treaty status or deal with such matters as waste disposal, pollution prevention, or the assessment of the environmental impact of new development, which were the subject of separate ATCM decisions. In 1990, the ATCPs agreed to negotiate a new Protocol on Environmental Protection to the Treaty itself, and this entered into force in 1998. It superseded the Agreed Measures which were, however, restated (with some adjustments) as Annex II to the protocol. All the SPAs and SSSIs were relisted in a new category, Antarctic Specially Protected Areas (ASPAs), and management plans for these areas have been adopted at various subsequent ATCMs.

CONTINENTAL SHELVES AND SLOPES

Antarctica is one of two island continents (the other being Australia) and hence is completely surrounded by its continental shelf and slope. This marine border comprises an astounding 1.5×10^4 km in circumference and some 4.36×10^6 km^2 in area extent, as measured along the shelf break and for the continental shelf respectively. Along this continental periphery are to be found some of the world's greatest relief and bathymetric complexity. Our knowledge of the Antarctic margin is a study in contrast. Vast regions remain unsurveyed and yet with the increased use of mulitbeam swath mapping in the last 10 years portions of the Antarctic margin are better known in detail than many seafloors around the world.

A general definition of a continental shelf holds that the shelf represents a submerged continuation of the continental physiography beyond the coastline, to some distance (on average 80 km) over which the prevailing seaward slope of the ocean floor is gentle (1:1000) and in continuity with the landscape inland of the coast. The coastal boundary in Antarctic is somewhat variable depending upon whether one is focusing upon the sea surface contact with an ice shelf, its submerged grounding line, bedrock, or a tidewater glacier margin (GEBCO 2003).

As a continent with a long glacial history, one that extends back at least 32 million years, Antarctica has a continental shelf that exhibits evidence of deep glacial erosion and sediment progradation (Johnson et al. 1982). The depth of the shelf is also influenced by the presence of the continental ice sheet via isostatic depression of the crust. The continental shelf break delineates the boundary between the shallow continental shelf and the continental slope, the latter of which represents a steep, ever-deepening incline that can be up to 200 km wide. The continental slope merges with a broad apron of the continental rise at depths of ~2000–3000 m. Together the shelf, slope, and rise constitute the continental margin.

Tectonics

The deep, underlying tectonic context for most of the Antarctic periphery is one of a passive, rifted margin. In such settings the shelf and slope reflect an origin related to continental rifting and subsequent continental drift. The timing of separation between Antarctica and its Southern Hemisphere neighbors ranges from 115 Ma for Africa, 90 Ma for India, 75 Ma for New Zealand (Campbell Plateau), 33 Ma for Australia, to 30 Ma for South America. Such progressive isolation over the last 100 million years is generally believed to have contributed to the development of Antarctica's ice sheet, although it is becoming increasingly clear that punctuated shifts in the earth's atmospheric composition during the Cenozoic may have also played a significant role (Zachos et al. 2001).

The pattern of passive tectonism for the Antarctic margin is broken along a 450 km stretch bordering the South Shetland Islands, near the Antarctic Peninsula. Here a small segment of oceanic crust of the Scotia/Drake plates is actively subducting beneath the edge of the South Shetland microcrustal plate, producing a 5000 m South Shetland ocean trench and associated volcanism. The related South Shetland platform) is narrower (50 km) than the rest of the continental shelves surrounding Antarctica.

The overall deep physiography of the Ross Sea, and indeed much of West Antarctica, is due to protracted crustal subsidence which is focused within continental rifting that borders the Trans Antarctic Mountains. This process of crustal extension is overprinted by glacial erosion, which reduces relief and rift volcanism and uplift that constructs relief.

General Physiography

In many ways the continental shelf and slope surrounding Antarctica escape both the physiographic and political definitions applicable to the rest of the world's continental margins. First, the depth of the Antarctic shelf is far greater than the global average, 500 m versus 100 m. Second, the progressive and gentle seaward slope of most of the world's shelves is not typical for Antarctica. Instead, deep troughs extend well below 1000 m (up to 2000 m) along both the inner shelf, as near coast-parallel features, and out across the shelf itself, as transverse troughs, to the shelf break. Consequently relief is far greater on the Antarctic continental shelf than in any other shelf region of mid to low latitude. However, the shelves of Greenland, Norway, and the NE Canadian Arctic are quite similar to Antarctica because they share a glacial history (Johnson et al. 1982).

The deeper crustal structure of the Antarctic margin is inherited from the rifting phase and, as with most mid to high latitude passive margins, has largely been buried beneath a seaward thickening wedge of terrigenous sediment. In the case of Antarctica the sediment wedge comprises a thick succession of glacial and glacial marine deposits (Anderson 1999) that date back to the earliest Oligocene (Barrett 1999). However due to deep glacial incision across the inner portions of the shelf the underlying structure of the margins is revealed in the pattern of bathymetric troughs which highlight contrasts in crustal composition, such as from crystalline basement to sedimentary rock. These so-called coast-parallel troughs are the deepest features in the world's shelves and some extend to just over 2000 m. They owe their origin to selective linear erosion beneath ice streams and ice sheets over many periods of past glaciation.

In comparison, somewhat more shallow troughs cut across the shelf toward the shelf break and these transverse features are interpreted as sites of enhanced erosion due to localization of convergent flow or ice streaming during Neogene glacial expansion. In both such features mesoscale seabed features such as megascale glacial lineations, bundles, and drumlins, mark the streamlining effect of past glacial flow upon glacial sediments and even bedrock (Anderson 1999; Canals et al. 2000).

Much of the continental shelf of Antarctica (nearly 35%) actually lies beneath large floating ice shelves (some 1.5 million km^2). The implications of this are that much of the bottom remains inaccessible to direct observation. However, bathymetric maps of the sub-ice-shelf seafloor have been produced via geophysical surveys across the ice shelves (Vaughan et al. 1994). A significant portion of the continental shelf also lies beneath impenetrable sea ice, mainly portions of eastern Wilkes Land and in the Amundsen Sea sector. These regions lack any sounding data whatsoever. The future use of robotic survey technology may improve our knowledge of those areas.

Regional Variability in Physiography

The geographic division of West Antarctica and East Antarctica applies equally to the character of the associated continental shelves. West Antarctica includes both the elongate Antarctic Peninsula and the pronounced embayments of the Weddell Sea and Ross Sea.

The Weddell Sea Region

The Weddell Sea is the oldest of the continental margins having formed from the separation of Africa some 115 Ma. The margin is largely covered by the floating extent of the Ronne-Filchner Ice Shelf and the persistent pack ice of the Weddell Sea. The shelf is broad and extends with an unusually wide continental slope and rise to a width of 300 to 500 km. It is delineated by a series of broad troughs and banks including the prominent Crary Trough (1200 m deep, 500 km long, and 100 km wide), Berkner Bank, General Belgrano Bank, and Ronne Basin. The Crary Trough is an extension of the subglacial Thiel Trough, which runs an additional 200 km beneath the West Antarctic ice sheet beyond the grounding line (Drewry 1983).

The Antarctic Peninsula Region

The Antarctic Peninsula presents a striking juxtaposition of two continental margins on opposite sides of an elevated (up to 2.5 km) but narrow (only 50–200 km wide) landmass. The western or Pacific side is broad (on average 200 km wide) and deeply incised into several transverse troughs, the deepest of which extend into near shore areas (Rebesco et al. 1998). The largest of these is the Marguerite Trough, which extends 400 km, from the George VI Ice Shelf between Adelaide Island, Alexander Island, and Palmer Land. The Palmer Deep is one of the deepest inner shelf troughs, dropping to over 1400 m in depth. The Palmer Deep is found offshore Anvers Island and the Graham Land coast, near the US Palmer Station (Domack et al. 2005). The Palmer Deep is like other such inner shelf basins along the western Antarctic Peninsula as it is fringed by a channeled morphology, strongly suggestive of erosion via subglacial meltwater processes (Lowe and Anderson 2002). The channeled regions of the inner shelf transition seaward into a more streamlined glacially sculpted seafloor that is more typical of the rest of the Antarctic continental shelf. Beyond the shelf the continental slope is characterized by extensive sediment mounds and channels that are linked genetically to shelfwide glaciation (Amblas et al. 2005).

The Eastern or Weddell Sea side of the peninsula is less well known and is near inaccessible in most years due to the heavy Weddell Sea pack ice. Yet the shelf here comprises one of the widest features of the Antarctic continental margin extending on average 250 km. It appears to be less deeply incised, as inner shelf troughs extend to 800 to 1000 m, some 400 m less than basins on the western side of the Antarctic

Peninsula. Transverse troughs also appear to be broader with less well defined margins (Evans et al. 2005). But, as with much of the Antarctic margin, a great deal remains to be discovered and mapped in the NW Weddell Sea.

Amundsen Sea Region and the Ross Sea

A significant portion of the continental shelf runs from the Amundsen Sea to the Ross Sea, offshore Marie Byrd Land and Victoria Land. This portion carries from 100° W to 170° E and represents the most varied portion of the entire Antarctic continental shelf. The Marie Byrd Land coast is punctuated by three major embayments: the Ronne Entrance/Eltanin Bay, Pine Island Bay, and Sulzberger Bay. In places the shelf is as wide as 440 km, and is not extensively surveyed. Between these embayments continental promontories extend seaward, causing the shelf to narrow to less than 90 km.

The Ross Sea opens into a very broad shelf that extends beneath the Ross Ice Shelf (Davey 2004). In fact most of the shelf is covered by the ice shelf, with the open water portion extending some 180 to 620 km north, beyond the calving line. In the far western Ross Sea the full width of the shelf runs parallel to the Victoria Land coast and includes some 1200 km, 650 km of which extend beneath the ice shelf to the grounding line. The shelf is marked by a highly lineated set of transverse troughs and banks.

East Antarctic Margin

The East Antarctic continental shelf runs from 170° E to 25° W, roughly from Cape Adare (North Victoria Land) in the east to the Riiser-Larsen Ice Shelf to the west, a total distance of 7800 km parallel to the margin. Much of the margin remains unexplored yet there are some areas of intense study, such as within Prydz Bay. Most work along the margin has been conducted by the Australian Antarctic Division, the Russian Antarctic Program and the Japanese Antarctic Program, with some contributions from the US, Italian, and to a lesser extent the French Antarctic Programs. Within the total length of the continental shelf there are three distinct physiographic regions: Wilkes Land, Prydz Bay, and the composite of Queen Maud Land and Enderby Land continental shelves.

Wilkes Land comprises the eastern sector and on average is 170 km wide with minor deviation from this mean. The shelf is marked by a progression of *en echelon* inner shelf troughs (coast parallel) that project toward the northwest and are interrupted by transverse troughs. The deepest region of the Antarctic continental shelf is found just west of Casey Station where the inner shelf trough reaches just over 2000 m depth (at 66°08′ S and 109°08′ E).

Prydz Bay constitutes a large extension of the Lambert Graben, a rift basin that serves to drain the Lambert Glacier and its floating terminus, the Amery Ice Shelf. The physiography of Prydz Bay is basically like that of a large transverse trough and it extends at least 320 km, making it much wider than the rest of the East Antarctic continental shelf and therefore distinct (O'Brien 1994).

To the west the continental shelf of Enderby Land and Queen Maud Land is uniformly narrow, at about 90 km wide. It is dissected in places by very narrow and somewhat sinuous transverse troughs unique for this margin. A good example is the Nielsen basin, which winds its way across the Mac.Robertson shelf just east of Mawson Station. The Queen Maud Land shelf is distinct as well in that along its western end, toward the Weddell Sea, fringing ice shelves such as the Riiser-Larsen and Fimbul ice shelves cover nearly the entire extent of the shelf where they float out over the upper continental slope or shelf break.

Sediments

Seafloor sediments on the Antarctic continental shelf are varied and range from relict glacial tills, reworked (palimpsest) deposits of varied texture, and recent muds to diatom oozes. Their distribution is controlled by water depth, ice cover, and regional bathymetry. The most recent glacial expansion across the continental shelf took place during periods of lowered sea level coincident with Northern Hemisphere ice sheet growth during the late Pleistocene (about 20,000 years ago). Subsequent melting and recession of the great northern hemisphere ice sheets allowed global sea levels to rise, thus initiating instability along the expanded Antarctic ice sheet periphery that led to recession toward the modern coastline. The seafloor reflects this episode of glacial expansion and retreat in the fact that poorly sorted subglacial sediments (tills) cover most of the continental shelf. In addition these poorly sorted glacial sediments were sculpted by glacial flow into a variety of streamlined bedforms ranging from classic drumlins to increasingly elongate ridges and grooves referred to as megascale glacial lineations and bundles. Morainal banks also mark the glacial termini (Anderson 1999). Where glacial sediments remain exposed at the seafloor they comprise a relict surface which can be observed in many places to be overgrown by epifaunal (encrusting) organisms.

Most commonly the glacial sediments are disturbed by the plowing action of icebergs, a process that may have been more pervasive during deglaciation, when icebergs were probably more numerous and larger than today. Modern iceberg turbation is limited to depths generally less than 400 m and produces a variety of large to intermediate scours, pock marks, and impressions that migrate across the banks and outer continental shelf. In some regions iceberg scour has completely obliterated the relict glacial morphology of the seafloor and resulting palimpsest sediments have been sorted by a combination of iceberg ploughing and resuspension.

In some regions where strong currents interact with the seafloor, such as the outer shelf and shallow banks, bedload transport of sorted sand and bioclastic (skeletal) carbonate takes place forming veneers above the glacial sediment. Some mesoscale bedforms (dunes or sandwaves) result in many of these sandy regions attesting to the efficiency of current action.

The deep troughs of the continental shelf serve as important depocenters for modern (Holocene) mud and ooze. In fact some of the highest accumulation rates in the world's oceans are to be found along portions of the East Antarctic continental shelf, where up to 200 m of Holocene mud and siliceous ooze are to be found. These sediments form distinct deposystems referred to as drifts and drapes that form under the influence of variable bottom currents or blanket the underlying seafloor evenly in the absence of currents, respectively. Their distribution is generally limited to water depths greater than 500 m, within enclosed basins that are separated from the continental slope by broad sills. The accumulation of these fine grained sediments is often so rapid that the occurrence of ice-rafted debris (poorly particles released by icebergs) is often diluted or not evident with the mud. This is a somewhat odd association given the abundance of debris-laden icebergs observed across the continental shelf today.

Bathymetric Database

The General Bathymetric Chart of the Oceans (GEBCO, www.bodc.ac.uk) maintains a compilation of single-channel survey data collected over the years in collaboration with a number of international organizations including the Scientific Committee on Antarctic Research (SCAR). Charts and data are now available digitally as part of a global atlas of the ocean floor. The data are easily accessible although are somewhat lacking in the detail provided by more recent multibeam surveys of the region. At present five nations routinely collect multibeam data across the Antarctic continental margin. The respective nations and platforms are the US Antarctic program (RVIB *N. B. Palmer*), the British Antarctic Survey (RV *James Clark Ross*), the German Polar Program (RV *Polarstern*), the Spanish Antarctic Program (RV *Hesperides*), and the Italian Antarctic Program (RV *Explora*). These data are archived with the various national programs. An Internet-based data set is archived on GeoMapApp (www.geomapapp.org) which includes nearly 75% of all the US multibeam data acquired across the margin in the last 10 years. The most completely mapped region is the northern Antarctic Peninsula and several national programs are collaborating to provide integrated seafloor maps of the region. It is likely that with the onset of the International Polar Year in 2007–2008 several integrated efforts will soon be published or be made available electronically.

Traditional bathymetric charts are published by the US Defense Mapping Agency, the British Admiralty, the Australian Antarctic Division, the Canadian Hydrographic Office, and the German Hydrographic Office. Many of these databases are included in Chilean and Argentinean charts of Antarctic offshore waters. Coarse resolution bathymetric data can also be obtained from electronic versions of satellite data derived from gravity and ocean surface elevations (Smith and Sandwell 1997).

Legal Continental Shelf and Law of the Sea

The United Nations Convention on the Law of the Sea (UNCLOS) treats the continental shelves of the world as economic zones for each country along the respective coastal border. In addition, exclusive economic zones (EEZ) extend to depths beyond the typical continental shelf but to no more than 200 nm. For a number of reasons it is unclear how this agreement applies to the continental shelf of Antarctica. While living marine resources are protected in the Southern Ocean (for instance through the Convention on the Conservation of Antarctic Marine Living Resources agreement) and exploration and/or extraction of mineral deposits is not allowed (the Madrid Environmental Protection Protocol), seabed resources are not clearly protected in any existing agreement. While the establishment of a Special Conservation area with the Antarctic region could (under the Madrid Protocol) protect a portion of marine seafloor from economic activity, the broader rights of any nation under international law related to the high seas are indeed preserved in Article VI of the Antarctic

Treaty. Yet in Article IV, paragraph 2, treaty nations are explicitly prevented from extending or in any way modifying the territorial claims made prior to the signing of the treaty in 1959. Since the EEZ associated with continental shelves went into effect with UNCLOS in 1980 it does not appear that an EEZ can be applied to the Antarctic continental shelf (even if the portion of the shelf in question is adjacent to territorial land claims). This condition will hold as long as the Antarctic Treaty remains in effect.

CONVENTION ON INTERNATIONAL TRADE IN ENDANGERED SPECIES OF WILD FAUNA AND FLORA (CITES)

History

The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) was adopted at Washington DC on 3 March 1973 and entered into force on 1 July 1975. By July 2004 there were 166 state parties. All the state parties to the Antarctic Treaty are also parties to CITES.

The convention originated from concerns expressed at the 8th Session of the General Assembly of the International Union for Conservation of Nature and Natural Resources (IUCN) held in Nairobi in 1963 over "the export, transit and import of rare or threatened wildlife species or their skins or trophies." Between 1964 and 1970 successive texts of a draft treaty prepared by the IUCN Commission on Law were circulated to about ninety governments and international organizations. The driving force was Dr. Wolfgang Burhenne, then chair of the commission and legal adviser to the Bundestag (German parliament).

The IUCN text was criticised (notably by the United States) for its unduly European style, and the negotiations in Washington, D.C., in 1973 were based on an alternative prepared in consultation with the United Nations Environment Programme. UNEP also accepted responsibility for providing the Secretariat to the Convention, although between 1973 and 1984 it used IUCN as its agent. Conferences of Parties to CITES are now held every 4 years in different cities around the world.

Content

CITES has a relatively narrow focus. It seeks to safeguard species that are threatened with extinction by *international* trade. It operates by placing such species in one of three appendices. Appendix I lists those most severely endangered and permits trade only in exceptional circumstances. Appendix II lists species whose international trade is controlled in order to avoid utilization incompatible with their survival. Appendix III lists species that are protected, in particular countries that have asked other CITES parties to assist them by controlling trade. Where trade is permitted, CITES requires detailed export and import certificates, records being supplied to the CITES Secretariat.

Development

Since its adoption, the number of states party to CITES has more than doubled, making it the most widely supported of all international conservation treaties. Revisions of listings in the appendices are considered by Conferences of Parties, where expert advice is provided by IUCN (especially its Species Survival Commission), WWF (the World Wide Fund for Nature), and the UNEP World Conservation Monitoring Centre in Cambridge, UK.

Antarctic Relevance

CITES overlaps with other international legal instruments, including the Antarctic Treaty and its Protocol on Environmental Protection, the International Convention on the Regulation of Whaling, and (potentially) the Convention on the Conservation of Antarctic Seals. All species of great whale are listed in Appendix I, as are fur and elephant seals. These listings have been questioned because there is virtually no commercial trade in these species today, and hence no threat from it—but the listings have been retained because any proposal to resume commercial exploitation would restore what was obviously a severe threat in the past. If whaling were to resume, the products could not be traded internationally unless the species were delisted or transferred to CITES Appendix II, and this would certainly be hotly contested. Similarly, should Antarctic sealing commence, attempts might be made to block international trade in the products by proposing listings under CITES. The convention cannot therefore be wholly disregarded as a potential factor in Antarctic politics.

CONVENTION ON THE CONSERVATION OF ANTARCTIC MARINE LIVING RESOURCES (CCAMLR)

The Southern Ocean surrounds the Antarctic Continent. It is seen as being confined south of the Antarctic Convergence (or Polar Front) at about 50° S where cold Antarctic waters meet warmer northern waters. The Convergence constitutes a relatively effective biogeographical barrier for marine species to the south, thereby characterizing a single, large Antarctic marine ecosystem around the Continent.

Humans commenced hunting and fishing in the Southern Ocean during the eighteenth century. These activities often had extremely negative impacts on the animal populations being exploited and they comprised cycles of intensive fishing followed by depletion of target species then a switch to other stocks. For example, many large whales were virtually exterminated in the early to mid-twentieth century in a harvesting progression that moved from large to small species. A number of Southern Ocean fish species have also been reduced to very low levels.

By the mid-1970s, Antarctic krill *(Euphausia superba)* was seen as a major food item for many Southern Ocean whales, seals, birds and fish, as well as a fishery resource of almost limitless potential. This led to concern that krill overharvesting could negatively affect the entire Southern Ocean marine ecosystem leading to recently protected whale populations failing to recover with other species dependent on krill as a food source also being detrimentally affected.

The 1977 Antarctic Treaty Consultative Meeting therefore initiated negotiations, under Treaty Article IX, which culminated in the 1982 Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR, pronounced "kammelar"). Together with the 1964 Agreed Measures for the Conservation of Antarctic Fauna and Flora, the 1972 Convention on the Conservation of Antarctic Seals and the 1991 Protocol on Environmental Protection to the Antarctic Treaty (Madrid Protocol), CCAMLR is an important element of the Antarctic Treaty System.

All CCAMLR parties are eligible to become members of an associated commission that oversees the convention's implementation. Initially, fifteen states signed the convention in September 1980. Eight of these (Australia, Chile, Japan, New Zealand, South Africa, the Soviet Union [after the dissolution of the USSR in 1991, responsibilities were assumed by Russia], United Kingdom, and United States) subsequently ratified the convention, which lead to its entry into force on April 7, 1982. All these CCAMLR parties became commission members and were later joined by a further sixteen states (Argentina, Belgium, Brazil, France, German Democratic Republic [commission membership ceased on 2 October 1990 following unification with the Federal Republic of Germany], Federal Republic of Germany, India, Italy, Namibia, Norway, Poland, Republic of Korea, Spain, Sweden, Ukraine, Uruguay) and the European Community. An additional seven countries (Bulgaria, Canada, Finland, Greece, Netherlands, Peru, Vanuatu) are parties to the convention, but are not members of the commission.

Excepting seals south of 60° S and whales, the CCAMLR applies to all marine living resources between the Antarctica and the Antarctic Convergence. In carrying out its tasks, the commission works closely with institutions implementing the Convention on the Conservation of Antarctic Seals and the International Convention for the Regulation of Whaling as well as the Committee for Environmental Protection under the Madrid Protocol.

As many animals (e.g., birds) cross the convention's northern boundary, the commission also cooperates with other international organisations and national institutions responsible for living resource management and conservation in adjacent areas or in the oceans generally. Most notably, these include the Food and Agriculture Organisation (FAO) of the United Nations (UN) and the 2002 Agreement on the Conservation of Albatrosses and Petrels. CCAMLR also shares a close affiliation with the Scientific Committee on Antarctic Research (SCAR).

The commission's main objective is to conserve marine life in the area for which it is responsible. This does not exclude harvesting carried out in a sustainable (i.e., "rational") manner following the various principles set out in CCAMLR Article II. Nonetheless, this objective is difficult to achieve. It not only requires the collection of large quantities of information, it also requires development of appropriate management, scientific and analytical techniques.

The commission uses advice from various subsidiary bodies to guide its management activities. These include the Standing Committee on Implementation and Compliance (SCIC) and the Scientific Committee (SC-CAMLR). The latter bases its recommendations on scientific assessments carried out by its Working Groups on Ecosystem Monitoring and Management (WG-EMM) and Fish Stock Assessment (WG-FSA).

As economic interest in CCAMLR-regulated resources increases, there is a growing temptation to harvest these resources in defiance of the organisation's regulatory measures. Since 1996, this has lead to a dramatic increase in illegal, unreported and unregulated (IUU) fishing in the CCAMLR Area, particularly for toothfish *(Dissostichus spp.)*. The Southern Ocean's vastness and inclement weather make it extremely difficult for member states to enforce or police commission measures to combat such fishing. The commission has therefore developed a comprehensive suite of measures, including an innovative scheme to monitor toothfish trade, landings, and imports.

Like many other regional agreements, CCAMLR does not impose or police its own regulations. Rather it agrees on measures that its members are legally obligated to implement and enforce. The recent entry of non-CCAMLR members into the lucrative toothfish fishery has compounded the commission's efforts to combat IUU fishing and promote enforcement of its management measures to the extent that such fishing now constitutes a major threat to CCAMLR's effectiveness.

The commission strives to implement a holistic or ecosystem approach to the management of the resources for which it is responsible. This approach distinguishes CCAMLR from many other international fisheries agreements as it addresses both direct and indirect effects of harvesting on ecological linkages between species. To improve understanding of relevant ecological linkages, the CCAMLR Ecosystem Monitoring Program (CEMP) was set up in 1985 to monitor and understand "natural" as opposed to "human-induced" variability in the Antarctic marine ecosystem. On the strength of such initiatives, the

CCAMLR commission leads the way in developing ecosystem-based approaches to marine living resource management.

CCAMLR's ecosystem approach also requires exercising a level of precaution in developing management measures. This strives to minimize risks associated with unsustainable practices in the face of uncertainty arising from incomplete knowledge of either the fishery, or species, concerned. Again, the CCAMLR commission leads the way internationally in developing precautionary ecosystem management approaches. In particular, its efforts to develop operational definition of key parameters and precautionary reference points preempted many later instruments agreed under the 1982 UN Convention on the Law of the Sea. This has allowed the commission to account for uncertainty in many of its conservation measures and to react in a proactive rather than reactive manner to prevailing, or changing, circumstances.

CONVENTION ON THE CONSERVATION OF ANTARCTIC SEALS (CCAS)

History

The Convention on the Conservation of Antarctic Seals (CCAS) was adopted in 1972 and entered into force in 1978.

Unregulated sealing led to the near-extinction of fur seals, *Arctocephalus tropicalis gazella,* at South Georgia and in the South Shetland and South Orkney Islands between 1775 and 1820. In the twentieth century the resurgent fur seal population at South Georgia was effectively protected and the exploitation of southern elephant seals, *Mirounga leonina,* was strictly regulated. The adoption of the Agreed Measures for the Conservation of Antarctic Fauna and Flora by the Third Antarctic Treaty Consultative Meeting (ATCM) in June 1964 brought special protection to fur seals and Ross seals, *Ommatophoca rossi,* on land and shelf ice south of 60° S, but did not affect the rights of treaty parties on the high seas.

In August–September 1964, MV *Polarhav* made an exploratory voyage to the Antarctic and killed 322 seals in pack ice around the South Orkney Islands. Of these, 218 were crabeaters, *Lobodon carcinophagus,* recognised as the world's most abundant seal, with estimates of total Antarctic populations ranging from 13 million to 35 million animals. Although the theoretical annual sustainable yield from this population was calculated in the millions, there was concern that an unregulated industry might develop and overexploit the resource.

In response, the Scientific Committee on Antarctic Research (SCAR) drew up "Guide Lines for the Voluntary Regulation of Antarctic Pelagic Sealing" in 1966 (extended in 1968). The Convention on the Conservation of Antarctic Seals (CCAS), as a free-standing international legal measure, was negotiated in London in 1972. The driving force behind CCAS was Dr. Brian B. Roberts of the Scott Polar Research Institute and UK Foreign and Commonwealth Office, who believed strongly that international regulations should be drawn up in advance of commercial development and the establishment of vested interests. The initial signatories of CCAS were Argentina, Australia, Belgium, Chile, Japan, New Zealand, Norway, South Africa, United Kingdom, USA, and the USSR. Subsequently, Brazil, Canada, Germany, Italy, and Poland acceded. New Zealand has not ratified CCAS but has attended meetings as an observer, as have Peru and Sweden.

Content

CCAS applies to all seas south of 60° S. The preamble emphasises that Antarctic seal stocks are a resource of potential value which should be used in a rational way, with harvests at or below the optimal sustainable yield, and sealing operations should be conducted in ways that will not disturb natural ecosystems. The initial annual catch quotas were for 175,000 crabeater, 12,000 leopard, and 5000 Weddell seals. Ross, fur, and southern elephant seals are accorded total protection, and Weddell seals are protected in their breeding season. Zones (identical to those used by the whaling industry) are closed to sealing in rotation, and sanctuaries are defined around the South Orkney Islands, in the southwestern Ross Sea and in Edisto Inlet. Records of all seals taken are to be kept, and data exchanged between contracting parties. SCAR is charged with special responsibilities for research and advice on catch limits. The CCAS was to be reviewed by conferences held at 5-year intervals.

Development

Although CCAS entered into force in 1978 and was reviewed in 1988, no commercial sealing has taken place in the Antarctic since its adoption. International opinion has meanwhile hardened against commercial sealing, while the Antarctic region has become increasingly valued as an international protected area. It seems unlikely, therefore, that CCAS will become an operational regulatory instrument, but it remains available for use if the need arises.

CONVENTION ON THE REGULATION OF ANTARCTIC MINERAL RESOURCE ACTIVITIES (CRAMRA)

Following the signature of the Antarctic Treaty in Washington in December 1959, it was predicted that the treaty would collapse as soon as any mineral resource was found worth exploiting. By 1982, no such mineral had been found; so why did the Antarctic Treaty Consultative Parties embark on what many saw as a "mission impossible"? Elsewhere in the world mineral resource activity is regulated on the basis of acknowledged ownership of the resource itself or the land it is in by a person or a state. No such basis existed in Antarctica.

Three arguments led the Consultative Parties, some reluctantly, to take up this challenge. The first was that mineral activity in Antarctica carried environmental risks of a much higher order than elsewhere in the world. (What might happen if an iceberg collided with an offshore oil rig?) The second was that in the absence of a governing agreement, it was not possible definitively to deny that prospecting for minerals in the Antarctic might take place (a high proportion of the world's mineral resources have been found by people who were not looking for them). The third was that if a mineral resource were found in Antarctica before an equitable international regulatory regime had been established, negotiating such a regime afterwards would be virtually impossible.

The negotiations began in June 1982 in Wellington, New Zealand, between Argentina, Australia, Belgium, Chile, France, Federal Republic of Germany (as it then was), Japan, New Zealand, Norway, Poland, the Union of Soviet Socialist Republics (as it then was), the United Kingdom, and the United States. By the end of the negotiations in June 1988 Brazil, China, German Democratic Republic, India, Italy, and Uruguay were also participating as Consultative Parties. The convention consists of 67 articles, covering prospecting for, exploration of, and exploitation of any mineral resources in the Antarctic Treaty area.

In addition to environmental impact assessment procedures required at every stage leading to exploitation there was an innovatory *sufficiency of information test* that had to be passed before any affirmative decision could be made—the information provided in an environmental impact assessment might the best available, but was it sufficient? At each of numerous decision points leading to exploitation it was required that a judgement be made as to whether *enough* was known to make an *informed judgement* about the probable environmental impact were a positive decision to be made—if not, no go.

Had CRAMRA entered into force the development of this sufficiency of information test would have added greatly to the armoury of environmental protective measures available in international law. But within a year after its adoption the convention was dead following the decisions of Australia and France not to ratify it, and within a further two years the convention had been replaced by an outright ban on all mineral resource activity (except scientific research) in Article 7 of the Protocol on Environmental Protection to the Antarctic Treaty (Madrid 1991).

COOK, JAMES

The three voyages of James Cook (1728–1779) are better remembered for the warm seas of the tropical Pacific than for the long and arduous investigations of the icy latitudes. But his systematic demolition of the theories that a southern continent existed in habitable latitudes was a hard-won discovery that brought reality to geographical speculation and left the outlines of the Pacific looking much as they do today.

A southern continent had been appearing on maps and charts since the days of the ancients, who argued that a large land mass had to exist in the Southern Hemisphere in order to balance the continents in the north. The precise size and location of this mythical continent was something of a mystery, but it was generally placed somewhere in the South Pacific Ocean, which, because of the strong westerly currents and winds prevailing in high latitudes, had remained uncharted by European ships entering the ocean from the east, even though they had been doing so since 1520.

In the 1760s, an English East India Company official, Alexander Dalrymple, began forcefully lobbying the British government for a full-scale search for the continent, which, he said, would be found in the latitude of 40° S. The potential commercial rewards were enormous, he argued, for it was larger than Asia with a population of 50 million people and was, moreover, rich in mineral resources. In 1767, Samuel Wallis, aboard *Dolphin,* thought he might have seen this continent's outline on the horizon south of Tahiti. A year later James Cook was ordered to follow up Wallis's report and establish a British claim to the continent once the observations of the transit of Venus at Tahiti—the primary purpose of the *Endeavour* voyage (1768–1771)—were completed.

Cook entered the Pacific in the usual way around the bottom of South America and sailed northwest across the Pacific to Tahiti. From there he made due south for seven weeks but found no trace of the continent and turned back, returning to Britain via New Zealand and Australia. But he was conscious that his had been a tentative foray and one that still left unanswered questions. He began to develop a plan for a systematic search that would take advantage of the prevailing winds and currents rather than fight against them. Instead of entering the Pacific from Cape Horn he would approach from the opposite direction, sailing south from Cape Town into high latitudes and circling the globe in an easterly direction, wintering in New Zealand. This plan became his second and greatest voyage of exploration, on *Resolution* and *Adventure* (1772–1775). As on his first voyage, he took scientists to study the natural history of the continent—not Joseph Banks this time, but the father-and-son team of naturalists, Johann Reinhold and Georg Forster.

Resolution and *Adventure* headed south from Cape Town at the end of November 1772. The expedition searched initially for Cape Circumcision, reported by the French navigator Bouvet in 1739 and believed by him to be part of the southern continent. Bouvet's position was inaccurate, his cape was in fact a small island, and Cook failed to find it anyway, so the ships pushed on south. The cold was intense. Cook issued thick, warm clothing made from a material called "Fearnought," supplementing it with extra rations of spirits as often as he thought necessary. By the middle of December visibility was poor in the frequent snow and sleet storms, and ice was a constant threat to his small vessels, neither of which had reinforced hulls. The icebergs were also a source of fresh water, and as Cook shared the contemporary belief that salt water could not freeze, he thought the ice could only have come from fresh water; he speculated correctly—but for the wrong reason—that land therefore did exist farther to the south, although it would prove to be uninhabitable even if it could be reached.

On January 17, 1773, *Resolution* and *Adventure* became, as far as is known, the first ships to cross the Antarctic Circle. At this point they were unknowingly little more than 70 miles from the continent of Antarctica, but pack ice stretched before them and Cook prudently turned north and east. The ships became separated in thick fog and after again trying to cross the Antarctic Circle but being stopped by ice, Cook headed east towards a rendezvous in New Zealand, where *Resolution* and *Adventure* met again in April 1773.

Here Cook departed from his original plan and spent the southern winter in a leisurely sweep through the central Pacific islands before continuing the search for the southern continent. The ships became separated once more and were not to meet again, as Tobias Furneaux, the commander of *Adventure,* headed for home via Cape Horn and Cape Town, reaching as far as 61° S. The *Resolution,* however, pushed farther south, reaching the exact antipodes of Britain on December 7, 1773, and crossing the Antarctic Circle on December 20. Conditions once more were appalling: the sails froze solid, as did the sheaves in the blocks, "so that it required our utmost effort to get a Top-sail down and up; the cold so intense as hardly to be endured." Cook turned north, causing great excitement and relief among the crew. Their hopes were dashed a few days later when he turned south again, having achieved his aim of intersecting his old course across the Pacific in 1769, so establishing that the continent could not exist in that particular triangle of the ocean. On January 30, 1774, they reached a new farthest south, 71°10′ S, and were prevented from going farther by ice.

Although he had proved conclusively that a southern continent did not exist in the Pacific and the original intention had been to now return to Britain, Cook decided to spend one more summer extending the search into the South Atlantic. The decision was not popular among his exhausted officers, scientists, and crew, but the next spring the ship obediently turned south once more, discovering the isolated island of South Georgia, which impressed no one, before finally setting a course for Cape Town and home. "A final end [has] been put to the searching after a Southern Continent," wrote Cook with some feeling, "which has at times ingrossed the attention of some of the Maritime Powers for near two Centuries past and the Geographers of all ages."

COPEPODS

The subclass Copepoda is a group of small aquatic crustaceans arguably forming the most abundant multicelled animal group on the planet, exceeding even insects and nematodes in number. The name copepod is derived from the Greek words "kope" meaning "oar" and "podos" meaning "foot," referring to their paddlelike swimming legs. They are diverse, with more than 10,000 species described, inhabiting aquatic habitats worldwide, from the deepest ocean trenches to Himalayan lakes. They comprise both free living and highly specialised symbiotic and parasitic forms. Free-living copepods are planktonic (i.e., drifting in the water), in marine, intertidal, and freshwater habitats and also occupy sediments, seaweeds, and damp terrestrial and subterranean habitats. Planktonic copepods, the most numerous and ecologically important group, are typically small, often 0.5–5 mm, and are segmented. Copepods are highly adapted to aquatic life, with their fossils dating back at least to the mid-Cretaceous period, more than 100 Ma.

In the Southern Ocean, copepods are the most numerous and conspicuous components of the zooplankton (i.e., animal plankton). Here, their diversity is highest in the warmer water found at depth, where many species characteristic of lower latitudes are found. The colder surface layers are characterised by low copepod diversity, and a high proportion of large, endemic Antarctic species.

Three orders of copepods are prevalent in Antarctic waters. The first, Calanoida, includes characteristic marine species such as *Calanoides acutus, Calanus propinquus,* and *Rhincalanus gigas,* and the freshwater *Boeckella poppei*. The second comprises a group of highly numerous small species including *Oithona similis,* which can exceed 10,000 individuals per m^3 of seawater. The third group, Harpacticoida, includes *Drescheriella glacialis,* one of the few species adapted to exploiting the rich feeding within sea ice.

Both in Antarctica and worldwide, the free-living copepods form important intermediaries in the food web. By feeding on phytoplankton (i.e., planktonic algae) and protozoans, they connect the base of the food web to higher trophic levels. Major copepod predators in Antarctica include petrels and fish, as well as a wide range of larger zooplankton species. Therefore, alongside Antarctic krill, they are important in the marine ecosystem, both in terms of supporting commercially fished species and in terms of biogeochemistry, in the ocean carbon cycle. In addition to herbivorous copepods, there are also many detritus feeders, omnivores, and carnivores.

The life cycles of the important planktonic copepods of Antarctica involve egg laying, often in the spring at the time of the phytoplankton outburst or "bloom." This timing provides a food resource for the various instars to grow rapidly in near-surface layers in spring and summer, moulting through six nauplius stages and six copepodite stages. The last copepodite stage is the adult, which completes the life cycle. Given the intense seasonality of polar marine habitats, winter food can be scarce for herbivorous zooplankton. Thus copepods may overwinter in diapause at depth (similar to hibernation), or by feeding at low rates and more carnivorously, or by feeding on algae associated with sea ice.

CORMORANTS

Cormorants are web-footed, mainly fish-eating, aquatic birds, occurring in both marine and fresh waters. They belong to the avian order Pelecaniformes, which they share with five other families: the pelicans, gannets and boobies, darters (anhingas), frigate birds, and tropic birds. A total of thirty-five species is usually recognized, all within a single genus and family (*Phalacrocorax,* Phalacrocoracidae), although some taxonomic treatments allow for more genera and a greater number of species. Cormorants are widespread globally, occurring in most seas and on inland waters on nearly all continents. They are largely absent, however, from tropical marine waters.

Only one species is a breeding resident within Antarctic and sub-Antarctic waters, the imperial cormorant *Phalacrocorax atriceps,* for which a number of taxa has been described. A modern genetic study has yet to be published on this taxonomically confusing group, so the conservative treatment followed here should not be regarded as the last word on the subject. Indeed, it is quite likely that the various taxa will be awarded full species status (as they are already in some accounts). If this happens, then many of them will automatically become single-island or island group endemics, and will then have to be considered for inclusion within the "red data list" of globally threatened species.

Overview of Biology

The imperial cormorant (often referred to as the imperial shag, and also as the blue-eyed cormorant or shag) is a large, primarily blue-black (dorsally) and white (ventrally) seabird with a thin, hooked bill, striking blue orbital ring, bright orange caruncles (bare raised skin) at the base of the bill and, in prebreeding or display plumage, a distinct crest. The closed wing usually (but not in all taxa) shows a white bar. Legs and feet are a dark pink in adults. Juvenile birds are less brightly marked, without obvious eye ring, caruncles or crest, and their dorsal plumage is more brown than black. Nonbreeding adults are also less conspicuous, usually lacking a crest. The species has a body length of 65–75 cm and a body mass of 2000–3500 g. The sexes are alike in appearance, although like all cormorants, males are somewhat larger and heavier than females. There are slight differences in size and appearance between the various taxa recognized within the species group.

Imperial cormorants have a large range, occurring in southern South America, the Antarctic Peninsula, and at most maritime Antarctic and sub-Antarctic islands in the southern Atlantic, Indian, and Pacific oceans. The species is absent from the larger part of the Antarctic Continent. It also does not occur on the more northerly cool-temperate islands of the

Southern Ocean, such as the Tristan da Cunha Group in the south Atlantic or on the various island groups south of New Zealand (the latter of which each have their own distinct species of island-endemic cormorants). Other than in South America, where some birds can be found on freshwater lakes, the imperial cormorant is a strictly marine species. The total population has been estimated as between 300,000 and 1,300,000 individuals, the large range reflecting the lack of adequate surveys at many breeding sites. Because of its large numbers and wide range, it is not considered to be globally threatened, and has thus been classified as "Least Concern" by BirdLife International.

Imperial cormorants breed in colonies during the austral summer, usually close to the water's edge on raised rocks or on cliffs tops and offshore stacks, building nests of seaweed and terrestrial vegetation that becomes cemented by guano. Prior to breeding, adult birds assume a "prenuptial" plumage, with the crests being particularly noticeable. Birds breed monogamously, with incubation and chick-rearing duties shared between the sexes. However, the male first occupies the nest site and builds the nest. For seabirds, fidelity to mate is low (as it seems to be in several cormorant species studied in detail, so it may well be a general trait of the whole family), and birds often take new partners between seasons. They lay from two to four white unmarked eggs, which they incubate by drawing them onto their webbed feet. Staggered hatching leads to young of differing sizes, which compete for food regurgitated by their parents; as a consequence only the older (and larger) chicks may survive to fledging. Breeding may commence at three years of age, but the average age of commencement is closer to five years. Breeding success fluctuates from year to year, probably related to changes in the inshore food supplies of the species.

The species is a resident one, not undertaking any migrations of note. It is an inshore forager during daylight hours, diving from the sea surface and foraging on the sea bottom, primarily on fish, but also on crustaceans and cephalopods (octopuses). Individual dives may last a few minutes, partially correlated to water depth. Foraging may be solitary or take place in groups of up to several hundred birds, when synchronized diving can occur. A foraging trip normally consists of a series of dives over a period of an hour or more, interspersed with rest periods on the sea surface. Prey is usually swallowed underwater, but large prey items may be brought to the surface, presumably to make them easier to swallow.

The imperial cormorant appears to have few natural enemies, although skuas *Catharacta* spp. may snatch eggs or small chicks from inadequately guarded nests. The species is susceptible to human disturbance, when temporarily deserted nests will often loose their contents to aerial predators. It is also susceptible to oiling and there are records of birds drowning in fish traps and nets.

The *"atriceps"* cormorant group is usually recognized as consisting of seven taxa, each of which is considered in detail to follow.

Blue-Eyed Cormorant *P. [atriceps] atriceps*

This taxon is restricted to southern Argentina and Chile and to the Falkland Islands. The Falklands population (which has also been described as belonging to *P. [atriceps] albiventer* and is sometimes called the king cormorant) has been estimated as between 45,000 and 84,000 breeding pairs, representing 135,000 to 252,000 birds. "Albiventer" may be distinguished from the majority of South American birds by having black instead of white cheeks, giving it a black-faced appearance. However, the forms co-occur in South America, where mixed pairs have been observed, resulting in the black-faced albiventer birds being considered a colour-morph of a polymorphic taxon and not a distinct taxon of its own.

The Falklands population breeds in densely packed colonies of up to several hundred pairs on flat cliff tops, often associated with rockhopper penguins *Eudyptes chrysocome* and black-browed albatrosses *Thalassarche melanophrys*. Breeding takes place from October to February. Outside the breeding season, birds use breeding sites as roosts. The taxon forages on small fish and crustaceans in large flocks, notably in winter when not breeding.

The blue-eyed cormorant coexists on the Falklands with the rock cormorant or shag *P. magellanicus,* which is smaller in size, and usually forages singly in shallower, more inshore waters among kelp beds. The Falklands population (the species is also found in South America) has been estimated as 32,000 to 59,000 pairs. It breeds in the austral summer (September to February) in small colonies on cliff ledges. The rock cormorant may be told apart from all *atriceps* cormorants by its red, not orange, bare facial skin that extends around the eye, and an all-black head and neck save for a white cheek patch. In breeding plumage the crest is noticeably smaller than that of the imperial group of cormorants.

All the other *atriceps* cormorant taxa are the sole breeding representatives of their family where they occur, so their identification is unproblematic.

Antarctic Cormorant *P. [atriceps] bransfieldensis*

The Antarctic cormorant is found on the Antarctic Peninsula and on the South Shetland Islands, and is thus endemic to the Antarctic Treaty area. It is the most southerly breeding cormorant, and, indeed, the most southerly member of its order. This taxon is among the largest of the *atriceps* group of cormorants, reaching 3.25 kg in mass. Antarctic cormorants are white-faced, with the white cheek line extending to or above the eye, distinguishing them from the Falklands Islands' blue-eyed cormorants. Its population has been estimated at 40,000 birds. The species appears to be sedentary in the main, although local movements occur to seek out open water.

The taxon breeds colonially, in colonies, often of 20–40 pairs but sometimes larger—729 nests were counted in 1985 in one colony on Cormorant Island, near the United States' Palmer Station on Anvers Island. Breeding colonies are often intermixed with those of pygoscelid penguins, especially the chinstrap *Pygoscelis antarctica* and the gentoo *P. papua*. Foraging in shallow waters occurs singly or in small flocks. Diet consists of fish, mainly Antarctic rock cod of the family Nototheniidae, cephalopods, and crustaceans, such as isopods and euphausiids (krill). Interestingly, clear patterns in timing of foraging occur, with males and females being away from nests during different time periods.

The Cormorant Island population was severely affected by an oil spill in 1989, leading to a local population decline from about 970 pairs to 165 pairs in 1996. Mass chick starvation has been observed, leading to low breeding success at times. Population declines since the 1980s have been recorded at several other sites within the taxon's range, with changes in abundance of juvenile year-classes of prey fish suggested as the cause.

South Georgia Cormorant *P. [atriceps] georgianus*

As is to be expected from its common name, this taxon occurs on the sub-Antarctic island of South Georgia. It also breeds on the Shag Rocks in the Scotia Sea, and on the maritime Antarctic South Orkney Islands and South Sandwich Islands. However, some accounts place the South Sandwich and South Orkney populations with the Antarctic cormorant. The South Georgia cormorant is very similar in appearance to the Antarctic cormorant, but the white cheeks do not extend quite as high, with the line of demarcation from the black cap passing through the ear coverts rather than reaching the eye. The taxon's total population has been variously estimated as 20,000 birds and 7500 to 11,000 pairs. Perhaps 1000 pairs occur on the isolated Shag Rocks and 2000 pairs at the South Orkneys, with the larger South Georgia population estimated as 4000 pairs. The South Sandwich Islands' population is not well surveyed but has been said to be between 100 and 1000 pairs in size. In 1997, only an estimated 265 pairs were found on two of the islands in the group (Montagu and Bristol), with a colony of about 100 pairs on a third island (Zavadoski) found previously apparently no longer present.

The South Georgia cormorants breeds in often small colonies (less than 100 pairs) on sea cliffs and islets in the austral summer, laying two to three eggs in November–December. It is a sedentary taxon, foraging solitarily or in small groups in shallow, inshore waters on nototheniid fish. In whaling and sealing days South Georgia cormorants were sometimes taken for food, but are now largely unthreatened.

Crozet Cormorant *P. [atriceps] melanogenis*

The Crozet cormorant occurs on two island groups approximately 950 km apart in the southern Indian Ocean: South Africa's Prince Edward Islands and the French Îles Crozet. This taxon is one of the black-faced forms of the imperial cormorant. The total population was estimated as 1500 pairs in 1980s, placing it (along with the Heard and Macquarie cormorants) among the rarest forms of the imperial cormorant. At the Prince Edward Islands the population on the larger Marion Island has declined with numbers of breeding pairs dropping by 68% from 841 in 1994–1995 to 272 in 2002/2003. During this period breeding success has generally been too low to sustain the population, with mortality of chicks attributed to starvation. The population on little-visited and smaller Prince Edward Island was 120 pairs in 1984 but only 50 pairs in 2001. These decreases have coincided with a period of warming that is thought to have affected the cormorant's prey (primarily nototheniid fish, but also octopuses and the shrimp *Nauticaris marionis*). The Îles Crozet population was estimated as 815–835 pairs in 1981–1982.

At Marion Island birds breed on coastal cliff tops and offshore rocks in small colonies, mainly in summer, although winter breeding has been reported. Breeding sites are also used as winter roosts by nonbreeding birds. Foraging occurs singly or in small groups, mainly among the kelp beds close inshore. Crozet birds may forage up to 6 km from shore.

There are no records of banded birds moving between the two island groups, so the Prince Edward and Crozet populations would appear to be reproductively isolated (and may thus be genetically distinct). At the Prince Edward Islands all cormorant colonies have been zoned as Special Entry Areas from 2005, with entry (within 100 m of nests) allowed under permit issued for monitoring and research purposes only. (This measure was taken to reduce human disturbance since Subantarctic skuas are known to take eggs and small chicks from unattended nests.) However, it seems doubtful that this action will be sufficient to reverse the population's decline. If a genetic study resulted in the Crozet cormorant attaining specific status, there seems little doubt it would be awarded the threatened category of Endangered.

Kerguelen Cormorant *P. [atriceps] verrucosus*

This taxon is restricted to Îles Kerguelen, a French sub-Antarctic possession in the southern Indian Ocean. Kerguelen is the largest of the sub-Antarctic island groups, and probably as a consequence supports a large cormorant population, variously estimated as 30,000 to 35,000 birds, and as 10,000 to 12,000 pairs in the mid-1990s. The population appears to be stable. The Kergeulen cormorant is the smallest of the taxa within the imperial cormorant complex, with a length of 65 cm and a mass reaching only 2.2 kg. The bill is noticeably slender and short. The Kergeulen cormorant is black-faced and most birds lacks the white wing bar common the other forms, making it overall the darkest taxon. Birds with white in their wings occur only in eastern parts of Kerguelen and it has been hypothesized their recent presence might suggest the arrival of individuals from other island groups in the southern Indian Ocean. However, there have been as yet no genetic studies published to check this idea. The species is sedentary, although there are local movements reported from within the island group. Single records of birds from Western Australia and Heard Island are known or thought to be ship-assisted.

Breeding colonies may be large (up to 400 nests) in the eastern part of the island, but small colonies of three to thirty pairs are more usual.

Birds forage in sometimes large groups, mainly in the sheltered bays that are common along the island group's heavily indented coastline. However, there are records of juveniles 80 km from land, reflecting the large area of shallow water, equivalent to a continental shelf (required for a bottom feeder), which is absent at other sub-Antarctic islands.

Heard Cormorant *P. [atriceps] nivalis*

The Heard Cormorant is found only at the Australian Heard Island in the southern Indian Ocean. It has not been recorded at nearby McDonald Island 40 km away. This is a large member of the imperial group, weighing as much as 3.3 kg. It is a white-faced taxon, in appearance more similar to the Antarctic and South Georgian taxa than to those occurring on the geographically closer sub-Antarctic islands of the southern Indian Ocean.

The island's total population was thought to be no more than 1000 birds, with the breeding population fluctuating from 90 to 200 pairs. However, in 2000–2001 a new colony was discovered at Cape Pillar on the remote and rarely visited southwestern side of the island, containing about a thousand nests. Previously only three much smaller breeding sites were known. Thus has suggested that the total population is more of the order of 2500 to 3600 birds. The discovery of the Cape Pillar colony explains earlier (and puzzling) observations of up to 600 roosting birds, which far exceeded the then estimates of the total size of the breeding population.

This is a little-studied taxon. Diet is broadly similar to those of the other forms of the imperial cormorant group: fish, cephalopods, and crustaceans, especially polychaetes, with birds foraging by pursuit diving close inshore.

Macquarie Cormorant *P. [atriceps] purpurascens*

The most easterly of the imperial cormorant taxa, the Macquarie cormorant occurs only at the Australian Macquarie Island and the Bishop and Clerk Islets 33 km to the south. The latter population may be an isolated one. The taxon is a large, black-faced form, considered most closely related to the Crozet and Kergeulen cormorants. The taxon's total population has been recently estimated as 3750 birds with 1250 breeding pairs. In the 1970s, the total population was put at 760 pairs. Perhaps 100 pairs occur at Bishop and Clerk Islets, although census data are sparse. Twenty-three breeding colonies are known (3–320 nests), not all active every year, and breeding numbers fluctuate annually.

The diet consists mainly of fish, but also crustaceans and polychaetes, caught by solitary diving during the summer breeding season, although small foraging flocks of up to forty birds may form in winter months, diving simultaneously.

Birds have been killed by collision with aerials, and chicks have been killed by Subantarctic skuas and possibly by feral cats *Felis catus,* now thankfully eradicated from the island. Breeding failure sometimes follows heavy storms. Indeed, the whole imperial cormorant group is at risk from losing nests and their contents to bad weather, as all taxa breed close to the water's edge. Rough seas may also inhibit foraging by breeding birds, leading to starvation of chicks and lowered breeding success. Poor weather and changes in food supply are most probably the driving forces behind the large population fluctuations that have been observed at many breeding localities, both at Macquarie and elsewhere.

The larger and all-dark Great Cormorant *P. carbo* has been recorded more than once as a nonbreeding vagrant at Macquarie Island. This species breeds in both Australia and New Zealand, so either may be the source.

COSMIC MICROWAVE BACKGROUND RADIATION

The Cosmic Microwave Background Radiation (CMBR) is broadband radio emission from the early universe. Its brightness as a function of frequency is a nearly perfect blackbody or Planck curve that increases with frequency up to 168 GHz and declines exponentially at higher frequencies. The blackbody temperature characterizing the radiation is 2.7 K. The CMBR was emitted by normal matter about 400,000 years after the Big Bang, some 13 billion years ago, at the "time of recombination." Previous to the time of recombination, electrons and ionized nuclei were embedded in an all-pervading sea of photons, similar to the interior of the Sun. At the time of recombination, the electrons and nuclei combined to form atoms, allowing the sea of photons to stream freely through a now nearly transparent universe. After billions of years, those photons, highly redshifted by the universal cosmic expansion, have become the CMBR we see coming from all directions today.

The CMBR was first observed by Arno A. Penzias and Robert W. Wilson at Bell Laboratories at Crawford Hill, New Jersey, in 1964. Cosmologists soon recognized that the existence of the CMBR was strong evidence for the Big Bang theory, and that further observations should show small departures from a perfect blackbody curve, as functions of direction on the sky, frequency, and polarization. These departures, or anisotropies, result from small irregularities in the early universe, the same irregularities that eventually evolved into stars and galaxies. Thus began a new field of observational cosmology, the quest to detect and study CMBR anisotropy. This goal was vigorously pursued by many scientific groups for decades, but there was little initial success. It became clear that the anisotropies were very small, about one part in a million, and that noise in the data caused by fluctuations in the Earth's atmosphere was a serious problem when making the observations. CMBR instruments were placed on high mountain sites, in balloons, and on satellites in space. By 1992, the Cosmic Background Explorer (COBE) satellite launched by NASA detected CMBR anisotropy by comparing patches of sky that were separated by angles of 7° or more. This is "large scale" anisotropy, and its measurement provides information about primordial physics. This was just the beginning. Measurement of anisotropies on smaller scales could provide information on the ultimate fate of the universe, the mechanism of galaxy formation, and unknown physics. Of particular interest is the increase in CMBR fluctuations at a scale size of 1° on the sky, which are created by gravity-driven sound waves at the time of recombination and are therefore known as the acoustic peak. The Sunyaev-Zel'dovich effect occurs when CMBR photons are scattered by foreground clusters of galaxies, resulting in anisotropies at scales of 0.03°. The CMBR is also slightly polarized, and the way in which it is polarized can distinguish between different theories of the early universe. Small-scale measurements require large telescopes that would be expensive, perhaps prohibitively expensive, to launch into space. Scientists therefore searched for the best possible telescope sites on the Earth's surface, and that search led to Antarctica.

The Antarctic Plateau is an exceptionally good site for CMBR observations. The altitude is fairly high, but more important are the cold temperatures and the low level of absolute humidity. The dominant source of error in ground-based CMBR measurements is thermal radio emission from irregular blobs of atmospheric water vapor being blown across the aperture of the telescope by the wind. This is called sky noise. Less water vapor and colder water vapor both result in less sky noise and hence more accurate measurements. Cold air can hold only a little water vapor. Air at the freezing point of water (0°C) can hold over 80 times more water than air at the South Pole's average annual temperature of –49°C. The amount of water vapor in a column of air extending through the entire atmosphere is measured by the precipitable water vapor (PWV), the amount of rain that would fall if all the water vapor within that column were somehow turned into rain. The average level of PWV at the South Pole in the winter is 0.25 mm. This compares to 1.65 mm at the top of Mauna Kea in Hawaii (an excellent high-altitude observatory site), and several centimeters at a typical place on the Earth's surface. The South Pole is an excellent site for CMBR observations, and higher locations on the Antarctic Plateau are probably better still.

The first attempt at CMBR observations from the Antarctic Plateau was an expedition to the South Pole in December 1986 by Mark Dragovan, Antony A. Stark, Robert Pernic, and Martin A. Pomerantz, under the sponsorship of the US Antarctic Program with support from Bell Laboratories. No CMBR anisotropies were observed, but sky noise and opacity were measured. The results were sufficiently encouraging that in the Austral summer of 1988–1989, three CMBR groups led by M. Dragovan, Jeffrey Peterson, and Philip Lubin participated in the "Cucumber" campaign, where three Jamesway tents and a generator dedicated to CMBR anisotropy measurements were set up at a temporary site 2 km from Amundsen-Scott Station. These were summer-only campaigns, where instruments were shipped in, assembled, tested, used, disassembled, and shipped out within a single three-month-long summer season. Considerable time and effort were expended in establishing and then demolishing observatory facilities, with little return in observing time. What little observing time was available occurred during the warmest and wettest days of midsummer.

Wintertime observations became possible with the establishment in 1990 of the Center for Astrophysical Research in Antarctica (CARA), a National Science Foundation Science and Technology Center. CARA developed year-round observing facilities in the "Dark Sector," a section of Amundsen-Scott South Pole Station that is dedicated to astronomical observations. CARA scientists fielded several CMBR instruments: White Dish, Python, Viper, Arcminute Cosmology Bolometer Array Receiver (ACBAR), and the Degree-Angular Scale Interferometer (DASI). By 2001, data from these instruments, together with Boomerang (Balloon Observation of Millimetric Extragalactic Radiation and Geophysics), a CMBR experiment on a long-duration balloon launched from McMurdo Station on the coast of Antarctica, showed clear evidence for the acoustic peak in the

CMBR anisotropy at an angular scale of 1°. This is interpreted to mean that the overall geometry of the universe is flat, as opposed to being positively or negatively curved. Soon thereafter, this result was confirmed and improved by the Wilkinson Microwave Anisotropy Probe (WMAP) satellite launched by NASA. In 2002, the DASI group led by John E. Carlstrom reported the detection of polarization in the CMBR. These observations strongly support a "Standard Theory" of cosmology, where the dynamics of a flat Universe are dominated by forces exerted by the mysterious Dark Energy and Dark Matter.

CMBR observations continue on the Antarctic Plateau. The South Pole Telescope (SPT) is a 10 m diameter offset telescope designed to measure anisotropies on scales much smaller than 1°, especially the Sunyaev-Zel'dovich effect. This is a scattering of CMBR photons by hot electrons in clusters of galaxies. It is an efficient way to discover clusters of galaxies at high redshift, which are otherwise difficult to detect. A comprehensive survey of galaxy clusters is planned using the SPT, with the aim of better understanding Dark Energy.

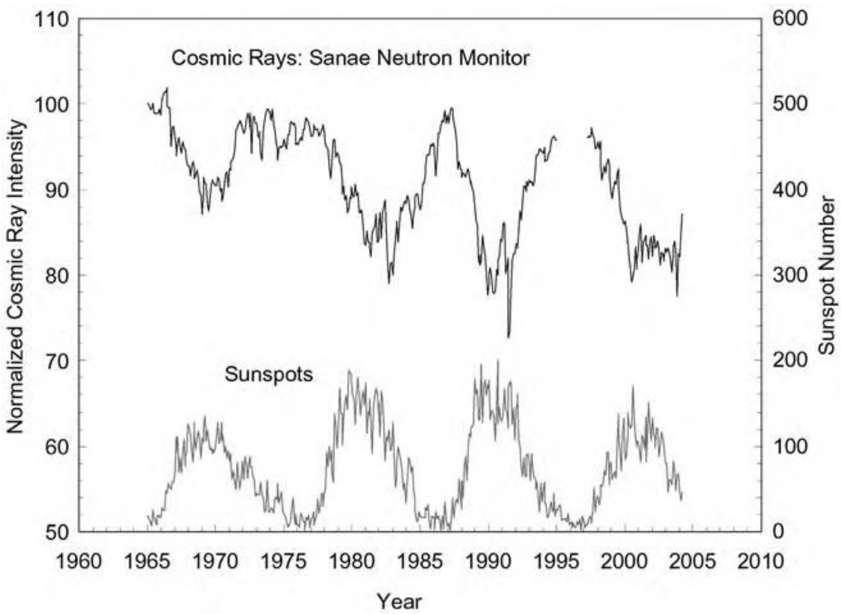
COSMIC RAYS

Introduction

Cosmic rays are charged particles—not rays—coming from the cosmos. They are characterized by extremely high energies. This radiation was discovered by Victor Hess on his famous balloon flights in 1912, when he found that the "natural background radiation" increased with altitude, against his expectation that it would decrease as he moved farther away from the presumed radiation sources inside the Earth. It took until the mid-1930s to establish unambiguously that these "rays" were particles, and it has subsequently been learned that they consist about 90% of protons (H nuclei) and 9% alpha particles (He nuclei). The remaining percent or so is made up of heavier nuclei, electrons, and positrons. This composition is very similar to that of "ordinary," low-energy matter in thermal equilibrium in the universe.

Cosmic ray energies are indeed extremely high. Particles with energies higher than one million (10^6) electron volts (eV) are generally classified as cosmic rays. Cosmic rays with energy in excess of 10^{20} eV have been detected. The number of cosmic rays decreases with increasing energy, and only a few of these 10^{20} eV particles have been observed. In more common units, an amount of energy of 10^{20} eV is equivalent to about 10 joules (J). To get a feeling for these numbers, a 100 watt (W) light bulb uses 100 J of electricity per second, the metabolism of the human body is a 100 W machine, and a small ball weighing 50 grams and flying at 100 km per hour has about 2000 J of energy. Against these numbers, 10 J of energy in a cosmic ray does not sound like much, but bear in mind that this energy is all concentrated into one single elementary particle, instead of the 10^{24} particles or so contained in the ball! Another way to look at this is that this energy is about one million times higher than can be achieved with the largest particle accelerators. This implies extremely efficient acceleration mechanisms in the cosmos, and one of the prime aims of cosmic ray research is to find the sources that can do this. During the last 30 years it has become ever better established that cosmic rays with energies up to 10^{15} eV are accelerated by the blast waves of supernova remnants in our own galaxy, while those with higher energies have been accelerated several times by such remnants, or may come from other galaxies.

It is difficult to pinpoint these cosmic ray sources because cosmic ray astronomy is fundamentally different from the well-known optical astronomy, and its



Count rate of the SANAE neutron monitor, with the number of spots on the surface of the sun.

more general cousins of radio, x-ray, and gamma ray astronomy. In the latter cases, the electromagnetic waves or photons travel in straight lines from the source to the observer. Thus, when one sees light from a certain direction, one knows where the source of that light is, and from the brightness and color of that light (intensity and frequency), one can immediately start to analyze the properties of the source. For cosmic rays this is different, because the universe is pervaded by magnetic fields: the geomagnetic field around the Earth, a heliospheric magnetic field that is set up by the Sun and blown away for several 100 Sun-Earth distances by the solar wind. (One Sun–Earth distance is called an astronomical unit, or AU.) Beyond that, there is an interstellar or galactic magnetic field, while there is even an intergalactic field between individual galaxies. According to the standard theory of magnetism, the charged cosmic ray particles spiral around these magnetic field lines. This corkscrew motion makes them slide along the magnetic field direction, while they cannot readily move in directions across the field. Since these fields are random, the cosmic rays get scattered, and once they arrive at Earth, their arrival direction has become entirely unrelated to the direction of their source. This means that the origin and properties of cosmic rays must be unraveled differently, and this is primarily done by measurement and study of (1) their energy spectrum (i.e., the number of cosmic rays as function of their energy); (2) their composition, which is the number of cosmic rays of different type; and (3) their anisotropy, which is the number of cosmic rays as function of direction in the sky.

Cosmic ray experiments in Antarctica can be divided into two categories: experiments at high energies that basically search for the sources of cosmic rays in the galaxy, and those at lower energies that study the propagation of cosmic rays in the heliosphere and the geomagnetic field. This second category will be discussed first.

Cosmic Ray Modulation Studies with Neutron Monitors

The counts of the SANAE neutron monitor show that the cosmic ray intensity at these lower energies, typically from 10^9 to 10^{10} (one billion to 10 billion) eV, varies with time. It has become well established that this variation is in response to solar activity. The Sun's atmosphere is so hot, with a temperature of about 10^6 degrees, or equivalent particle energy of about 100 eV, that it blows away supersonically at 400 km/s, and is called the solar wind. (Notice, however, that this solar wind energy is so low that the particles do not nearly qualify to be called cosmic rays.) The Pioneer 10 and Voyager 1 and 2 spacecraft have observed this wind up to 100 AU from the Sun. Since it is fully ionized, a state of matter that is called a plasma, this wind carries the solar magnetic field with it, and this solar plasma and magnetic field set up a region around the Sun that is called the heliosphere. Cosmic rays must work themselves in along this outward moving field to be observed at Earth. The plasma and field properties vary with time, with the dominant variation being an 11-year cycle, as observed for instance by the number of sunspots. It indicates that when solar activity is high, the cosmic ray intensity is low and vice versa. This 11-year cycle is also seen in the wind speed and strength of the magnetic field in the heliosphere. Thus, the cosmic ray intensity varies opposite to solar activity because when the Sun is active and the heliospheric field strong and turbulent, it is more effective to keep the cosmic rays away from the inner parts of the heliosphere (and Earth). This process is called heliospheric modulation of the cosmic ray intensity.

The neutron monitors that record this modulation process are large proportional counters, almost 2 m long and 15 cm in diameter, embedded in lead and wax (or polyethylene) boxes. They were designed in the late 1940s by John Simpson of the University of Chicago, and they work as follows: When a cosmic ray strikes the atmosphere, it breaks up the nuclei of air molecules to form secondary particles, so that deep inside the atmosphere one ends up with a shower of secondaries from the single cosmic ray. Some of these secondaries are neutrons. These neutrons are captured in the $^{10}BF_3$ gas inside the proportional counter to produce electrically charged alpha particles, which are attracted to the high voltage wire of the counter, and are registered electronically. The neutrons will, however, be captured in the gas of the counter only if they are slowed down. This is achieved by the wax/polyethylene around the counter. The detection efficiency for neutrons is only a few percent, so there is also a lead ring around the counter that produces up to ten additional neutrons for each one striking a lead nucleus. In this way, a neutron monitor registers approximately one count for every cosmic ray hitting it. Neutron monitors can have up to twenty of these counters, and because of the lead, they are massive, at about 3 tons per counter.

There are approximately forty of these neutron monitors around the Earth that measure variations in the cosmic ray intensity. Of these, eleven are in the Southern Hemisphere, with six in Antarctica. These six are Larc, Mawson, McMurdo, SANAE, South Pole, and Terre Adelie.

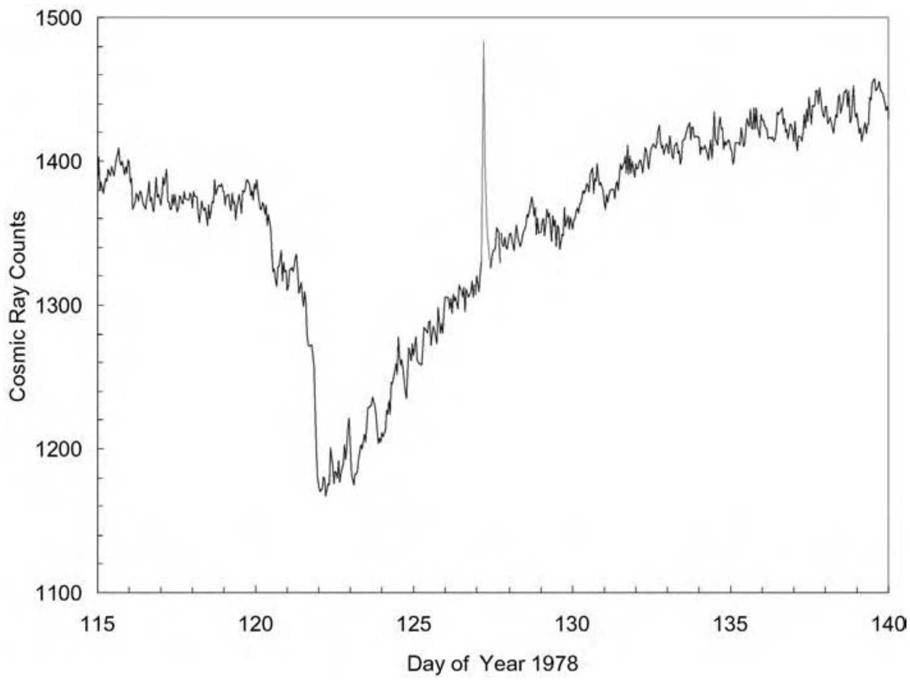
The French group also operates a neutron monitor on sub-Antarctic Îles Kerguelen (49°35′ S, 70°22′ E). Apart from these currently operating neutron monitors, the following Antarctic ones existed for some time since the early 1960s: Cape Hallet (USA), Casey/Wilkes (Australia/USA), Ellsworth (USA), General Belgrano (Argentina), Mirny (USSR/Russia), Syowa (Japan), and Vostok (USSR/Russia).

The form of the geomagnetic field is the primary reason for placing neutron monitors in Antarctica. This field is dipole-like, and it becomes more radial with increasing latitude away from the equator. This means that cosmic rays "slide in" easier along this field in the polar regions than at lower latitudes, leading to more low energy particles at the poles. These low energy particles are more subject to variations in the solar and heliospheric parameters, leading to larger modulation effects. This is a good example of why the polar regions are appropriately called "windows into geospace."

Apart from the 11-year modulation, there are also shorter-term changes in the cosmic ray intensity. The graph shows the variations seen on the SANAE neutron monitor from April 25 (day 115) to May 20 (day 140) in 1978. The big decrease commencing on days 120 to 122, and resetting subsequently, is called a Forbush decrease. Such an event happens when an active region on the surface of the Sun erupts to release an intense cloud of plasma and field, in a so-called Coronal Mass Ejection (CME). The strong magnetic field inside this blob can keep the cosmic rays out of its interior. It propagates away from the Sun at about twice the solar wind speed, and when it engulfs Earth after about 2 days, the cosmic ray intensity suddenly decreases. As the CME recedes beyond the orbit of Earth, the intensity resets again. These Forbush decreases occur, on average, once per month, with a higher frequency towards solar maximum.

Sometimes these solar eruptions and their accompanying fields are so intense that they can accelerate the available pool of solar particles to cosmic ray energies. Such an event is shown by the sharply pointed spike on May 7 (day 127). It is called a Ground

Station	Lat.	Long.	Alt(m)	Opened	Operator
Larc	62°12′09″ S	58°57′42″ W	40	1991	University of Rome, Italy
Mawson	67°36′17″ S	62°52′15″ E	15	1957	Australian Antarctic Division
McMurdo	77°50′53″ S	166°40′06″ E	48	1960	Bartol Research Institute, USA
SANAE	71°40′25″ S	02°49′44″ W	856	1964	Northwest University, South Africa
South Pole	89°59′51″ S	139°16′22″ E	2820	1964	Bartol Research Institute, USA
Terre Adelie	66°39′46″ S	140°00′05″ E	32	1967	L'Observatoire de Paris, France



Short term cosmic ray variations (a, Forbush decrease, a Ground Level Enhancement and diurnal variations) observed by the SANAE neutron monitor.

Level Enhancement (GLE). In these events the particles are created by our own sun, and are therefore called solar cosmic rays. They are studied intensely with neutron monitors because the Sun is the only object near enough so that one can literally look into the face of the source. The Sun is a very weak source, however, because these GLEs invariably die out within a day, and since 1942 only sixty-nine of them have been observed. The strongest one was on 23 February 1956, and the second strongest one was on 20 January 2005. These events are usually highly anisotropic, which means that the particles come towards us in well-defined beams. To unravel the size, intensity, direction, and energy of these beams requires that one must have simultaneous observations from several neutron monitors. Polar neutron monitors are particularly well suited for this because they preferentially register the low energy particles as previously mentioned. In addition, these polar neutron monitors also tend to look into better defined, narrower regions of space than the ones at lower latitudes. With this in mind, the Bartol Research Institute, in collaboration with Russian and Australian scientists, operates Spaceship Earth, a network of eleven polar neutron monitors that is designed to study these events optimally. Spaceship Earth consists of the South Pole, McMurdo, and Mawson neutron monitors, plus eight neutron monitors in the Arctic.

Diurnal variations of amplitude of about 1% are due to the Earth's rotation on its axis, which causes the neutron monitor to look into and away from the beam once per day. Careful analysis of these small, almost insignificant variations over a period of more than 40 years has yielded valuable information about the propagation conditions of cosmic rays in the heliosphere.

Apart from the neutron monitor stations listed above, the Bartol Research Institute and the Australian Antarctic Division also jointly operate a mobile neutron monitor on annual voyages by vessels of the US Coast Guard, from the US west coast to McMurdo in Antarctica. The purpose of these so-called latitude surveys is primarily to measure the energy response of neutron monitors, which is needed to unfold and interpret the observed variations.

Other Modulation Experiments

The Antarctic ice sheet offers an ideal opportunity to study the intensity of cosmic rays backwards in time, before the advent of the technological era in the middle of the twentieth century. One of the secondaries produced by cosmic rays when they strike atmospheric nuclei is ^{10}Be, an isotope of the element beryllium. This ^{10}Be is not produced in significant quantities by other processes. It filters out to the surface within about a year and gets lost, except in polar ice where it is perfectly preserved for hundreds of thousands of years. This ^{10}Be concentration is a signature of the cosmic ray intensity back into the past, and it can be recovered from ice cores drilled by several international collaborations, up to 3 km deep at locations such as South Pole, Kohnen, Dome C, Dome Fujii, Vostok, and Byrd. The results from South Pole and Vostok have shown that the cosmic ray intensity has always been variable, and that there were extensive periods in the last 1000 years where it was much higher than at present. This, in turn, implies a lower solar activity during these periods. This cosmic ray/^{10}Be record therefore enables one to study helioclimatology in the distant past.

The modulation process is also studied with a variety of other particle detectors, on Earth as well as in space. Space detectors have the advantage that they observe the cosmic rays directly and can record different species separately, while they are also sensitive to lower energies. Neutron monitors, however, provide a much longer and more stable baseline, while their higher count rates allows for more detailed studies of small effects. Another type of detector that is used inside the atmosphere is the so-called muon telescope, one of which is operated by the Australian Antarctic Division at their Mawson station. These muon telescopes are actually older than neutron monitors, originating in the early 1940s. They consist of stacked proportional counters or scintillation detectors in several layers, and their electronics is set up in such a way that two or more counters in different layers must be triggered simultaneously. This allows for the reconstruction of the direction of arrival of the detected particle and, therefore, of the original cosmic ray. These muon telescopes are sensitive to about 10 times higher energies than neutron monitors, especially when they are placed underground, because the additional overburden filters out the lower energy particles. Consequently, heliospheric modulation effects are much smaller on these muon telescopes, and they are more effective to "look through" the heliosphere, straight into the galaxy, to study arrival directions of cosmic rays from their sources.

Cosmic Ray Source and Composition Studies

Cosmic ray source studies are, however, more actively pursued with so-called air shower and neutrino detectors. There is one such air shower detector in Antarctica, at the Amundsen-Scott base at South Pole. Air shower detectors measure a variety of secondary particles caused by cosmic rays in the atmosphere. Like the muon telescope, they are scintillation detectors, producing light flashes when the particles interact with the scintillator, and this light is detected by photomultipliers. They are built in units of a few square meters each, and these units are not stacked on top of one another as with the muon telescope, but they are arranged in patterns covering several square kilometers. When more than one of these horizontally separated detectors is triggered simultaneously, it means that the particles should be secondary products of a single cosmic ray. The number of triggers and the distance between the triggered units indicate the energy and type of the original cosmic ray particle, while any small time differences that may exist between the individual hits indicate the direction from which the particle came. This information about the energy spectrum and the direction enables one to study the sources of cosmic rays and their propagation through the galaxy and the intergalactic medium. Currently there are about ten of these large air shower experiments around the world. The largest one is the Pierre Auger experiment in Argentina, in which the detectors are spaced over an area of 3000 km^2. It is sensitive to the very highest energies at about 10^{20} eV, and it is about to deliver its first results.

The South Pole Air Shower Experiment (SPASE) at the Amundsen-Scott base at South Pole started in 1987 as a collaborative project between the Bartol Research Institute of the University of Delaware and the University of Leeds in the UK. It was upgraded in 1995 to its current configuration of 120 scintillators, spread over an area of 16,000 m^2. This is much smaller than the Auger experiment, which means that it is sensitive to cosmic rays of much lower energy, between 10^{12} and 10^{14} eV. A big advantage of its unique location is that at the pole sources always maintain the same altitude—they don't "rise" and "set." This is one of the reasons why this experiment makes an important contribution to unraveling cosmic ray composition and sources in this crucial energy range.

An entirely different way to study cosmic rays in the same energy range is with balloon experiments. An example is the Cosmic Ray Energetics and Mass (CREAM) experiment, in a collaboration led by scientists of the University of Maryland. Because these balloons fly near the top of the atmosphere, they can detect the original cosmic rays before the rays interact with the atmosphere. The CREAM instrument consists of detectors that can simultaneously measure cosmic ray energy, charge and species, ranging from protons to iron. Once again, these measurements are designed to study the acceleration and propagation of cosmic rays in the galaxy. The first CREAM experiment was launched from McMurdo in December 2004 on a Long Duration Balloon (LDB) flight, setting a record for such balloons with three circumpolar passes in 42 days. An earlier series of balloon experiments of the same kind was the Japanese-American Collaborative Emulsion Experiment (JACEE), with launches in Antarctica between 1990 and 1995. In yet another US–Japanese joint project, the Balloon-borne Experiment with a Superconducting Spectrometer (BESS) searches for antimatter in the cosmic radiation and measures energy spectra of less exotic components. After nine successful previous launches, this collaboration also had their first 8-day-long Antarctic launch from McMurdo in December 2004.

Another big advantage of SPASE is its proximity to the Antarctic Muon and Neutrino Detector Array (AMANDA), which is the world's largest muon and neutrino telescope, also at the Amundsen-Scott base. Neutrinos are produced by the decay of radioactive elements and particles, such as pions, in the cosmic ray showers. They are very light, with a mass of less than one millionth of an electron, they are uncharged, and they have almost no interaction with matter. This makes them unique messengers of the cosmos because they can travel across the universe with the minimum interference of matter and magnetic fields. They are studied to answer questions about their own properties such as their mass, their oscillation between different types, and their contribution to the so-called missing mass in the universe. But their elusiveness also makes them extremely difficult to detect, and immense instruments are required. To achieve this, the scintillation process is again used, but the scintillator is supplied by nature, in the form of clear and transparent polar ice. When a neutrino crashes into an atom of this ice, it produces a muon, which is detected by a photomultiplier through the light it produces, just as in the muon telescopes and air shower experiments. Once again, directions are preserved, which means that projections back to the source can be made. However, only about one in a million of these muons is produced by neutrinos. The others come from cosmic ray showers produced in the atmosphere. To suppress this atmospheric background, the neutrino detector must be several kilometres deep. In addition, the electronics are set up to make it look downwards instead of up, so that it actually looks for muons that are produced by neutrinos that come from the North Pole direction, and that have a reasonable opportunity to interact as they move through the entire Earth.

AMANDA is sensitive to neutrinos with energy up to 10^{12} eV. It is an international collaboration comprising nineteen participating institutions, led by scientists of the University of Wisconsin. Construction began in the early 1990s and it was subsequently upgraded to AMANDA II. Its 700 photomultipliers hang between 1500 and 2000 m below the ice, like beads on nineteen strings that are 2 km long. The diameter of the string array is 200 m, which means that the array fills an effective volume of about 15,000,000 m^3.

So far, AMANDA has not seen any of these cosmic messengers, but has only detected neutrinos produced by cosmic rays in the atmosphere. For this reason, the AMANDA and SPASE experiments are presently upgraded into the much larger IceCube/IceTop experiment. IceCube will view one cubic kilometre of ice with 5000 photomultipliers, making it about 60 times larger than AMANDA, while IceTop will be a 1 square kilometre air shower detector on the surface. The first IceCube string was lowered in January 2005.

COUNCIL OF MANAGERS OF NATIONAL ANTARCTIC PROGRAMS (COMNAP)

The Council of Managers of National Antarctic Programs (COMNAP) brings together the National Antarctic Programs from twenty-nine countries: Argentina, Australia, Belgium, Brazil, Bulgaria, Canada, Chile, China, Ecuador, Finland, France, Germany, India, Italy, Japan, The Netherlands, New Zealand, Norway, Peru, Poland, Russia, South Korea, South Africa, Spain, Sweden, Ukraine, the United Kingdom, the United States, and Uruguay. Two more countries—Estonia and Romania—are currently in the process of joining.

COMNAP is a council of managers and operators that, under the Antarctic Treaty System, helps oversee operational implementation, safety, technology, and information sharing. It provides the Antarctic Treaty, on request, technical advice developed using members' pool of expertise.

National Antarctic Programs are those agencies tasked by their governments to implement and manage national activities in Antarctica, including organising expeditions. While most of these activities focus on the support of scientific research, they also contribute to the governance and environmental protection of the Antarctic under the auspices of the Antarctic Treaty.

The National Antarctic Programs had their foundation in several early exploring and scientific expeditions that had international components. The most notable of these were in the closing years of the nineteenth century. The Belgian Antarctic expedition aboard *Belgica* (1897–1899), under Belgian Adrien de Gerlache, was the first to winter in the Antarctic, which was done aboard ship. The British Antarctic expedition aboard *Southern Cross* (1898–1900), led by the Norwegian Carsten Borchgrevink, was the first to winter on the continent, at Cape Adare. These two wintering parties involved twenty-nine men from nine nations, all part of the COMNAP nations. COMNAP has its roots in this long-standing, ongoing tradition of international collaboration in the conduct of Antarctic research.

COMNAP was established in 1988. Its primary function and activities are related to the exchange of operational information in order to improve the way National Programs fulfill their various missions, jointly or independently. That includes mutual support in the design, ongoing improvement, and operation of Antarctic facilities and transport infrastructure.

The infrastructure includes year-round and seasonal stations, ships, airfields, and aircraft. In 2005, COMNAP members operated thirty-seven year-round stations and twelve significant seasonal stations in Antarctic Treaty territory. The combined average of these stations was 1030 for the winter population and 3760 for the peak summer population. COMNAP nations also operated thirty-nine vessels of between 1400 and 40,000 tons displacement in the Antarctic Treaty area.

COMNAP includes a permanent Standing Committee on Antarctic Logistics and Operations (SCALOP) and a number of other groups focused on various areas of expertise. The bulk of COMNAP's work is achieved through these technical groups. Their continual exchange of information provides a vehicle for addressing a wide range or issues, sometimes highly technical, to identify practical solutions in the support of National Antarctic Programs.

A COMNAP Executive Committee (EXCOM) is responsible for all matters between full meetings of the council. A secretariat provides a central point of contact; operates communications and support infrastructure, runs a central information repository; and maintains coordination between members.

In addition to supporting its members, COMNAP works with the other Antarctic organisations to support effective, sustainable Antarctic expeditions and the success of the Antarctic Treaty System.

CRABEATER SEAL

The crabeater seal *(Lobodon carcinophaga)* has a circumpolar Antarctic distribution. The vast majority of crabeater seals spend their entire lives in the shifting pack ice surrounding the Antarctic continent, hauling out regularly on ice floes to rest, breed, and moult, and foraging in the surrounding ocean. Some crabeater seals have been found on the southern fringes of South Africa, Australia, New Zealand, and South America, but such vagrants are very rare. Crabeater seals are also occasionally found on fast ice close to the Antarctic continent, and some carcasses of crabeater seals have even been found on the Antarctic continent up to 100 km from open water.

The crabeater seal is by far the most frequently sighted seal species in the pack ice region. Crabeater seals can be distinguished from other species by their slender body form and pointed, slightly upturned snout. The pelt is usually medium-brown to silver over most of the body, although darker colouration and spotting are not uncommon on the front and rear flippers and flanks. Because the hair fades in colour throughout the year, recently moulted seals may be darker than those about to begin their moult, whose pelts can appear silvery white. Crabeater seals can be highly mobile on ice, using their front flippers to assist them and moving the hind flippers in a sinuous, sideways motion. Adults may reach maximum weights of up to 410 kg and lengths of 260 cm, but a typical size range during the summer moulting period would be 180–225 kg weight and 205–240 cm length. Females are usually slightly heavier and longer than males. Crabeater seals may live for up to 40 years, but a life span of 20–25 years is more typical.

Crabeater seals are known to move seasonally in northward and southward directions with the seasonal expansion and contraction of the pack ice, and some individuals have been observed to move substantial distances in east-west directions around the continent. Although crabeater seals can occur anywhere in the pack ice, they have been observed at highest densities in the frontal zones associated with the shelf break and the ice edge. Upwellings, currents, and eddies at the shelf break are thought to result in high concentrations of Antarctic krill, the crabeater seal's preferred prey.

The crabeater seal is very abundant in the pack ice, and it is often claimed to be the most abundant seal species in the world. However, estimating abundance of this and other seal species in the remote and inaccessible pack ice is extremely difficult. Existing estimates of crabeater seal abundance vary widely (2–75 million) and can only be considered approximate. Estimates in the range of 10–15 million are currently considered to be the most realistic, but these are based on surveys undertaken over two decades ago. A recent international research effort in the late 1990s aimed to improve knowledge of the status of this species at both regional and circumpolar scales. Genetic studies suggest there are no subspecies and the circumpolar population is panmictic.

Except when breeding and moulting, crabeater seals generally haul out daily throughout the year to rest on ice floes. During the summer period most individuals begin to haul out in the early morning and cease hauling out late in the afternoon, with the population reaching a peak around midday. At the midday peak in summer about 80% of individuals are generally on the ice, with the other 20% remaining in the water. This pattern appears to change seasonally, with one study finding less than 40% of seals hauled out at the peak time in the months March to May, and more seals hauling out at midnight than at midday in April and May. When breeding, crabeater seals haul out on the ice continuously for extended periods of up to three weeks, thereby undergoing an enforced fast.

Periods of diving and foraging typically occur at night during the summer period, but at other times of the year diving and foraging activity has been observed more frequently during the day than at night. Such daily foraging periods may extend for up to 16 hours, and in one instance an individual has been recorded diving repeatedly without a rest for 44 hours. Most dives by crabeater seals are relatively shallow (<40 m) and short (<5 minutes), but occasionally individuals dive to depths of 300–500 m. Dives during the crepuscular periods are often deeper than dives during the night. It has been suggested that deep dives of several hundred metres may be undertaken to listen for other seals, hear navigation cues or locate new krill swarms, rather than to catch prey.

The pupping season occurs from late September through to early November. At this time, pregnant females haul out on the ice to give birth to a pup, and are joined by a male just before or after parturition. Pups weigh 20–35 kg at birth. Lactation lasts approximately three weeks, during which time the pups gain about 60–80 kg in weight. Once they have located a female, males remain with her throughout the lactation period and defend her from other approaching males. Females may react aggressively to the close approach of any male until ready to mate. Small wounds around the head and neck on both sexes are likely to be due to aggressive intraspecific encounters during the breeding season. Mating has never been observed, but is generally considered to occur after weaning, which may be initiated by the male forcing the female away from the pup to form a male-female pair. When the male and female cease extended haulout and enter the water, they appear to remain close together for only a few days at the most, suggesting that the male-female bond does not last beyond a single season. Some males have been observed to haul out for more than one extended period during the breeding season, indicating that they may try to mate with more than one female. After reaching sexual maturity, female crabeater seals mate and pup during most years. One study estimated the pregnancy rate of sexually mature females at 0.87. The gestation period is 8.5 months.

Very little is known about crabeater seals between the time they are weaned and the time they enter the breeding population at age 2.5–4.5 years. It is thought that mortality in the first year may be as high as 80% due to predation by leopard seals. A high proportion of adult crabeater seals have large, raking scars on their lower flanks, which by their size, form and shape are thought to have been inflicted by leopard seals during unsuccessful attacks.

Apart from predation by leopard seals, little is known about other causes of mortality. Killer whales have been observed hunting crabeater seals and suggested as an additional predator of all age classes, but there is no information on the importance of such predation. An incident of mass mortality involving several hundred crabeater seals near the Antarctic Peninsula in 1955 was speculated to have been caused by a distemperlike virus specific to crabeater seals. Weddell seals in the same area did not appear to be affected. Later studies of crabeater seals along the Antarctic Peninsula confirmed the presence of antibodies similar to those related to canine distemper and phocine distemper, which were responsible for major epizootic die-offs of harbour seals in the Northern Hemisphere in the late 1980s.

Outside of the breeding season, crabeater seals are usually solitary or occur in small groups, but large aggregations have occasionally been observed. The reason for such aggregations remains speculative. Contraction of the ice in summer may force seals to aggregate on the remaining isolated floes, particularly in January and February when they moult, in which case there may be no behavioural or ecological benefit associated with aggregation. On the other hand, aggregations have been observed in the water with apparent coordinated diving behaviour, suggesting a possible benefit of improved feeding efficiency.

Contrary to its name, the crabeater seal feeds primarily on krill. Most investigators have reported krill comprising over 95% of the diet, with fish and squid being minor dietary items. The species does not appear to switch prey seasonally in response to varying availability as does the leopard seal. Crabeater seals have finely divided, lobed teeth that are thought to be an adaptation to their specialised diet of krill. The multiple cusps of the upper and lower postcanine teeth closely interlock to form a sieve that can be used to filter krill from seawater. A bony protrusion on the lower jaw behind the most posterior postcanine teeth fills a gap in this sieve so that krill cannot escape at the rear of the mouth. Given the abundance of crabeater seals, their size, and the dominance of krill in their diet, the crabeater seal is likely to consume more krill in the Southern Ocean than any other single species.

Krill predators, including the crabeater seal, are considered useful as indicators for management of the Southern Ocean ecosystem, particularly in relation to the harvesting of krill. The Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) aims to manage the harvesting of krill in a sustainable manner. The crabeater seal was selected as an indicator species for the CCAMLR Ecosystem Monitoring Program, which aims to detect any effect of krill harvesting on the krill-based ecosystem. The age at sexual maturity of crabeater seals is one population parameter thought to be responsive to changes in krill availability. Age at sexual maturity for crabeater seals fell from 4.5 years in the 1940s to 2.5 years in the late 1960s, then increased again to approximately 4 years in the 1970s. These variations have been interpreted as a response to changes in krill availability and competition between krill predators across a period when harvesting of krill-consuming whales was reduced.

Crabeater seals have been harvested for commercial purposes sporadically in the past: in 1964–1965 by Norway, and in 1986–1987 by the former Soviet Union. While both harvesting ventures proved to be economically unsuccessful, concern over possible future exploitation of this and other Antarctic seal species resulted in the establishment of the Convention on the Conservation of Antarctic Seals, which came into effect in 1978.

CRESTED PENGUINS

Penguins in the genus *Eudyptes* are referred to as crested penguins. They are small to medium penguins, blue-black on their backs and white ventrally, that in adult plumage have plumes of yellow or orange feathers above their eyes and red bills. Immature birds are duller in their colour. They are capable swimmers and agile on land.

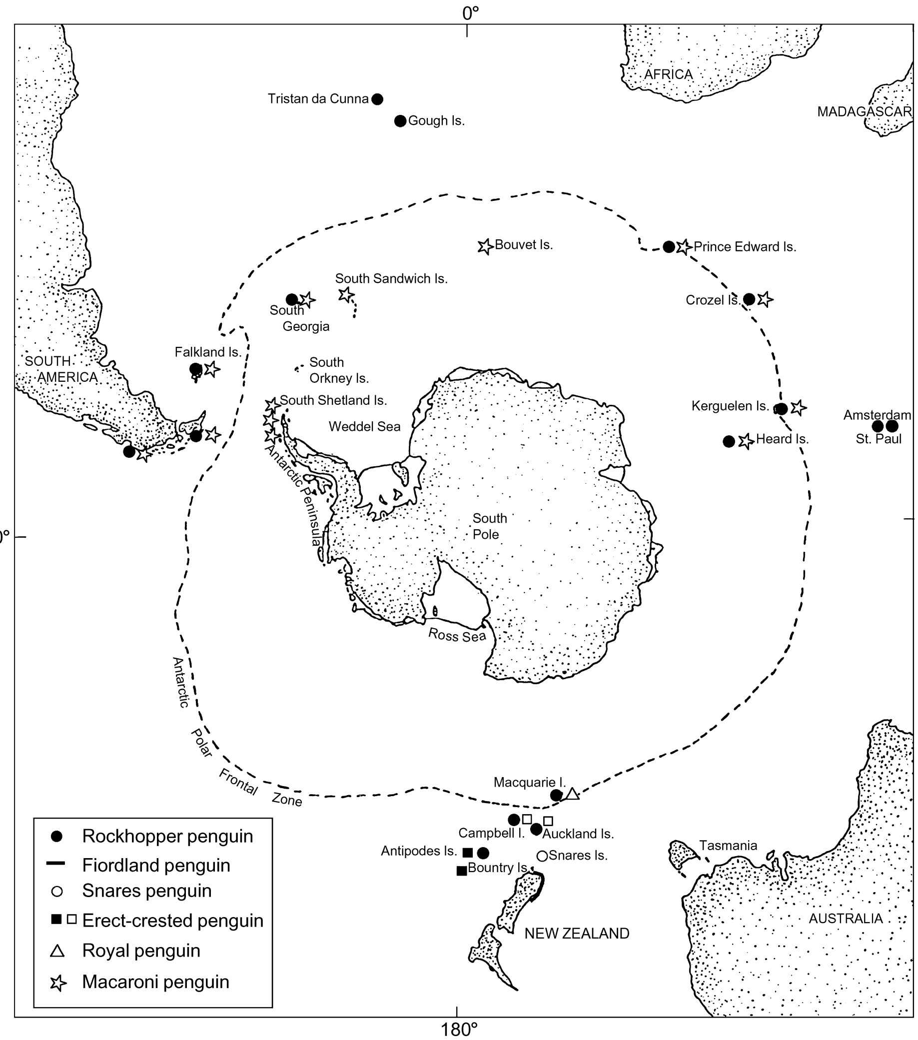
Six species of crested penguin are usually recognized: rockhopper penguin *E. chrysocome,* Fiordland penguin *E. pachyrhynchus,* Snares penguin *E. robustus,* erect-crested penguin *E. sclateri,* royal penguin *E. schlegeli,* and macaroni penguin *E. chrysolophus*. However, the systematics of the genus have not been straightforward. Both the Snares and erect-crested penguins have been treated as races of the Fiordland penguin, although there are morphological grounds to differentiate between them, breeding seasons are dissimilar and hybridization has not been recorded. The rockhopper penguin is divided into three subspecies, one of which, *moseleyi,* has been considered by some sufficiently different to qualify as a separate species. The royal penguin, which is found only on Macquarie Island, was previously treated as a subspecies of the macaroni penguin, which occurs in the southwest Indian and South Atlantic oceans. The two species are similar, except for the amount of blue-black feathering on their cheeks and throat. Whereas these feathers are dark in macaroni penguins, they are white or pale grey and highly variable in royal penguins. There are also differences in measurements between these two penguins. However, penguins with white faces and throats have been found in colonies of macaroni penguins at several islands. The traditional treatment of six *Eudyptes* species has been followed here. The macaroni penguin is treated in greater detail in a separate entry.

The Snares (2.5–2.6 kg) and rockhopper (2.9–3.1 kg) penguins are the smallest of the crested penguins. The macaroni and royal (both 5–6 kg) and erect-crested (5.4–6.4 kg) penguins are considerably larger. Of intermediate size is the Fiordland penguin (4.0–4.5 kg). Males are typically larger and heavier than females.

Distribution

The crested penguins are found in the cool temperate, sub-Antarctic and Antarctic regions of the Southern Hemisphere. The rockhopper penguin has a circumpolar distribution. The northern race, *E. c. moseleyi,* has the most northerly distribution of any crested penguin, breeding at Tristan da Cunha and Gough islands in the Atlantic Ocean and at Île Amsterdam and Île St. Paul in the Indian Ocean. The southern race, *E. c. chrysocome,* breeds around Cape Horn in southern Chile and Argentina, at the Falkland Islands and occasionally at South Georgia. The eastern race, *E. c. filholi,* breeds in two well-separated regions: on the Prince Edward Islands, Îles Crozet, Îles Kerguelen, and Heard Island in the south Indian Ocean and at Macquarie Island, the Auckland Islands, the Campbell Islands, and the Antipodes Islands to the south and east of New Zealand.

Four crested penguins breed only in the southwestern Pacific Ocean. The Fiordland penguin breeds along the south and southwest coasts of New Zealand's South Island, including several islands off these coasts. The Snares penguin is endemic to the Snares



The breeding distributions of crested penguins.

Islands, south of New Zealand. The erect-crested penguin breeds in high numbers at the Antipodes and Bounty groups of islands, to the southeast of New Zealand. Farther south, it previously bred in low numbers at Auckland Islands and at Campbell Island. Still farther south, the royal penguin breeds only at Macquarie Island and adjacent islets.

The breeding distributions of the different crested penguins generally do not overlap. Overlaps exist: Southern rockhopper penguins occur with macaroni penguins around Cape Horn, at the Falkland Islands and at South Georgia, and eastern rockhopper penguins occur with macaroni penguins in the south Indian Ocean, with royal penguins at Macquarie Island and formerly with low numbers of erect-crested penguins at the Auckland and the Campbell islands.

Crested penguins are thought to migrate away from their breeding localities in the nonbreeding season. However, their nonbreeding distributions are often poorly known. Southern rockhopper penguins at Falkland Islands move to the north, west, and south when not breeding, utilizing a number of areas including the slope of the Patagonian Shelf and coastal areas off South America. Vagrant crested penguins are often recorded far from their breeding colonies. For example, rockhopper, Fiordland, Snares, erect-crested, and royal penguins all have been recorded along southern Australia.

Annual Cycle

Crested penguins moult once each year, when they replace all their feathers. During this time, they are ashore for 3–8 weeks, the period varying between species and breeding localities, and cannot feed as they cannot enter the water. They often moult at nest sites but Fiordland penguins do not usually do so. Before moulting, crested penguins leave to sea for average periods of 13–70 days (depending on the species) to fatten up. Once the moult is complete, they go back to sea to regain condition. They return to their colonies to breed for the following season.

Fiordland penguins start to arrive at colonies to breed from mid-June, Snares penguins from mid-August, erect-crested penguins from early September, royal penguins from mid-September, and rockhopper penguins, which generally breed later at higher latitudes, in October or early November. Usually males arrive at colonies for breeding several days earlier than the females. After returning for breeding, the parents fast again for periods that differ among species and between the sexes, but average 33–43 days. During this period, courtship occurs and eggs are laid. Soon afterwards males leave to feed and then return to relieve their partners, the early incubation shifts of the two parents lasting 10–14 days on average.

The females are back at their nests shortly before the eggs hatch. Both parents attend the nest for a few days following hatching, after which the female goes to sea to provision the chick leaving the male to guard it. In rockhopper penguins, the guard stage may last 26 days and the male may fast at this time for 36 days. When chicks are about 3 weeks old, they start to form crèches. The males then leave to sea to feed. Once they have regained condition, they assist the females in feeding the chick. In crested penguins, the incubation period averages between 33 and 36 days, and the fledging period between 60 and 75 days.

Breeding birds depart on their premoult feeding trip soon after their chicks have left the colony. There is often considerable synchrony in the timing of moult, arrival at colonies for breeding and subsequent departure, so that during premoult and postmoult feeding trips colonies are mostly devoid of birds.

Breeding and Survival

Crested penguins typically nest in colonies, some species being more densely packed than others. Rockhopper penguins often breed on rocky terrain, including shores, lava flows, cliffs, and overhangs. Fiordland penguins use dense, temperate rain forest in addition to caves, rock falls, and rock overhangs along coasts. Snares penguins breed on flat, muddy areas or on gentle rock slopes. Nests are under the shelter of forest or scrub, or in swampy areas, among rock falls or on exposed granite. Erect-crested penguins use rocky terrain, often without substantial soil or vegetation. Royal penguins breed on beaches, scree slopes, or hills, on sandy, rocky, or pebbly ground without vegetation.

Most rockhopper and Fiordland penguins breed with the same mate (if alive) in successive seasons, but some may change partners. Snares and erect-crested penguins show strong fidelity both to nest sites and to partners. Bonds of royal penguins are also long lasting.

Nests are often scrapes in the ground that are formed by the female, rotating her body and raking backwards with her feet, and lined with material collected by the male (pebbles, bones, pieces of vegetation).

Crested penguins typically lay clutches of two eggs, which are laid with an interval of 4–5 days. The first (A) egg is on average 17%–44% smaller than the second (B) egg. It usually does not survive, and is discarded by some species after laying of the B egg. Eggs are held by the feet and incubated with a brood patch. Chicks gain mass rapidly after hatching. If both eggs hatch, the chick from the A egg will usually die. Crested penguins do not rear more than one chick to fledging in any year. For Snares penguins, chicks of all ages are able to recognize the calls of their parents.

Most rockhopper penguins breed for the first time when 4–5 years old, Fiordland penguins when 5–6 years old, and Snares penguins when 4–7 years old. Some royal penguins lay eggs when 5 years old but others do not start breeding until aged 11 years. Age at breeding of erect-crested penguins is not recorded. In some seasons, for example when food is scarce, it is likely that not all mature birds breed.

Annual survival of rockhopper penguins is about 39% for birds in their first year and 84% for adults. Fiordland and Snares penguins may live for 10–20 years. For Snares penguins, survival is about 15% in the first year and 57% in the following two years. Annual survival of adult royal penguins is 86% or higher.

Food and Feeding

The food of crested penguins varies among species, breeding localities, and seasons, consisting primarily of crustaceans (especially euphausiids), cephalopods, and fish. Rockhopper penguins eat mainly crustaceans at southerly sites, with fish and cephalopods increasing in the diet that is fed to older chicks at these sites, and predominating at some northern localities. Fiordland penguins feed mostly on small cephalopods or fish. Snares and erect-crested penguins feed mainly on crustaceans and cephalopods.

At Macquarie Island, royal penguins, which feed near the Polar Front while breeding, eat more fish and less crustaceans than rockhopper penguins. Food is caught by pursuit diving. Crested penguins feed solitarily or in small- to medium-sized groups.

Population Sizes

There are very large differences in the estimated sizes of the populations of the different species of crested penguins. Those species having a restricted distribution in New Zealand, or at its islands, are the least abundant. The Fiordland penguin is thought to number 2500–3000 breeding pairs, the Snares penguin 23,250 pairs, the erect-crested penguin 77,000–81,000 pairs, the royal penguin about 850,000 pairs, the rockhopper penguin about 1.5 million pairs, and the macaroni penguin about 9 million pairs. For the subspecies of rockhopper penguins, there are about 600,000 pairs of *chrysocome,* 365,000 pairs of *moseleyi,* and 563,000 pairs of *filholi.*

Conservation Status

On the Red List of IUCN (the World Conservation Union), the erect-crested penguin is listed as Endangered and the other five crested penguins as Vulnerable. The macaroni penguin's status is discussed under the entry for that species.

The erect-crested penguin is regarded as Endangered because its population has decreased by at least 50% in the last 25 years, a time period well within the 45 years considered to span the three most recent generations of this species. In 1972, one pair was breeding at the Auckland Islands and it was thought likely that others were breeding amongst rockhopper penguins. There was a small population of twenty to thirty pairs at the Campbell Islands in 1986–1987, but there have been no recent records of breeding at this locality. The population is now confined to the Antipodes and Bounty groups of islands. At Antipodes Islands, the population decreased by about 50% between 1978 and 1995, when there were 49,000–57,000 breeding pairs, and there have been further decreases since. Different census methods estimated the population at Bounty Islands to be 115,000 pairs in 1978 and 28,000 pairs in 1997–1998.

The Fiordland penguin qualifies as Vulnerable because it has a small population that, based on monitoring at a few sites, is assumed to be undergoing a rapid long-term reduction. The Snares and royal penguins have been classified as Vulnerable because they are restricted either to a small group of islands or to a single breeding location and subject to a number of threats. Populations of both species are thought to be stable, although there is little information for Snares penguin and no recent data on the population size of royal penguins since the early 1980s.

The rockhopper penguin is regarded as Vulnerable because many populations have undergone massive decreases. At the Falkland Islands, southern rockhopper penguins decreased by more than 80% from 1.5 million pairs in 1932–1933 to 264,000 pairs in 1995–1996, at a rate of about 2.75% per annum. In 2000–2001, the population was about 273,000 pairs, suggesting recent stability in the population trend. At Straten Island in Argentina, numbers are also thought to be stable. At Amsterdam Island, the breeding population of the northern race decreased at a rate of 2.7% per year between 1971 and 1993. At the Campbell Islands, the breeding population of the eastern race decreased by 94% between the early 1940s and 1985. The breeding populations at Auckland and Antipodes Islands also have decreased. At Marion Island, the population decreased from 173,000 pairs in 1994 to 67,000 pairs in 2001. Some decreases may have resulted from an altered availability of food caused by increased sea temperatures. In 1985–1986, a mass mortality of rockhopper penguins at the Falkland Islands was thought to be linked to starvation before moult. The arrival mass of adult rockhopper penguins at Marion Island has decreased steadily since 1994–1995, suggesting a decreased availability of food there. An increase in numbers of sub-Antarctic fur seals *Arctocephalus tropicalis* may have influenced the decrease in numbers of rockhopper penguins at Île Amsterdam.

CROZET ISLANDS (ÎLES CROZET)

Îles Crozet is an isolated archipelago lying in the Southern Indian Ocean (45°68′ to 46°26′ S, 50°14′ to 52°15′ E), some 2400 km southeast from South Africa and 2400 km north of the coast of Antarctica. The archipelago consists of five main oceanic and volcanic islands in two groups. The western group consists of three parts. Île aux Cochons (46°05′ S, 50°15′ E) is a volcanic cone, 9 km in diameter, 770 m high, with an area of about 70 km^2, and with steep western slopes. It is the least eroded of the group, probably the last to erupt. Île des Pingouins (46°27′ S, 50°22′ E) is 53 km to the south of Île aux Cochons. With 4.6 km^2 and a height of 340 m, it consists of a young volcano, about 1 million years old, the main part of which has sunk down into the sea. Ilôts des Apôtres comprises two islands and 12 rocks. The principal island (45°58′ S, 50°25′ E), named Grande Terre, is 3 km long, 2 km^2 in area, and 289 m high, with steep western cliffs.

The eastern group (which lies about 100 km to the east) consists of two islands. Île de la Possession (46°25′ S, 51°45′ E) is the largest island in the archipelago (146 km^2). It is roughly rectangular in shape, 30 km by 15 km. The topography is dominated by an inland chain of mountains, up to 934 m (Pic du Mascarin), with deep glacial valleys to the north and east, and high cliffs to the west and south. Île de l'Est (46°25′ S, 52°15′ E), 20 km east of Île de la Possession, is oval, 18 km by 10 km, with an area of 130 km^2. It has numerous peaks, with deep valleys, the highest point being 1090 m (Pic Marion). Most of the coastline is bordered by high cliffs.

Mostly magmatic, the eastern group of islands present volcanic and plutonic rocks, whereas the western group is only volcanic, with sedimentary levels.

These islands lie north of the Polar Front. The climate is oceanic and cold: the mean air temperature is 5.1°C, with a weak seasonal thermal range (monthly mean temperatures range between 3.0°C in winter and 7.9°C in summer). There is high rainfall (2400 mm per year) and strong winds. There are no glaciers, but there is evidence of past glaciations, as suggested by large glacial valleys on Île de l'Est and Île de la Possession.

On the coasts, the herbs *Crassula moschata* and *Leptinella plumosa* are common. Tussock grassland of *Poa cookii* dominates in the coastal areas influenced by elephant seals or penguins. At higher altitude and up to about 150 m asl, dwarf shrub (*Acaena magellanica*) and fern (*Blechnum penna-marina*) are dominant, with the Kerguelen cabbage *Pringlea antiscorbutica* in the moist places. In the inland valleys, numerous mosses, liverworts, and the grass *Agrostis magellanica* grow on peaty soil. Above 150 m, fellfield vegetation predominates, comprising the cushion herb *Azorella selago* with *A. magellanica*. The vegetation cover is very low in these areas. Twenty-four autochtonous vascular plant species have been recorded at Île de la Possession. There is no endemic species to the archipelago, but most of the flora belongs to the Southern Indian Ocean biogeographical province. Alien plants are mainly localised in the vicinity of the base station on Île de la Possession. Among the fifty-nine species recorded in 1996, few of them colonise the island: *Poa annua* and *Cerastium fontanum* are the most widespread. *Rumex acetosella* and *Poa pratensis* grow near the old sealers camp at Baie Américaine. *Sagina procumbens* is currently in a rapid spreading stage, developing along tracks and near the field huts. Few alien species have been recorded on the other islands of the archipelago, and Île des Pingouins is entirely free of introduced species.

The islands host more breeding seabird species than any other island group in the world. Thirty-six species of bird breed in the group (eighteen on Île aux Cochons, twenty-four on Île de la Possession, thirty on Île de l'Est), with the total number of birds estimated at 25 million. Among the most common birds are king penguin (world's largest colonies), macaroni penguin, rockhopper penguin, wandering albatross, sooty albatross, light-mantled sooty albatross, northern giant petrel, southern giant petrel, several other petrel species *(Pachyptila salvini, Pterodroma brevirostris, Procellaria aequinoctialis, Pelecanoides georgicus),* Subantarctic skua, kelp gull, Crozet shag *(Phalacrocorax albiventer melanogenis),* Antarctic tern, Kerguelen tern, Kerguelen pintail *(Anas eatoni),* and the endemic Crozet lesser sheathbill *(Chionis minor crozettensis)*. Several species are very abundant on the small off-lying islands, but not on the main islands. Île des Pingouins, for example, hosts large numbers of yellow-nosed albatross, blue petrel *(Halobaena caerulea),* and fairy prion *(Pachyptila turtur)*.

Southern elephant seals are abundant. Antarctic furs seals and sub-Antarctic fur seals, previously hunted to the verge of extinction, are rapidly recovering.

Introduced mammals occur on several islands: black rats on Île de la Possession, rabbit on Île de l'Est and Île des Cochons, and cats and domestic mice on Île des Cochons. Their impact on the native communities is not well documented, but the presence of rats on Île de la Possession seems responsible for the rarefaction of some petrel species that remain abundant in similar habitats of Île de l'Est. In addition, salmonid fishes have been introduced in two rivers of Île de la Possession *(Salmo trutta* and *Salvelinus fontinalis)*.

The rate of endemism is exceptionally high in the invertebrate fauna: 57% of the sixty-three insect species recorded on Île de la Possession are known only in Îles Crozet. Among the thirty-five weevils recorded, twenty-six are endemic. There are few introduced invertebrates, and those are mainly present at the research station on Île de la Possession: for example, earthworms *(Dendrodrilus rubidus tenuis)* and aphids in glasshouses *(Myzus ascalonicus)*.

The Islands were discovered on January 22, 1772, by a French expedition headed by Marion Dufresne whose first mate, Julien Crozet, made the official claim two days later. The islands were visited sporadically by sealers in the nineteenth century. Several shipwrecks occurred.

A scientific and meteorological station was established on Île de la Possession in 1962: the Alfred-Faure station hosts about thirty-five people in summer, and twenty people in winter. The main scientific activities are related to geophysical observations and biology. There is no economic activity (fishing or tourism).

CRYOCONITE COMMUNITIES

Cryoconite holes form as windblown particulates accumulate on the surface of a glacier, are warmed by the sun, and melt into the ice producing a cylindrical basin of liquid water. Organisms released from the melted glacial ice and attached to deposited airborne particulates provide the biological inoculum for these ecosystems. This environment lacks a significant source of allochthonous nutrient input and relies on photosynthesis and nitrogen fixation carried out by the resident algae and cyanobacterial species, which provide carbon and nitrogen resources which can be assimilated by the community. Cryoconite holes occur globally in glaciated environments of the Arctic and Antarctic, and are also present in alpine glaciers.

Unlike the open holes found in temperate latitudes, cryoconite holes in the McMurdo Dry Valleys of Antarctica are sealed with an ice lid (up to 30 cm thick) and are frozen solid for the majority of the year. During the austral summer (November–March), the 24 daylight hours and increased temperature enable liquid water to exist, as heat-absorbing sediments in the bottom of a mature cryoconite hole are warmed by solar irradiation, melting a portion of the overlying ice. The austral summer is also a time when new cryoconite holes form, and this process is greatly accelerated by the presence of cracks and depressions within the glacial ice surface, which serve to collect and concentrate sediment. During the few months in which liquid water is present, photosynthetic primary production is possible and these aquatic ecosystems become metabolically active, but are then destined to refreeze and become dormant through the cold, dark winter months.

Bacterial species (including cyanobacteria) in cryoconite hole environments are similar to those found in ecosystems within the permanent ice cover of lakes and in microbial mats (layered groups or communities of microbial populations) of this dry valley ecosystem. This implies that the species within cryoconite holes originate from adjacent terrestrial sources and suggests that similar survival strategies may be in effect in both lake ice and cryoconite holes. Besides the dry valleys of Antarctica, no other ecosystems are known in which nematodes (unsegmented worms), rotifers (multicellular organisms with a wheellike organ), and tardigrades ("water bears"; small, segmented animals) represent the highest trophic levels in the food web. Although it is still uncertain if these metazoans are active in Antarctic cryoconite holes, there is evidence that they are preserved in these environments. Some nematode, tardigrade, and rotifer species can enter a dormant resting state in which they are resistant to desiccation and freezing, and then commence metabolism when conditions for growth are favorable.

In addition to the inherent interest of Antarctic cryoconite holes as discrete and unique ecosystems, these environments could function as a biological refuge, serving in reverse to reseed surrounding environments in the summer during glacial melting. Cryoconite hole ecosystems exist and thrive under the harsh conditions associated with an Antarctic desert, and therefore provide a terrestrial analog for plausible past or present environments for life in ice on Mars, and may have been an important haven for life during past ice ages.

CRYOSAT

Six and a half years after the program was initiated, CryoSat was launched on 8 October 2005. Unfortunately, it failed to reach orbit due to a problem with the launch vehicle.

CryoSat was the first in a series of Earth Explorer satellites prepared as part of the European Space Agency's (ESA) Living Planet Programme. Approved in 1999, CryoSat was developed as an *Opportunity* mission, the purpose of which was to provide rapid answers to important scientific questions about a specific aspect of the Earth's environment. Its main goal was to determine the variability and trends in the thickness of the Arctic marine ice cover and of ice sheets in the Arctic and Antarctic. To accomplish this goal, CryoSat was to measure ice surface elevation from a 720 km altitude polar orbit (circling to 2° latitude off each Pole) over a nominal three-year mission lifetime. Resulting data would have been used to calculate rates of change in thickness and mass of the polar ice cover in response to climate variations and to validate predictions of diminishing polar ice due to global warming.

The CryoSat satellite carried a primary instrument known as the SAR/interferometric radar altimeter (SIRAL), which was complemented by three other instrument packages for precise orbit determination and accurate attitude knowledge. SIRAL is a microwave radar altimeter operating at a frequency of 13.6 GHz. Altimeters transmit pulses of electromagnetic energy that are reflected or scattered back from the surface. The precisely timed delay between each pair of transmitted pulse and received echo is used to calculate the ice surface height with respect to the known orbital position and orientation of the satellite.

SIRAL is capable of operating in three different modes selected autonomously using commands triggered from knowledge of the satellite ground track position over specific target areas. Over regions of sea ice, SIRAL operates in Synthetic Aperture Radar (SAR) mode, making measurements at 250-metre intervals along the ground track (10 times better than its predecessors). Over steeply sloping or variable ice-sheet terrain, SIRAL operates in SAR interferometric (SARIn) mode using two antennas, which provides greater agility and improved ranging accuracy. Over the level ice-sheet plateaux and global oceans, the default Low Resolution Mode (LRM) acquires data comparable with previous radar altimetry. CryoSat was designed to measure average changes in surface elevation to 1.6, 3.3, and 0.17 cm/year accuracy over sea-ice areas (100,000 km^2), ice-sheet drainage basins (10,000 km^2), and on a continental scale (14,000,000 km^2) for ice-sheet interior regions, respectively.

CRYPTOENDOLITHIC COMMUNITIES

Cryptoendolithic communities—microorganisms inhabiting the structural cavities of porous rocks—are perhaps the most obvious example of how a biotope can be exploited to avoid climatic extremes. Microbial cryptoendolithic communities were first described in 1976 in the Dry Valleys region of South Victoria Land, Antarctica. Although cryptoendoliths are distributed worldwide, they have been most intensively studied in this region through the efforts of E. Imre Friedmann and his coworkers. The Dry Valleys are one of the largest ice-free regions of the Antarctic continent. The climate of the Dry Valleys is characterized by its extreme cold and dryness. In winter, a period of continuous darkness, temperatures drop to as low as –60°C, and winds of up to 100 km/h sweep through the valleys. During summer, average daily air temperatures range from –35°C to –3°C. Constant summertime sunshine can raise the inner temperature of rocks to above the freezing point, to as high as 10°C more than the outside temperature. Added to the cold, the region is also one of the driest on the planet. Such rapid oscillations in temperature and wet-dry cycles create an extremely hostile living environment, described by some as a potential analogue for the conditions on early Mars.

The cryptoendolithic microbial communities of the Dry Valleys are confined to rock types that offer suitable microhabitats with appropriate microclimatic conditions. These conditions are met in the fine-grained sandstones, the dominant substratum of the Dry Valleys, but are also characteristic of coarse-grained quartzite and limestone. Organisms inhabiting rock surfaces and shallow cracks are subject to physical abrasion (from wind-blown sand) and rapid temperature fluctuations. On the contrary, cryptoendolithic microbial communities, even if only a few millimetres below the rock surface, are protected from extreme temperature oscillations because of the thermal buffering of the rocks. Based on the assumption that the lower temperature limit for endolithic metabolism is around –10°C, cryptoendolithic communities can only meet their metabolic needs in less than 1000 hours per annum. An adequate water supply is generally thought to be limiting in endolithic environments, particularly during the short summer period, when the elevated temperatures and presence of sunlight are conducive to photosynthesis. Intermittent snowfall may be the only source of water. Recently a novel endolithic microbial habitat was described in Alexander Island, Antarctic Peninsula. Small cryptoendolithic colonies, composed of cyanobacteria, bacteria and fungi, were found within the translucent gypsum crusts. This microhabitat is proposed to provide protection from desiccation, rapid temperature variation and UV radiation flux while allowing penetration of radiation for utilization by phototrophs.

Cryptoendolithic environments are good examples of absolute extreme environments (i.e., regions where the physical conditions are beyond adaptability). Organisms colonizing rocks are not adapted to their environment; they survive by tolerating it. Thus microorganisms in Antarctic rocks live near the lower limits of their physiological potential, and have no reserves to compensate for changes in the environment should conditions deteriorate. As a consequence, even a minor change in climate can result in local extinctions. In fact, close to 80% of the cryptoendolithic communities of Antarctica are dead or fossilized. The presence of microbial fossils of cryptoendolithic microorganisms in sandstones from Mount Fleming and Taylor Valley (Dry Valleys) was recently demonstrated.

Cryptoendoliths have been the subject of intense investigation, originally by microscopy, chemical, and culture-based methods, and recently through the use of molecular-based tools. Two dominant community types have been identified: lichen-dominated and cyanobacteria-dominated assemblages. Cryptoendolithic lichens are the predominant organisms colonizing the subsurface of sandstone. It appears under the rock crust as a conspicuous zone up to 10 mm deep consisting of distinct parallel colour bands. Typically, a black zone under the crust is followed by white and a green zone. Throughout the colonization zone, the reddish iron oxyhydroxide stain is leached out, and the quartz grains appear colourless. This leaching is caused by oxalic acid, apparently produced by fungi. The black and white zones are formed by filamentous fungi (mycobiont—a term used for the fungal partner of a lichen) and algae (photobiont—the algal partner of a lichen), which together form a cryptoendolithic lichen association. The dark pigmentation of the mycobiont, which in turn, encloses groups of algal cells may be an adaptation to the environment: it absorbs light, thereby increasing the temperature. Below this dark zone, colourless mycobiont filaments form a loose woolly web around the crystals of the rock substrate. The green zone of the lichen-dominated cryptoendolithic community is formed by an association of algae and cyanobacteria. Colourless fungi may also be present in this layer, but they do not form lichen associations with the algae. In some cases the green zone can be absent. A recent comprehensive molecular-based study of both lichen and cyanobacteria dominated communities has shown that these biotopes contain an extensive and varied bacterial population.

The cryptoendolithic growth form is probably the most conspicuous morphological adaptation by lichens to the extreme environmental condition of the Dry Valleys. These cryptoendolithic lichens represent an entirely different type of organization and morphology. In "typical" thallose lichens the mycobiont filaments form a coherent pseudotissue. In cryptoendolithic lichens, in contrast, loose filaments and cell clusters grow between and around the crystals of the rock substrate, and are embedded in the rock matrix. The lichen enters the airspaces of the porous rock for protection against the hostile outside climate.

A further task of Antarctic microbiology will be to test microbial responses under several stressing conditions of aridity, temperature fluctuations, and low temperatures, as well as environmental changes such as increasing UV exposure, to explore how these organisms can outstretch their ability to adapt and also to evaluate their capacity to survive in space conditions. Further investigations of these communities will shed light on their limits of survival, adaptation, resistance mechanisms and on the genes involved. Microbiological research in Antarctica is also relevant in the light of today's discussions on global climate change. Another new line of investigation is the astro/exobiological approach to the search for biosigns (biomarkers and microbial fossils), because we might expect to find similar cryptoendolithic traces of life in Martian rocks.

D

DALLMANN, EDUARD

On the basis of Sir James Clark Ross's reports of numerous "black whales," presumed to be southern right whales, during his Antarctic voyages of 1839–1843, the whaling company Deutsche Polarschiffahrtsgesellschaft of Bremerhaven dispatched their vessel *Groenland* to the Antarctic in 1873 on a reconnaissance whaling voyage. She was a bark-rigged vessel of 458 tons with an auxiliary steam engine of 95 hp. In command was Captain Eduard Dallmann. Born on March 11, 1830, in the village of Flethe, now part of Vegesack between Bremen and Bremerhaven, Dallmann had first gone to sea at the age of 15, and from the age of 20 had sailed on whaling vessels from the tropical waters of the Pacific to the Chukchi Sea. He commanded his first ship, a whaler, at the age of 29.

Groenland sailed from Hamburg on July 22, 1873, and it reached King George Island in the South Shetland Islands on November 18. There was no sign of right whales. To compensate for this Dallmann sent his men ashore on Robert, Livingston, Rugged, King George, Elephant, Clarence, and Snow Islands to kill elephant seals and Weddell seals (for their blubber) and fur seals (for their pelts).

Thereafter Dallmann headed south into uncharted waters and coasted along the west coast of what he called Palmer Land (now Brabant Island). Among the features he discovered and named were Cape Groenland, Hamburg Harbour, Bismarck Strait, the Wilhelm Islands, Booth Island, and Petermann Island. Other names he bestowed have been superseded; for example, Roosen Strait is now Neumayer Channel, named by Adrien de Gerlache de Gomery. Dallmann's farthest south was about 66° S. Open water continued farther south, but since there were neither whales nor fur seals he started back north. On January 11, he discovered a deep, sheltered embayment (later named Dallmann Bay).

Rounding the northern tip of Brabant Island into Hughes Bay, Dallmann corrected the positions of several islands, as shown on the Admiralty chart. He also discovered Lüttick (now Liège) Island and Orléans Strait, although he did not name it.

Dallmann then headed east along Bransfield Strait past Astrolabe and Hope islands to the South Orkney Islands, where he took significant numbers of fur seals, Weddell seals, and elephant seals on Coronation Island. On February 6–7, in fog and among icebergs, *Groenland* encountered a violent gale with dangerously high seas; three of her whaleboats were swept away. After watering at Potters Cove on King George Island, Dallmann headed for home. *Groenland* reached Hamburg on July 22, 1874.

In terms of whaling, the voyage was disappointing; not a single southern right whale had been seen, although numerous rorquals (humpback, fin, and blue whales) had been sighted. However, Dallmann had managed to cover the expenses of the voyage by taking more than five hundred pelts of fur seals, as well as the blubber of Weddell and elephant seals, and the blubber and spermaceti of a sperm whale. On the other hand, he had made a significant contribution to the map of the Antarctic Peninsula and its off-lying islands, although several of the names given by Dallmann were later superseded.

DAVID, T. W. EDGEWORTH

Tannatt William Edgeworth David (1858–1934) was born at the Rectory, St. Fagan's, Wales, the son of the Rev. William David and his wife Margaret (née Thomson), on January 28, 1858. Schooled at home and at Magdalen College School, Oxford, he entered New College, Oxford, in 1876, and graduated BA in 1880, being influenced to study geology by professors Sir Joseph Prestwich and John Ruskin. He began mapping the glacial features around his home, and, thinking to take geology as a profession, enrolled at the Royal School of Mines under J. W. Judd in 1882. He had only a few months at the college, but Judd was impressed with his abilities and recommended him for a position in the Geological Survey of New South Wales, Australia. He began field work in New South Wales soon after he arrived there in November 1882, and was influenced in studying Late Palaeozoic glaciation in Australia by meeting R. D. Oldham, visiting New South Wales in 1885. David's researches in recent, Palaeozoic, and Precambrian glaciation continued through his life (leading to some thirty-eight publications). In 1891, David was appointed professor of geology at the University of Sydney and began to exert influence in both scientific and political circles in Australia, continuing to do so for more than 40 years.

From his childhood days, David had been intrigued by a map in the rectory showing Mount Erebus, but his first direct contact with Antarctic science was in 1895, when he described rocks collected by Carsten E. Borchgrevink (1864–1934) at Cape Adare in 1895. In 1901, he directed his students' attention to Scott's first expedition and the scientific problems that might be answered by Antarctic exploration, and sent written support to Scott.

In mid-1907, David learned of Shackleton's proposed British Antarctic Expedition (1907–1909) and wrote asking to accompany the expedition on the voyage down and returning after the ship had unloaded. He suggested a number of scientific experiments that might be carried out by the then-sole geologist of the expedition, the geology student Raymond Priestley. When Shackleton arrived in Australia, David was influential in raising funds from both government and private sources, had his former student Douglas Mawson appointed as physicist, and for the ship's voyage down and return, students Leo Cotton and W. Hammond. Another Australian, Bertram Armytage, was also in the party. En route, Shackleton persuaded David (who needed little persuasion, although he did not have sanction from the University Senate) to stay for the whole expedition, appointing him chief scientist. David's series of articles written during the short but harrowing trip to Antarctica from Lyttelton, New Zealand, on *Nimrod,* towed for much of the distance by *Koonya,* published in Sydney, were widely circulated, and helped keep the expedition in the news. In later years David's articles and interviews on Antarctic matters supported many Antarctic projects and individuals and often helped separate fact from fantasy.

Although not appreciated by all members of the party (some thought there were too many colonials), David's age (50) and experience helped to maintain the equanimity of the party during the winter months. In March 1908, Shackleton gave David permission to lead an attempt to climb Mount Erebus. Although not particularly difficult in technical terms, this was a first mountaineering challenge for most of the six members of the party (David, Mawson, Alastair Mackay, Jameson Adams, Philip Brocklehurst, and Eric Marshall), with relatively unsuitable equipment and little experience of Antarctic and altitude conditions. The expedition, lasting six and a half days, during which there were a few lucky escapes from injury, reached the active summit—then thought to be above 13,000 feet (13,370 or 4064 m, although now measured as 12,450 feet or 3795 m)—David and Mawson making geological observations en route and at the summit. As Brocklehurst was suffering severe frostbite the party came down quickly, glissading down numerous steep inclines. David provided a long description of the ascent for the volume *Aurora*

Australis, produced at Cape Royds during the winter months. David carried out considerable detailed mapping and collecting in the Cape Royds area.

David took two kites (made in Sydney) to the Antarctic, hoping to use them for meteorological work. These followed the design by the pioneer aeronautic engineer Lawrence Hargrave, who advised how they could be controlled. David was unable to test them before leaving Sydney, and with little or no experience made only one unsuccessful attempt to fly one, being pulled into the air before the kite plunged to Earth with considerable damage.

In early October 1908, David, Mawson, and Mackay set out north from Cape Royds to study the coastal geology and, if possible, to reach the position of the (variable) South Magnetic Pole, as well as exploring the Dry Valleys for minerals, if time allowed. This expedition became one of the legends of Antarctic travel, as it was a man-hauled expedition of some 1260 miles (2030 km), involving a considerable amount of relaying. David's hyperactivity in chasing geological information after periods of heavy hauling, his classical quotations in the midst of pulling, and his physical strength, which was less than that of his colleagues, played upon the nerves of his two younger companions and there were periods of tension between the three, not unusual in such conditions. In the end, they reached only the vicinity of the South Magnetic Pole, their equipment being inadequate for true measurement. Despite this, and the disparity in the physical and mental characters of the three, they made many geological discoveries and succeeded against great natural difficulties. In the next few years David's fundraising in Australia helped in the preparation of the scientific results of the expedition, finally published during the First World War.

David returned to Sydney before the other members of the expedition, which placed him in the centre of attention and invoked numerous articles, cartoons, and events. He was only to be replaced as Australia's Antarctic hero after the tragic events and epic return to base of Mawson in 1912–1913.

David continued to exert considerable influence in Antarctic circles, being responsible for the appointment of all three geologists (Griffith Taylor, Frank Debenham, and Raymond Priestley) to Scott's last expedition (1910–1913). He ensured funding from the Australian Commonwealth and state governments, as well as advising Scott and Edward Wilson on Antarctic conditions. He gave similar help to the Shirase expedition after it arrived in Sydney in dire straits in May 1911, helping it to reorganise before going south again in November 1911.

David was one member of the three-man committee helping organise and gain funding for Mawson's Australasian Antarctic Expedition (1911–1914), and he effectively controlled much of the Australasian end of its affairs. David was supportive of Amundsen when he was being criticised for his assault on the South Pole, and ensured a hearty welcome for him in Australia in March 1912. He was also to the fore when Scott's fate was known, and assisted various members of that expedition when they returned through Sydney.

In 1914, David was instrumental in making *Aurora* available to Shackleton's Imperial Trans-Antarctic Expedition, and he advised later when searches began for the expedition. His interest in Antarctic affairs continued throughout the 1920s, and his help was again invoked in the planning and operation of Mawson's BANZARE of 1928–1930.

Besides his key role in helping Antarctic geologists, many others involved in Antarctic exploration—including Frank Hurley, Frank Wild, Herbert Ponting, Joop Waterschoot van der Gracht, Tryggve Gran, Æneas Mackintosh, and H. T. Ferrar—had David to thank for advice and even financial assistance.

David's charisma, his extraordinary energy, and his organisational abilities ensured that he remained at the forefront of Australian (and indeed international) activities related to the Antarctic until his death in Sydney on August 28, 1934.

DAVIS, JOHN KING

One of the longest-lived and least-well-known Antarctic explorers of the Heroic Age, John King Davis was born in Surrey, England on February 19, 1884, and died aged 83 in Melbourne, Australia on May 7, 1967. A meticulous navigator and skilled ice pilot, he captained five expedition voyages to Antarctica and served on two more between 1907 and 1930, the highlights of a nautical career that spanned 50 years. From 1920 to 1949 he was Commonwealth Director of Navigation in Australia, his adopted country, and even after his retirement he maintained an interest in Antarctica as a member of the Planning Committee of ANARE (Australian National Antarctic Research Expeditions) until 1962.

All of Davis's Antarctic voyages were made on behalf of expeditions led by Ernest Shackleton (three) or Douglas Mawson (four). Both of those leaders relied totally on Davis's competence, but occasionally felt irked by his caution and his insistence on maintaining the safety of his ship—the paramount responsibility of a professional skipper, whatever might be the desires of the "layman" (as he once called Mawson) expedition leader. For Davis was a seaman, first and last. His initiation came at the age of 16 when he ran away to sea to join the full rigged ship *Celtic Chief* as an apprentice. Her skipper Captain John Jones provided Davis with a role model of "a shipmaster of great integrity and skill, vested with supreme authority over the lives of men, charged with the safety of the ship, her cargo and those who served in her, doomed to that loneliness and austerity inseparable from command" (Davis 1962).

This inspired his entire subsequent career. Within seven years, Davis had gained his first mate's ticket and by March 1907 was back in London on the lookout for a new berth. By chance, a friend took him to visit an exhibition of polar equipment in Regent Street—at the headquarters of Shackleton's British Antarctic Expedition. Learning that the expedition's ship, *Nimrod,* needed a first mate, Davis applied and was eventually signed on. To win a chief's berth so soon after getting his ticket was a very rapid career advance and it was this, as much as his interest in Antarctica, that led Davis to accept the job. But he carried it out so efficiently and enthusiastically that Antarctic exploration shaped his career, and his life, from then on.

After two seasons in the Ross Sea, during which Shackleton and three companions reached 97 geographical miles (180 km) from the South Pole, Davis was rewarded, at the age of 25, with his first command, on *Nimrod*'s return voyage to England. Also on the expedition was a young Australian geologist, Douglas Mawson, a member of the first party to reach the vicinity of the South Magnetic Pole, then in Victoria Land.

With his fierce professionalism, Davis was Mawson's ideal choice for skipper of *Aurora,* the ship of his 1911–1914 Australasian Antarctic Expedition (AAE). Mawson's objectives were to engage in scientific research and chart new territory in the section of Antarctica south of Australia, as well as landing a party on Macquarie Island to set up a radio relay station for the first transmissions from his main base, which was eventually set up at Commonwealth Bay in Adelie Land. After establishing the main base in early 1912, Davis sailed westwards along the unexplored coast to the Shackleton Ice Shelf, where the Western Base party remained under the command of Frank Wild. The next season, after waiting in vain for three weeks at Commonwealth Bay for Mawson to return from an inland expedition, and losing three anchors and almost the ship in the fierce katabatic winds that scoured the anchorage, Davis fought his way west again to pick up the party at the Western Base, as they lacked the resources for another winter. The following year, for yet a third time, Davis negotiated the hazards of the Adelie Land pack to retrieve Mawson and his companions, finally reaching Adelaide in February 1914, "very glad they are all safe in Australia again without mishap" (Davis 1914), an outcome largely due to his skills and commitment.

Davis regarded these three voyages of the AAE as his main life's work, and en route to the ice he also carried out pioneering oceanographic research for which he was awarded the Murchison Medal of the Royal Geographical Society, and which Mawson acknowledged was comparable in scientific value to the research results achieved by the expedition's shore parties.

On his return, Shackleton sought Davis's services as skipper of *Endurance* on the Imperial Trans-Antarctic Expedition (ITAE) of 1914–1917, a post that Davis refused and in so doing escaped being trapped in the ice of the Weddell Sea for 2 years. Instead, he spent the war in the Sea Transport Service, commanding troopships carrying soldiers and horses to the Gallipoli and Western fronts until 1916, when he was drawn back to the ice, as captain of his old ship *Aurora,* to rescue the Ross Sea Party of the ITAE, marooned at Cape Evans.

The final call to Antarctica came in 1929, when Davis was appointed captain of *Discovery,* Robert Falcon Scott's old ship, and second-in-command to Mawson of the British, Australian, New Zealand Antarctic Research Expedition (BANZARE). Although undoubtedly the most experienced Antarctic navigator, Davis was by then 45 and had not held a seagoing command for more than 10 years. From the beginning there were disagreements between Mawson and Davis about the expedition's route, which stemmed from Davis's concern about *Discovery's* limited coal capacity and poor sailing qualities. In addition, Davis believed his extensive experience of oceanographic work in *Aurora* should give him authority over the scientific program. Mawson saw this as his responsibility as expedition leader, and a series of conflicts between the two men led to Davis's resignation from the second BANZARE, of 1930–1931.

There is no doubt that Davis's dour and sometimes irascible personality as ship's captain well deserved his nickname, "Gloomy." But this was as much a reflection of his exceptionally high standard of seamanship, which he demanded also of others, and, although a martinet at sea, his friends found him a delightful companion ashore. Their stormy passage on BANZARE was only a brief interlude that both Davis and Mawson put behind them in resuming their long friendship. Mawson later paid tribute to Davis's skill in navigating the sturdy wooden sailing ships that were the backbone of the Heroic Age of Antarctic exploration, and acknowledged that "beneath a rugged exterior he was a God fearing man, kind, trustworthy and courteous" (Davis 1962).

Davis's skill and professionalism as an Antarctic navigator were recognised by the award of two Polar Medals and two bars, and his work as Commonwealth Director of Navigation with a CBE.

DE GERLACHE DE GOMERY, BARON ADRIEN

Adrien de Gerlache de Gomery was born on August 2, 1866, in Hasselt in Belgium, the son of Colonel Auguste de Gerlache and Emma-Thérèse, née Bicops. At the age of 16 he enrolled at the Ecole Polytechnique of the Free University of Brussels to study engineering. But during the summer vacations he worked as cabin-boy on North Atlantic liners. From January 1886, he served on a variety of ships, and in 1890, he joined the Belgian Navy, whence, in 1893, as a lieutenant, he joined the hydrographic vessel *Le Belgique* as first officer.

Having conceived the idea of mounting a Belgian expedition to the Antarctic, in order to gain practical experience in ice navigation he made a cruise to the Greenland Sea on board a Norwegian whaler. Early in 1895 his plans were approved by the Royal Belgian Geographical Society, and a public subscription was opened. In July 1896, de Gerlache bought the Norwegian whaling ship *Patria,* which he renamed *Belgica*.

Belgica put to sea from Ostend on August 23, 1897, and having called at Punta Arenas on January 14, 1898, headed south. Having passed the South Shetlands, de Gerlache headed into the strait now named after him. Then, pushing farther south, *Belgica* crossed the Antarctic Circle on February 15 and finally, on March 2, 1898, became solidly beset in the ice at 71°30′ S, 85°16′ W.

With numerous twists and turns, the route of its drift thereafter was generally westerly, roughly along the 70° S parallel. The expedition members suffered greatly from scurvy and cold; one man died and at least one became seriously mentally unbalanced. Finally, on March 14, 1899, the ship broke free of the ice. She reached Antwerp on November 5, 1899. This was the first expedition to survive an Antarctic winter.

Soon afterwards, de Gerlache took charge of an expedition aboard the yacht *Selika* to investigate the pearl fisheries of the Persian Gulf, but attempts at pearl fishing were disastrous.

In 1905, *Belgica* was chartered by the Duc d'Orléans and, with de Gerlache in command, made three voyages to the Arctic, in 1905, 1907, and 1909, visiting East Greenland, Svalbard, Novaya Zemlya, and Zemlya Frantsa-Iosifa.

With the outbreak of World War I, de Gerlache was very active. For example, he directed the landing and reembarkation of British troops and guns, and coordinating the evacuation of Belgian refugees to Britain. In October 1914, he took refuge in England, then in Christiana (Oslo), and later Stockholm, where he became a persuasive propagandist for the Belgian cause.

After the war he was closely involved with the reorganization of the Belgian Navy and with officer training. He was made Inspector-General of the Navy in 1926 and Director General of the Navy in 1928.

De Gerlache had married Suzanne-Marie-Jeanne Poulet in Nice on December 21, 1904; they had a son and a daughter. After their divorce in 1913, de Gerlache married Elisabeth Höjer in Stockholm on December 28, 1918; they had one son.

He made Baron Adrien de Gerlache de Gomery on November 19, 1924, he died on December 4, 1934.

DEBENHAM, FRANK

Frank Debenham was born in Bowral, New South Wales, on December 26, 1883. He attended the King's School, Parramatta, and then entered the University of Sydney to read Classics, graduating with a BA in 1906. He later taught at Armidale School, before in 1908 reentering the University of Sydney, where he took a BSc Honours degree in Geology and Petrology. While Debenham was at Sydney the second time, Professor T. W. Edgeworth David returned from Ernest Shackleton's British Antarctic Expedition and began working up the results of the expedition's geological field studies.

In 1910, through the influence of Professor David, Debenham was chosen by Robert Falcon Scott and Edward Wilson to be one of three geologists on Scott's second British Antarctic expedition. Debenham was twice a member of the Western Party, which carried out geological work in the mountains and on the glaciers to the west of the McMurdo Sound. His greatest contribution lay in his expertise in plane-table surveying. The plane-table had never been used before as a regular Antarctic sledging instrument prior to Debenham's doing so. On his first western journey, he made a detailed, large-scale plane-table map of the area traversed, gaining considerable experience not only in general survey methods but particularly in the measurements of glaciers. Meanwhile Debenham also collected a great many geological specimens that were subsequently brought back to the museum of the University of Cambridge's Geography Department.

Debenham was much interested in natural phenomena, and, finding a headless fish on top of the Ross Ice Shelf, he used it to formulate a theory on how the ice shelf was formed. He also became the expedition's official photographer after Herbert Ponting left in 1912. In November 1912, Debenham and fellow geologist Raymond Priestley first raised the idea of establishing a "polar centre."

In 1913, Debenham went with other members of the expedition to Cambridge to work up the many scientific results obtained in the Antarctic. His studies were interrupted by the outbreak of the First World War, and he joined the Oxford and Buckinghamshire Light Infantry, serving in France and Salonika, in the latter of which he was severely wounded. He was demobilized as a major and returned to Cambridge, from where he graduated in 1919.

In 1919, Debenham was appointed to the Royal Geographical Society's lectureship in surveying at Cambridge and he was elected into a fellowship at Gonville and Caius College. He also sent a proposal for the founding of a polar institute to the Captain Scott Memorial Mansion House Fund, which began the process by which Scott Polar Research Institute (SPRI) was founded. Debenham became the first director of SPRI, remaining in the position until 1946. He also was made Reader in the Department of Geography in 1928 and the first professor of that subject at Cambridge in 1931. It was to a great extent because of Debenham's abilities that both SPRI and the Department of Geography became leading world research centers.

Debenham retired from the University of Cambridge in 1949, following which he traveled extensively and continued to publish numerous books and papers. He died in Cambridge on November 23, 1965.

DECEPTION ISLAND

Deception Island (62°57′ S, 60°38′ W) is an active volcano in the South Shetland Islands. Its unique landscape comprises barren volcanic slopes, steaming beaches, and ash-layered glaciers. It has a distinctive horseshoe shape with a large flooded caldera. This opens to the sea through a narrow channel at Neptune's Bellows, forming a natural sheltered harbor. It is one of the very few places in the world where vessels can sail directly into the centre of a restless volcano.

The total land area is 98.5 km^2. It is 15 km in diameter and rises to 539 m above sea level at Mount Pond. More than 57% of the island is covered by permanent glaciers. A ring of hills runs around the island and is the principal drainage divide—ephemeral springs flow toward the inner and outer coasts. Several lakes are located on the interior side of the watershed. Kroner Lake is the only geothermal lagoon in the Antarctic.

Approximately 10,000 years ago, a violently explosive eruption evacuated about 30 km^3 of molten rock from Deception Island. The volcano summit collapsed to form the Port Foster caldera. The volcano was particularly active during the eighteenth and nineteenth centuries. Twentieth-century eruptions occurred during two short periods, 1906–1910 and 1967–1970. In 1992, enhanced seismic activity on Deception Island was accompanied by ground deformation and increased water temperatures. Today, the floor of Port Foster is rising rapidly in geological terms, and there are areas of long-term geothermal activity. It is classified as a restless caldera with a significant volcanic risk.

The climate of Deception Island is polar maritime. The mean annual air temperature is –3°C. Extreme temperatures range from +11°C to –28°C. The mean annual equivalent of rainfall is 500 mm. Prevailing winds are from the northeast and west.

Deception Island has a sparse but exceptional flora, including at least eighteen species of moss or lichen that have not been recorded elsewhere in the Antarctic, two of which are endemic. No other area in Antarctica is comparable. Of particular importance are the unique plant communities that grow at the island's geothermal areas, and the largest known community of Antarctic pearlwort *(Colobanthus quitensis)*. Eleven subsites of botanical importance have been proposed as Antarctic Specially Protected Area (ASPA) No. 140.

The benthic habitat of Port Foster is also of ecological interest due to the natural disturbance caused by volcanic activity. Two subsites are currently protected as ASPA No. 145.

Nine species of seabird breed on the island. The world's largest colony of chinstrap penguins is located at Baily Head, on the southwest coast, where an estimated one hundred thousand pairs nest.

The first authenticated sighting of Deception Island was by the British sealers William Smith and Edward Bransfield from the brig *Williams* in January 1820. It was named by the United States sealer Nathaniel Palmer later that year. Also in 1820, Pendulum Cove became the base of the US sealing fleet led by Captain Benjamin Pendleton.

The first scientific expedition to Antarctica, led by the British Captain Henry Foster, visited aboard HMS *Chanticleer* in 1829. Lieutenant Kendall compiled a map of Deception Island, the first accurately surveyed map of an Antarctic landmass.

In 1842, William Smiley of the US sealing vessel *Ohio* gave the first account of a volcanic eruption on Deception Island.

Whaling activities started in 1906–1907. The Norwegian Adolfus Andresen, founder of the Chilean Sociedad Ballenera de Magellanes, used Whalers Bay as an anchorage for whaling factory ships. Between 1908 and 1910, the French explorer Jean-Baptiste Charcot visited to stock up with coal, food, and water and to make repairs to his vessel *Pourquoi Pas?*. In 1912, the Falkland Island Dependencies Government issued a license to Hektor Whaling Company to establish a shore-based whaling station. Approximately 150 people worked at the station during the austral summer, producing more than 140,000 barrels of whale oil. Hektor whaling station was abandoned in April 1931, when whale oil prices slumped.

In 1928, the Australian Hubert Wilkins and the Canadian Carl Ben Eilson undertook the first powered flight in Antarctica, taking off from an improvised ash runway at Whalers Bay. Later, in 1935, Lincoln Ellsworth assembled his aircraft *Polar Star* at Deception Island prior to his pioneering trans-Antarctic flight from Dundee Island. Deception Island was also the base of the Falkland Islands Dependencies Aerial Survey Expedition (1955–1957).

During the 1940s and 1950s, overlapping territorial claims of the Antarctic Peninsula region were upheld by Argentina, Chile, and the UK, and were the source of political tension. Deception Island played a central and important role in the international affairs of Antarctica. In February 1944, the secret British wartime mission Operation Tabarin (the forerunner to the British Antarctic Survey) established its first base (Base B) in the abandoned Hektor whaling station. In 1948, Argentina built Decepción Station at Fumarole Bay. Later, in 1955, Chile built Pedro Aguirre Cerda Station at Pendulum Cove.

Today, Argentina and Spain operate scientific stations on the island during the austral summer. Gabriel de Castilla Station (Spain) is located on the western shore of Port Foster. Science at Deception Island focuses principally upon volcanic monitoring.

The remains of Hektor whaling station, a whalers' cemetery (the largest cemetery in Antarctica), and Base B, partially destroyed by a volcanic eruption in 1969, are now protected as Antarctic Treaty Historic Site and Monument (HSM) Number 71. The remains of Pedro Aguirre Cerda Station, which was destroyed by the 1967 eruption, are listed as HSM No. 76.

Deception Island is the most visited site in Antarctica by tourists. It provides the opportunity for visitors to learn about volcanoes, geothermal activity, and other aspects of the natural world, as well as Antarctic exploration, whaling, and science.

Deception Island was adopted as Antarctic Specially Managed Area (ASMA) No. 4 at Antarctic Treaty Consultative Meeting XXVIII (Stockholm, 2005). The ASMA will incorporate a matrix of ASPAs, HSMs, and visitor sites. This will assure its long-term protection from the competing pressures of science (and the logistical support of science), nature conservation, and tourism.

DECOMPOSITION

Decomposition is the process whereby substances are actively broken down into a number of constituent parts. This might be achieved through biological, chemical, or physical action.

Biological decomposition is primarily mediated by microorganisms. Microbiological decomposers are a key component of the food web and occur at the base of the food chain—in this way, microbial decomposers help to regulate the biogeochemical cycles, including the carbon, nitrogen, and sulphur cycles. They recycle waste materials from living organisms (and indeed the dead organisms themselves), to release bioavailable nutrients; for example, the microbial decomposition of uric acid releases ammonium. Microbial decomposition occurs mainly through bacterial or fungal action, primarily through the excretion of extracellular enzymes, although other types of microorganism are also involved. Often these microorganisms are associated in multispecies groups as consortia or biofilms, thereby enhancing the efficiency of decomposition. Decomposition processes, however, are not restricted to microorganisms—decomposition of food material by digestive enzymes in the gut is also seen in higher organisms.

Chemical reaction can also drive decomposition; for example, consider the chemical decomposition of ozone (O_3) by nitrogen oxide (NO) or chlorofluorocarbons (CFCs) in the atmosphere or the chemical weathering of rock minerals, where minerals in rocks become chemically altered, and subsequently decompose and decay.

Physical processes include the thermal decomposition of minerals, a process particularly associated with volcanic and geothermal activity; shock decomposition through impact, as seen in meteorite impacts; or photolytic decomposition, such as that seen in the chlorofluorocarbons by ultraviolet light.

A variety of experimental methods can be used to quantify rates of decomposition in Antarctic ecosystems. This methodology is based on either direct measurement, for example, in the use of biomarkers and stable isotope analyses to track degradation pathways or indirect measurement, such as the use of cotton strips buried in soil samples to quantify *in situ* rates of decomposition—a method currently in use in the Dry Valley soils. Here, the cotton strips can be recovered after a period of time has elapsed and the level of decomposition determined.

In the Antarctic, decomposition is a relatively slow process, as rates of decomposition are directly affected by both temperature and moisture. Many decomposition processes rely on enzymes and are therefore temperature dependent, while dryness inhibits decomposition. Although the amount of water on the Antarctic continent is high, much of it is unavailable in the solid form, whilst air circulation over the South Pole ensures that the air remains dry. In many Antarctic locations, there is little apparent evidence of decomposition, as relatively small amounts of organic matter exist. In addition, the slow rates of decomposition are demonstrated by the presence of seal and penguin carcasses in the Dry Valleys, some of which have been dated as approximately 3000 years old. As global warming continues, so will these environments warm, suggesting increased rates of decomposition and increased levels of nutrient availability.

A further important consideration, particularly for increasing human activity in Antarctic ecosystems, is that decomposition of waste materials slow. Biodegradation is slow due to low temperatures, so that the removal of pollutants such as oil is difficult.

DEEP SEA

The deep sea (below 1 km) is by far the largest ecosystem on our planet and yet amongst the least well known. About two thirds of the Earth's surface is covered by the marine environment, of which 90% is deep sea. Despite this, mostly owing to its remoteness, less than a soccer-field-sized area has been studied in sufficient detail to reveal the mostly small organisms inhabiting it.

The absence of sunlight entails a lack of plants and algae, which elsewhere form the foundation of life. So in order to maintain their metabolism deep-sea organisms have to rely on other sources of energy. These stem from inhabitants of the narrow photic zone near the sea surface that eventually fall to the deep sea floor, from tiny single-celled algae and plankton fecal pellets to whole whale carcasses.

Not all life there is dependent on the fall of material from the surface, though. A specialized deep-sea community completely independent of light was discovered in 1974 near submarine hot springs, the so-called hydrothermal vents. In such communities chemosynthetic microorganisms are the primary producers by oxidizing sulphuric compounds. The giant worm *Riftia pachyptila* has reduced its digestive tract and instead relies on symbiotic chemosynthetic bacteria stored in its body that make up half of the worm's weight.

In comparison to other marine habitats, one of the defining characteristics of the deep sea, however, is the scarcity of nutrients, and hence the biomass of animals per recorded area is typically low. Of the larger animals, sea cucumbers and brittle stars are particularly numerous and speciose. Also of note are the giant scavenging *Eurythenes* and *Alicella* amphipods, which grow to more than 14 cm. These are attracted by the odour of bait in spectacularly large numbers. The majority of animal species, however, are significantly smaller than their relatives in shallower water and can only be retained by sieves with meshes of 1 mm (macrofauna) and 0.06 mm or smaller (meiofauna).

The single largest source of the deep-sea water masses is the Southern Ocean around Antarctica, where cold and saline surface waters begin to sink due to high density. The descent of the Antarctic Bottom Water into the deep sea and equivalent waters from the Arctic is part of a global hydrodynamic circulatory pattern (like a conveyor belt) and is the primary reason why the deep sea, except in enclosed basins such as the Mediterranean and the Red Sea, is cold (1°C–4°C) and well oxygenated. This high level of oxygenation is thought to explain why some deep-sea organisms achieve anomalously large size.

This continuity of water masses between the Antarctic shelf and the deep sea is closely mirrored by faunal distribution patterns. While deep-sea fauna are composed rather differently compared to shallow waters at lower latitudes, this distinctness fades at high latitudes. Around Antarctica typical deep-sea taxa are found colonizing shallow waters on the continental shelf (polar emergence) as well as shelf species descending into the deep sea (polar submergence). This faunal exchange is further facilitated by the fact that the continental shelf around Antarctica is at a much greater depth (500 m) than elsewhere (200 m) due to the enormous weight of the ice shield on the continent.

The unexpectedly high biological diversity in the deep sea continues to be debated because it is difficult to understand how so many species could evolve and can coexist today in a habitat that appears rather homogenous. Although records of benthic storms, submarine tides, and debris flows help overcome the idea of physical stability of the environment, the few ecological studies carried out so far have failed to demonstrate the degree of specialization that would traditionally be associated with the coexistence of so many species.

The number of species in the Antarctic deep sea is of importance for answering the question of whether there are indeed fewer species living in polar than in tropic latitudes and if so, what processes might be responsible. This trend is well established for terrestrial habitats but is far less evident or even absent for the marine realm, especially in the Southern Hemisphere.

Although hydrostatic pressure is not *per se* stressful for organisms permanently living in the deep sea, it requires physiological adaptations because the equilibria of biochemical reactions may be shifted, sometimes dramatically, compared with shallower depths when the catalysed reaction involves changes of volume of the reagents.

Experimental deep-sea mining for ferromanganese nodules has been carried out but is in its infancy still. It is currently under investigation whether the disposal of carbon dioxide in deep-sea sediments on an industrial scale can lessen the effect of global warming, but concern about the environmental consequences exists. Disposal of used equipment and waste into the deep sea is a reality, although subject to debate (Brent Spar). To date, the Antarctic part of the deep sea south of 60° S has been environmentally protected since 1959 under the Antarctic Treaty as "...a natural reserve, dedicated to peace and science."

DEEP STONE CRABS

Crabs are nearly absent from the Southern Ocean (within the Polar Front), but one group, the stone crabs, are known to occur in several hundred meters of water at South Georgia and along the Antarctic Peninsula. Recently they have also been found at Bouvetøya and at a continental Antarctic site.

The term ''stone crabs'' encompasses several crab-like species pertaining to the family Lithodidae. The best-known representative is the Alaskan red king crab *Paralithodes camtschaticus*. Lithodid crabs are phylogenetically more closely related to hermit, coconut, or mole crabs (such as *Pagurus, Birgus,* and *Emerita*), or to squat lobsters (such as *Munida*) than to true crabs (brachyurans). Lithodid crabs rank among the world's largest arthropods (invertebrates with articulate legs), and some species attain a leg span of 1 m.

Lithodids have ''tails'' or fan-shaped abdomens that are folded underneath the shell. Crabs have a pair of strong claws, three pairs of walking legs, and a pair of rudimentary legs used for grooming branchiae and egg-masses, or for sperm transfer. The female abdomen is distinctly asymmetrical, bearing four to six pleopods (modified legs) to which eggs are attached and carried during a variable period of time (up to 22 months). True crabs (brachyurans) have four pairs of walking legs and always a symmetrical abdomen, and females have four pairs of pleopods (swimmerets).

Lithodids are widely distributed in depth, from the intertidal as *Lithodes confundens* to the abyssal depths (4152 m) as *Paralomis bouvieri*. They typically inhabit the subpolar regions of both hemispheres. The high concentrations, size, and tasty flesh of king crabs promote their fisheries in different locations. In the North Pacific, landings of *P. camtschaticus* and the blue king crab *P. platypus* peaked at 74,000 tonnes in the early 1980s. In southern South America, the fishery for *Lithodes santolla* and *Paralomis granulosa* yields 3000 tonnes per year, and an exploratory fishery for *P. spinossisima* and *P. formosa* has been conducted off South Georgia and Shag Rocks. The gear used to fish for stone crabs is the baited trap.

Lithodids have a notable migratory pattern intertwined with mating, and associated with seasonal abiotic factors, mainly temperature, salinity, and photoperiod. They move in discrete groups that are often segregated into sex and size classes. Sub-Antarctic stone crabs migrate to very shallow waters for female moulting and mating in early summer. On average, Alaskan king crabs move 1 km per day and can reach up to 13 km per day, with a range of 12 km^2.

Deep stone crab *(Lithodes santolla)* from Tierra del Fuego. (Courtesy of David K. Barnes.)

Females moult under the protection of a larger male. Moulting is followed by mating: fertilization is external, occurring under the female abdomen. Females carry thousands of embryos for at least one year. Once these embryos are fully developed, they hatch as a swimming larva, which is morphologically different from an adult crab. Larvae undergo several body changes until they metamorphose into a juvenile crab, which settles to the sea bottom. Since crab exoskeleton is principally made of calcium, they moult their shell to grow. Moulting frequency decreases with age: juvenile crabs moult six to seven times during their first year and large adult crabs moult annually or even biennially. Lithodids can live up to 20 years.

Stone crab feeding habits vary with species, age, size, and depth. They are generalists (eating upon several items and mostly according to the environmental availability) and prey on snails, mussels, sea-urchins, squat lobsters, crabs, and algae. Stone crabs are also scavengers.

Lithodid crabs are the only representatives of "reptant" decapods (crabs and lobsters) that occur south of the Polar Front. In invertebrates low temperatures result in low metabolic rates and reduce their activity. Lithodids may tolerate constraints imposed by the cold and short periods of food availability at high Antarctic latitudes. Stone crabs have a prolonged brooding, and larval development is abbreviated and independent of external food. At hatching, larvae are provided with enough yolk to survive until metamorphosis and overcome the mismatch to the short period of food availability (planktonic algae). Larval hatching occurs over an extended period of time, not involving strong flapping movements of female abdomens, which would demand high energy consumption.

The family Lithodidae is of recent origin, arising between 25 and 13 Ma in the northeastern Pacific Ocean. Although the ancestor and primitive lithodids lived in the intertidal, radiation (diversification from an ancestral form to adaptively specialized forms) is thought to have occurred via deep cold water. Hence, tropical lithodids crossed the tropics into the temperate, sub-Antarctic (later), and Antarctic (recent) regions of the Southern Hemisphere. In the sub-Antarctic waters there are thirteen stone crab species, among which are the commercial *Lithodes santolla, L. confundens,* and *Paralomis granulosa*. In the Antarctic, from the eight recorded species, three still remain to be described for science. The most common Antarctic stone crabs are *L. murrayi* and *P. birsteini*.

DESICCATION TOLERANCE

Although survival of low temperature is perhaps the most obvious challenge to living in the Antarctic, the ability to survive the desiccating conditions of this cold desert is equally important. Most of the continent is permanently covered by snow and ice, and in its frozen form water is not available for organisms to use. This leaves only 1% of the continent, mainly the coastal regions, where there is ice-free ground and where melt water may be seasonally available during the brief Antarctic summer. Many of the organisms that are successful here are similar to those found in hot deserts. In fact, there is considerable overlap between the adaptations for cryoprotection and desiccation tolerance.

Some of the largest animals that can survive these extreme conditions are the cold-tolerant mites and springtails, but these are only a few millimetres long. The mite *Alaskozetes antarcticus* has a waxy cuticle, which reduces water loss. Mites and springtails are freeze avoiding and accumulate antifreeze compounds during the winter, which allow them to survive in a supercooled state. These compounds, such as glycerol, are also thought to aid water retention, while others, including trehalose, are known to protect membranes during desiccation. While the animal's body fluids remain liquid, in a supercooled state, they are susceptible to dehydration in a way similar to how uncovered food will dry in a domestic refrigerator. This occurs because the water vapour pressure of the animal's supercooled body fluid is higher than that of ice in the environment, even at the same temperature. This loss of water causes an increase in the solute concentration of the body fluids and a reduction in the diffusion gradient until a state of equilibrium is reached. If the temperature reduces further, more water will be lost. Some animals, such as the Arctic springtail *Onychiurus arcticus,* synthesise high concentrations of trehalose from glycogen stores, enabling them to survive the loss of 80% of their water. Desiccation protects against freezing, as without water they cannot freeze. However, organisms that can survive freezing are not susceptible to desiccation.

Many plants and microscopic animals survive the Antarctic winter in an anhydrobiotic state and remain dormant until water becomes available. Few higher plants survive in this way, but some mosses, lichens, algae, and cyanobacteria can exist without water for long periods. Some of these produce specialised proteins called dehydrins, which are responsible for the production of compounds that protect cells from damage during desiccation. A feature of these organisms is that they can survive even rapid drying and can recover in a matter of minutes. Other organisms change their physical form during periods of drought to reduce water loss. Nematodes, such as *Panagrolaimus davidi,* coil during desiccation, while some tardigrades form a tunlike structure. The macroalgae *Prasiolla crispa* has thick cell walls and an absence of vacuoles, which enable it to survive up to 90% water loss. As it dries its form changes from a crinkly lettuce leaf to a thin, polythenelike structure. In this form it maintains a slightly moister environment beneath it where microarthropods can survive. Some snow-free areas of the Antarctic continent, such as the Dry Valleys, receive very little precipitation. Here, only the most desiccation-resistant organisms, such as nematodes, rotifers, and tardigrades, are found.

DISCOVERY INVESTIGATIONS (1925–1951)

The Discovery Investigations were initially intended to research scientifically the biology of whales in the Atlantic sector of the Southern Ocean in order to conserve the whaling industry in the area of the Falkland Islands Dependencies. The work was funded by a tax on all whale oil produced in the Dependencies. Shore-based whaling started in South Georgia in 1904, and a suspicion that whales were being overfished was being voiced by 1910.

An advisory interdepartmental committee, set up by the British government, recommended an executive committee to manage a scientific expedition to investigate the total ecology of whales in the South Atlantic. Ernest Rowland Darnley of the British Colonial Office and Dr. Sidney Frederick Harmer, keeper of zoology at the British Museum (Natural History), became chairman and vice chairman, respectively, of a committee that oversaw the equipping, staffing, and execution of the investigations.

The first ship chosen for the scientific work was *Discovery,* built for the British National Antarctic Expedition (1901–1904), which gave her name to the Committee. Her captain was Commander Joseph Russell Stenhouse. Dr. Stanley Wells Kemp was the director of research from 1924 to 1936 and overall leader of the investigations. Two further purpose-built ships were employed: *William Scoresby,* initially intended to mark whales with retrievable darts to show the migration and movements of the population, and *Discovery II,* an oceanographic research ship equipped with up-to-the-minute technology. To enable anatomical and analytical studies to be made, a laboratory with residential accommodation was built at Grytviken, South Georgia, near the whaling station. This enabled scientific investigation of whale carcasses. Work there also included analysis of sea water and the fauna of South Georgia.

In the first three years of the program (1925–1927), *Discovery* investigated the environment of the whales, including their food and its distribution, taking water samples regularly. They visited South Africa, South Georgia, the Falkland Islands, the South Orkney Islands, the South Shetland Islands, and the Bismarck and Gerlache straits. The farthest point south was 64°58′ S. They took measurements between Deception Island and Cape Horn. *Discovery* proved unsatisfactory as an oceanographic research vessel and was replaced in 1929 by *Discovery II*.

The results of the investigations laid the foundations of almost all Southern Ocean science. The scientific papers resulting from the work were published in *Discovery Reports,* twenty-five volumes before 1949 and twelve more by 1980. The external details of the size and proportions of the principal species of whales were defined, together with their life histories, details of breeding, pregnancies, periods of lactation, and growth rates. Their summer diet in the Antarctic was defined and their parasites described. The seasonal migration of humpback whales and the segregation of their different communities was established, as was the tendency for blue and fin whales to return to the same Antarctic areas.

As a result of this knowledge gained, it became apparent that it would be useful to study the oceanography of the Southern Ocean. The origin of water masses was accounted for, and variations caused by geographical features were mapped. The effect of wind on currents was estimated together with the actual and relative speed of water movements. The important effect of the Weddell Sea on the Southern Ocean, and the formation and distribution of bottom water, was demonstrated. They also mapped the Antarctic Convergence. The concentration, distribution, and circulation of nutrient salts were described and mapped. The detailed topography of the Scotia Arc and its hydrological and geological significance were explained.

They surveyed the plankton in detail and found out what influenced its growth and migration. Intensive studies of krill established that it migrated vertically as well as horizontally and had connections with the movement of plankton in general. Detailed information was gained of the oceanographic conditions around South Georgia and the South Shetland Islands.

Although it was not a surveying expedition, surveys were made of the South Sandwich Islands, the South Orkney Islands, and the South Shetland Islands, and some of the coastline of Queen Maud Land, Kemp Land, and Mac.Robertson Land was surveyed and sounded. Visits were made to remote islands such as Tristan da Cunha, Marion, and Campbell islands.

A few surveys were made outside the Southern Ocean, including one of the Peru Coastal Current, a trawling survey of the Patagonian Continental Shelf, and lines of deep-sea stations at 30° W from the Antarctic to 15° N, and one on the eastern side of the Indian Ocean to 10° N.

A large collection (thirty thousand jars) of specimens of marine fauna was made and stored at the Natural History Museum, London.

The ships were occasionally used for assistance to explorers. Sir Hubert Wilkins made use of *William Scoresby* when exploring Graham Land in 1929. *Discovery II* was used twice. On the first occasion, in 1934, it met *Bear of Oakland* in the Ross Sea in order to exchange Richard E. Byrd's expedition doctor, who had dangerously high blood pressure, for a relief doctor from New Zealand. The second rescue, in 1936, was to collect Lincoln Ellsworth and his pilot Hollick Kenyon from Little America, when they were supposedly lost after flying across Antarctica.

The active part of the research work was suspended during the Second World War, although N. A. Mackintosh, then director of research, continued desk work in the UK. A small subcommittee chaired by James M. Wordie advised on the organization of Operation Tabarin, a British Antarctic operation set up towards the end of the War. *William Scoresby,* then a minesweeper based in the Falkland Islands, was used as transport. Operation Tabarin ultimately developed into the British Antarctic Survey.

By 1949, the ships had not been returned by the government for use after wartime requisitioning. The Discovery Investigations were therefore absorbed into a new organization, the National Institute of Oceanography. This organized *Discovery II*'s sixth commission, a second winter circumnavigation.

DISEASES, WILDLIFE

Disease can be due to parasites, viruses, bacteria, or fungi that invade the tissues of an animal to visibly and deleteriously affect its health.

Very little is known of diseases in populations of seals and birds in Antarctica although they are known to be prone to a wide range of diseases in captivity. Reported occurrences are rare and it is not known whether the infective agents are native or nonindigenous. It is likely that infective agents are present among populations but diseased individuals appear not to be observed. As healthy animals can carry low levels of potentially harmful organisms without succumbing to disease, such subclinical disease is hard to detect as its symptoms may be confused with other conditions such as starvation. Further, the problem of detection is great in Antarctica and even on the sub-Antarctic islands where there are few observers and the animal populations are located remotely from human activity.

Ectoparasites are found on most species. The flea *Glaciopsyllus antarcticus,* which infests Antarctic fulmars *Fulmaris glacialoides* and snow petrels *Pagodroma nivea* is the only flea found on the Antarctic continent. Several species are found among sea birds of the sub-Antarctic Islands. The tick *Ixodes uriae,* which can transmit disease, is widespread among sub-Antarctic sea birds but is absent from those breeding on the Antarctic continent. Heavy infestations of ticks, particularly on chicks, can affect survival even in the absence of disease. Ectoparasites infesting seals include sucking lice and nasal mites.

Gastrointestinal nematodes and cestodes appear widespread in a number of species of birds. Burdens of these endoparasites tend to be heaviest in juvenile birds and generally only contribute to mortality when combined with starvation or other forms of stress. Blood smears from a number of wild Antarctic and sub-Antarctic species of bird have been examined for the presence of parasites. Except for a hematozoan *Hepatozzon albatrossi* in the blood of three albatross species on South Georgia, all tests have been negative.

Avian cholera *Pasteurella multocida* was reported as the cause of death in the brown skua *Catharacta lonbergi* on Livingston Island, rockhopper penguins *Eudyptes chrysocome* on the Campbell Islands, chinstrap penguins on South Georgia, and the yellow-nosed albatross *Diomedea chlororhynchos* on Île Amsterdam. A variety of bacterial species of unknown pathogenesis but including *Escherischia coli* and *Salmonella* sps. have been isolated from Adélie penguins *Pygoscelis adeliae* and skuas *Catharacta maccormicki* in the Ross Sea region. *Campylobacter* spp. have been isolated from skuas, penguins, and albatrosses on Bird Island, South Georgia. The zoonosis Lyme disease is caused by the spirochaete *Borrelia burgdorferi,* which is carried by sea birds transmitted by *Ixodes* ticks. It has been found through DNA analysis in ticks on the Campbell Islands and Îles Crozet. King penguins on Îles Crozet have antibodies to *B. burgdorferi*. There is evidence to suggest that emperor and Adélie penguins near Mawson Station and penguins, skuas, and albatrosses on Bird Island have been exposed to *Chlamysophylia psittaci,* which causes psittacosis (ornithosis).

Several mass mortalities have occurred in penguin colonies. All have been localised to single colonies and single species, and appear to be self limiting. Causal agents were not identified. Gentoo penguins *Pygoscelis papua* on Signy Island were reported with symptoms resembling the virus disease puffinosis found in several Northern Hemisphere sea birds. Adélie penguin chicks, seemingly well fed, were found dead and dying near Mawson Station. A loss of normal muscular coordination (ataxia) was observed before death.

The presence of antibodies suggests that several species have been exposed to viral or bacterial agents that can cause disease. However, there is no evidence to suggest that any clinical expression of these diseases has occurred. Antibodies to avian paramyxoviruses (APMV) and Avian Influenza (AI) appear widespread and persistent among Adélie penguins and skuas in Antarctica. Antibodies to Newcastle disease virus (NDV), a paramyxovirus, have been found in Adélie penguins. Either AI or NDV, if present as a virulent strain, could be catastrophic for avian populations. Antibodies to Avian Influenza (AI) virus have been found in Adélie penguins at Casey Station and in skuas in the Ross Sea region; no actual virus particles have been isolated from those birds. Antibodies to flaviviruses have been found on several species of sub-Antarctic birds. Infectious bursal disease virus (IBDV) serotype 1 appears endemic in Adélie penguin, emperor penguin, and skua populations.

Among seals, antibodies to canine distemper virus (CDV) (a morbilli virus) have been found in crabeater seals *Lobodon carcinophagus* and leopard seals *Hydruga leptonyx* but not Weddell seals *Leptonychotes weddelli* at the Antarctic Peninsula. Antibodies against European phocine herpes virus were detected in Weddell and crabeater seals in the Weddell Sea. These seals were suffering from respiratory disease at the time and titres in some animals were high, suggesting that the symptoms may have been due to the virus. No antibodies to influenza A have been detected in Antarctic seals despite its presence in the birds. Anti-Brucella antibodies were found in Antarctic fur seals and Weddell seals at Cape Shirreff. Brucellosis is a zoonotic bacterial disease that can cause abortion in affected animals. Approximately 1500 crabeater seals were found dead in 1955 in the Crown Prince Gustav Channel to the northeast of the Antarctic Peninsula. A contagious viral disease was suspected but no samples were taken or pathological investigations made. A mass mortality of fur seals occurred on the Auckland Islands in 1988. No definitive cause was determined despite extensive tests.

The significance of finding antibodies to a number of viruses and bacteria known to cause infectious disease elsewhere is uncertain. It does not follow necessarily that the animal has actually suffered from the disease. The host species could have been exposed in the recent past to the specific disease-causing agent or alternatively to a serologically related but nonpathogenic strain. This latter case may provide some cross-immunity to the pathogenic strain.

It is likely that most disease outbreaks will be due to organisms now endemic in the populations. There are also many natural pathways, for example, through migratory species, for the potential introduction of disease-causing organisms. Human activity also has the potential to introduce diseases or help spread them from one site to another, though there is no evidence that this has occurred to date. Vigilance is required to ensure that increasing human activity does not introduce infectious agents or contribute in other ways to the development and spread of disease.

DIVING—MARINE MAMMALS

The essential concepts of diving biology revolve around one central issue: how do marine mammals remain underwater for such a long time while exercising? This seems contradictory to us as a terrestrial species: if humans wish to extend their ability to breath-hold, they remain as quiet as possible. The equivalent idea would be for humans to perform aerobics while breath-holding. Add to this the problem of withstanding extreme pressure from diving and, in polar regions, where water is at freezing temperatures, and it becomes a very interesting question how marine mammals dive.

To approach this question, we need to think about what is "normal" for a marine mammal. For these animals, they must be able to navigate, find food, in many cases reproduce, vocalize, and migrate while underwater. In fact, for species that rarely come to the surface, it might be easier to classify them as "surfacers" rather than divers—that is, being underwater is "normal" and being at the surface is relatively infrequent. Thus, their environment is not extreme to them, because they have adapted to those conditions over millions of years. With that perspective, it becomes easier to compare terrestrial and marine mammals and explore the nature of diving.

Maximum Diving Depth and Duration for the Different Pinniped Species That Live Near or in Antarctic Waters.

Species	Maximum Depth (m)	Maximum Duration (minutes)
Weddell seal	700	92
Crabeater seal	713	24
Ross seal	372	11
Southern elephant seal	120	1500
Antarctic fur seal	100	10

All of these data were collected with versions of time-depth recorder (TDR) technology.

By itself, diving in polar regions is not different from diving in the tropics in terms of fundamental biological adaptations. However, the additional factors of cold water, dealing with sea ice, and living through months of complete darkness add difficulties to the marine system. In spite of these problems, most of the detailed physiology and biochemistry of diving have been discovered in Antarctic studies.

We should begin by exploring some of the methods that are *not* used by diving mammals to remain underwater for long periods.

The primary marine diving mammals are whales, seals/sea lions, and dugongs/manatees. There are also other diving species that live near the sea, but usually don't dive as well (polar bears, sea otters). All of these animals are mammals, like humans, dogs, cats, cows, and elephants. They do not have gills like fish, they cannot breathe underwater through their lungs, nor do they absorb oxygen through their skin like some amphibians. They must take all the oxygen with them from the surface and use it at such a rate that they have enough oxygen to make it back to the surface. They need oxygen like other mammals and don't have any significant biochemical adaptations that would allow them to live without it. They do not hibernate underwater nor reduce their body temperature to such a low level that they do not need to use oxygen at normal rates. In fact, for the most part, they have a body temperature (37°C) very close to that of humans and maintain that temperature even in polar waters below freezing (–1.8°C). This is an important point because of the well-known cases of human children falling into ice-cold waters for long periods and not drowning. The children essentially shut down their need for oxygen by being extremely cold and thus survive what could have been a lethal event. While there are some components of diving biology involved in these cases, the primary event is that their entire body becomes very cold and their need for oxygen drops significantly. Marine mammals must stay alert underwater, swim, exercise, vocalize, digest their meals, and perform a host of other behaviors that require them to stay warm.

A more surprising aspect of diving is that the amount of oxygen carried in the lungs of most divers is not an important part of their diving ability. Again, this is contrary to the human response of taking a large breath before swimming underwater. In many cases, marine mammals exhale before diving. There are a variety of reasons for this particular adaptation, but complications dealing with the extreme pressure of diving and how that would impact air in the lungs seem to outweigh the need to carry oxygen in the lungs for use underwater. It turns out that they carry most of the oxygen they need in the blood and in the muscles.

Finally, we know most about diving in seals and sea lions because of our ability to work with them in the field and in laboratories. We know much less about manatees and even less about whales. We can watch all of these species from the shore, from planes, boats, and other platforms. We can put dive recorders on them to time their dives and track their locations. But even the simple question of asking the heart rate of a diving sperm whale while underwater at a mile deep becomes a major technical challenge.

If these are many of the aspects of how marine mammals don't dive, we can more easily turn to the question of what mechanisms they do utilize to dive underwater and what we know about marine mammal diving from the Antarctic.

In order to dive for long periods, there are primarily two levels of adaptation that have been successfully utilized by the diving mammals: maximize the amount of oxygen carried and use it more slowly. In both of these areas, fundamental studies of the mechanisms involved have been carried out in the Antarctic, mostly with Weddell seals *(Leptonychotes weddellii)*. Weddell seals are superb divers (the duration record is over 90 min) and are able to dive very deeply (up to 700 m or more). They are large seals, are easy to approach and handle, occur in large numbers near their rookeries, and spend a great deal of time on the frozen ice surface. The unique features of their behavior and habitat have made them the most studied of all marine mammals for diving physiology under natural conditions.

The study of diving Weddell seals began with Gerald Kooyman, at the Scripps Institution of Oceanography. In the late 1960s, he was a graduate student, working at McMurdo Station on Ross Island in the Ross Sea. He observed Weddell seals on the ice and noted that they seemed to dive for very long periods (over 20 min). Eventually, he built a homemade dive recorder and found out that the seals could dive for over 40 min and up to several hundred meters deep. This was a revolutionary result and he found it hard to convince the scientific community with such simple devices. Thus began a 30-year program of research for him in the Antarctic working with Weddell seals and other superb divers, such as the emperor penguin. His laboratory built more sophisticated recording devices to attach to the seals and also described a unique method of conducting detailed physiological diving studies on the seals.

McMurdo Sound is seasonally covered with ice for at least 20 miles away from the research station. This ice is about 2 m thick in normal years and forms a stable platform for research, logistics, and travel. The Weddell seals move into this area in late August to begin their breeding season and do so by exploiting natural cracks in the ice, which they use as breathing holes and for accessing the surface to rest. By early November, hundreds of them are on the ice within 10 miles of McMurdo Station. Kooyman put a 1-m-diameter hole in the ice about 5–6 miles offshore and far away from other cracks. He constructed a hut over the hole and equipped it with a variety of medical and research tools for studying the seals. His team would then capture a seal near the shore and bring it to the hut. Once there, they could put on diving monitors and release the seal into the hole. The seal could dive, swim, sleep, or rest, but it would always have to come back to the hole to breathe, unless it found a way out and escaped back to the shore. Using this method, Kooyman was able to resolve fundamental issues such as breathing rates while recovering from dives, diving lung volume, heart rate during initial dive descents, and a suite of other fundamental aspects of diving recovery. He and Bob Elsner, also from Scripps, studied pregnant Weddell seals at isolated holes and determined how fetuses responded to long-duration diving of the mother. By the late 1970s, Kooyman's laboratory was building very sophisticated Time–Depth Recorders (TDRs), which were able to trace diving duration and depth for up to two weeks. He initially put these devices on seals in the huts, and then on seals at the rookeries. The combination of these innovations, the isolated diving hole and the TDR, revolutionised the field of diving physiology and biochemistry. Both of these methods continue to be used for diving studies in the Antarctic and the manufacture of TDRs is now a competitive business with companies producing smaller, lighter, and more powerful devices. Needless to say, the original TDRs are obsolete relative to their electronic descendants. But their origins were on the ice, in the Antarctic.

From the pioneering work of Irving and Scholander in the 1940s, models of how diving mammals functioned had been built on laboratory studies at Universities and other research sites. They proposed the dive reflex theory, which suggested that marine mammals could alter blood flow during the dive such that the oxygen-rich blood would be redirected to the more central organs (heart, lung, brain) and heart rate would decline while the animals were submerged. They postulated that the peripheral organs (muscle, liver, kidney, etc.) received relatively little blood flow and thus became oxygen limited. As supporting evidence, they documented the increase in lactic acid in the blood (a waste product of metabolism that occurs when oxygen is low). Scholander later referred to the refined ability in marine mammals of redistribution of blood flow as a component of the "Master Switch of Life." Kooyman noted that Weddell seals could dive many times in a row without much time at the surface to recover. This seemed at odds with the dive reflex theory, which held that seals stay at the surface to restore their oxygen levels and to metabolize the lactic acid that has built up in their blood.

In an early isolated hole study, Kooyman found that heart rate would drop in Weddell seals during diving, as predicted by Scholander, but not in the expected pattern: during short dives, the heart rate stayed relatively elevated while longer divers had lower heart rates. Could it be that the dive reflex could be modified by the seal depending on the length of the dive? By 1977, Kooyman had designed a study where seals were taken to the isolated diving holes and simple blood-collecting catheters were placed in the animals along with TDRs. He and his colleagues found that short dives (less than about 20 min) did not show the expected increase in lactic acid, but lactate appeared in longer dives in a graded manner. Further, the longer dives had correspondingly longer recovery times at the surface in order to remove the lactic acid from the blood. It appeared, at least with Weddell seals diving in these experiments, that they did not use the Master Switch as described by Scholander, but more accurately used a "Master Dimmer Switch"; they could tune the strength of the diving response to the nature of the upcoming dive. Long dives required a strong response so that they could remain underwater for long times. Short dives did not. The dive duration break point was named by Kooyman the Aerobic Diving Limit (ADL) and was defined as the dive time under which lactic acid would not appear in the blood after the dive.

Armed with this information, the Kooyman team returned to McMurdo, but this time worked only with seals at their natural haul-out sites. They placed dozens of TDRs on seals and left them alone for up to

2 weeks. On recovering the devices they found that about 95% of the natural dives were shorter than the ADL. Further, the surface recovery time followed the same pattern: short dives had short recoveries, while longer dives had longer recoveries. ADL theory is now the most accepted model of diving physiology and has been cited hundreds of times on multiple species.

Once the TDR and the isolated diving hole method became accepted by the scientific community, the number of studies using them increased and the studies became more complex. Warren Zapol from Boston (Massachusetts) General Hospital developed sophisticated surgical methods and diving devices that could be used to collect blood samples from Weddell seals while they were diving at depth. They found that the seals apparently altered the amount of oxygen in the blood while diving, perhaps by controlling the number of blood cells that were in circulation during a dive. They also monitored the body temperature of Weddell seals while they were diving and found the seals cooled down by a few degrees. As previously discussed, cooling can help lower the need for oxygen, and this allows the seals to dive longer. Eventually, students of Kooyman (including the author) adapted the isolated hole methods to our own questions: I and my students explored the nature of how Weddell seal pups develop their diving abilities, what happens when they sleep (it turns out they hold their breath while sleeping), and how they digest their meals when they successfully capture fish or squid. Randall Davis from Texas A&M developed small and robust seal-mounted cameras that have shown us how Weddell seals navigate and find and capture their prey underwater. Terrie Williams (a Kooyman postdoctoral fellow) from the University of California at Santa Cruz (UCSC) has discovered fundamental swimming adaptations (gliding and stroking balance) that allow the seals to be extremely efficient underwater and thus conserve the precious oxygen they carry with them. Paul Ponganis, also from Scripps, has taken the isolated hole technique and applied it to study diving in emperor penguins in the Ross Sea. Elsner and Wartzok used isolated hole studies to examine how Weddell seals navigated under the ice.

The Antarctic has provided a rich seam for the study of diving in seals, but what about the diving biology of whales? Most diving studies of whales cannot be conducted using the methods developed for seals, but since whales share many of the features of seals, even the studies of seals have provided an important guide to the biology of diving in whales. There is still a lot of potential to work on diving mammals in Antarctic waters. Experiments based on the isolated-diving-hole paradigm are becoming more complex and providing deeper knowledge of the physiological, biochemical, and medical bases for diving.

DOGS AND SLEDGING

Dogs

For thousands of years, dogs have been pulling the sledges of the Inuit in the Arctic. It was therefore not surprising that the first party to winter on the Antarctic continent in 1898, Carsten Borchgrevink's *Southern Cross* expedition, took dogs. Otto Nordenskjöld's Swedish expedition used dogs very successfully in 1901 on the Larsen Ice Shelf with a journey of 380 miles. However, they proved of much less value on the British National Antarctic Expedition (1901–1904) under Robert Falcon Scott and on Ernest Shackleton's expedition on *Nimrod* (1907–1909). Little did the British realize at the time that this was due more to their inexperience in training and driving dogs than to the capabilities of the animals.

Roald Amundsen's magnificent journey to the South Pole in 1911 proved beyond a doubt that dogs were the best means of pulling loads in the Antarctic. He took ninety Greenland dogs plus twenty pups to his base at the Bay of Whales in the Ross Sea. He eventually took four thirteen-dog teams on his main southern journey, each pulling slightly more than 1000 pounds, except for the lead team, which had a load about 100 pounds lighter. Twenty-four of Amundsen's dogs were killed at the top of the Axel Heiberg Glacier and fed to the men and other dogs. In total, forty-one dogs were killed, and the party returned to the base at Framheim with eleven very fit animals having covered 1860 miles in 89 days. When Amundsen reached Hobart, Tasmania, he ended up donating twenty-one dogs to Douglas Mawson's Australasian Antarctic Expedition (AAE), although these did not engage in extensive work on the AAE, as they were in the Antarctic only for the second year, in which much less sledging was undertaken.

In contrast to Amundsen's efforts, none of the two British expeditions of the Heroic Age gave such an important place to dog transport. Scott's first expedition had thirty-three smaller Western Siberian Ostiak-type dogs, plus two Greenland dogs presented by the American Arctic explorer Robert E. Peary and one New Zealand collie bitch. Shackleton took a small number of Siberian huskies but concentrated his efforts on his ponies; the dogs only came into their own on Ernest Joyce's depot-laying trip late in the expedition. On Scott's second expedition, he intended to use ponies, motor transport, and, most importantly, man-hauling, as well as his thirty-three Siberian huskies. Shackleton's Imperial Trans-Antarctic Expedition planned to cross the continent relying on dogs, but was halted in the Weddell Sea. Mawson's AAE originally obtained fifty Greenland dogs, although only twenty-eight remained alive by the time they established the main base at Cape Denison.

After this mixed start, dogs remained the main form of transport for British expeditions in the mountainous landscapes of the Antarctic Peninsula until the mid-1970s. As tractors, ski-doos, and aircraft became more reliable, they gradually replaced dogs. Americans relied entirely on mechanical transport in the 1950s, although more than 100 dogs had supported the pioneering flying efforts of Richard E. Byrd's first expedition.

Dogs were finally banned from the Antarctic, officially on environmental grounds, under the 1992 Protocol on Environmental Protection to the Antarctic Treaty. The last fourteen dogs left the British base at Rothera on the Antarctic Peninsula on February 22, 1994.

British Sledging and Dog Expertise

The greatest impetus to Antarctic dog-sledging came with the British Graham Land Expedition (BGLE) (1934–1937). John Rymill's party brought with it the skills and techniques of the Inuit from Greenland, where Rymill, W. E. Hampton, Quinton Riley, Alfred Stephenson, and Edward Bingham had all been with Gino Watkins on the British Arctic Air Route Expedition. Bingham, as well as being surgeon, was also in charge of the dogs. They traveled extensively down King George VI Sound and proved that the Antarctic Peninsula was part of the mainland without channels across to the Weddell Sea. They showed that it was possible to travel safely with dogs and to use them for support for surveying and scientific work for extensive periods of time.

In 1945, the British brought dogs down from Labrador, establishing them at Hope Bay and later at Stonnington in Marguerite Bay. Bingham was in charge at Stonnington and gave that continuity from the Inuit via the BGLE. The pattern remained basically unchanged for the next 50 years. Most members of the Falkland Islands Dependencies Survey (later the British Antarctic Survey) spent two and a half years working in the Antarctic. During their first year, they were "apprenticed" and picked up skills and knowledge about a broad range of areas, including dogs and sledging. After that, they were able to pass on their skills and experiences. Through this system, a well-tried and relatively safe method of traveling was developed.

Several species of dogs were used, each with distinct characteristics and suitable for different roles. Siberian, Alaskan malamute, and Samoyed dogs were used, but Greenland/Labrador dogs—also known as polar Eskimo dogs or, more recently, Inuit dogs, Canadian Inuit dogs, or Quimmiq—proved by trial and error to be the best for the common "freighting" type of work. Generally in the Antarctic, the term "husky" referred to the Greenland breed. Greenland/Labrador dogs were used almost entirely after 1945, and by inbreeding a distinct Antarctic husky developed. These were strong, short-legged, had a short but thick coat, and had a temperament to pull for hours, days, and months in both summer and winter conditions. They typically measured some 23 inches in height to the shoulder, about 60 inches from nose to tail, and had a shoulder width of about

10 inches, a hip width of 8 inches, and a weight (for males) of about 90 pounds. Their long, bushy, curled tail was essential in protecting the head and paws of the dog when curled up in a blizzard. They came in a variety of colours, although darker dogs suffered in the summer heat. Traveling at night in the summer helped to overcome this heating, and the freezing of soft surfaces at night was beneficial for travel.

Bitches came on heat every six months with a gestation period of 63 days. They had an average of four to six pups, with a record of fourteen. The litters were sometimes born on long journeys, with successful survival rates. The pups needed to be handled constantly to establish a relationship with men. They were fed minced seal meat, vitamins, and cod liver oil. The pups joined the team at 12 months; if they did earlier they were more likely to develop osteoarthritis in later life. New blood was introduced from Greenland to prevent over-inbreeding. Each dog was registered with an individual dog card showing its good and bad characteristics, progress, etc. In theory only the best dogs were used in the breeding programme.

In training, a lead dog and the front pair were selected and trained to words of command. The dog teams normally consisted of seven or nine dogs, expected to pull their own weight. Numerous styles of hitching dogs to the sledge have been used, the most common being a centre tandem trace or a modified Greenland fan trace. The centre trace was used most and was more efficient mechanically. Fan traces give more freedom and allow the team to develop more naturally as a "pack" and perhaps lead to a more contented team. They also give freedom to negotiate ice floes on sea ice. However, a fan trace can become badly tangled. The modified BGLE fan was a good compromise.

The words of command were adopted with the first set of dogs in 1945. When the last Antarctic dogs were given to the Inuit at Inukjuak on Hudson Bay, they immediately recognized the commands, which had not changed in 50 years. These were:

- To start: "Up dogs, away you go"
- Faster: "Huit, huit, huit"
- Turn left: "Irra, irra, irra"
- Turn right: "Auk, auk, auk"
- Slow down: Long, drawn-out "Ah now"

Harnesses were made of 1.5-inch lampwick as used on oil paraffin lamps and introduced by the BGLE. This material is soft and prevents chafing. It can easily be sown and adjusted, which is essential to avoid a dog's falling out of a harness in a crevasse incident. Harnesses need to be dried in the apex of the tent on journeys. Whips were rarely used. Rope thumpers were used to break up dog fights.

A king or alpha dog naturally developed in each team or pack. The king dog was normally tethered at the rear of the hitch where he could command those in front. He eventually would be challenged by a younger dog. The lead dog was usually the most intelligent one. Often a bitch was chosen. As dogs can weight 20–30 lbs more than bitches, one did not want to lose the extra pulling power, as a lead dog did not pull as much as the other dogs.

When not working on base, dogs were fed 6 lbs of seal meat every other day. The blubber on the meat was fed to the dogs in winter but removed in the summer. Initially, while sledging, they were fed dehydrated meat, pemmican, and, later, Nutrican. These gave 2000–3000 calories. Work by Dr. Henry Wyatt and Dr. Neil Orr in the 1950s showed that this dehydrated food was inadequate. Working huskies need closer to 6000 calories per day. Gutted seal meat proved the ideal food, and, as huskies are coprophagic, little food was wasted. Water was only given to them in summer when snow was unavailable at some bases.

Short names were chosen, like for working sheep dogs. Teams of seven to nine dogs were also named, and these were passed down from driver to driver. The last two teams in the Antarctic were the Huns and the Admirals, and two small peaks on Alexander Island are named after them. The Admirals were formed in 1958, and so lasted 36 years with sixteen drivers and thirty-nine dogs.

Travelling

A team of seven dogs and two bitches should pull a load of 770 lbs, assuming they can pull their own weight. Dogs respond to a routine. It was normal to travel around 50 minutes with a 5- to 10-minute break. They traveled around 3–4 miles per hour, about the speed of a human trotting, but all depended on surfaces, loads, and the fitness of the team. They could make 30–45 miles a day on a good surface, with an average being 10–15 miles. With relaying on bad surfaces, 2–5 miles might be all that could be achieved. These figures are based on heavy loads.

Various techniques were used to get the most out of a team, especially towards the end of the day. A common technique was to put bells on the lead dog for the last hour. The pack associated this with rest and food. It was essential to check the dogs at night if there was a blizzard or heavy snow to ensure that they did not suffocate and were not strangled, as they were tied to night stands.

The lead dog was supposed to be able to lead without a human in front. This was especially important in crevassed country, as a dog can give warning of crevasses, or if one falls down a crevasse it can be rescued much more easily than a man.

The dogs had a working life of 6–7 years, with an exceptional leader working up to 9 years. They began to suffer from arthritis and sometimes the coats of the older dogs would become thin, losing their insulation. One of the saddest jobs of a dog-driver was at the end of the season deciding which animals had to be culled. To shoot a friend and companion who had pulled a sledge for 1000 miles was very hard. However, it was essential to have new, young blood joining the teams. Some old dogs with unique records were allowed to retire to static island bases and perhaps be involved in a breeding programme. Very few came back to Britain, although Sir Vivian Fuchs had his old lead dog Captain in Cambridge, an entire team of dogs put in 2000 appearances at the Festival of Britain in 1952–1953, and a few returned to help breeding of husky dogs in the UK. Equally, a few were given to or exchanged with other nations in the Antarctic.

Dogs sledged in winter temperatures of –40°F. They suffered, but continued to work hard providing they were well fed. Heavy snowfalls on the western side of the Antarctic Peninsula were always a challenge for sledging. On northern Adelaide Island, 12-foot survey poles disappeared in three months. Dogs were expected to work throughout all of this. Dogs can suffer from scurvy, but this was overcome by feeding them fresh seal meat. Blocked intestines and gynecological problems were also revealed in post-mortems carried out by doctors with the assistance of the dog-drivers.

Some Dog Facts

There were a total of 900 dogs used by the British Antarctic Survey, of which about 850 were born in the Antarctic. About forty dogs were lost in crevasses, twenty-five drowned, and thirty lost to fights and natural causes. The longest unsupported journey by members of the British programme was 700 miles in 67 days in 1947. The average distance covered by an individual dog in a career was 3000 miles. The longest distance sledged in the life of a dog was 14,440 miles by Mac and Bryn, born at Hope Bay in 1958.

Dogs were also a component of the first crossing of the continent, the Commonwealth Trans-Antarctic Expedition (CTAE), led by Vivian Fuchs. The dogs had originally come from the Antarctic Peninsula, and Ken Blaiklock and John Stephenson were with the first dog team to reach the South Pole since Amundsen in 1911.

Between July 1989 and March 1988, the International Trans-Antarctic Expedition carried out the longest supported dog journey. They traveled from the north of the Peninsula, along the spine to the South Pole, across to Vostok Base, and finally to the Russian base on the coast at Mirnyy. The expedition was led by Will Steger and Jean-Louis Etienne, but Geoff Somers, a former member of BAS on the Antarctic Peninsula, was in charge of logistics and dogs.

Other nations made journeys with dogs that were equally notable to those of the British. On the Peninsula, the Argentines made long journeys from Esperanza to their base at San Martine in Marguerite Bay. The New Zealanders used dogs they obtained from the Australians and from Greenland to support the CTAE. In 1960, Wally Herbert was commissioned by the New Zealand programme to find a dozen Greenland dogs. Within three years, they had four teams of nine dogs plus a number of backup animals. These were used extensively in the region of the Axel Heiberg Glacier and in northern Victoria Land until tractors began to take over.

The Australians obtained dogs that had been used by a French expedition and left in a Melbourne zoo in 1949. These were subsequently used at Mawson, Davis, and Casey stations. They were especially useful for travel on sea ice in connection with biological studies. The last dogs left Davis in 1965, Casey in 1970, and Mawson in November 1992.

Japan kept dogs at Syowa Station between 1956 and 1959. In February 1958, the relief ship could not get closer than 60 miles, and weather prevented them from flying in a new wintering party. The fifteen dogs had been fed and left awaiting that new party. Somehow two of these dogs survived the winter without humans on base. One of these dogs, Taro, returned to Japan a hero and lived nine years at the University of Hokkaido. A special film was made about this pair of dogs.

Sledges

A variety of sledge designs have been used in the Antarctic, but the 12-foot Nansen sledge has dominated travel, especially with dogs. Sledges have been developed in response to purpose of use, types of surface, and building materials available. The Komatik or Greenland sledge, with its deep, narrow edge-runners and robust structure, has served the Inuit well on the hard coastal sea ice, rocky foreshore, and related conditions in the Arctic, but has not proven so suitable for work in the mountains of the Antarctic or the changing surfaces of the ice shelves and Polar Plateau.

The Nansen sledge, with ski-type runners, copes with these constantly changing surfaces of hard, wind-packed snow and ice, lumpy sastrugi, deep soft snow, or even clear, brittle corrugated blue ice. It must be able to carry a load in excess of 1000 lbs, be able to twist as it moves through the sastrugi, and be able to survive very low temperatures and rapid changes in temperature. The Nansen sledge has a long pedigree and meets all of these demands.

Fridtjof Nansen modeled his sledge on the Greely sledges of the 1880s, aiming for a light but supple model. It is made of a wood that "gives" or "bends," such as ash or hickory. These woods can also withstand the low temperatures and be handled reasonably comfortably. To provide the "twist," the runners, bridges, and longitudinals are assembled with treated hide thronging and flax lashing. These give the required flexibility to the structure.

The runners are flat, 4 inches wide, and curved at both ends. Their surfaces were covered by a resin like Tufnol and more recently by plastics of high molecular weight like polyethylene, with soles 1/4 inch thick. When traversing slopes, metal heels are used. These are placed three quarters of the way towards the rear and dig in 1–4 inches when dropped. Loads are held on laminated beech bridges with 1 1/4-inch-square ash longitudinals. The load sits 12 inches above the surface. The bow at the front is formed by a 9-foot piece of bamboo, bent from runner to runner and called the cowcatcher. It helps to prevent the sledge from overrunning the dogs and braces the front of the sledge.

On a dog sledge, there are handles or a handlebar standing 45 inches high. Pickets, picket hammers, rope thumpers, and a canvas sledge bag hang from this braced structure. A waist-support rope is attached to the handlebar when skiing alongside. A fixed compass is also attached.

For measuring distance traveled, a sledge bicycle wheel is attached with a mileometer gauge. With the help of the compass, a dead-reckoning record can be kept (although this is now almost entirely obsolete with GPS equipment). Traces and tie-lines are nylon rope or lightweight wire. Braking was achieved by using a 4-inch plank of ash with three or four stout studs to dig into the ice. The plank was lashed to the top of the laminated beech bridges. It could be operated by ski or foot. In addition, ropes or chains were fixed under the front of the runners on steep descents.

The Nansen sledge was used by Adrien de Gerlache and his company on the *Belgica* expedition, when they were the first to winter in the Antarctic, as well as by Carsten Borchgrevink and the other members of the *Southern Cross* expedition. It continues to be used as a trailer sledge with motorized ski-doos.

Loads can be heavy, but they need to be evenly distributed. The reinforced plywood boxes, with galvanized edges and weighing 12 lbs, are the favoured way of carrying man and dog food, pots and pans, and the scientific gear. These boxes have wooden blocks on their bottoms and tops to allow them to fit snugly on the sledge and to be stacked. They echo the Venesta boxes of an earlier age. Tents, sea-ice probes, and emergency equipment are lashed down on top of the load. The packing is done in a methodical and similar way on each sledge so everyone knows where equipment is in an emergency or when unpacking at the end of a day's travels. If pups were born on a journey, they frequently were carried on top of the load with the mother running alongside ready to feed them at the halts. On Douglas Mawson's sledge journey with Xavier Mertz and B. E. G. Ninnis, the adult dogs tended to eat newborn pups quickly.

DRAKE PASSAGE, OPENING OF

Drake Passage is the stretch of deep water, some 500 km in width, separating the southern tip of Tierra del Fuego from the northern tip of the Antarctic Peninsula. Today, this passage serves as a "gateway" through which flows the Antarctic Circumpolar Current, the largest ocean current on Earth, with an eastward transport of some 130 million cubic metres of water per second. Opening of the deep-water gateway occurred at some time between 34 and 22 Ma, as South America moved away from Antarctica at a rate of about 20 kilometres per million years. This removed the final barrier to a complete circum-Antarctic pathway for ocean currents, following the slightly earlier creation of another Southern Ocean gateway between Tasmania and East Antarctica. Moreover, this pathway lay within the zone of strong and persistent westerly winds, which began to drive the Antarctic Circumpolar Current, the course of which is closely associated with the position of the Polar Front, the boundary between subantarctic waters in the north, and the cold, polar seas to the south.

Drake Passage opening also had a profound effect on biological evolution, by creating a barrier for land animals migrating across the land bridge between South America and the Antarctic Peninsula. Studies of fossil animals and plants have shown that a number of species passed through a land bridge between the two continents during the warm period that preceded gateway opening, when sea levels were low. Some groups, including a number of small marsupials, were then isolated in Antarctica as a shallow seaway formed, becoming extinct as climate cooled (Reguero et al. 2003).

The Antarctic Circumpolar Current exerts a profound influence on circulation and climate today, and its onset and development are thought to have played an important role in the transition from a warm or "hothouse" Earth in the early Cenozoic (65–50 Ma), to the "icehouse" Earth of more recent times. In particular, one of the most profound climate changes in Earth history occurred 34–33 Ma, at the boundary between the Eocene and Oligocene geological epochs. Records from deep ocean sediments show that, at that time, the Earth experienced a very abrupt cooling, accompanied by the development of extensive ice sheets on the Antarctic continent. This event has long been associated with the initiation of the Antarctic Circumpolar Current as the Southern Ocean gateways finally cleared (Kennett 1977). The essence of this "gateway model" is that the formation of a deep circum-Antarctic ocean, and the consequent onset of the Antarctic Circumpolar Current, effectively cut Antarctica off from warm, southward-flowing currents, resulting in polar cooling and Antarctic glaciation.

The gateway model has recently been questioned, in particular by those using computer models to simulate global oceanic and atmospheric circulation. Results of some recent simulations suggest that opening of Southern Ocean gateways was relatively insignificant, and that the principal driving force for climate change and Antarctic glaciation was declining concentrations of atmospheric greenhouse gases, primarily carbon dioxide. A critical factor in this debate is the relative timing of gateway opening and global cooling. A close correlation between the timing of earliest opening in Drake Passage and abrupt changes in global temperatures would constitute evidence in favour of the gateway model, whereas opening at other times would suggest that gateways were relatively unimportant. Details of the nature and timing of events leading to the establishment of an ocean gateway at Drake Passage are therefore of great importance in understanding the causes of the major global changes that led to the present climate regime.

The sea floor of Drake Passage is formed mainly of oceanic crust, similar to that which lies beneath the major ocean basins, and is covered by a variable thickness of sediments. It was created by the process of *sea floor spreading,* involving the formation of new crust by volcanic and tectonic processes at so-called *spreading centres,* such as the East Pacific Rise and Mid-Atlantic Ridge. Spreading occurs in response to the separation of tectonic plates—the fragments of the outermost 100 to 200-km-thick shell of the Earth that are in constant relative motion—and results in the formation of the deep ocean basins, with typical depths of 2500–5000 m.

In Drake Passage, an extinct spreading centre, known as the West Scotia Ridge, is visible on bathymetric maps as a segmented trough, about 20 km wide, lying at depths 500–1000 m greater than surrounding sea floor, and extending throughout the west Scotia Sea. The period during which the oceanic crust in Drake Passage formed has been dated from the characteristic shapes of marine magnetic anomalies measured by ships as 26–6.5 Ma (Barker and

Burrell 1977). However, anomalies are absent or irregular within about 100 km of the northern and southern margins of Drake Passage, where the oldest crust exists, so that the precise age of the first crust is uncertain. If early rates of opening were similar to those measured for 26-million-year-old crust, then spreading could have begun as early as 34–30 Ma. This accords with an age of c. 31 million years for initial opening of a deep-water pathway suggested on the basis of reconstructions of the past positions of the South America and Antarctica (Lawver and Gahagan 2003).

When continents rift and spreading begins, so-called "passive" continental margins are formed on either flank of the new spreading centre, at the boundary between continental and oceanic crust. These conjugate margins, for example, those off western Africa and eastern South America, can usually be fitted together on a map, so that the sequence of early rifting and separation can be reconstructed. However, while the margin of Tierra del Fuego conforms to this model, there is no obvious southern counterpart to which it may be fitted. This probably results from crustal stretching and deformation within what is now the South Scotia Ridge. This area has been an active plate boundary for at least 6 million years, during which time it has been modified and steepened by faulting.

The onset of deep circumpolar ocean currents need not have been synchronous with the formation of the oldest deep sea floor by spreading at the West Scotia Ridge. It was suggested long ago by Barker and Burrell (1977) that, even though spreading had begun in Drake Passage by 26 Ma, the gateway remained blocked until about 22 Ma by a shallow ridge of continental crust at the Shackleton Fracture Zone. Recent work seems to show that this ridge is actually composed of oceanic rocks and, moreover, may have been uplifted only within the past 6–10 million years (Livermore et al. 2004). It thus appears unlikely that the ridge presented a barrier to an early (i.e., pre-22 Ma) circumpolar current. Other fragments within and around the Scotia Sea, such as Pirie Bank, Bruce Bank, and South Georgia, are more likely to be composed of lighter, continental crust, and hence could have formed a barrier to Antarctic Circumpolar Current flow during the early history of the Drake Passage.

Part of the present controversy surrounding the manner and timing of the Drake Passage opening and the onset of the Antarctic Circumpolar Current stems from uncertainty about the age of the crust beneath the central and southern Scotia Sea. Older models suggest that oceanic crust in the central Scotia Sea, and in the small Protector and Dove basins to the south, was created at about the same time as the West Scotia Sea (i.e., between 23 and 6 Ma). This implies that the continental fragments now separated by these basins were formerly joined, possibly forming an effective barrier to deep-water circulation. An alternative model suggests that these basins may all be older than 31 million years, so that a pathway for the Antarctic Circumpolar Current may have been available soon after spreading commenced at the West Scotia Ridge. A third possibility is that, while the small basins in the southern Scotia Sea opened between 40 and 31 Ma, the central Scotia Sea is younger. In this model, an early "proto-Drake Passage" formed by stretching and rifting of continental crust between 50 and 34 Ma, and was then supplanted by spreading at the West Scotia Ridge. Deep pathways were created and eliminated by the northward movement of South Georgia during this time. All models require that Pirie Bank, Bruce Bank, and South Orkney were part of the former continental connection between South America and Antarctica. If the younger models of central Scotia Sea opening are correct, then South Georgia also formed part of this agglomeration, whereas in the older model, it remained close to the Falkland Plateau throughout and presumably did not present a barrier to deep currents.

Marine geophysical work suggests that a shallow (i.e., less than 1000 m) marine connection was probably established during the Middle/Late Eocene (50–34 Ma), following a major change in the movement of South America relative to Antarctica. Support for the idea of an early opening to shallow depths comes from studies of deep-sea sediments sampled within the international Ocean Drilling Program, which measures various so-called "proxies" for changes in ocean temperature, circulation, and biological productivity. Studies at sites downstream from (i.e., to the east of) Drake Passage, in the South Atlantic and Indian oceans, have shown increases in biological productivity, coupled with a decline in ocean temperature and changes in clay mineralogy, between 40 and 37 Ma, that have been attributed to the opening of Drake Passage to east-flowing currents (Latimer and Filippelli 2002). Likewise, measurements of neodymium isotopes in fossil fish teeth from drill sites in the South Atlantic suggest an influx of Pacific water through Drake Passage at about the same time.

A number of computer simulations of ocean circulation and temperature have been attempted, to assess the effects of gateway opening at Drake Passage on global circulation and climate. The numerical models upon which such simulations are based are highly complex, incorporating global atmosphere, ocean, sea ice, fresh water, and even biological components, but have low spatial resolution (currently 1.25° latitude by 1.25° longitude for the ocean component in the Hadley HadCM3 Model), and so cannot reproduce effects caused by features such as narrow yet deep passages, like those associated with the present Antarctic Circumpolar Current. This may be one reason why recent attempts to model global effects of Drake Passage's opening have produced mixed conclusions. An influential study by DeConto and Pollard (2003) concluded that gateway opening played only a minor role in the abrupt cooling and glaciation event 34–33 Ma, and that the primary cause was declining concentrations of atmospheric greenhouse gases, principally CO_2. Another study by Huber and Sloan (2001), also based on numerical modelling, concluded that changes in heat transport to high latitudes caused by gateway opening were small, and insufficient to bring about Antarctic glaciation. Conversely, other recent simulations (Sijp and England 2004) suggest that Drake Passage's opening, even to shallow depths, could have had a major effect on global ocean circulation, and perhaps on climate too. Resolution of this problem will require much future research, involving deep ocean drilling, to sample and date the crust within Drake Passage, and so develop an evolutionary model for its development as an important ocean gateway.

DRY VALLEYS

The conventional image of Antarctica is most probably of a vast empty continental whiteness, almost unrelieved by any of the more familiar features that are associated with the Earth's other landmasses. Although ice dominates the continent, it is a more complex and diverse environment, for Antarctica contains so-called dry areas or oases, atypical regions that are not covered by large ice sheets. Scattered along the coasts and protected by high mountains that block the flow of ice from the interior, these oases, with exposed bedrock, frozen lakes, and flowing waters, have engaged the interests of scientists and explorers alike.

The largest and most widely investigated of the oases is the McMurdo Dry Valleys, a region of some 4800 km^2 between the Ross Sea and the interior of East Antarctica. To enter these parallel valleys—the most prominent of which are the Victoria, the Wright, and the Taylor—is to become part of a strange mosaic of mountain ranges, glaciers, streams, and wind-carved stones.

Exploration of the Dry Valleys began when the members of Robert Falcon Scott's British National

Antarctic Expedition discovered it. Given the harshness of their journey, they marveled at the presence of liquid water and at the sight of exposed earth—the pebbles at their feet and the muddy ground moraines. They also took note of the apparent absence of life. In *Voyage of the Discovery,* Scott wrote: "It is certainly a valley of the dead; even the great glacier which once pushed through it has withered away."

Only several decades separated the journal notes of the *Discovery* expedition from a short article that Barry Lopez wrote for Harper's Magazine in the 1980s. Lopez spoke of the valleys as being "breathtakingly beautiful," of having air of such clarity "that the eye can fasten effortlessly on the details, the sharp break of shadow creases, in distant mountains, making binoculars curiously redundant." The valleys, in his words, were "bold, balanced, serene."

Between the early explorers and the more recent ones, the Dry Valleys have been described largely in the technical literature of biologists, geochemists, glacial geologists, and paleontologists. What has been communicated to the public has been done through the rare television special or through the photographs of Eliot Porter or Craig Potten, whose Dry Valleys are indeed the balanced and serene landscapes about which Lopez wrote.

Nevertheless, the technical summaries of scientific research offer a portrait of the land that is rich and compelling. The valleys are treasure troves of information about ancient landscape processes, ongoing changes in the Earth's climate, and the quality of life *in extremis*. In seemingly lifeless soils, there exists a community of nematodes—tiny worms whose length is measured in millimeters, and yet who are the largest organisms native to the valleys—living among yeasts, bacteria, and filamentous fungi in a matrix of coarse stone and in bitter cold and extreme aridity. Endoliths are another example of life taking anchorage in the harshest desert. These organisms, lichens and bacteria, have colonized the Beacon Sandstone in the high mountains and terraces above the valley floors, growing between the rock crystals just below the surface to be protected from the climatic extremes.

Much has been made by recent researchers of connections and linkages, simple food webs, and survival strategies. In the technical descriptions of the scientific literature, rocks are linked to soils, soils to streams, and streams to lakes. The flows of matter and energy are recorded and modelled, as is the change in temperature over time. And there is a deep concern for the human impact, for the way in which the conduct of science itself may be changing the land, and devaluing its unique features for future generations. Now a rigorous code of conduct for scientific activities is being applied to stop contamination, limit the development of trails, and remove all introduced materials from the valleys.

In the technical scientific literature, a curious and oddly poetic term has often been used to capture the essential mix of elements that interact and give identity to the McMurdo Dry Valleys and that sets them apart from landscapes anywhere else on Earth, and, indeed, from the landscapes of Mars, to which they have often been compared. The word is "mosaic," and it refers to the inlaying of glaciers, ephemeral streams, permanently ice-covered lakes, exposed bedrock, sandy soils, and richly patterned ground, as well as the time and climate that combined to create the valleys.

Glaciers are especially prominent and exotic features of the landscape, flowing down the slopes of the Asgard and Olympus Ranges. Some glaciers, such as those in the Wright Valley—the Denton, the Meserve, the Goodspeed—extend only partway down the mountainside. Others, like the Suess, the Canada, and the Commonwealth, go all the way to the valley floor. The glacier fronts of the Dry Valleys are unusually tall and vertical and, in springtime, thin waterfalls cascade down their faces. In a warming climate many of them appear to be in retreat.

Remarkable, too, are the permanently ice-covered lakes, so oddly out of place in this, the world's driest desert, where annual precipitation is less than 100 mm of water equivalent and where the average temperature is near –20°C. The lakes have long and varied histories and their physics, chemistry, and biology have been the subjects of countless studies over the past 5 decades. Permanent ice covers, some as thick as six meters, float atop liquid water, which may be as deep as 70 m, as in Lake Vanda, or as shallow as 18 m, as in Lake Miers. Past episodes of evaporation have resulted, in some cases, in highly saline brines and in the production of extraordinarily stable, density-stratified water columns. The upper waters of Lake Vanda are cold, fresh, and oxygen rich, while the waters at depth are warm (25°C), salty (three times the salinity of seawater), and anoxic.

The lakes differ in more obvious ways: on Lake Vanda, in Wright Valley, the permanent ice is clear and hard and, across the entire lake, smooth and regular. But this is rare. The surface of Lake Hoare, in Taylor Valley, is rough and deeply undercut and patchy with sand deposits. Divers have found mounds of sand on the lake bottom, and these have apparently been funneled through deep cracks in the surface ice. Lake Bonney is known for the long columnar gas bubbles that are encased in its ice, while Lake Fryxell has mounds of blue-green algae that have become detached from the lake sediments, floated up through the water column, and, gradually, over the course of many years, worked their way to the ice surface. A small water body in Wright Valley, Don Juan Pond, is so saline that it never freezes and so viscous that its waters rarely form ripples.

The lakes do not exist in isolation. They are intimately linked to the glaciers and to valley rocks and soils by the melt water streams. And the streams provide water and nutrients to the few organisms—algae and bacteria, mostly—that can survive in these extreme environments. The ice covers serve as barriers to material inputs from the atmosphere and they prevent direct wind mixing. They also provide extremely useful information about recent climate changes, since ice thickness is related to local meteorological conditions.

Geological history is written clearly in the surrounding rocks. High above are the buff-colored Beacon Sandstones, laid down in the Silurian or Devonian or Jurassic—400 to 200 Ma—when Antarctica was a land of warmth and water and when it was joined to other lands in the great supercontinent of Pangaea, and then Gondwana. It was a time when the land, driven by tectonic plate motion, lay far to the north, long before the onset of the ice sheet. Farther down the slopes of the mountains, the sandstones are cut by the sills and dikes of the Ferrar Dolerites. These dark igneous intrusions appeared in the late Jurassic (170 Ma) and are the signatures of the Earth's mantle and of the welling up of molten rock from beneath the crust. On the valley floor, more recent volcanic deposits have been dated at 4 million years.

By contrast with the mountains, the ice-covered lakes are mere thousands to tens of thousands of years old, and the waters that feed them are days to hours in age.

The wind is also evident in the Dry Valleys. The katabatics from the Plateau develop over the cold ice interior. When pressures fall along the coast of the Ross Sea, air masses rush downward, often at extraordinary speeds. These are desiccating winds, and they are capable of picking up moisture as they move down slope and as they warm under adiabatic compression. Protected from massive glacial incursion by the walls of the Transantarctic Mountains, the McMurdo Dry Valleys are further maintained as arid deserts by these winds. Wind, too, shapes the open land. Throughout the valleys, there are regions of patterned ground where the Earth is tessellated into acres of polygons having diameters as large as thirty meters. When the permafrost slumps into hexagonal or pentagonal rings, the lines that define the perimeters become sites of deposition for windblown sand and sediment. In time, the flat euclidean figure acquires walls, perhaps more than a meter high.

In places, the wind has changed the landscape. Bull Pass, which stretches across the Olympus Range and connects the Wright and Victoria Valleys, offers some of the world's great examples of wind erosion—huge boulders that have been hollowed by salt and moisture, by the freezing and thawing of water, by infinitesimally small accretions acting to pry and loosen the stone. Wright Valley is the site of other wind-shaped stones. The ventifacts—literally made by the wind—lie scattered about in passes and on the valley floor, where they are often subjected to winds of extreme velocity. In 1970, at Vanda Station, winds in excess of 61 km/hr were recorded for a period of 55 days and the maximum wind speed for that winter was nearly 150 km/hr. Carrying an appropriate abrasive material, like sand or ice crystals, winds blowing at these velocities can polish stone to a glassy smoothness in only a few hundred years.

It is still uncertain how the McMurdo Dry Valleys were formed. Early accounts, including those of the British explorers, emphasized the role played by past glaciation events in carving out the three major valley systems. Geologists from the United States and New Zealand, working in the period after the International Geophysical Year (1957–1958), also argued that multiple glaciations in the McMurdo Sound area were largely responsible for shaping the present landscape. More recent interpretations of the geomorphology, however, have also emphasized the role of ancient rivers. The geological history of the McMurdo Dry Valleys remains a subject of great interest and its ongoing study contributes to the developing picture of global change.

In the last two decades, the understanding of the McMurdo Dry Valleys has been greatly expanded by the efforts of scientists working through the Long Term Ecological Research Program in Taylor Valley. This project, sponsored by the US National Science Foundation, has successfully integrated knowledge of ecosystem functions (glaciers, soils, streams, lakes, climate, and weather) through time and has advanced knowledge of nutrient cycling (especially carbon), microbial intervention, and local and regional climate change.

Recognition of the uniqueness and fragility of the McMurdo Dry Valleys has led to efforts to regulate the conduct of scientists and other visitors to the region. An Environmental Code of Conduct now restricts materials brought into the valleys and requires that everything—including human waste—be removed. Among other things, it mandates that oil and fuel spills be reported and remedied; that marked trails be followed where possible; that the number of helicopter landing sites be minimized; and that tourist zones of high aesthetic value be established. These and other provisions of the Code are based on an understanding that the Dry Valley ecosystems operate under severe stress and date back nearly unchanged for thousands and millions of years.

DRY VALLEYS, BIOLOGY OF

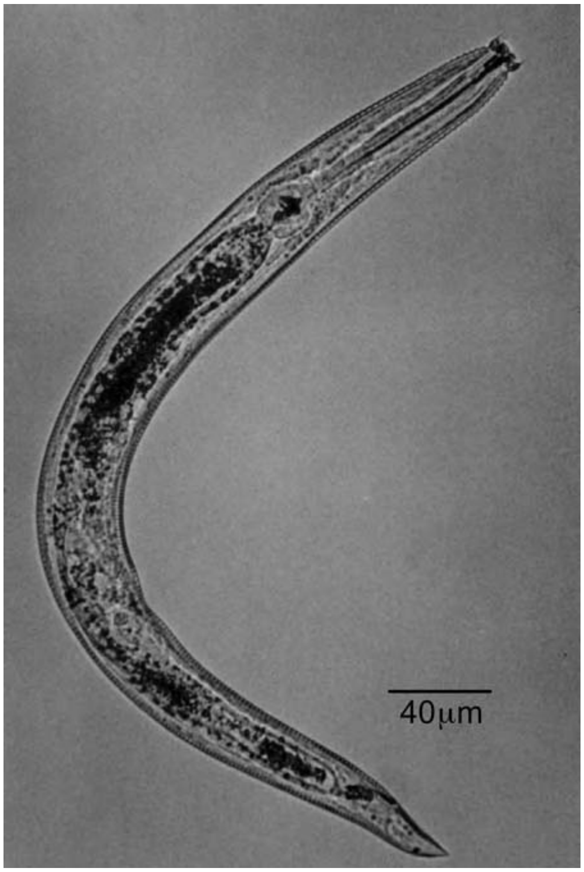
The Dry Valleys are a polar desert with a landscape mosaic of soils, rocks, ephemeral glacial meltstreams, ice-covered lakes, and surrounding glaciers. Although there are no vascular plants or vertebrate animals, they contain a surprising amount of hidden life. This life is mostly microscopic and dependent on minimal moisture from ephemeral glacial meltstreams, permafrost, and snow of less than 4 inches (10 cm) water equivalent per year. The moisture sublimates rapidly, is not readily available in liquid form, and, combined with a mean annual air temperature of –20°C, makes the Dry Valleys one of the most extreme habitats for life.

The landscape is dominated by soils, not ice, that on the surface are patterned into polygon shapes. Soils are poorly developed, coarse in texture (about 98% sand), and, compared to hot deserts, have much lower organic carbon, a more alkaline pH, and higher salinity. Carbon to support the soil food web is from two sources: a legacy of ancient paleo-lakes, and contemporary carbon produced primarily by algae. Organisms are not uniformly distributed across soils in this extreme environment. The more unfavorable soil habitats compose about 40% of the Dry Valleys and are highly saline, more alkaline, lower in carbon and moisture, and inhabited by only a few types of organisms (bacteria, fungi, and/or protozoa). Favorable habitats have the greatest number of taxa (bacteria, fungi, protozoa, nematodes, rotifers, tardigrades, mites, springtails, mosses, lichens, and algae) and occur in soils with higher carbon, higher moisture, and lower salinity, such as those near glacial meltstreams.

Most species occurring in the soils of the Dry Valleys are endemic to the Antarctic, with the exception of protozoa, which are dominated by flagellates and amoebae, with ciliates and testacea rarely found. Fungal-feeding mites and springtails occur under rocks or near meltstreams among mosses, algae, and cyanobacteria. Nematodes exist in about 80% of the favorable soil habitats and have a greater distribution compared to other invertebrates. For example, tardigrades and rotifers occur in less than 20% of Dry Valley soils. The three species of Dry Valley nematodes rarely co-occur, but one and two species communities are frequent in favorable soil habitats. *Scottnema lindsayae,* a nematode that feeds on soil yeast and bacteria, is the most widespread invertebrate in the Dry Valleys, particularly in drier soils, while the two other species, an algal feeder and an omnivore, occur mainly in highly favorable habitats near stream beds or frozen lakes.

Soil is blown onto the surface of lake ice and glaciers, and over time is eventually carried deeper into the glacier or through the ice to the lake bottom, serving as a source of nutrients for the microscopic life. Cryoconite holes on the surface of glaciers are also inhabited by simple communities of organisms, most of which occur elsewhere in the Dry Valleys and include cyanobacteria (e.g., *Chlorococcus, Nostoc*), rotifers *(Philodina gregaria, Cephalodella catellina,)* tardigrades (*Acutuncus antarcticus, Hypsibius* species), and protozoa (ciliates).

The cold, saline, dimly lit, perennially ice-covered lakes house numerous taxa of phytoplankton, algae, bacteria, and fungi. The lakes have alternating layers of benthic (lake bottom) sediment and cyanobacterial mats that are thousands of years old. Floating in water above the mats are protozoa (phytoplankton), including ciliates (e.g., *Oxytrichia, Euplotes, Halteria*) and flagellates (e.g., Chrysomonadida, Volvocida). Protozoan diversity varies between lakes, from approximately forty-seven to seventy-five taxa, and is lower than in temperate lakes. Sediments at lake



Scottnema lindsayae, a nematode that feeds on soil yeast and bacteria, is the most widespread invertebrate and the predominant animal of the Dry Valleys. (Courtesy of D.H. Wall.)

edges support dense populations of algae, bacteria, fungi, protozoa, rotifers, tardigrades, and nematodes *(Plectus)*. Like soils, lakes are influenced by geological history and climate. Lakes with nutrient-rich bottom saline waters have the highest primary production rates. Input of nutrients to lakes varies with the number and length of streams and the presence of nutrient sources amongst them (i.e., algal and bacterial mats and mosses).

Ephemeral streams carry glacial meltwater flow for days to a few weeks during austral summers. Collembola and mites are carried by water as the stream moves across dried soils. The amount of water that flows is highly variable because of the temperature changes affecting the glaciers. Stream channels have predominantly orange microbial mats dominated by several species of *Phormidium* and *Oscillatoria*. On the underside of rocks in the center of the stream, a common but less abundant green algae dominated by *Prasiola* species can occur; in damp areas at the stream margin, one or two black-colored *Nostoc* species are common. A red-colored *Phormidium* algal species occurs in a few streams. Diatom assemblages including *Navicula, Hantzschia,* and *Stauroneis* occur on mobile sediment surfaces. Stream bank vegetation is limited to small patches of mosses. Nematodes occur in stream sediments.

Cryptoendolithic communities composed of several taxa of lichens, algae, fungi, and bacteria live below the surface of translucent rocks (e.g., Beacon quartzite sandstone), where they are protected from the most extreme environmental conditions. As these rocks weather, they provide a source of carbon to soils and serve as propagules for life in other rocks.

Survival mechanisms vary by organism. Algae and cyanobacteria survive periods of desiccation in a freeze-dried state and respond quickly to periodic moisture by beginning photosynthesis. Mites and springtails use supercooling as a mechanism of cold-hardiness. Rotifers, tardigrades, and nematodes avoid desiccation and freezing by entering anhydrobiosis and in this ametabolic state are dispersed by wind across the Dry Valleys. Once favorable environmental conditions return, they revive. Most protozoa are cryophiles (cold lovers).

DRYGALSKI, ERICH VON

Erich Dagobert von Drygalski was born on February 9, 1865, at Königsberg (today Kaliningrad), and died on January 10, 1949, at Munich.

After studying mathematics, physics, and geography at the universities of Königsberg, Bonn, and Leipzig, Drygalski finished his Ph.D. thesis on the deformation of the geoid during the Ice Age under the well-known geographer Ferdinand Freiherr von Richthofen (1833–1905) at Berlin in 1887. He became the assistant at the Geodetic Institute in Potsdam (1888–1892), before investigating the movement of glaciers and the inland ice during two expeditions to the west coast of Greenland (1891, 1892–1893). During the overwintering there, Drygalski was accompanied by a meteorologist and his old friend and biologist Ernst Vanhöffen.

Through the scientific results of his expeditions, Drygalski passed his habilitation in Berlin in 1898. This paved the way for him to be selected as the leader of the first German Antarctic expedition (1901–1903). Drygalski was very skillful in organizing the comprehensive preparations involving his ship officers and participating scientists, while he entered upon his associate professorship for geography and geophysics in Berlin in 1899. He also was named to lead the physical geography department of the Institute and Museum of Marine Research in Berlin, which had been newly founded by Richthofen. During the Seventh International Geographical Congress in Berlin (1899), Drygalski initiated an international cooperation of simultaneous magnetic and meteorological observations to be carried out by the upcoming British, Scottish, and German Antarctic expeditions.

Throughout his own expedition, Drygalski followed the Humboldtian practice of exploring every aspect of everything new as comprehensively as possible. Unfortunately, his ship was beset by ice close to the Antarctic Circle at 90° E, near where he discovered Kaiser Wilhelm II Land. Although the expedition returned home with a tremendous data set and remarkable collections, his success was overshadowed by Robert Falcon Scott's farthest south of 82°17′ S, which counted much more in the imperial mentality of the time than did any scientific result.

When Richthofen died in 1905, Drygalski temporarily deputized for him, but, due to the lack of popular interest and political support following his Antarctic expedition, he was not named Richthofen's successor. Rather, in 1906 he was given the newly founded chair of the Institute of Geography at Munich. He also presided over the Geographical Society of Munich for 29 years.

In 1910 Drygalski participated in the Zeppelin-Study-Journey to Spitsbergen. During World War I he volunteered to command a company in France and Belgium, but in the final stages of the War he became dean of his faculty (1918), following which he became the rectorate in 1921–1922. As main official advisor for the Emergency Society for German Sciences, Drygalski oversaw the *Meteor* Expedition (1925–1927) and Alfred Wegener's (1880–1930) expeditions to Greenland (1929, 1930–1931). Before his retirement in 1935 he made two study trips to Russia and Siberia (1930, 1931).

Due to political circumstances after World War II, Drygalski returned to his chair at the Institute of Geography for a year. During his entire career, he supported his students, who called him "father," in carrying out their own research. When he died he was recognized as the man who had been the foremost German polar authority during the first half of the twentieth century.

DUMONT D'URVILLE, JULES-SÉBASTIEN-CÉSAR

Jules-Sébastien-César Dumont d'Urville, French naval officer and Antarctic explorer, was born May 25, 1790 in Condé-sur-Noireau in Normandy. His family suffered reversals of fortune during the French Revolution. On the death of his father in 1797, the Dumont d'Urville family placed itself under the care of his mother's brother in Caen. Here Jules, a bookish and solitary child, flourished. He studied at the nearby lycée but, missing a place at the Ecole Polytechnique, he joined the navy as an aspirant, or midshipman, in November 1807, serving on a number of vessels, although for much of this time, the fleet was blockaded by the English. In May 1812, after some string-pulling, he was promoted to ensigne de vaisseau. Dumont d'Urville never had much time for the bonhomie of naval life, and during this time he was given the nickname "the owl."

After the fall of Napoleon, his first important cruise was made on the Ville de Marseille to Sicily with the Duc d'Orléans, the future monarch, Louis-Philippe. Over the objections of his mother, on May 1, 1815, he married Adèle-Dorothée Pépin, the daughter of a watchmaker.

Hydrographic duties in the Mediterranean were spent on *Chevrette* (1816–1820). During this time he was instrumental in France's acquisition of the Venus de Milo. Dumont d'Urville's next great opportunity was to serve as second-in-command to Louis-Isidore Duperrey (1786–1865) in an expedition to the Pacific on *Coquille* (1822–1825). He collected three thousand botanical specimens and eleven thousand insects.

On returning to Marseille in March, Dumont d'Urville soon proposed a follow-up expedition, and later that year he was offered command of *Coquille,* now renamed *Astrolabe*. It sailed for the South Seas in April 1826. The high point of this expedition was the confirmation in the Solomon Islands of the loss in 1788 of the mission led by La Pérouse, and the construction there in March 1828 of a modest cenotaph. Its dedication, which Dumont d'Urville was too ill to attend, is depicted in a small painting by Louis-Philippe Crépin (1772–1841) at the National Library of Australia, Canberra.

On returning to France the following year (1829), Dumont d'Urville began the huge task of editing the account of the voyage, published in many volumes between 1830 and 1834 as *Voyage de la corvette* l'Astrolabe. This work established the anthropological distinctions of Polynesia, Micronesia, and Melanesia.

Some years elapsed before another command; the expedition that departed Toulon in September 1837 consisted of two ships, the now-veteran *Astrolabe,* accompanied by the *Zelée*. During this voyage—which took place at the same time as British and American expeditions—Dumont d'Urville made landfall upon Antarctica and in January 1840 claimed Adélie Land, named for his wife. The expedition returned to France in November 1840. Once again he began to compile the account of the expedition. The multi-volumed *Voyage au pôle Sud et dans l' Océanie,* one of the great accounts of exploration of the nineteenth century, was published between 1841 and 1854.

On May 8, 1842, while returning by train from Versailles, Dumont d'Urville and his wife and son Jules died in a derailment at Meudon. They are buried at Montparnasse Cemetery in Paris. A commemorative medal was struck in 1844. Described by a contemporary as "avid for fame," Dumont d'Urville was tireless in the field, and famously indifferent regarding his appearance. His great achievements came, however, at the cost of being considered cold and peevish. His portrait by Jérôme Cartellier (1846) is at the Château de Versailles.

DUNDEE WHALING EXPEDITION (1892–1893)

By the 1890s, the Scottish whaling industry was faced with declining stocks in Arctic waters and was looking for new fishing grounds to meet a continuing demand for whale blubber and bone products. The prospect of good fishing in Antarctic waters had been heralded as early as James Clark Ross's expedition in *Erebus* and *Terror* in 1839–1843. Ross had reported sighting the "Greenland," "Right," or Bowhead whale *(Balaena mysticetus),* in and around the Weddell Sea. This was precisely the species sought by northern fleets, the decline of which had made much of the Scottish whaling industry bankrupt. In 1874, a pamphlet was published in Peterhead, *Report on the new whaling grounds of the southern seas,* by the brothers Daniel and John Gray, owners of a well-established whaling fleet. Outside interest for such a venture was also sought in Australia, and an Antarctic exploration committee was formed. Contact was made in Norway with Svend Foyn of Tønsberg and Christen Christensen of Sandefjord—shipbuilder and principal owner of Norway's whaling fleet—as well as with Robert Finnes of Dundee, an important Scottish whaler.

The competition appeared to be fierce: Christensen equipped the Arctic whaler *Jason* for his own expedition and appointed as captain Carl Anton Larsen. They sailed on September 4, 1892. In Scotland, Kinnes assembled a fleet of four ships with 130 crew, at a cost of £28,000. These were sailing ships with auxiliary steam engines: the aptly named *Balaena* was captained by Alexander Fairweather; *Active* by Thomas Robertson, who later would captain the Scottish National Antarctic Expedition ship *Scotia; Diana* by Captain Robert Davidson; and *Polar Star* by Captain James Davidson. The fleet was noteworthy for the signing on as surgeon and naturalist of the young William Speirs Bruce, and his university friend and artist William G. Burn-Murdoch as assistant surgeon. Although Bruce had some medical training, neither was qualified for these posts, and in the event they were fortunately not required to give much medical assistance on the voyage. They hoped, however, to carry out scientific observations and experiments, this being their introduction to oceanographic work in high latitudes.

The fleet sailed from Dundee for the western Weddell Sea on September 7, 1892, and reached their destination December 23. On Boxing Day, December 26, they met with *Jason* to compare observations. However, not a single "Right" whale had been seen and the search was abandoned. In order to recover their substantial costs, they began instead to hunt seals off Joinville Island and northern Trinity Peninsula (the northernmost part of the Antarctic Peninsula), and to fill the ships' holds with sealskins and blubber. It was expected that Bruce and Burn-Murdoch would take part in this slaughter, which both found distasteful. So plentiful were the seals that the fleet sailed toward home waters on February 20, 1893, fully laden. No profits were made, but the costs of the expedition were recovered.

The commercial goals of the expedition had failed, and science had, unfortunately, done little better. Bruce had carried with him instruments loaned by a number of British scientists and by the Royal Geographical Society, and both he and Charles Donald, surgeon on *Active,* carried out meteorological observations. However, the ships' captains had little interest in anything but whaling and sealing, and the scientists found the whole expedition disappointing. However, it gave them a baptism in Antarctic exploration and science, and, for William Speirs Bruce, it formed a major turning point in his life.

E

EARTH SYSTEM, ANTARCTICA AS PART OF

Images of Earth from space in the 1970s, and the phenomenon of Southern Hemisphere springtime stratosphere ozone depletion, brought home forcibly the truth that planet Earth is a closed system and that no part can be taken in isolation. Antarctica is an important part of the Earth system, constituting 9.5% of Earth's land surface area. In winter, when sea ice is at its maximum, some 35 million km^2 of the Southern Hemisphere is ice-covered. The Antarctic Circumpolar Current circulates over approximately 22% of Earth's surface, flowing uninterrupted across the southern ends of the three major oceans. The region is an important and very different part of the Earth system and it has been since it was first discovered.

Antarctica is assuming a key global role as an observatory site, and meteorological and seismological data are routinely gathered at many stations; monitoring facilities in support of the Comprehensive Nuclear Test Ban Treaty have been established.

Historical Influence

The earliest ventures to Antarctica were commercial; they were searches for seals to supply the needs of a Northern Hemisphere market. Indeed, this led to the discovery of Antarctica.

Its discovery coincided closely with a time when scientists began to take a holistic view of Earth, through the study of gravity to define the shape of the Earth, and of its magnetic field to define and understand its magnetic characteristics. Henry Foster in *Chanticleer* visited Deception Island in 1829 to take pendulum measurements as part of an international movement; he also took magnetic measurements. In 1839/1840, the expeditions of Charles Wilkes (US) and Jules-Sebastian-Cesar Dumont d'Urville (France) sought in vain the South Magnetic Pole, their efforts thwarted by ice and the continent. In 1840/1841 the Brit James Clark Ross came south in search of this elusive target. He also failed but came close enough to locate it. The Gaussian model of the Earth's magnetic field was vindicated.

Some of the mid-nineteenth-century expeditions had the object of identifying living resources (whales, seals). These were successful in their search, and whaling and sealing industries were of global significance, supplying products, again dominantly for the Northern Hemisphere. From the beginning conservation issues emerged, even among the sealers who were overexploiting the resource.

In the early twentieth century, Antarctica caught the world's imagination through the "Heroic Era" of Roald Amundsen, Robert Falcon Scott, Ernest Shackleton, Douglas Mawson, and others of many nations. Some achievements were overshadowed by the events surrounding the quest for the South Geographic Pole and World War I. The valuable scientific achievements have perhaps been less obvious than the personal.

After World War II, science again began to address global issues, and the International Geophysical Year

(IGY) of 1957–1958 was conceived, the first time that such a program included the Antarctic. It can be viewed as a grandchild of the Wilkes/d'Urville/Ross expeditions 120 years earlier, and forerunner of the Antarctic Treaty.

Recent Recognition

The so-called ozone hole brought home the dangers that face Antarctica and showed that the causes of many problems lay in activities taking place dominantly in the Northern Hemisphere. Within 2 years of publication of the discovery (1985), international diplomatic efforts led to development of the Montreal Convention (signed 1987, in force 1989).

The ozone issue highlighted another feature: the environment is often seen as consisting of the land, ocean, and troposphere. Concerns over ozone highlighted the role of the stratosphere and the attendant solar–terrestrial interaction, which causes, *inter alia,* the northern and southern aurorae.

The Ice and Its Record

The overwhelming feature that distinguishes Antarctica from other parts of the world is its ice, both onshore and offshore. The debate on the environment and global change has drawn out the role of Antarctica as a site for monitoring the health of our Earth's atmosphere and oceans through studies on ice and sediment cores.

The ice sheet contains a record from the past, through the present, into the future. Antarctic ice is an incomparable source of information on baselines against which to monitor change in global environmental parameters, including airborne pollutants; it is far enough removed from sources of pollution that local influences are minimised and only a global signal remains.

The Antarctic ice sheet has a volume of 30×10^6 km^3, enough to raise sea level 60–70 m should it melt. It has a maximum thickness in East Antarctica of almost 4.8 km. In locations where it is thick, elevation is high enough that no melt of the ice occurs, even during summer, when the maximum temperature may be as low as –40°C. Under these circumstances, air trapped between the falling snowflakes and ice grains gets isolated as bubbles. What is sealed off in such bubbles is modern air, but the ice may be 80–250 years old, depending on local conditions and rate of snowfall. The ice has been cored continuously to a depth of more than 3 km, and is over 900,000 years old at Dome C, providing a detailed record of composition of the atmosphere over that time. In the upper part of the section, where annual layers can be identified, changes in composition can be detected seasonally, sometimes even monthly.

The composition of the ice and contained gases can be measured in great detail and tells of variation in global ice volume (and thus sea level), temperature, atmospheric composition, volcanic eruptions, and global wind strength through dust content. Detailed measurements of atmospheric CO_2 over the last 2000 years yield a baseline against which the impact of human activity since the Industrial Revolution can be measured. Volcanic eruptions are recorded as an increase in sulphate in the core leading to an increase in acidity in the ice. Krakatoa (1883), Tambora (1815), and probably El Chichon (1259) show up well and match the annual layer counts. A peak at 1457 coincides with a major explosive eruption at Kuwae in Vanuatu in 1453, identified initially by anthropological research.

Sea Ice and the Influence of the Global Marine Environment

The annual cycle of sea-ice growth and decay causes the formation of cold, dense, high-salinity Antarctic Bottom Water (AABW), which sinks and is a major control on the vertical thermohaline circulation of the world's oceans. This water can be recognised in the North Pacific and Atlantic Oceans. As it sinks down the Antarctic continental margin, it takes with it oxygen to ventilate the deep ocean and provides a basis for life for the organisms living there. Without this oxygen, the deep sea would become stagnant and eventually the life there would die out. This water also acts as a carbon sink by carrying dissolved CO_2 to CO_2-depleted deep-sea water. It also carries atmospheric pollutants; CFCs are a useful marker for water movement because they became available only recently, and are far from completely mixed through the oceans.

The difference between summer and winter distributions of sea ice is a major influence on weather patterns of the Southern Hemisphere through its control on heat exchange between atmosphere and ocean; in winter, the ice insulates the warm ocean (–1.8°C) from the cold atmosphere (–30°C). Southern Hemisphere cold fronts are clearly related to an Antarctic source.

Antarctica in the Long Term

Modern Antarctica is the result of its geological history. Study of the Antarctic provides examples to explain observations made on ancient rocks that formed in continentally glaciated regimes. There are also very important questions, on varying time scales, about rate and amplitude of natural global change that are best studied in the Antarctic.

Antarctica contains examples of some of Earth's oldest lithosphere, almost 4 billion years old in Enderby Land. It tells of conditions and processes at 15- to 35-km depth in an era in planetary development when Earth was without thick modern-style continental crust. As space exploration commences and models of planetary evolution are needed, Antarctica will provide important information for understanding the way this and other planets have evolved.

Earth has evolved through many cycles of continental assembly and reassembly; the latest was formation and breakup of Gondwana. Antarctica has assumed a critical role as a link between former partners in Gondwana and is often referred to as the keystone or centrepiece of Gondwana. It may now best be regarded as the remnant of Gondwana as other continents moved away and recombined in new configurations. The role of Antarctica in Gondwana poses ongoing questions, including the suggestion that much of North America came from the Pacific Ocean between Australia and South America approximately 1 billion years ago—the Rodinia concept. Data gathered in Antarctica were key elements leading to this hypothesis.

The Antarctic Plate is unusual in that the centre is virtually static and surrounded by midocean spreading ridges that are moving away. The exception is the Scotia Arc, where the South Atlantic sea floor is being subduced. The stability goes some way to explain an apparent oddity, that of the lack of earthquakes in Antarctica.

Antarctica is emerging as a source of information on the evolution of life in cold climates. Seymour Island near the Antarctic Peninsula contains a continuous succession of fossiliferous sediments across the Cretaceous/Tertiary boundary (K/T), the time, 65 Ma, of extinction of the dinosaurs due to asteroid or meteor impact in the Gulf of Mexico. This section is valuable because the section is in shallow-water sediments providing insights not available elsewhere.

Thirty million years after the extinction of the dinosaurs, other Gondwana continents had moved far enough away that circumpolar deep-water circulation could commence and the modern ice sheet and global oceanic circulation patterns emerge. This occurred after 99.3% of Earth history had passed.

Fauna and Flora

As Antarctica has evolved, so have its fauna and flora. The current biota is isolated from that of the rest of the world by the Antarctic Polar Frontal Zone (or Antarctic Convergence). This is a clear boundary and only a few whales and flying birds cross it. The isolation of the Antarctic biota is very marked and this has been the case since the Frontal Zone evolved about 20–15 Ma when the oceanographic barriers between Tasmania and Antarctica and South America and Antarctica opened.

This long isolation guaranteed that fauna and flora evolved strategies to survive in an environment different from that elsewhere, and that some of these adaptations will be valuable to humanity in the form of pharmaceuticals and industrial applications. Already whale and fish oils and other products are in use, and antifreeze chemicals identified in the blood of ice fish may pave the way for improved storage of organs for human surgery. These applications will expand as new biochemicals are discovered and developed.

The Antarctic biota became extinct through unusual mechanisms. Most species become extinct as they evolve to new species. Many species and lineages become extinct through mass extinctions such as those 220 and 65 Ma. The Antarctic extinction was different. As circum-Antarctic oceanographic circulation became established, almost all terrestrial vegetation and dependent animals became extinct because the ice sheet grew and pushed them off the land. Until that time, there had been a migration pathway between South America, through Antarctica to Australasia. While the terrestrial biota became extinct, a new biota evolved in the marine environment. It is likely that Antarctica underwent deglaciation and revegetation at times and that a flora typified by the southern beeches *(Nothofagus)* may have lived at 86° S as recently as 3 Ma, raising issues of how readily things can change.

As this extinction occurred, none of the species on land took the opportunity to return to the marine realm as the ancestors of seals, whales, dugongs, and others had done earlier.

Space Links

Part of human nature is to explore; today it is Antarctica; space and the deep sea are emerging. In space, the moon and Mars will be first. The beginnings are much closer to the present day than is the "heroic era." As people explore, the issue of conditions in space becomes focused. Space weather and its prediction are now growing in importance, as is the role of the outer levels of the Earth's atmosphere in the dynamic functioning of Earth and in global change issues. Antarctica already is important in training humans for space travel, in space-related research in medicine, in using the Antarctic as an analogue for space travel, and equipment testing. Antarctic medical records provide some of the best data on how small groups survive long periods in isolated environments.

Antarctica is the best site to conduct optical astronomy and submillimetre infrared astronomy because of the extreme dryness of the atmosphere, lack of pollution, and reliable cold-temperature regime on the high plateau. Concordia was constructed at Dome C in East Antarctica to take advantage of these characteristics.

Antarctica is now the source of 65%–70% of the world's meteorites, and it was one of these meteorites that was claimed in 1996 to preserve evidence of Martian life. Will fragments of other solar system planets and satellites also show up here?

Imaging of the Antarctic from space is now *de rigueur* and saves a great deal of resources.

Bipolar Issues

Both polar regions have phenomena relevant to magnetic poles; they have annual growth and decay of sea ice with consequences for bottom water generation; and they have organisms that are adapted to the cold environment but differ in other ways. There are several groups of microorganisms that have identical species living near both poles but no existence between. What is the mechanism for genetic exchange and similarity between both regions? Perhaps the answer lies in the thermohaline circulation patterns. One region is a continent surrounded by ocean; the other is ocean surrounded by continents. Antarctic research concentrates on those areas that cannot be conducted more cheaply elsewhere. The modern focus on environmental issues in the Antarctic provides an ideal case for cooperation in research around both poles.

The Antarctic as a Commercial Resource

Antarctica has had a commercial value since its discovery, initially for seals and later whales, and now for tourism, krill, and finfish. Increasing population, food, and space requirements and the capacity to produce food ensure that Antarctica will not be quarantined from the needs of the rest of the world.

Fisheries

Antarctic fisheries probably will expand in response to global needs and as fisheries elsewhere decline or come under more stringent control.

Water

As climate changes, conditions for food production in some regions of the world will improve while others will decline. Antarctic ice is already of some interest for water. Any developments in this area will need support from oceanography, glaciology, environment studies, and logistics.

Minerals and Hydrocarbons

Antarctic mineral exploitation is currently far too expensive compared with elsewhere. In addition, the Protocol on Environmental Protection to the Antarctic Treaty (the Madrid Protocol) has put it to one side, and there is growing pressure to move to other forms of energy generation.

Biochemicals

The distinctiveness of the Antarctic biota virtually ensures that biochemically and pharmaceutically useful substances will be found. Already there is considerable interest in compounds from bacteria, in potential sunscreens from algae, and in antifreeze compounds from ice fish. Elsewhere on earth, sponges have proven to be an excellent source of valuable compounds; there is no reason to suspect that those from the Antarctic will be less so.

Tourism

Antarctic tourism is emerging as a popular and diversifying industry. Some ten thousand people see Antarctica from ships during summer and another few hundred see it from overflights. Interest will grow, as will pressure for facilities and for access to new areas.

The Antarctic Treaty

Because of the peculiar features of the Antarctic Treaty, the Convention for the Conservation of Antarctic

Marine Living Resources (CCAMLR) was negotiated after the commencement of the activity that needed to be regulated. The "ecosystem approach" and its attendant "precautionary principle" are important elements and other fisheries management regimes are beginning to incorporate some of these concepts.

The Scientific Committee on Antarctic Research (SCAR) has been successful in stimulating international cooperation and information exchange. The International Arctic Science Council (IASC) has evolved, employing many of the principles and practices developed for SCAR.

Cultural Value

The area is so large and poorly known that a scientist has a greater chance of making a fundamentally new discovery here than anywhere else on Earth.

An identifiably Antarctic culture is emerging and is expressed by an increasing number of works of fiction, of art, and of philately.

As population grows, cities get larger, and individuals get more isolated from their roots, become an older population with time to think and consider their place in the scheme of things, and get hemmed in by more rules and regulations, there will be increasing need to escape. Antarctica will continue to provide a mental release. It is clean, has no indigenous people, is relatively unpolluted, and is inspirational. As more is learned of this region, ideas on the functioning of the Earth's dynamic systems will change.

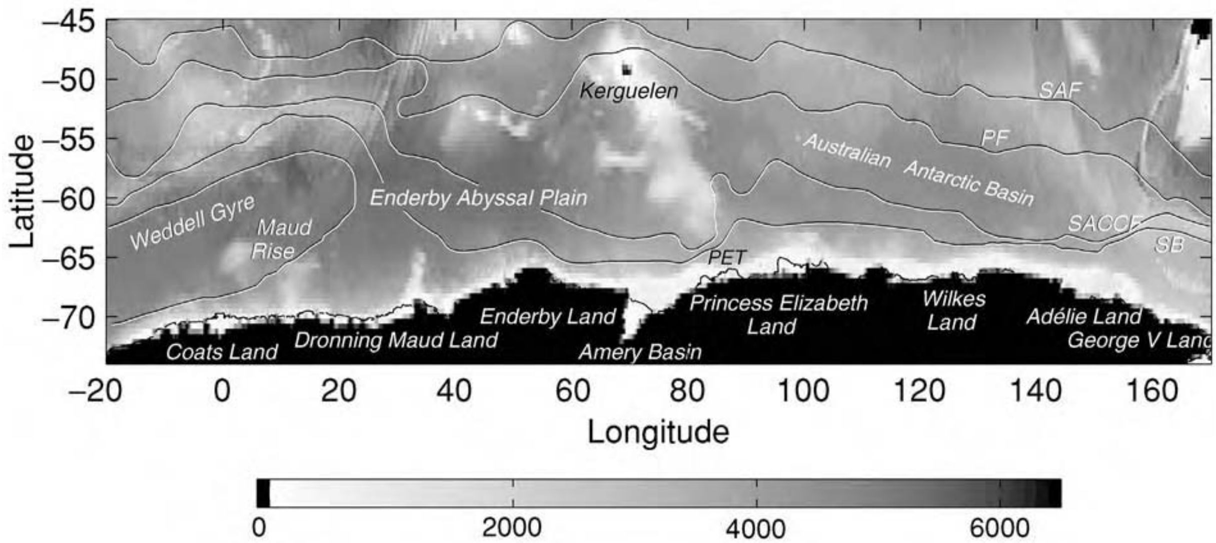
EAST ANTARCTIC CONTINENTAL MARGIN, OCEANOGRAPHY OF

Location and Features

The region that comprises East Antarctica is commonly considered to be that between the Weddell Sea to the west and the Ross Sea to the east (i.e., between around 20° W and 170° E). This encompasses the Antarctic coast and shelf between Coats Land and George V Land, including Enderby Land, Princess Elizabeth Land, and the Amery Basin. The shelf region here differs from those in other sectors of Antarctica in that it is relatively narrow (typically around 50–100 km), especially compared with the much broader shelves in the Weddell and Ross Seas. As for most of the Antarctic, the shelf regions are rather deep compared with ocean shelves around the world, normally a few hundred to several hundreds of metres.

The open ocean adjacent to the East Antarctic margin is dominated by two deep basins, the Weddell-Enderby Basin in the west and the Australian-Antarctic Basin in the east. The Weddell-Enderby



The bathymetry of the ocean adjacent to East Antarctica is shown (depths are in metres). Lines denote the predominant eastward-flowing fronts of the Antarctic Circumpolar Current (ACC); these are (north to south) the Subantarctic Front (SAF), Polar Front (PF), and the Southern ACC Front (SACCF). The Southern Boundary denotes the southern limit of the ACC. The approximate position of the cyclonic (clockwise) Weddell Gyre is also marked. Assorted place names, topographic features, and ocean basins are marked, including the Princess Elizabeth Trough (PET).

Basin is the deeper of the two, with depths in excess of 5000 m. The Australian-Antarctic Basin is, on average, around 4500 m deep. Dividing the two basins is the Kerguelen Plateau, a ridge-like system oriented roughly north–south between 60° and 80° E. Typical depths for the peak of Kerguelen Plateau are between a few hundred metres and a couple of thousand metres, and there is a deep passage separating it from the Antarctic Continent to the south. This is the 200- to 300-km-wide Princess Elizabeth Trough (PET), with a sill depth of 3750 m. The Weddell-Enderby Basin is punctuated by a few rather isolated ridges and seamounts, notably the Conrad Rise (40°–50° E, 55° S), Maud Rise (65° S on the Greenwich Meridian), and the Southwest Indian Ridge, which fringes the basin to the north (between around 55° and 60° S). The Australian-Antarctic Basin has fewer such features, and it is flanked to the north by the Southeast Indian Ridge at around 50°–55° S. This is dissected by a sequence of deep, narrow passages at around 120° E.

At around 70°–80° E lie Prydz Bay and the Amery Basin, containing the Amery Ice Shelf. This is the third-largest embayed ice shelf in Antarctica, and it forms the floating portion of the Lambert Glacier system. Although much smaller than the vast ice shelves in the Weddell and Ross Seas, its presence has potentially significant oceanographic implications (discussed later). While the front of the Amery Ice Shelf accounts for only 2% of the total Antarctic coastline, its catchment area accounts for 16% of the grounded East Antarctic ice sheet. Other, smaller ice shelves fringe the East Antarctic continent, such as the Fimbul Ice Shelf close to the Greenwich Meridian, and the West and Shackleton Ice Shelves in the Australian-Antarctic Sector.

Atmospheric and Cryospheric Forcings

The large-scale barometric pressure field over the ocean in the East Antarctic sector mimics that around Antarctica as a whole. There is a ridge of high pressure in the far north (around 25°–35° S), and a trough just north of the Antarctic continent itself, close to 65° S. This pattern produces strong westerly (eastward-flowing) winds between the ridge and the trough. The circumpolar westerly winds are strongest in the East Antarctic region (around 40°–120° E) and are characterized by frequent storm events, especially in the austral (Antarctic) winter. These winds are, on average, the strongest over the world ocean as a whole. Combined with the absence of land barriers north of Antarctica (i.e., unlimited fetch), this leads to the largest waves in the world during the austral winter. South of the trough around 65° S, the wind direction reverses from westerly to easterly.

The band of strongest winds around Antarctica (around 50° S) coincides with a region of relatively high precipitation. Evaporation is weak throughout the Southern Ocean due to the low air temperatures; thus, precipitation dominates the exchange of freshwater with the atmosphere. Also of great importance are processes associated with the seasonal sea-ice cover in the region. Whilst sea ice in the East Antarctic region melts back almost completely to the continent during summer, the wintertime ice cover extends northward to 60° S or beyond and is generally further north at the western edge of the East Antarctic sector. Maximum ice coverage is normally around September, with the most rapid advance of the ice in May/June. As sea ice forms, salt is rejected, leading to a salinification of the ocean. Conversely, the seasonal melting of sea ice injects a layer of freshwater into the surface ocean.

Not all areas are completely blanketed by sea ice during winter. Some are retained as open-water areas (polynyas), due either to the effect of winds or heat from the ocean. Wind-forced polynyas can form adjacent to the continent, for example, due to winds continuously pushing sea ice away from the coastline. Polynyas can also form over the open ocean; for example, a large polynya occurred in three successive years in the 1970s close to Maud Rise in the Weddell-Enderby region. Regions that are kept clear of ice during the austral winter, despite the extremely low atmospheric temperatures, are free to continuously form more ice as a consequence. Sea-ice formation in general, and in polynyas especially, can be important for dense water formation (explored later).

General Circulation

Originally, the wind pattern previously described led to concepts of a "west wind drift" (eastward-flowing ocean current) associated with the strong circumpolar westerlies over the open Southern Ocean, and an "east wind drift" (westward-flowing current) adjacent to the continent itself. In between these lay the Antarctic Divergence, a region where the Coriolis force (due to the Earth's rotation) tends to push the surface waters apart, leading to upwelling of deeper water from below. These terms are now archaic and the physics they describe is somewhat simplistic, but it is still believed that upwelling of deep waters in the Southern Ocean is important for global ocean circulation. The Antarctic Divergence is notable for being one of the most biologically productive regions in the world's oceans, since the upwelled water is rich in nutrients. This leads to strong production of phytoplankton and zooplankton, which support communities of higher predators such as penguins, seals, and whales.

Modern thinking ascribes the eastward flow in the open Southern Ocean to the Antarctic Circumpolar Current (ACC), a banded feature comprising several fast-flowing current cores, each of which can have surface speeds of several tens of centimeters per second. The fronts are generally termed (north to south) the Subantarctic Front, the Polar Front, and the Southern ACC Front, with the southern boundary marking the poleward limit of the ACC. The fronts are deep-water features, and hence divert north and south of Kerguelen Plateau to negotiate their way around the topography. The forcing for the ACC is at least partially winds, but it has been argued that buoyancy forcing (due to heat and freshwater inputs) is important also. Different estimates for total flow of the ACC in this region exist, but it is normally considered to be in the range of 140–160 Sv, where 1 Sv is 1 million m^3 of water per second.

The western side of East Antarctica contains the easternmost extension of the Weddell Gyre. This cyclonic (clockwise-flowing) gyre fills the Weddell Sea to the west, but also extends out to reach nearly 30° E. The presence of this gyre is the main reason that sea ice extends farther north here in winter then elsewhere along the East Antarctic region.

The term "East Wind Drift" is now rarely seen in oceanographic studies, due in part to a realization that the driving mechanisms for the westward flow south of the ACC can include thermohaline (temperature/salinity) forcing as well as wind stress. Some workers describe an Antarctic coastal current that runs westward around much of the continent, roughly parallel to the Antarctic coastline. This contains water that is colder and fresher than the water from the ACC, which resides close to the shelf break along most of East Antarctica. However, this nomenclature is also not ideal, since the "coastal current" can exist at a great distance from the continent itself in regions where the shelves are broad.

More commonly seen nowadays are descriptions of an Antarctic Slope Front. This is the interface between the cold, fresh water of the Antarctic shelves and the warmer, more saline water derived from the ACC. It often occurs above the upper continental slope, close to the shelf break along the edge of the continent. It is a nearly circumpolar feature that is strongly steered by the bottom topography, and it is characterized by distinct subsurface gradients in temperature (lateral gradients can exceed 3°C in just 25 km). The Slope Front exhibits higher alongshore current speeds than most areas on the adjacent continental shelf, and it has been observed to be a preferred route for icebergs traveling westward along the continental margin.

The Antarctic Slope Front can be a V-shaped double front if the continental shelf is sufficiently wide, but if it is narrow or relatively shallow only a single front (the northern half of the V) is normally present. Where the single front is present, it defines the edge of the cold, low-salinity coastal current extending seaward of the shelf break. Both the single-front and V-shaped frontal configurations can be found adjacent to the East Antarctic continental margin. For example, at around 160° E (off George V Land) and at 80° E (east of the Amery Basin) only single fronts are present, whereas at 145° E (off Adálie Land) and 70° E (close to the Amery Basin) the V-shaped front can be found. It is believed that the V-shaped front often denotes locations where dense waters on the continental shelf can spill off into the deep ocean.

Water Mass Characteristics

The most voluminous water mass in the open ocean close to East Antarctica is Circumpolar Deep Water (CDW). This is a warm, salty, midlevel water mass derived from waters forming in the northern North Atlantic. It is the main water mass of the ACC and is the oceanic source for all water masses that form around Antarctica. The core of the CDW rises up to the south across the ACC, so that despite being very deep at the northern side of the ACC it can impinge on the Antarctic shelf in certain locations. It does this in modified form, since it mixes with shelf and surface waters, which have very different properties.

The water above the CDW between the Polar Front and the Antarctic shelf slope is Antarctic Surface Water. This has changing properties depending on season: sea-ice formation/melting and warming/cooling by the atmosphere are very influential in determining its characteristics. During the austral winter, intense cooling lowers the surface water temperature to its freezing point, and sea-ice formation injects salt into the water. This makes it denser than in summer, and, combined with strong wind-induced mixing action, creates a thick layer (50–150 m) of very cold water at the surface. During the austral spring, the melting of ice freshens the surface of this layer, and the rising air temperatures warm it. This leads to a thin layer of warmer, fresher water at the very surface, with the core of the cold water persisting at depth. This cold core is generally called *winter water*.

Different types of waters exist on the Antarctic continental shelves depending on local processes and mixing with external water masses. These shelf waters are generally very cold (close to the freezing point), but show a wide range of salinities. The high salinity attained by some shelf waters reflects the strong ice production that can exist over the shelf (and hence the large quantities of brine rejected into the ocean). This is especially true for regions with polynyas, which can continue forming ice throughout the austral winter. Normally, it is broad shelf regions with topographic obstacles (such as the western Weddell Sea) that show the highest prevalence of high-salinity shelf water, although it can form in East Antarctica also, including close to the Adálie Coast.

As well as high- and low-salinity shelf waters, a third type of shelf water exists, one that is formed by the interaction of seawater with a floating ice shelf. In East Antarctica, the Amery Ice Shelf near 70° E is the main location for the formation of this Ice Shelf Water (ISW). This forms when dense water at the bottom of the continental shelf flows into the cavity beneath the ice shelf. The Lambert Glacier grounding point is almost 2500 m below sea level, and the huge pressure exerted on the water by the weight above it means that the freezing point is lowered from around –1.85°C to well below –2°C. As the inflowing seawater comes into contact with the glacier, it melts some of the glacial ice, thus becoming cooler and fresher. However, the decreased freezing point due to the great pressure means that the water can get significantly colder before freezing. Upon exiting the ice shelf cavity, the ISW is thus fresher than the inflowing water was, but is also cooler and is only kept liquid by the pressure it is under. Some of the seawater does freeze onto the underside of the ice shelf, forming layers of "marine ice." This is the reason that icebergs that calve from the Amery Ice Shelf are often reported to have an emerald-green appearance. Many of the green icebergs observed in the Weddell Sea are believed to have originated from the Amery Ice Shelf.

Bottom Water Formation in East Antarctica

The shelf waters close to Antarctica are globally important since they are crucial to the formation of *Antarctic Bottom Water* (AABW). This resides below the CDW in the open Southern Ocean and spreads out as the abyssal layer of the global ocean circulation. AABW is slightly fresher than CDW, but it is also much colder, and hence is dense enough to sit beneath CDW in a stable water column. AABW forms close to the Antarctic continent through the mixing of dense shelf waters (including possibly ISW) with modified forms of CDW. The mixing required can be facilitated by high levels of tidal energy near the shelf break. The sinking of dense waters along the Slope Front near the shelf break can contribute recently formed waters to the CDW layer as well as the AABW layer.

Until recently, it was believed that AABW production was restricted predominantly to the Weddell and Ross Seas. However, the relative prominence of East Antarctica in this role has been progressively more recognized in recent studies. The Wilkes-Adálie Land coast (between around 138° and 158° E) has received much interest in this context. That AABW forms here is in some ways surprising, since the region's shelf is comparatively narrow, contains no topographic barriers such as would help the pooling of brine-enriched shelf waters, and features no significant ice shelves that would promote the formation of large amounts of ISW. It does, however, show distinctive shelf waters in a depression between 142.5° and 145.5° E that have their salinity increased by intrusions of modified CDW. An unusually large and persistent coastal polynya also adds to the salinity enrichment of the shelf waters here. Mixing of these waters with the CDW that impinges on the shelf leads to the formation of AABW, dense plumes of which lie over the continental slope. AABW that forms in the Ross Sea further east can also enter the Australian-Antarctic Basin; however, the locally formed variety is distinctive based on its colder and fresher properties. These distinctive characteristics have enabled quantification of importance of the AABW formed in the southeast Indian Ocean. It has been suggested that this region contributes up to one-quarter of the total global ocean volume colder than 0°C.

The AABW in the Australian-Antarctic Basin can escape northward through gaps in the Southeast Indian Ridge or can flow westward through the PET into the Weddell-Enderby Basin. Much of the AABW that enters the East Antarctic region from the Weddell Sea either recirculates in the Weddell Gyre or escapes to the northeast through gaps between Kerguelen and other nearby islands. Small amounts of AABW formed in the Weddell Sea are believed to be able to enter the Australian-Antarctic Basin by being advected south of Kerguelen Plateau in the ACC, but this is unlikely to be volumetrically very significant.

In addition to the Adálie Coast area, the region of Prydz Bay and the Amery Ice Shelf has also received interest as a possible source of AABW. Whilst the issue is still somewhat unresolved, there are some strong suggestions of AABW formation in the vicinity. For example, high concentrations of dissolved chlorofluorocarbons (CFCs) along the continental slope further west of the Amery Basin have been interpreted to suggest a quite local source of AABW, and observations of high salinity shelf waters close to the shelf break here have lent further evidence.

It is important to note that the properties of AABW, and indeed other water masses in the East Antarctic region, will not be constant with time. Whilst this region is beset by a paucity of data from earlier periods, it has already been noted that the bottom water in the Australian-Antarctic Basin has shown a very pronounced freshening since 1994. Further, consideration of water mass properties over the continental rise between 140° and 150° E has shown a very significant drift toward lower salinity and temperature over the past 50 years. It is likely that the AABW derived from the Ross Sea in this region has also freshened over this same period, since the shelf waters there have been observed to have freshened dramatically. The causes of this large-amplitude freshening over this region of the Southern Ocean are not yet known, but they could include changes in winds and precipitation, long-period variability in sea-ice formation, and an acceleration of melting of glacial ice from Antarctica. Given the potential consequences for the global ocean, it is important that this issue be further explored.

EAST ANTARCTIC SHIELD

Shields and Cratons

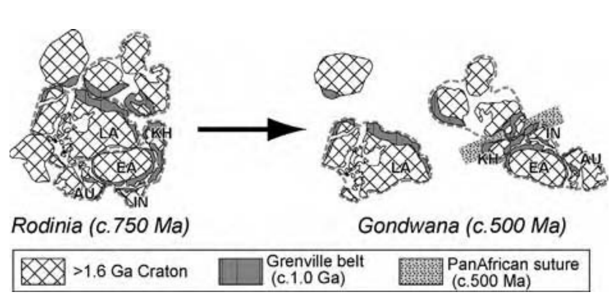
Most of the crust of the world's seven continents is composed of two types of rock: shields and platforms. In the 4.6-billion-year-long history of the Earth, the period before 570 Ma is called the Precambrian age. A shield is a land mass where ancient Precambrian rocks are exposed on the Earth's surface, whereas a platform is a part of a continent where younger sedimentary layers cover a basement of Precambrian rock. Shields and platforms are the two main components of cratons, which are the parts of a continent that have been tectonically stable since Precambrian times. Cratons are typically joined together by orogenic ("mountain-building") belts, where moving continental plates have collided. Many cratons have been stable since Archean times, in the early part of the Earth's history. Such old and stable continental pieces have been weathered and eroded for enormous periods of time. As erosion carries away the weight of the top of a craton, the continental crust slowly rises, exposing plutonic and metamorphic rocks that formed deep below the surface. This erosion produces a landscape that curves gently from the center to the margins of the craton, like the curved shields of the warriors of ancient Europe; hence the term "shield" (the phrase was first coined in 1888 by Eduard Suess [1831–1914] when he described the Canadian Shield). The heart of the Canadian Shield, in the area around Lake Superior, is a collage of Archean cratonic pieces, Proterozoic orogenic belts, intracratonic igneous rocks, and sedimentary layers. Most of Antarctica is composed of the East Antarctic Shield, which consists of a variety of Precambrian terranes, and although it is mostly hidden under ice, there is no reason to believe it is very much different from the other Precambrian shields of the world.

Subglacial bed topographic map of Antarctica. Numbers (1000, 0, –1000) indicate bed rock altitude contours (m). (Drawn based on the data set downloaded from BEDMAP [http://www.antarctica.ac.uk/aedc/bedmap/].)

Continental Drift and East Antarctica

More than 30 years before the discovery of plate tectonics, a theory of drifting continents was proposed by Alfred L. Wegener (1880–1930), a German climatologist. Using geological and geophysical evidence, he suggested that continental blocks now separated by oceans had once been joined as one great supercontinent.

Wegener thought the resemblance of the Atlantic coast lines of Africa and South America showed that the two continents were once contiguous. From the similarities between distributions of plant fossils that had grown in similar climatic conditions (Gondwana Flora), sediments deposited by Paleozoic glaciers,

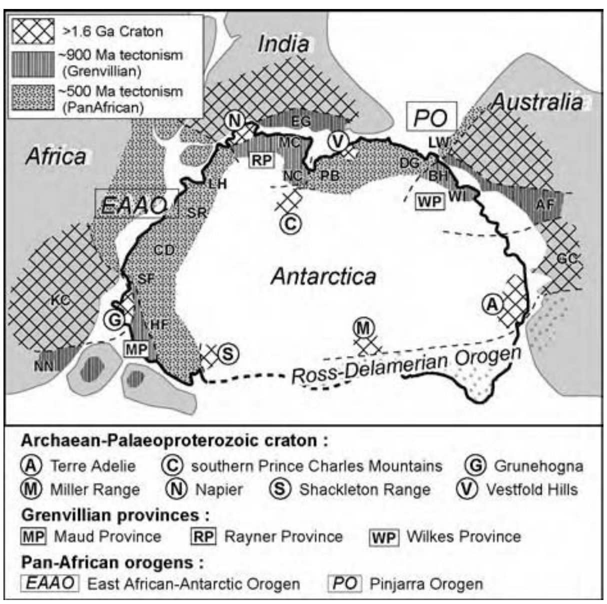


Traditional model of Rodinia and Gondwana supercontinents. EA: East Antarctica (after Hoffman, 1991), IN: India, AU: Australia, KH: Kalahari (southern Africa), LA: Laurentia (northern America).

fossils that had lived on land or in fresh water, and continuity of geology between the two facing continents, Wegener proposed that a supercontinent existed from the late Paleozoic to the Mesozoic: Gondwana or Pangea, in which Laurasia is included. Wegner could not understand, however, what forces had driven the movement of continents, and his hypothesis had little impact until the plate tectonics theory was developed decades later.

In Wegener's time, scientific understanding of Antarctica was very limited, but many plant fossils of Gondwana Flora were found in the Beacon Sandstone beds in the Transantarctic Mountains. Samples from the British Antarctic *(Terra Nova)* expedition (1910–1913) were later found to contain leaves and stems of *Glossopteris,* an extinct tree found in continents that were part of Gondwana. Thus it was proven that Antarctica was a part of Gondwana in the late Paleozoic to early Mesozoic (about 200 Ma).

A South African geologist, Alexander du Toit (1937), noted that East Antarctica was a key piece of the Gondwana supercontinent, because it was surrounded by continents such as South America, Africa, Australia, and India until about 180 Ma. In addition, East Antarctica is also a key component of an earlier Neoproterozoic supercontinent, known as



East Antarctica and neighboring continents in Gondwana reconstruction. Rodinia. In the following description, the general features of the East Antarctic Shield are discussed in terms of the history of crustal evolution.

East Antarctic Shield

Antarctica is divided into two geographic domains by the Transantarctic Mountains, a 3500-km-long and 4500-m-high mountain range. West Antarctica occupies the Pacific Ocean side, and East Antarctica is on the side of the Indian and South Atlantic Oceans.

West Antarctica is a complex assemblage of accreted terrenes, composed mainly of four continental blocks that have moved against each other and toward East Antarctica during the Phanerozoic (the part of the earth's history after 570 Ma).

The crustal structure of East Antarctica is less well understood. Geological information on the basement beneath the ice sheet, which covers more than 98% of East Antarctica, can only be obtained by indirect means of geophysical investigation such as seismic, magnetic, and gravimetric surveys, along with radio-echo sounding for ice-thickness measurement. An ice-thickness and sub-ice (or subglacial) topographic model of the Antarctic was compiled by an international project called BEDMAP (bed topography of the Antarctic).

The most prominent sub-ice topographic features in East Antarctica are the Gamburtsev Subglacial Mountains, which reach 2000 m above sea level below Dome A, the highest part of the East Antarctic ice sheet. The Lambert Glacier, which is the largest ice stream in the world, flows from the Gamburtsev Subglacial Mountains along a depression northwards to Prydz Bay. The ice depression is believed to overlie the Lambert Graben, a huge rift in the underlying continent that extends at least 700 km inland from the Antarctic coast. In the northern Prince Charles Mountains, the fault system of the Lambert Graben disrupts the Permo-Triassic Amery Group and juxtaposes it against Proterozoic basement.

Also prominent are two large subglacial basins in Wilkes Land, named the Aurora and Wilkes basins. The Wilkes Subglacial basin parallels the Transantarctic Mountains on the polar side and is thought to contain one to several vertical kilometers of sediment infill.

In contrast to the interior of the continent, rock exposures in the coastal regions and mountain ranges are generally glaciated pavements and large cliff sections, suitable for direct geological observations.

East Antarctica was once regarded as a single huge Precambrian craton, but intensive investigations since the 1960s and, in particular, recent advances in geochronological techniques have made it possible to reveal the complex history of the Precambrian East Antarctic Shield. Studies on Precambrian geology are based on the correlation of the field relationships of rock types, chemical compositions, and ages of rocks and constituent minerals. The ages of prefossil Precambrian rocks can only be determined by isotopic dating techniques. Combinations of rubidium–strontium, samarium–neodymium, potassium–argon, argon–argon, and uranium–lead geochronology have been most popular and, in particular, the recent development of uranium–lead geochronology by analysis of zircon with ion-microprobe has revealed much about the complex tectonic history of the East Antarctic Shield, because mineral growth is accelerated and controlled by the heating that accompanies tectonic events. In this article, age determinations are mostly derived from ion-microprobe data.

The complex history of the East Antarctic Shield includes three major stages of tectonothermal activity: (1) development and stabilization of various Archean to Paleoproterozoic cratons before 1600 Ma; (2) development of a late Mesoproterozoic orogen (1300–900 Ma); and (3) late Neoproterozoic to early Paleozoic (550–450 Ma) tectonism. The stabilization of Archean to Paleoproterozoic cratons may be subdivided into two stages: Late Archean to earliest Proterozoic (i.e., between 2840 and 2480 Ma) and Paleoproterozoic (2200 to 1700 Ma). The 1300–900-Ma orogeny is contemporaneous with the Grenville orogeny in North America and the Kibaran orogeny in Africa, whereas the late Neoproterozoic to early Paleozoic (550–450 Ma) event is coeval with the Ross Orogeny in the present-day Transantarctic Mountains and the Pan-African Orogeny (East African Orogeny) in east Africa.

In this article, we identify the late Mesoproterozoic to early Neoproterozoic orogeny as the "Grenville-age orogeny" and the late Neoproterozoic to early Paleozoic (550–450 Ma) tectonism as the "Pan-African event." The geographic directions in this article refer to the present-day positions of continents.

Since the East Antarctic Shield has a long history, the basement rocks of many areas have been repeatedly reworked by tectonism. The effect of the Pan-African event, which is the youngest regional tectonothermal event in East Antarctica, differs from place to place. Hence, in this article, the regional geology is described in key areas that are relatively well described in terms of tectonic evolution. These areas are grouped into (1) Archean and Paleoproterozoic cratons and (2) Grenville-age orogenic terranes, each of which may or may not be reworked by Pan-African tectonism. Then the discussion will be focused on the Pan-African event.

Archean and Paleoproterozoic Cratons

Archean cratons are mainly composed of metamorphosed igneous rocks (orthogneisses) containing zircons older than 2.5 Ga. These orthogneisses have been reported from coastal regions (Shackleton Range of Coats Land, Western Dronning Maud Land, Enderby Land, Princess Elizabeth Land, Queen Mary Land, and King George V Land) and inland regions (Southern Prince Charles Mountains and the Miller Range of the central Transantarctic Mountains). Many of the Archean cratons were repeatedly reworked into the Paleoproterozoic. The Archean–Paleoproterozoic cratons vary widely in size and age, reflecting the long and complex history of the early Earth.

The Shackleton Range of Coats Land consists of east–west-aligned mountain chains. It was once considered to be a part of the Ross Orogenic Belt of the Transantarctic Mountains; the structural trend of the range, however, is not consistent with that of the Transantarctic Mountains. It is now regarded to be a part of the East Antarctic Shield. The basement of the mountains is composed mainly of amphibolite facies (medium-grade metamorphic) rocks. The Shackleton Range can be divided into a northern block that is composed of reworked Archean–Paleoproterozoic cratonic fragments, along with ophiolite complexes (relics of ocean floor rocks) and low-grade metasedimentary rocks with Cambrian *Archaeocyathus* fossils, and a southern block that is entirely composed of Archean-Paleoproterozoic craton. The northern block of the range has been thrust over the southern block by Pan-African thrust faults, due to the collision between the East Antarctic Craton and Kalahari Craton.

No Archean craton has been reported from Dronning Maud Land, except for Archean granite of 3000 Ma exposed at Annandagstoppane in western Dronning Maud Land. This granite has been called the Grunehogna Craton and is regarded as a portion of the Kaapvaal Craton (the southern part of Kalahari Craton), which was detached from South Africa during the breakup of Gondwana.

In the 1970s, Russian geologists reported lead–lead ages of about 4.0 Ga from the Fyfe Hills in Enderby Land. The finding of such ancient crust generated intense interest in the metamorphic and igneous rocks of Enderby Land that form the Napier Complex. The oldest components of zircon in orthogneiss at Mount Sones crystallized at 3930 ± 10 Ma. This is the second-oldest age recorded for an *in situ* terrestrial rock and the oldest age in Antarctica, but later more precise studies showed the main igneous activity occurred at about 3800 Ma. The Archean orthogneisses are typically potassium-poor granitoids of the tonalite–trondhjemite–granodiorite (TTG) series, which plays an important role in the formation of new continental crust.

Several subsequent episodes of Archean thermal activity were identified via ion-microprobe dating of zircon, at c. 3300 Ma, c. 3000 Ma, c. 2900 Ma, and c. 2500 Ma. However, these events have not always occurred everywhere in the complex. The oldest crust is restricted around Mount Sones in the central part of the complex, but c. 2500 Ma a thermal event occurred throughout the complex.

The Napier Complex is also characterized by metamorphism at more than 1000°C (ultra-high-temperature (UHT) metamorphism). The age of UHT metamorphism is controversial because of the long complex metamorphic history. The source of such extreme heat is also uncertain, with most models invoking the deep-level emplacement of large volumes of magma into double-thickened continental crust.

The Archean-Paleoproterozoic cratons in the coastal regions of East Antarctica are comparable with those of adjacent Gondwana fragments. The Napier Complex would have adjoined the cratons of the Indian peninsula prior to the breakup of Gondwana.

In the southern Prince Charles Mountains, Archean granitic gneisses are overlain by Late Archean metasediments. Some were affected by Mesoproterozoic to Neoproterozoic medium-grade metamorphism, whereas greenschist-facies (low metamorphic grade) phyllites and banded iron formations are Late Archean to Paleoproterozoic in age. Ion-microprobe ages for zircon from the granitic gneisses are 3170–3000 Ma, and later undeformed pegmatites intruded at c. 2640 Ma.

In the Prydz Bay area, Archean high-grade metamorphic rocks crop out in the Rauer Islands and Vestfold Hills. These localities are separated by a glacier only 12 km wide, but the ages of the Rauer Group (2800 Ma and partly 3270 Ma) gneisses are significantly older than those of the Vestfold Hills (c. 2500 Ma).

In Queen Mary Land, there are at least three outcrops of Archean high-grade orthogneiss around the Denman Glacier region, with ages between 3000 Ma and 2640 Ma.

East of King George V Land, craton areas used to be regarded as mainly composed of Paleoproterozoic high-grade gneisses. Ion-microprobe zircon and monazite ages from paragneisses (medium- to high-grade metamorphic rocks of sedimentary origin) place the high-grade metamorphic event at c. 2420–2440 Ma, followed by a 1710-Ma overprint and granite magmatism at c. 2520–2560 Ma. Paleoproterozoic rocks on the coast of Terre Adelie and King George V Land are similar in lithology and age to those of the Gawler Craton in southern Australia. A large continental block consisting of these cratons together with the inferred sub-ice cratonic crust has been proposed and named the Mawson Continent after the Antarctic explorer and geologist Douglas Mawson.

In the Miller Range of the Transantarctic Mountains, the oldest gneisses represent Archean magmatic crust generated from juvenile mantle melts between 3.15 and 3.00 Ga, indicating that the East Antarctic Shield extends to the central Transantarctic Mountains. Later episodes of high-temperature metamorphism and magmatism occurred at c. 2.5 Ga and c. 1.7 Ga. The c.-1.7-Ga event is correlated with similar ages in Terre Adelie and King George V Land and the basement of the Miller Range is potentially a part of the Mawson Continent. Furthermore, inland cratons such as the southern Prince Charles Mountains and the Shackleton Range have been also correlated with the Mawson Continent, although the age data are limited. If all these areas were unified, combined with the Gawler Craton, the Mawson Continent represents a huge Late Archean to Paleoproterozoic continental province.

Late-Proterozoic to Early-Paleozoic Evolution of the East Antarctic Shield

The traditional model of Late-Proterozoic to early-Paleozoic evolution of the East Antarctic Shield has been described in a framework of amalgamation and dispersion of the Rodinia Supercontinent, followed by the collision of East and West Gondwana to form the Gondwana Supercontinent (e.g., Hoffman 1991; Dalziel 1992).

It has been proposed that a continuous Grenville-age (c.1300–900 Ma) mobile belt surrounds East Antarctica from Coats Land to Wilkes Land, through Dronning Maud Land, Kemp Land, the northern Prince Charles Mountains, Princess Elizabeth Land, and Queen Mary Land.

This belt was called the Circum-East Antarctic Mobile Belt (CEAMB) or the Wegener-Mawson Mobile Belt. The CEAMB in East Antarctica was considered to extend into Grenville-age mobile belts in North America, Africa, India, and Australia, resulting in the amalgamation of the early Neoproterozoic supercontinent Rodinia (see Hoffman 1991).

According to this model, the breakup of Rodinia occurred when the North American block split away from the continental blocks of East Antarctica, Australia, Peninsular India, Madagascar, and South Africa, which are collectively known as East Gondwana. East Gondwana subsequently collided with the West Africa, Congo, and Kalahali cratons, which form West Gondwana. The collision of East and West Gondwana is known as the Pan-African Orogeny or East African Orogeny. The suture of the collision is well documented in northeastern Africa to Mozambique, whereas the southern continuation of the suture in southeast Africa and East Antarctica has been more controversial, although Pan-African metamorphism and magmatic activity has been widely recognized in East Antarctica. The accumulation of zircon uranium–lead age data has revealed that the CEAMB was not continuous but separated into three major provinces, Maud, Rayner, and Wilkes, which are separated by two regions of Pan-African high-grade metamorphism and tectonism in Dronning Maud Land and the Prydz Bay-Denman Glacier region. Fitzsimons (2000a) also pointed out that the three Grenville-age provinces have different time spans: 1090–1030 Ma, 990–900 Ma, and 1330–1130 Ma, respectively.

Maud Province and Pan-African Overprint

The rocks in Dronning Maud Land (DML) are exposed in east–west-trending mountain ranges along the boundary between the plateau and shelf ice sheets. Maud Province, in the strict sense, was defined as a Grenville-age mobile belt in the western DML, which is a part of the Namaqua-Natal-Maud Belt (Jacobs et al. 2003). However, some authors regard areas of central and east DML that show intense Pan-African reworking as parts of the Maud Belt (see Frimmel 2004).

The lithology of the basement rocks of this belt is rather similar between Heimfontfjella in the western DML (c. 10° W) and the Sør Rondane Mountains in the east (c. 25° E). It is predominantly composed of multiply deformed medium- to high-grade metamorphic volcanic rocks and subordinate metasedimentary rocks, intruded by various, mainly granitic, plutonic rocks.

On the basis of chemical composition, the igneous protoliths from these areas have been interpreted as deriving largely from magmas in oceanic, island-arc, accretional complex and continental margin island arcs, analogous to modern plate-tectonic settings. Combined with ion-microprobe zircon ages and samarium–neodymium model ages, the basement of the DML is interpreted to be juvenile Mesoproterozoic island-arc material accreted to the Gurunehogna Craton and possibly an as-yet-unidentified older continent that existed further south in the DML.

In the western DML, the degree of Pan-African metamorphism decreases towards the west. The Heimfontfjella region is divided by the Heimfront Shear Zone. Northwest of the shear zone, the Pan-African overprint is limited to low-grade (greenschist facies) metamorphism and the intrusion of granites and pegmatite dykes, whereas the eastern zone records intense polyphase deformation and high-grade metamorphism. Thus the Heimfront Shear Zone has been identified as a major zone along the western front of the Pan-African Orogen in Antarctica. Jacobs et al. (2003) propose that the suture of collision between East and West Gondwana extends to Dronning Maud Land, and call the orogenic belt the East African-Antarctic Orogen (EAAO).

Rayner Province and Wilkes Province

The late Mesoproterozoic Rayner Complex in Enderby Land had originally been interpreted as a reworked part of the Archean Napier Complex. However, later geochronological studies showed that the Rayner Complex is composed of 990–900 Ma high-grade metamorphic rocks of pre-Grenvillian felsic plutonic rocks and subordinate paragneisses showing Mesoproterozoic depositional age. Similar terranes continue along the Mawson Coast of Kemp Land and further to the northern Prince Charles Mountains, and rocks in the Eastern Ghats Province of India show similar ages. Together these areas are called the Rayner Province and are regarded as a Grenville-age mobile belt that records the collision of the Indian shield with a central Antarctic craton exposed in the southern Prince Charles Mountains.

The Wilkes Province is the easternmost outcrop of Grenville-age mobile belt in East Antarctica, and lies along the coast in the Windmill Islands and Bunger Hills of Wilkes Land. Two episodes of high-grade metamorphism at 1330–1280 Ma and 1200–1130 Ma have been correlated with the Albany-Fraser province in Australia.

Pan-African Tectonism in the East Antarctic Shield

The EAAO is a Himalayan-type orogenic belt that extends over 8000 km. The western orogenic front of the EAAO is exposed as the Heimfront Shear Zone in Heimfrontfjella in western DML. Some geologists interpreted the Maud province, together with the Falkland Islands and the shear zone–bound Ellsworth-Haag Block, as laterally slipped (escaped) older crustal blocks that were not subjected to tectonothermal reworking c. 500 Ma. Similar escape-tectonic processes are happening today to crustal blocks in Southeast Asia that represent the southeastern extension of the Himalaya Orogen.

In Coats Land, there are few outcrops exposed. Only airborne geomagnetic mapping data suggest that the area, the Coats Land Block, is similar to the east of the Heimfront Shear Zone, indicating the zone of the EAAO. In the Shackleton Range, located in the south of the Coats Land Block, there are slices of Pan-African thrusts overriding the southern craton. Many authors suggest a Pan-African suture is involved in the Shackleton Range.

In the central and east DML, evidence of two distinct major orogenic events has been distinguished: the high-grade metamorphic Grenville event and the high- to medium-grade Pan-African event. Integration of the isotopic ages revealed that the Pan-African event in the DML is more complicated and two stages of metamorphic events succeeded by the post-tectonic granite activity have been recognized in several areas in the DML, although the time span is different from place to place. In H.U. Sverdrupfjella, which is adjacent to the Grunehogna Craton, an earlier Pan-African event (c. 565 Ma) is high-pressure-type metamorphism, suggesting the deeply subducted lithosphere preceded the main metamorphism at c. 540 Ma. In the central DML, the earlier metamorphism occurred at 570–550 Ma and the later granulite metamorphism at 530–515 Ma. In the Sør Rondane, eastern DML, two Pan-African metamorphic events are recognized prior to the youngest granite activities: at 630–590 Ma and c. 560 Ma. The youngest post-tectonic granite intrusions occurred at $\sim$515 Ma.

The extensive granitic activities after the peak metamorphism in the DML are explained by rising of the asthenosphere to heat the adjacent crust on a large scale, as a result of continental mantle delamination after the continent–continent collision between East and West Gondwana.

Lützow-Holm Suture

The basement rocks around Lützow-Holm Bay were named the Lützow-Holm Complex (LHC). The protolith of the LHC consists of continental components of various age and origin: Some outcrops are late Archean-Paleoproterozoic crustal fragments reworked during the Pan-African event, with no indication of the Grenvillian event. Other protoliths are derived from Grenvillian juvenile crust and recycled continental sediments from the margin of the craton. Thus the prehistory of the Pan-African LHC is not uniform from outcrop to outcrop.

The peak metamorphic age of the LHC is 530–550 Ma, and indication of older metamorphic events is not clear, except for the detrital inherited ages from the metasedimentary rocks.

In the Yamato Mountains to the west, two stages of Pan-African event are suggested, at c. 640–620 and c. 550–530 Ma. These two stages are similar to those recorded in the Sør Rondane Mountains (SRM) and central DML to the further west. The younger Pan-African peak metamorphic events of the LHC compared to those of the SRM implies that it is more probable for the LHC to record the last stage of amalgamation of East and West Gondwana.

Thus the LHC may be composed of a collage of pre-Grenvillian continental crusts and Grenvillian juvenile crustal components, suggesting a marginal zone of the Napier Craton before Pan-African collision. The high-grade metamorphism at 550–530 Ma is a product of subduction. The trend of the subduction is not clear, but the progressive metamorphic grade from east to west in the LHC and the active Pan-African plutonism in the Yamato Mountains suggest the subduction toward the Grenvillian Maud crust in the west.

Thus the Lützow-Holm Complex is most likely to be a Pan-African suture and, along with the so-called Mozambique Suture, can be regarded as the eastern front of the EEAO. The inland extension of the suture can be extended either to the Prydz Bay or to Shackleton Range.

Did Rodinia Exist?

In the Prydz Bay region, outcrops of the Prydz Complex show complicated histories. Protoliths in Archean and Grenvillian basement were metamorphosed to high-grade granulite conditions during Pan-African tectonism. Some Pan-African paragneisses contain detrital zircons that suggest late Neoproterozoic (i.e., post-Grenvillian) deposition. Boger et al. (2001) proposed a continuous mobile belt that connects Pan-African tectonism in Prydz Bay with that of the southern Prince Charles Mountains. The belt continues east through outcrops along the coast of the Queen Mary Land to the Leeuwin Complex in the Pinjarra Orogenic belt of Western Australia, and west to the Lützow-Holm Complex. The age of the tectonism is inferred to be 550–490 Ma, slightly younger than the age of collision along the Mozambique Suture. Thus this Pan-African suture represents the final suture between East and West Gondwana.

Although there is debate as to whether Pan-African metamorphism in Prydz Bay can be ascribed to collision at a convergent plate margin, if it is the case, the Prydz Bay suture links with the Lützow-Holm suture at a triple junction.

Alternate interpretations of the Leeuwin-Prydz Bay suture suggest that it continues southward and inland toward the Shackleton Range or further. Some researchers have proposed that the suture extends inland, dividing East Gondwana into Australo-Antarctic and Indo-Antarctic domains.

The final amalgamation of East Gondwana may not have been complete until the Early Cambrian. Two regions of Pan-African tectonism found in East Antarctica challenged the traditional model of the Rodinia supercontinent. Although the Rodinia reconstruction of the Neoproterozoic Supercontinent has dominated discussion of the late Precambrian Earth for the past decade, other views of continent assembly have been proposed.

Furthermore, it has been argued that a succession of supercontinents existed before the stabilization of early Paleoproterozoic cratons in East Antarctica. In the absence of clear paleomagnetic data, however, it is unclear whether pre-Rodinian continental fragments with similar ages represent former supercontinents.

In conclusion, it is more likely that the East Antarctic shield was created by the juxtaposition of three separate Grenvillian-age terranes separated by two regions of Pan-African tectonism and high-grade metamorphism, in the DML and the Prydz Bay-Denman Glacier region. The DML metamorphic belt is interpreted as an extension of the East African Orogen, and the Prydz Bay-Denman Glacier metamorphic belt is regarded as extending to the Pinjarra (or Darling) Orogen in western Australia.

The East Antarctic Shield is a large continental block assembled by the Pan-African event that formed the Gondwana supercontinent. After the formation of Gondwana in the early Paleozoic, East Antarctica was cratonized and no major geological event is recorded until the extensive eruption of the Ferrar dolerite in the Jurassic.

Since East Antarctica is mostly covered by thick ice sheet, full understanding of the amalgamation and dispersal processes of the East Antarctic Shield can be completed only by investigation of the sub-ice continent with aerophysical studies or direct sampling by deep ice core drilling.

ECHINODERMS

Echinoderms (particularly sea stars, brittlestars, sea cucumbers, sea urchins, and feather stars) are common and can be very abundant in the Southern Ocean. Of the world's seven thousand species, five hundred are Antarctic. The sea star *Odontaster validus* and the sea urchin *Sterechinus neumayeri* are two of the most familiar and important species in shallow waters. Echinoderms are an entirely marine group of invertebrates, with fivefold radial (the body is a hub) symmetry with a fossil record extending back to the Precambrian. The name echinoderm literally means "spiny skin" (from the Greek) but a few (sea cucumbers) do not actually have a spiny skin. They have a very unusual body based around an internal "water vascular system," which they use for feeding and locomotion. They have no brain; instead their nervous system is diffuse, so they receive stimuli equally from all directions. Most echinoderms are mobile, unlike their ancestors. Some echinoderm biologists think their great polar success is due to their bodies being mainly bone and their slow pace (a "bone idle" strategy!).

Most echinoderms are bottom dwellers, predators, detritus feeders, filter feeders, and herbivores. Some use more than one feeding strategy and others feed at more than one trophic level (on animals and algae). Many sea stars and sea urchins have been shown to be pivotal to the structure of communities; the most important are termed "keystone species" (exerting a strongly disproportionate effect on their ecosystem's structure through their predation). Echinoderms are found from the intertidal zone to the deepest ocean trenches and from tropics to poles. They are used by humans as food, as a source of medicine, as research subjects in development biology, and as ornamental accessories. Reproduction in echinoderms is typically by external fertilization; eggs and sperm are freely discharged into the water. Some species (e.g., most Antarctic echninoids) brood their eggs in special pouches. Most echinoderms go through several planktonic larval stages before becoming benthic.

The phylum Echinodermata is divided into two different groups: the subphylum Pelmatozoa exclusively includes the class Crinoidea (sea lilies and feather stars) while the subphylum Eleutherozoa includes the classes Asteroidea (sea stars), Ophiuroida (brittle stars), Concentriclycoidea (sea daisies), Echinoidea (sea urchins and sand dollars), and Holothuroidea (sea cucumbers). The Crinoidea have a rich fossil record, with five thousand known fossil species, and were most diverse between the Cambrian and Silurian periods. Most modern crinoids (six hundred species) live in deep water, but comatulids (feather stars) can be seen in the shallows. The crinoids have changed little since the Palaeozoic (250 Ma) and are considered living fossils. The twenty-two known species from the Antarctic continental shelf and surrounding oceanic islands (e.g., Bouvet, Kerguelen) are stenothermal (tolerant of a narrow temperature range) and are typically about 15 cm in size. In contrast to crinoids, sea stars and brittle stars are mainly predators or scavengers (but can be suspension feeders), and are often euryhaline and eurythermal. They are well represented in the Southern Ocean with 250 species, most of which (61%) are endemic. The sea urchins are typically algae scrapers or detritus scavengers on hard or soft bottoms. Some forty-four species are known from the Antarctic shelf, of which 57% are endemic. Sea cucumbers tend to be vagile (slow moving), soft bottom dwellers, with positive geotactism. A crown of tube feet around the mouth functions as feeding tentacles for suspension feeding or deposit feeding. The thirty-eight species recorded from coastal Antarctica have 58% endemism.

Antarctic echinoderms, particularly the sea urchins, have been important as model animal groups for scientists to study reproduction and ecological (abundance) versus evolutionary (species generation) success in Antarctica.

ECOSYSTEM FUNCTIONING

"Ecosystem functioning" is a very general and often imprecisely defined term that encompasses the processes and links between biota in an ecosystem through which "resources" (i.e., energy, matter) flow. The term is best understood as a means of integrating the entire food web within an ecosystem. Antarctic ecosystems are conventionally described as being very simple in structure. This can be seen at various levels, but it is most commonly expressed as their being species-poor or depauperate, dominated by "lower" faunal and floral groups, or having low trophic complexity and/or representation of higher trophic levels. While the general simplicity of these ecosystems is well known and widely accepted, at least in the context of multicellular animals and plants, and illustrations of their food webs available, there have been few rigorous attempts to prove and quantify the significance of what are often largely hypothesised links.

It is often the case that the classical view of ecosystem structure and function, derived from lower-latitude ecosystems with which we are most familiar, cannot easily be applied in an Antarctic context. Classical ecosystem structure allows the assignment of the component biota to a series of discrete trophic levels—autotrophic producers, primary, secondary, and higher-level consumers—with each of these groups also feeding into a separate decomposition pathway by which nutrients are either released for recycling into other biota or lost from biological pathways into the physical environment. In the Antarctic, ecosystems are present in which there is a progressive reduction in the presence or significance of all trophic levels. This reduction reaches its extreme limit in three very different Antarctic ecosystems: (a) those structured around endolithic microbial communities, where producers comprise algae and cyanobacteria, and consumers are represented by fungi and bacteria, which may operate either as symbionts or decomposers; (b) the hypothesised microbial ecosystems of continental subglacial lakes, which, if they exist, are likely to include little or no representation of primary producers and rely on extremely low levels of exogenous nutrient input to service the needs of a limited microbial decomposer community; (c) lake ecosystems of the maritime and continental Antarctic, which are dominated by microbial processes—the "microbial loop"—rather than a conventional metazoan food chain. Even where present in terrestrial ecosystems, true predators are yet to be demonstrated to play a detectable role in the control of populations of species at lower trophic levels. However, it is also the case that known predators, or at least facultative omnivores, are present in all terrestrial ecosystems in which multicellular fauna are present, indicating that we have much yet to understand in the functioning of these ecosystems.

A predicted, but largely untested, consequence of the overall simplicity of Antarctic ecosystems is that, as they include examples where one or more biological functional groups are not present or are poorly represented, this lack will exert a controlling influence on the form of overall ecosystem structure that can be supported. Subsidiary to this is a separate prediction that these ecosystems are vulnerable to invasion by nonnative species representing currently absent functional groups. Such invasions (e.g., the introduction of aggressive invertebrate predators to sub-Antarctic ecosystems currently lacking these) appear to be able to lead to rapid and deleterious consequences for native biota and stability of indigenous food webs, and are also predicted to become increasingly common in the event that contemporary regional climate change trends in Antarctica continue.

ECOTOXICOLOGY

Several thousands of synthetic new chemicals unknown to biota (xenobiotic) have come into use during the last 60 years. In the 1970s, it was recognized that anthropogenic chemicals may affect nontarget organisms and biotic communities, prompting the development of a new science: ecotoxicology. In contrast to toxicology (a much older science dealing with the harmful effects of chemicals on individual organisms), ecotoxicology is interdisciplinary and uses physicochemical, biological, and ecological parameters to characterize, understand, and predict the fate of chemicals in the environment.

Although pesticides have been neither produced nor applied in Antarctica, in the 1970s DDT-related compounds were discovered in Antarctic organisms. The understanding that harmful substances released into the atmosphere, water bodies, and soils of tropical and temperate regions may affect Antarctic ecosystems promoted the development of ecotoxicological research in this continent and the surrounding Southern Ocean. These regions are inextricably linked to global atmospheric, oceanographic, and climatic processes. They receive not only contaminants released by local human activities (scientific research and associated logistic support, fisheries, and tourism), but also trace elements, artificial radionuclides, and organic compounds from anthropogenic sources in other continents. Many organic compounds are persistent organic pollutants (POPs), which have a half-life of years to decades in soils and sediments and of several days in the atmosphere. Under ambient temperature at low latitudes, POPs may volatilize from water, soil, and vegetation into the atmosphere, where they are unaffected by breakdown reactions and are transported for long distances before redeposition. The volatilization and deposition cycle may be repeated many times and POPs assume a global-scale redistribution according to the theory of global distillation and cold condensation in polar or mountainous regions. In winter the sea ice behaves as a sink for airborne POPs, which are released into spring meltwaters. Since POPs are hydrophobic and lipophilic, with a strong partitioning in organic matter, they easily accumulate in the fatty tissues of marine organisms, especially in those at the higher levels of marine food chains. Many POPs are immunotoxic, endocrine disrupters, and tumor promoters, and Antarctic seabirds and marine mammals, which have developed few metabolic detoxification pathways for xenobiotics, are potentially exposed to their toxic effects. POP concentrations in the eggs, feathers, and internal organs of the South Polar skua (*Catharacta maccormicki,* a top predator and a scavenger bird that nests in Antarctica and migrates to the Northern Hemisphere during winter) are among the highest recorded in Antarctic organisms. Concentrations of 2378-tetrachlorodibenzo-*p*-dioxin equivalents in skua eggs are higher than those in polar-bear livers from Alaska. In contrast, trace metals occur naturally in the Antarctic environment. Several Antarctic marine organisms that evolved in isolation in an ocean with unique physicochemical characteristics, may naturally accumulate in their liver very high concentrations of cadmium and mercury, independently of human activities and global processes. Although the Antarctic and Southern Ocean environments are not pristine, they provide a baseline against which to monitor global processes.

EDDIES IN THE SOUTHERN OCEAN

Eddies are usually thought of as time-varying flows. In the ocean and atmosphere, the term eddy has multiple connotations. Eddies can be rings, vortices that swirl water around their centers either cyclonically (clockwise in the northern hemisphere) or anticyclonically (counter-clockwise in the southern hemisphere). Eddies can also be the transient part of a current, as distinct from the time-invariant or mean current. The role of transient ocean eddies is analogous to the role of storm systems in day-to-day weather fluctuations: they are responsible for the short time-scale variability in ocean currents. Finally, standing eddies are stationary in time and are computed as time-invariant deviations from a spatial mean, usually determined by averaging along lines of latitude.

Ocean eddies range in size from tens to hundreds of kilometers. Southern Ocean rings have been observed to have radii of between 30 and 100 km, and the predominant length-scale of other transient features is thought to be about the same size. This corresponds to the mesoscale, features that are large enough to be influenced by the Earth's rotation but small enough that many eddies can fit within one ocean basin. The baroclinic Rossby radius of deformation, L_D, is the length-scale at which gravitational and rotational effects have a comparable impact on depth-varying ocean flows. In the Southern Ocean, it varies from less than 10 km up to 30–40 km, and typical length-scales are therefore assumed to be $2\pi L_D$.

Sea-surface height measurements from satellite altimeter show that eddy variability is strong along the path of the Antarctic Circumpolar Current (ACC). Much of the variability is associated with the northward and southward meandering of the jets that make up the ACC. In addition, some of the variability is linked to warm-core or cold-core rings that have separated from the ACC jets and move independently. Baroclinic instability, the intrinsic variability of a fluid that becomes denser with increasing depth, is thought to be responsible for most of the observed eddy variability.

Eddies may also occur because of topography, either as lee waves downstream of topography or as Taylor columns located directly over topography. Since seafloor topography does not change position, at least on the timescales of eddy motion, these are usually thought of as standing eddies. However, if standing eddies experience small displacements, then they can be associated with enhanced transient variability. Altimeter data indicate high levels of transient eddy variability in regions where topographic lee waves are predicted. These regions occur eastward (or downstream following the flow of the Circumpolar Current) of Îles Kerguelen in the southern Indian Ocean, of Macquarie Ridge south of New Zealand, and of Drake Passage between South America and the Antarctic Peninsula.

Since the ACC is continuous around Antarctica, its mean flow provides no pathway to carry water southward from the low-latitude subtropical gyres. Thus eddies play a critical role in explaining the transport of heat, freshwater, and other properties across the ACC. For the most part, eddy transports are thought to carry properties along isopycnals, surfaces of constant density, rather than mixing waters of different densities. Overall, air–sea heat fluxes and upper-ocean transport estimates suggest that eddies carry roughly 0.45×10^{15} W of heat poleward across the ACC in order to maintain the heat balance of the high-latitude ocean. These estimates are consistent with eddy heat-flux estimates obtained from current meter observations and autonomous subsurface floats. In most estimates, regions with high transient eddy variability are also associated with high eddy heat flux.

In addition to transferring heat, eddies also transfer momentum, both horizontally and vertically. Observations from altimetry and current meters now indicate that horizontal eddy fluxes are small and have comparatively little effect on the mean flow. However, eddy fluxes are thought to be largely responsible for carrying momentum downward from the surface, where it is input by the wind, to the sea floor, where it can be transferred to the solid Earth. Downward transport of momentum is carried out by "interfacial form stress," the pressure work done by one layer of the ocean on the layer below. This pressure work can be expressed as a poleward eddy density flux, and it is commonly approximated as an eddy heat flux. Thus, eddies imply a clear link between the heat flux across the ACC and the dynamics required to balance wind forcing.

Eddies can influence biological productivity in several distinct ways. They can help to transport nutrients into otherwise low-nutrient surface waters, either through cross-frontal horizontal exchanges or through vertical exchanges. For example, the center of a cyclonic ring can be a region of upward vertical velocity, which can help bring nutrients from the deep ocean. Nutrients can be trapped within an eddy's surface layer, increasing their residence time within a particular region and therefore allowing a biological bloom to develop. Eddy processes can also influence productivity if they permit a shallow mixed layer to develop, thus trapping nutrients and phytoplankton at depths where sunlight is readily available.

Although Southern Ocean eddies have significant impacts on circulation, temperature patterns, and biology, their small length-scales make them difficult to observe and also difficult to resolve in global-scale numerical ocean circulation models. As a result, eddy processes are parameterized in ocean models, usually as diffusive processes. Typical parameterizations assume that eddies diffuse heat and momentum either horizontally or along density surfaces; in some cases, modelers allow the diffusion parameter to vary spatially depending on local conditions. The details of the global meridional overturning circulation can be sensitive to the exact form of the parameterization used for eddy processes; as a result, the impact that eddies might have on future climate scenarios has not yet been fully explored.

ELLSWORTH, LINCOLN

Lincoln Ellsworth (1880–1951) was the first to fly an airplane across Antarctica; he also explored by air its interior, and sponsored two other explorers. Born the son of James Ellsworth, a man of wealth who owned mines in Pennsylvania, Lincoln Ellsworth lived much of his early years in Chicago, and with grandparents in Hudson, Ohio. Although his opportunities were many, Ellsworth struggled to find a career that held his interest. Stories by President Theodore Roosevelt about the American West and about life outdoors inspired him. Wyatt Earp became his lifelong hero. Like Roosevelt, Ellsworth had an extraordinary interest in physical fitness and typically walked miles daily. Between 1903 and 1906, he learned surveying and planned railroad routes through rugged parts of Alaska and Canada. Throughout his life, Ellsworth had a continuing interest in natural history and traveled often to the Grand Canyon, Africa, and South America.

Polar exploration offered Ellsworth opportunities for sightseeing, adventure, and accomplishments. Stories about explorers such as Robert E. Peary, Frederick Cook, and Robert Falcon Scott convinced Ellsworth to undertake polar exploration himself. In October of 1924, he traveled to New York City, where Roald Amundsen, the most famous polar explorer in the world, was lecturing and raising money. Ellsworth offered to help Amundsen financially in exchange for participation on an expedition. Amundsen and Ellsworth met with James Ellsworth and persuaded him to provide $50,000 for an expedition north from Greenland in 1925.

> The primary objective of the new expedition was to fly two airplanes across Greenland to the North Pole. However, one of the two Dornier flying boats suffered engine failure and landed on the ice, although without loss of life; the other landed safely but quickly froze. The party lacked a radio to call for help and remained stranded for 25 days in May and June of 1925. Finally, they freed one of the planes and reached a ship at sea.

Undaunted, Ellsworth partnered with Amundsen again in 1926. This time, their goal was to fly an airship, more reliable than an airplane, from Spitsbergen, across the North Pole, and land in Point Barrow, Alaska. Money inherited from the estate of James Ellsworth, who had died while Lincoln was in Greenland, enabled them to buy an airship, *Norge,* which had been designed by an Italian, Umberto Nobile. On May 11, two days after Richard Byrd and pilot Floyd Bennett claimed to have flown over the North Pole from Spitsbergen, *Norge* took off. Nobile, Amundsen, Ellsworth, and an international crew reached the North Pole on May 12, and the next day landed the damaged *Norge* at Teller, Alaska.

In 1930, 2 years after the death of Amundsen, Ellsworth teamed up with Sir Hubert Wilkins. Wilkins had succeeded in flying an airplane from Point Barrow to Spitsbergen in 1928. The Wilkins-Ellsworth Trans-Arctic Submarine Expedition tried to explore the Arctic under the ice. Ellsworth provided financial support and served as science adviser, but Wilkins led the enterprise. Although *Nautilus,* a renamed submarine from World War I, suffered mechanical difficulties that limited its success, Wilkins and Ellsworth began a lifelong friendship and partnership.

Aided by Wilkins, Ellsworth determined to make his own mark in Antarctica as the first to fly an airplane across the continent. Apart from the adventure and prestige, Ellsworth expected to add to knowledge about the largely unknown interior of the continent. Geographers and explorers wanted to know if a channel connected the Weddell and the Ross seas. Others questioned whether the Queen Maud Mountains might stretch across the continent to Graham Land on the Antarctic Peninsula.

Ellsworth and Wilkins prepared meticulously for the flight. The expedition commissioned the Northrup Corporation to build a special airplane, *Polar Star*. Made of metal, it had a range of about 7000 miles (11,200 km). Its low wings enabled its two passengers to scoop a trench under the plane to install a landing gear with skis. Thus, the plane could land on an unprepared runway of snow and take off again. To design and pilot *Polar Star*, Ellsworth hired the experienced Bernt Balchen, the Norwegian flier who had flown with Byrd over the South Pole in 1929.

In January of 1934 Ellsworth's ship, *Wyatt Earp*—a redesigned Norwegian vessel—took Ellsworth and his party of seventeen to the Bay of Whales in Antarctica. It would be the first of three efforts by Ellsworth to fly across the continent. It began disastrously when ice cracked and damaged the airplane. In October 1934, a second attempt began when *Wyatt Earp* reached Deception Island. Unfortunately, a connecting rod on the airplane broke, and there was no replacement. After returning from Chile with a new rod, the weather had warmed so much that Deception Island no longer suited as an airfield. Instead, the party made its way to Snow Island and found that the ice was still frozen. Weather and menacing forecasts from Richard Byrd's base at Little America on the Ross Ice Shelf delayed takeoff until January 4, 1935. That flight lasted only 2 hours. Balchen turned back to Snow Island back because he detected changing weather. This decision, which Ellsworth had opposed, ended the expedition.

In November 1935 Ellsworth returned to Antarctica with *Polar Star* for a third attempt. He changed his base to Dundee Island and brought with him two Canadians as pilots, Herbert Hollick-Kenyon and J. H. Lymburner. On November 20, Ellsworth and Hollick-Kenyon took off but returned because of a broken fuel gauge. Finally, on November 22, they began their successful flight. Twenty-three days later, during which they landed and made three camps to avoid bad weather and make observations to check their position, Ellsworth and Hollick-Kenyon succeeded in reaching the Bay of Whales. They found Little America, the base that Byrd had left in February of 1935, under snow on the Ross Ice Shelf. There they remained to await *Wyatt Earp*. Unexpectedly, an Australian ship, *Discovery II,* reached them first. This ship had been sent at the request of Sir Hubert Wilkins, when failures in radio communication from Ellsworth caused concern.

In 1936 the US Congress awarded Ellsworth a special gold medal for his achievements. The series of flights had covered 2000 miles (3200 km), of which approximately 1200 miles (1900 km) had been seen for the first time. At each of the landings, Ellsworth had taken sun sights to confirm their navigational position and to claim land for the US. His flight proved that the Weddell Sea and the Ross Sea were not connected and that previously unknown mountains—the Eternity Range and Sentinel Range—extended across Antarctica. All in all, the expedition provided a basis for the US to claim some 350,000 square miles (900,000 km^2), including the land Ellsworth named in honor of his father.

Ellsworth's last trip to Antarctica had political as well as personal motivations. The United States did not recognize the claims of any nation to Antarctica. As it happened, Ellsworth's ambitions for exploration in Antarctica coincided with the US State Department's concerns that other nations, especially Germany, were seeking land and potential minerals in Antarctica. To compete with these claims became a secret agenda for the expedition.

In October of 1938, *Wyatt Earp* sailed with Ellsworth and two airplanes from Cape Town, South Africa. Ellsworth's goal was to fly over the Indian Ocean sector of Antarctica and map land not previously seen but that had been claimed. Equipped with two planes, including a new long-range one from Northrup, pilot J. H. Lymburner and Ellsworth took off on January 9 from 68°30′ S, 79° E, and reached 72° S, 79° E. Returning after two and a half hours, Ellsworth claimed 80,000 square miles (207,000 km^2)

for the United States, which he named the American Highland. Australia had previously claimed this area after Sir Douglas Mawson's BANZARE.

Ellsworth had planned to return to Antarctica and winter at the South Pole in 1941. However, World War II interrupted his plans, and then Ellsworth himself had a terrible accident. While hiking in Mexico in 1943, he suffered a severe fall that led to a concussion. This was the beginning of setbacks in health that resulted in his death on May 26, 1951. Specimens that Ellsworth had collected in expeditions to the Arctic and the Antarctic as well as safaris to remote places in Africa and South America were added to the treasures of the American Museum of Natural History. A foundation that bears his name continues to support polar history.

EMPEROR PENGUIN

Emperor penguins, *Aptenodytes forsteri,* largest of all living penguins, stand 1 m tall and weigh on average between 20 and 35 kg. Generally larger and more portly than king penguins, *A. patagonicus,* their nearest kin, emperors have shorter, more slender and decurved bills, and narrower blue or violet bill plates. The chest is lemon-yellow, the auricular patches (on either side of the head) are yellow rather than golden-orange, and the ankles are fully feathered. Emperors breed exclusively along the coast of Antarctica, on sea ice that is fast to the ice cliffs or on land. Adults seldom appear far from their breeding zone, but vagrants—probably young birds in their second to fourth years—are occasionally seen as far north as New Zealand, Tierra del Fuego, South Georgia, and once at Heard Island.

Discovery

A mysterious large egg, discovered on an Antarctic ice floe by the French Naval Expedition of 1837–1840, was the first indication that an unusually large penguin inhabited the Antarctic pack ice. Near-contemporary American and British expeditions brought home skins that, after initial confusion with king penguins, were finally identified as a new species and named in 1844. Later, nineteenth-century expeditions reported more of these splendid birds, but not until October 1902 was the first breeding colony discovered, by a party from Robert Falcon Scott's British National Antarctic Expedition of 1901–1904, who were visiting Cape Crozier, Ross Island. This discovery confirmed two strange facts about emperor penguins—that they incubate and rear their chicks on sea ice, and breed in the depths of the Antarctic winter.

Drygalski's German South Polar Expedition of 1901–1903 discovered a second colony, and the strong likelihood of a third was reported off the Larsen Ice Shelf by Nordenskiold's Swedish South Polar Expedition of 1901–1904; its existence was finally confirmed a century later. A fourth was found at Haswell Island by Douglas Mawson's Australasian Antarctic Expedition of 1911–1914. Meanwhile, in 1911, Edward Wilson, Apsley Cherry-Garrard, and Henry Bowers of Scott's British Antarctic *(Terra Nova)* Expedition of 1910–1913 made a mid-winter journey to the Cape Crozier colony, to collect eggs for embryological studies. Cherry-Garrard's account of the expedition, *The Worst Journey in the World,* is possibly the most celebrated of all Antarctic books. Shackleton's Imperial Trans-Antarctic Expedition of 1914–1917 collected large chicks afloat on the pack ice of the Weddell Sea, finding them a welcome addition to their diet. The discovery in 1948 of a small colony on the Dion Islands, off the west side of Antarctic Peninsula, made it possible for scientists to winter with the emperors and examine aspects of their winter breeding strategy.

Population Size

From the 1950s onward, an increasing number of expeditions were able to explore the Antarctic coastline during the winter months, locating in all between forty and fifty breeding localities, and French, Australian, New Zealand, German, and United States scientists have studied in more detail the numbers, ecology, behaviour, breeding biology, diving abilities, and vocalizations of emperor penguins.

The number of breeding colonies remains uncertain. All but two known colonies occur on the sea ice, in locations that may vary by several kilometers from year to year. For a similar reason, it is difficult to estimate sizes of colonies accurately. With no nesting sites, groups of incubating and brooding birds move and divide in the course of the winter, and a shift of wind may carry the whole or part of a colony out to sea. Among the largest known and most stable colonies is the one that forms each year near Cape Washington, Victoria Land, in the Ross Sea, estimated to include 20,000–25,000 breeding pairs. Many colonies involve 5,000–20,000 pairs, while the smallest colonies are numbered in the tens or hundreds of pairs. Some reported in early years may have disappeared, and a newly discovered colony is occasionally added to the list of known localities. A world total of approximately 220,000 breeding pairs is estimated, of which about half live in the Ross Sea area. Though estimates of individual colonies vary from year to year, there is no indication that numbers overall are decreasing. Some of the more accessible colonies are now open to visits by tourists from cruise ships.

Feeding, Swimming, and Diving

Emperor penguins feed mainly on crustaceans (particularly euphausiids), squid, and fish. Some they catch close to the surface, foraging for crustaceans and fish immediately under the sea ice. However, they are also deep divers, and may feed close to the bottom in water 400–500 m deep. On foraging journeys lasting several days they may travel over 1400 km, at mean speeds of around 2 km per hour; while hunting they can make bursts of 12 km or more per hour.

The Annual Cycle: Assembly and Courtship

Adult emperors spend late summer and autumn on the remnants of the pack ice, feeding and moulting. In late autumn, after a further bout of intensive feeding, they head southward to where the new season's fast ice is forming around the continent. By April and early May, they have gathered in their traditional areas, usually close to ice cliffs, often on sea ice that is locked and stabilized among islands or stranded icebergs. The newly returning birds, in peak condition, with ample subcutaneous and visceral fat, may have to walk and toboggan (i.e., slide on their stomachs over the snow, propelling themselves with flippers and feet), for the last 50–100 km to their colony sites.

Though the genders are superficially similar, males are on average slightly larger than females, and at the start of breeding they tend to be heavier: males average 35–40 kg, females 28–32 kg. Males usually arrive before females, taking up positions in the group from which they advertise their presence and status by calling. Females respond by approaching with similar calls, and the partners stand close together, fending off passersby with bills and flippers. They make no nest. In courtship, which extends over 3 to 5 weeks, the partners bow, call repeatedly to each other, take short walks with head flagging (flashing their brilliant auricular patches), and copulate frequently. They may be partners of previous seasons, though the proportion is low (about 15%), much lower than in species with identifiable nest sites (for example, Adálie or gentoo penguins), at which partners tend to meet repeatedly in successive seasons.

Laying and Incubation

Each female lays a single blue-white egg (mean dimensions 12.5 × 8.5 cm, mean mass 460 g), which she passes almost immediately to her partner. With his bill, he shuffles it onto the dorsal surface of his feet, covering it with a fold of feathered abdominal skin and immediately adopting a characteristic crouch. The females leave, usually within a few hours of laying, heading in groups for the open sea, which may by this time be well over 100 km distant. On a large colony all the eggs are laid within a period of 4 to 5 weeks.

After the cacophony of courtship, silence settles gradually over the colony. Incubating males, which can shuffle slightly with the egg on their feet, overcome earlier mutual hostility and stand close together, forming tightly packed huddles containing from dozens to a thousand birds. This stance they maintain for the full incubation period of 60–68 days (mean 64 days). On calm days with temperatures close to freezing point, the huddles may open, the birds standing free, shaking, stretching, and preening, always with the eggs on their feet, and eating copious amounts of snow. On cold, windy days, they pack tightly together, effectively reducing their surface area and conserving body heat.

Birds on the windward side shuffle deeper into the huddle, or move round to the lee. In this way, the huddles may move steadily downwind, some over distances of several km during the 2 months of incubation. Birds that lose their eggs may find and hold substitute eggs that others have lost. Those that cannot find substitutes lose the urge to incubate within a few hours and leave the colony. During courtship and incubation, the males lose up to 40% of their initial body mass, mostly in subdermal and abdominal fat. By the end of incubation, they look relatively thin and jaded; some that appear to have reached a limit of starvation abandon their eggs and disappear toward the sea.

All-male incubation is more efficient than shared incubation, removing the necessity for partners to make long journeys over the sea ice in winter. Winter breeding is the only way of ensuring that chicks are ready for the sea by summer, when their chances of survival are highest.

Chick Rearing

In early July, simultaneously with the first hatching, the females begin their return. Looking distinctly fresh and well-nourished, they find their partners by repeated calling, take over the chicks as they hatch, and begin immediately to feed them from the contents of their crop. Relieved by their partners, the males leave the colony in droves, returning to the sea for their first swim and feed. Away for about 3 weeks, they recover some of the body mass that they have lost (on average 12 kg, or 40% of their original mass) during their long fast.

Chicks on hatching weigh about 300 g, and are covered with thin grey down, with a striking black head and white facial mask. A chick that hatches before its parent returns may be fed by the male for over a week from a crop secretion. During the first 2 weeks the chicks grow slowly, doubling their body mass and developing a denser, warmer grey down. Thereafter the parents alternate, feeding at sea and returning to their partners at about weekly intervals. They feed only their own chicks, identified by their shrill piping calls.

At 4 to 5 weeks of age, the chicks are big enough to step down occasionally from their parents' feet; at 6 to 7 weeks they begin to cluster together in crèches. In bad weather, adults on the colony cluster around them, helping to keep them warm. As the season advances, food becomes more plentiful in the sea, open water approaches closer to the colonies, and gaps appear in the local sea ice, allowing the adults to forage closer to home. By late November, aged about 5 months, the earliest chicks have begun to moult, acquiring during 3 to 4 weeks a distinctive juvenile plumage similar to that of their parents, but with grey rather than yellow auricular patches. Though now ready for the sea, they are notably smaller than their parents, weighing only 12–15 kg. At about this time the parents cease to feed them, and prepare for their own postbreeding moult.

Breeding Success

At any time from October onward, the sea ice on which the colony is present may break away. Alternatively, in years when the sea ice persists, the young birds may have to follow their parents several km to the ice edge. Survival rates of eggs and early chicks are generally high, but decrease as the chicks grow. Their grey down is not waterproof: snowstorms at temperatures around freezing point may wet the half-grown chicks, chilling them beyond recovery. Persistent sea ice may lengthen the parents' feeding journeys and reduce the frequency of feeds, slowing growth or causing starvation. Early breakout may cause adults to abandon their half-grown chicks. Southern giant petrels *(Macronectes giganteus)* can be major predators of chicks on some colonies. Overall, breeding success is usually around 50%–60%.

Once in the water, leopard seals *(Hydrurga leptonyx)* are primary predators of juveniles. Recoveries of banded birds suggest that only about 20% reach the end of their first year, when they moult into full adult plumage. We know little of their subsequent life. Starvation, being trapped in or under the sea ice, and predation by seals and killer whales *(Orcinus orca)* are likely perils during adolescence. Young birds are reported to appear in the breeding colonies in their fourth year, and start breeding 1 or 2 years later. Those that survive the dangers of growing-up are estimated to live on average 20 years.

ENDERBY, MESSRS.

Rarely were Antarctic exploration and commercialism more closely tied together than during the first half of the nineteenth century by the firm of Messrs. Enderby, alternatively known as Enderby and Sons or Enderby Brothers. Founded by the brothers Samuel and George Enderby in London in the mid-eighteenth century, the company owned a number of ships involved in the northern and southern sealing and whaling fisheries. In 1775, Enderby vessels were among those sent to the South Atlantic and Falkland Islands in an attempt to establish a southern whaling fishery, and a little more than a decade later a voyage under Captain James Shields was the first to sail around Cape Horn for the purpose of extending that trade into the South Pacific.

Once the Messrs. Enderby were deeply involved in the far south, the masters of their ships were encouraged to discover new grounds, to chart new coastlines, and to contribute to the growth of geographical knowledge. This became an even more significant aspect of the company's operation after the death of Samuel Enderby, son of the founder, in 1830, when *his* sons, Charles, Henry, and George, took over the operation. Charles and George were founding members of the Royal Geographical Society—Charles was also a member of the Society's Council—and they strongly promoted geographical discovery and the extension of knowledge about natural history, in addition to their commercial interests.

The company's first major geographical discovery was in 1806, when Abraham Bristow discovered the Auckland Islands. The following year he claimed them for the British Crown, made a rough chart of them, and gathered a cargo of fur seal skins. Two years later, on a visit to South Georgia, two Enderby vessels rediscovered the mysterious Bouvetøya, and in 1825 George Norris, master of the Enderby ship *Sprightly,* "rediscovered" it yet again, this time calling it "Liverpool Island" and claiming it for King George IV.

The 1830s were the height of the Enderbys' geographical contributions in the far south, although these voyages of discovery often involved considerable financial loss to the company. In 1830 an expedition in the Enderby ships *Tula* and *Lively,* under the overall command of John Biscoe, sailed from London. Before returning in 1833, they circumnavigated the Antarctic continent, discovered Enderby Land, discovered and annexed Graham Land on the Antarctic Peninsula, and visited the South Sandwich Islands, Chatham Islands, Bounty Islands, South Shetland Islands, and Falkland Islands, in the last of which *Lively* was wrecked. However, upon their return to London, they brought only thirty sealskins.

The year of Biscoe's return, Enderby sent two more vessels, *Hopefull* and *Rose,* to extend his discoveries. However, *Rose* was crushed in the ice north of Clarence Island in the South Shetland Islands, and the expedition was abandoned.

Undeterred, in 1838 the Enderbys dispatched John Balleny, in command of *Eliza Scott* and *Sabrina,* to search for new lands and sealing or whaling grounds. This was a crucial voyage, because the Enderbys' finances had so suffered that they were forced to sell more than 80% of the shares of the vessels to other London merchants. Balleny visited Île Amsterdam and the Campbell Islands, meeting Biscoe at the latter. Passing south through areas in which ice had previously turned back Fabian von Bellingshausen's ships, on February 9, 1839, they discovered the Balleny Islands. After a fog lifted, Thomas Freeman, captain of *Sabrina,* made a landing, the first reported anywhere south of the Antarctic Circle. They later described an "appearance of land" in the vicinity of the Antarctic continent that later became known as the Sabrina Coast. Turning north, *Sabrina* was lost in a gale with all hands on March 29, 1839. *Eliza Scott* returned to England, and Balleny provided a great deal of helpful information for the British naval expedition under James Clark Ross, which was soon to depart for the Antarctic. However, Balleny returned with only 179 sealskins, and the voyage proved yet another financial disaster for the Enderbys.

The combination of the series of disastrous voyages and a fall in the profit from the southern sealing fishery struck a hard blow at the fortunes of Messrs. Enderby. Inspired by reports from Ross's expedition, in 1849 Charles Enderby leased the Auckland Islands from the British government to establish a land-based whaling station, which would be run under his subsidiary, the Southern Whale Fishery Company. In December 1849 three ships loaded with settlers, stores, and equipment with which to establish the station and attendant colony landed at Port Rosson Enderby Island in the Auckland Islands. Land was cleared for farming, for the harbour and dockyard, and for a village of eighteen buildings, which was named for the Earl of Hardwicke. However, agriculture proved impossible due to the cold climate, lack of sunshine, and heavily acidic soil. Moreover, very few whales were found by the eight ships stationed there, and the remoteness of the colony meant few other ships used the dockyard facilities for refitting, as had been expected. Many of the disillusioned colonists soon departed, and the settlement was dismantled and officially closed on August 5, 1852.

The financial setbacks caused by the Enderby settlement, atop the heavy losses on a number of the major voyages, put such a strain on the company's resources that it was forced into liquidation.

EXOBIOLOGY

The link between Antarctica and extraterrestrial environments has its origins in the fact that most extraterrestrial environments of potential biological interest are cold, polar-like environments. Antarctica has been used as an "analog" environment to understand physical and potential biological processes in extraterrestrial environments. A particularly important focus has been the planet Mars. The surface of Mars has a mean annual temperature of –60°C and in the northern latitudes there is ground ice. Patterned ground similar to that observed in Antarctica bears witness to a world that can be considered a "polar desert."

The soils and lakes of Antarctica, particularly the McMurdo Dry Valleys, have been used to develop life detection strategies and technologies for Mars; field tests in these regions predate the Viking Landers, sent to Mars in the mid-1970s. The low bacterial counts and the biomarkers that microorganisms leave are used as a basis to plan robotic missions to search for life in the ground ice and near-surface soils of Mars.

Antarctica provides clues to the nature of the cold early Martian environment, when surface liquid water was more abundant than it is now. The physical characteristics of perennially ice-covered lakes have been used to understand the physics of early ice-covered lakes on Mars, satellite evidence for which has been dramatically improving. The microbiota of the Antarctic lakes provides tantalizing insights into the way in which extreme lake environments can provide oases for life in regions where the macroclimate is otherwise hostile. Sediments within the ancient Martian lakes will one day be cored by robotic explorers and humans in the search for past life, taking their lessons from Antarctica.

Perhaps one of the greatest ironies of Antarctic exobiology is that the Antarctic itself is the location for many of the Martian meteorites that have so far been discovered. Concentrated at the edge of mountain ranges, these meteorites yield clues to the physical and chemical conditions on Mars and the potential habitability of the planet, insights that aid our understanding of Antarctica itself as a Mars analog environment.

Subglacial lakes in Antarctica are being used as analogs for the ice-covered ocean of the Jovian moon, Europa, a moon approximately the same size as our own. These lakes, which are formed under the ice sheet, have physical and geochemical processes that might bear similarities to the interior of the Europan ocean. Data from Antarctic subglacial lakes will be used to plan experiments for future robotic craft that will be sent to the outer solar system to characterize these extraterrestrial oceans and search for signs of life.

Finally, it should be emphasized that the study of Antarctica as an exobiological analog is not merely a matter of enthusiastic speculation concerning extraterrestrial life. If robotic and eventually human explorers do not find life on Mars or Europa, life in Antarctica might help answer the question "why not?'', the answer to which would be as profound and revealing as the discovery of life itself.

F

FALKLAND ISLANDS AND DEPENDENCIES AERIAL SURVEY EXPEDITION (FIDASE) (1955–1957)

The Falkland Islands and Dependencies Aerial Survey Expedition (FIDASE) (1955–1957) was undertaken during a period of mounting political tension between the United Kingdom, Argentina, and Chile over territorial claims to the Antarctic Peninsula. At that time, the only maps of this region were expedition charts, giving an incomplete and fragmented coverage. The British government called for a program of detailed mapping, an act of administration to demonstrate its long-established sovereignty rights.

The contract was awarded to Hunting Aerosurveys Ltd. on May 26, 1955. The main requirements were (1) to undertake vertical photography of Graham Land (Antarctic Peninsula) and adjacent islands between 62° S and 68° S; (2) to provide a framework of ground control to enable the preparation of accurate maps; and (3) to provide airborne magnetic profiles for geological investigations.

Peter Mott, the chief surveyor of Hunting Aerosurveys, was chosen to lead the expedition. John Saffrey was the deputy leader in control of flying operations. The rest of the expedition staff, mostly Hunting's employees, comprised the aircrew, engineers, radio staff, camera operators, laboratory technicians to process and develop film, surveyors, a geophysicist, a meteorologist, a doctor, a cook, and a steward.

Mott had only 5 months to make the necessary preparations for the expedition. He chartered the 950-ton Danish freighter *Oluf Sven* to transport the expedition to Antarctica, and to serve as a mobile platform from which helicopters could be deployed to allow the surveyors to establish ground control points. The crew of *Oluv Sven* were led by Captain Jan Ryge. The vessel was modified with an ice-patrol bridge and a propeller guard. Further modifications enabled it to carry 60,000 gallons of drummed aviation fuel, two Sikorsky S51 helicopters, and a prefabricated expedition hut, supplies, and the 22 expedition personnel.

Two amphibious Canso flying boats were acquired for the expedition. Their range of nearly 2,000 miles and their rugged and proven reliability meant that they were ideal for operating under harsh Antarctic conditions.

On October 22, 1955, *Oluv Sven* departed from the Port of London. The journey south included calls at Las Palmas to effect repairs to the ship's generator, Montevideo to receive the aviation fuel, and Port Stanley to take on bunkers and water. Seven weeks later, on December 3, the expedition sailed through Neptune's Bellows to arrive at Whalers Bay, Deception Island.

Deception Island, a horseshoe-shaped volcanic caldera in the South Shetland Islands, was chosen because of its sheltered natural harbor, which would allow the Cansos some protection from ice when taking off and landing. Whalers Bay was the site of the abandoned Norwegian Hektor whaling station, in which a seven-man team from the Falkland Islands Dependencies Survey (FIDS) was also based.

Most of the first austral summer was spent setting up the base at Deception Island. The 60- by 20-ft (18.3 x 6.1 m) prefabricated expedition hut, named "Hunting Lodge," was erected on concrete foundations left by the whalers. It comprised a generator room, a kitchen and mess room (complete with Esse Stove), a photographic dark room, and a fourth room for drying, checking, and storing the aerial film and print. A melt stream running past the site served as the water supply necessary for processing the film.

Two of the whale oil tanks were cut open—one to serve as a warehouse for the expedition stores, the other as a garage for a David Brown tractor. The aircraft engineers occupied a wooden hut to the east of Hunting Lodge. "Radio Control Deception" was housed in a hut on the beach. A pierced steel plank slipway was laid for the Cansos, and supplemented with corrugated iron and bricks from the whaling station. Finally, a blind radar approach landing system was mounted on Cathedral Crags.

On January 10, 1956, Cansos CF-IGJ and CF-IJJ landed in Port Foster (the interior of Deception Island), after a 6-week journey from Canada via South America and the Falkland Islands. Poor weather conditions meant that it was not until February 6 that both Cansos were airborne for their first sortie. The weather barely improved, and little flying was undertaken during the first season. Furthermore, the ailerons (the movable flaps on the wings, used to control banking and rolling) of one of the aircraft were damaged during a storm. Brackets and aileron controls were improvised from steel salvaged from the whaling station.

Before returning to the UK, Mott sailed south aboard *Oluf Sven* to establish an advance base for the aircraft. Nothing suitable was found. At the end of the first season, little progress had been made towards meeting the requirements of the contract.

During the intervening period in the UK, Mott oversaw a number of logistical improvements. A lift was mounted on *Oluv Sven* for the helicopter, and heating added in the cockpits of the Cansos. One Bell 47D helicopter, fitted with a perspex bubble and flotation landing gear, replaced the Sikorskys. *Oluv Sven* departed from Harwich on October 20, arriving back at Deception Island on November 26. The Cansos arrived a fortnight later, having achieved a supplementary complete vertical aerial photography of the Falkland Islands, used to compile the first detailed map of the islands.

Disaster struck the expedition on December 10. While positioning a ground survey party in whiteout conditions, the Bell was caught in a downdraft and crashed on Tower Island. The pilots were unharmed, but the aircraft was a write-off. Valuable time was lost whilst *Oluv Sven* returned to Montevideo to collect a replacement. A visit from HRH Prince Philip aboard the Royal Yacht *Britannia* on January 3, 1957, accompanied by HMS *Protector,* helped to boost morale, and the remainder of the season carried on without further mishap.

In total, the crew of the Cansos took 10,753 vertical photographs, covering an area of 25,000 square miles (65,000 km^2). Oblique photographs taken from the sides of the aircraft extended this by a further 10,000 miles. In total, the Cansos logged 906 flying hours. The laboratory processed 113 aerial films and produced 17,000 nine-inch (22.9-cm) square contact prints. The ground control observations were sufficient to map 6000 square miles (15,500 km^2) of the South Shetland Islands and the Antarctic Peninsula.

Today, FIDASE remains the most comprehensive systematic vertical aerial photography coverage ever undertaken of the Antarctic Peninsula. Maps of the region compiled during the 1960s and 1970s were based upon the achievements of the expedition. Furthermore, the work of FIDASE serves as a time capsule of the Antarctic Peninsula glaciers and coastline as they were in 1955–1957. It predates satellite imagery, and is now used to determine glacial retreat and coastal change.

The dilapidated remains of Hunting Lodge are visited by more than 9000 tourists a year. In 2003, it was adopted as part of an historic site under the Antarctic Treaty. As long as the building stands, it is to be protected from human disturbance.

FERRAR SUPERGROUP

The early explorers with the Scott and Shackleton expeditions to Antarctica noted the conspicuous thick dolerite sills in south Victoria Land and along the Beardmore Glacier in the Transantarctic Mountains. The formal name Ferrar Dolerite was introduced by Hilary J. Harrington in recognition of the geologist on Scott's first expedition, Hartley T. Ferrar, who first described them.

The name Ferrar Supergroup now encompasses related basaltic rocks, which include a layered mafic intrusion, pyroclastic rocks, and overlying flood basalts. Dating of the lavas and a few sills by radiometric techniques has shown that magma emplacement occurred in early Late Jurassic time (c. 180 Ma) and was of limited duration (<1 million years). Jurassic basaltic rocks in Dronning Maud Land are age-equivalent but geochemically distinct, forming a province with affinities to the Karoo of southern Africa.

The Dufek layered mafic intrusion crops out in two ranges separated by 40 km. The areal extent is estimated to be about 50,000 km^2, but depends on interpretation of magnetic data. The Forrestal Range exposes the upper evolved (silica-rich) part with a thick granophyre, whereas the Dufek Massif exposes some of the lower stratified gabbroic part, although not the base. If chromite- and platinum-bearing layers are present, they most likely occur in the hidden basal zone. The estimated thickness is 8–9 km.

Sills and dikes of Ferrar Dolerite are spread out in a linear belt over 3500 km from the Theron Mountains near the Weddell Sea to the Horn Bluff region of Wilkes Land. Sills range in thickness up to more than 700 m, but commonly are 100–200 m. Sills occur mainly in the subhorizontal Devonian to Triassic Beacon Supergroup, but a few occur in cut basement rocks and the capping basaltic pyroclastic rocks. Sills commonly migrate stratigraphically, thicken and thin slightly too abruptly, and may terminate in narrow dikes. A number of sills form inclined sheets. The Basement Sill in the Dry Valleys is exceptional in its thickness (700 m locally) and the presence of thick tongues of coarse-grained orthopyroxene–clinopyroxene–plagioclase crystals. Details of these tongues provide important information on the manner in which crystals may accumulate and layering is formed. Dikes are relatively uncommon. No dike swarms are known, and no dike has yet been found cutting the lavas.

Extrusive rocks are widely scattered, forming summits in Victoria Land and the Beardmore Glacier region. Everywhere the lavas occur they are underlain by basaltic pyroclastic rocks. These pyroclastic deposits are predominantly formed by magma/water interaction (phreatomagmatism) and consist of tuff breccias, lapilli tuffs, and tuffs. In some places these rocks are extravent stratified deposits, locally they constitute remnants of tuff cones, and in two regions they are intravent deposits filling large volcanic necks and collapse structures. The filling for these structures is mainly unstratified tuff breccia as much as 360 m thick.

Flood basalt lavas form sequences as much as 750 m thick. Individual flows range from 1 to 225 m thick. In general the flows are either relatively thin (less than about 20 m) or thick (more than about 50 m), with the thick flows occurring predominantly near the base of the sequence. The flows show a range of cooling features, including columnar jointing and quench textures caused by flooding with water. Many thick flows were probably ponded (confined by topography) and may have been fissure eruptions, although no feeder dikes have been observed. The thin flows form sets of flow lobes and may have been formed by breakout from thick flows or, possibly, were erupted from local shield volcanoes.

The highly distinctive geochemistry of the Ferrar tholeiites is also recorded in the Tasmanian tholeiites and other basaltic rocks of the same age in southeastern Australasia. Ferrar geochemistry is characterized by enriched initial strontium and neodymium isotope ratios, and by trace element patterns and ratios that indicate a strong crustal imprint. There are two quite distinct chemical types: (1) the Scarab Peak Chemical Type (SPCT), which shows strong iron enrichment, forms the capping lava flow(s), and also sills in the Theron Mountains and Whichaway Nunataks, but constitutes only about 1% of the Ferrar rocks; and (2) the Mount Fazio Chemical Type (MFCT). The bulk of the Ferrar belongs to the MFCT. The least evolved (highest in MgO and lowest in SiO_2) rocks are olivine dolerites with chilled margins having MgO of 8.5%–9.0%. Dolerite with accumulations of orthopyroxene has MgO up to 20%. Chilled margins of dolerite sills range from 9.0% down to 3.7% MgO, whereas the range for lavas is 7.5%–2.5% MgO. The more evolved MgO-poor rocks in this range are andesites rather than basalts. The full range of compositions shown by the MFCT can be explained by normal crystallization processes, which separate out minerals formed at higher temperatures, accompanied by the incorporation of no more than about 5% crustal (granitic) rocks.

The SPCT forms scattered outcrops over a linear distance of about 3000 km. These rocks have an evolved composition and the same crustal imprint as the MFCT. It is remarkable because the initial isotope ratios of strontium and neodymium and the major and trace element abundances from all analyzed rocks throughout the Transantarctic Mountains fall largely within analytical uncertainty. This remarkably uniform geochemistry is the basis for suggesting a single point of origin for Ferrar magmas in the Weddell Sea region and long-distance crustal transport. The distribution of the extrusive rocks and concentrations of large volumes of dolerite suggest the magmas may have risen at a limited number of sites, including the upper Beardmore Glacier region and the Dry Valleys region of south Victoria Land. These sites were the centers of the initial explosive eruptions and subsequent effusion of flood basalts. In north Victoria Land, sills must postdate extrusive activity and the same may apply elsewhere.

The Ferrar Supergroup is the expression in Antarctica of the initial breakup of Gondwana. Magma distribution from the Weddell Sea region appears to have been controlled by preexisting Lower Jurassic rift structures that were parallel with the not-far-distant Late Paleozoic–Early Mesozoic subduction margin of the Gondwana plate.

FICTION AND POETRY

Poetry aside, in its broadest sense Antarctic fiction encompasses novels, treatises, short stories, children's stories, and even drama. From the earliest authors (writing before the age of Antarctic exploration) to latter-day writers, much fiction continues to define the Antarctic as a mysterious, imaginary space populated by otherworldly people, strange creatures, and extraordinary occurrences located in fantastic geography. While many stories emphasise the otherworldliness of the Antarctic (sometimes as a comparison to their own cultures), only in the late twentieth century did novels begin to appear where the Antarctic was the stage for more catastrophic global fears including volcanic eruptions, wars, and melting ice.

Generally believed to be the earliest example of preexploration Antarctic fiction, Bishop Joseph Hall's Mundus *Alter Et Idem* (1607) imagined the Antarctic as a satirical foil to criticise contemporary culture. Anthanasius Kircher, another early writer, fancied the Earth to be open at the poles, in his *Mundus Subterraneus* (1665), a motif perpetuated in the age of exploration by Captain Adam Seaborn's *Symzonia* (1820) and Edgar Allan Poe's novella *The Narrative of Arthur Gordon Pym of Nantucket* (1838) (written as the American Exploring Expedition [1838–1841] was about to depart). While the mid-nineteenth century produced occasional works of realism such as *The Sea Lions* (1849), James Fenimore Cooper's novel about seal hunting, the remainder of the century continued to be dominated by fantasy novels such as James de Mille's *A Strange Manuscript Found in a Copper Cylinder* (1888), Rudyard Kipling's *The Jungle Books* (1893), and Jules Verne's *Le Sphynx des Glâces* (1897).

By the twentieth century Antarctic expeditions were obliquely, but identifiably, the subject matter of fiction. Allan Villiers' *Whalers of the Midnight Sun* (1934) dealt with Antarctic geographical discoveries while detective novels like Hammond Innes' *The Survivors* (1949) drew heavily on Shackleton's *Endurance* expedition (1914–1916), and the plot of Thomas Keneally's *Victim of the Aurora* (1977) was populated by characters similar to Scott's final *Terra Nova* Expedition team (1910–1913). More recently, a spate of disaster novels centred on environmental change, like Thomas Block's *Airship Nine* (1984) and Richard Moran's *Cold Sea Rising* (1986), have shared the Antarctic stage with a new generation of novels more obviously centred on Antarctic expeditions. These include Caroline Alexander's *Mrs. Chippy's Last Expedition* (1997), a journal of the cat that accompanied Shackleton's *Endurance* expedition, and Adrian Caesar's *The White* (2001), a fictional rendering of the final days of Scott's *Terra Nova* Expedition.

Many of the early Antarctic short stories fell into the mystery and horror genres, which were ideally suited to the impact of reading stories at a single sitting—a key characteristic of the short-story form.

In the nineteenth century, Edgar Allan Poe's "MS Found in a Bottle" (1833) (written to coincide with the return of the American Palmer-Pendleton Expedition, 1829–1831) and "The Unparalleled Adventures of One Hans Pfaall" (1835) capitalised upon the Antarctic regions as a terra incognita ripe for marvellous occurrences and the fictionalisation of popular theories. In "MS Found in a Bottle," Poe's protagonist disappears into a hole at the South Pole seemingly in fulfilment of John Cleves Symmes' theory of a hollow earth composed of concentric spheres, connected (and with possible transit) between the poles.

Short stories written by explorers themselves include Douglas Mawson's "Bathybia" and A. F. Mackay's "An Interview with the Emperor" in *Aurora Australis* (1908), which took as their subject matter the British Antarctic *(Nimrod)* Expedition (1907–1909). Exploiting the mysterious nature of the South Polar regions, short stories from the 1930s and beyond became a staple not only of the mystery and horror genres, but also science fiction, appearing in such pulp magazines as *Astounding, The Macabre Reader, Alfred Hitchcock Mystery Magazine,* and *Analog Science Fiction and Fact*. These and later examples include S. W. Ellis' "Creatures of the Light" (1930), J. M. Leahy's "In Amundsen's Tent" (c. 1930), Ursula LeGuin's "Sur" (1982), Emmy Lou Schenk's "Ice Cave" (1987), and Brenda Clough's "May Be Some Time" (2001).

Although often ignored, children's stories dominated by penguins, exploring heroes, adventuresome children/adults, and even rocket ships have proved an extraordinarily durable staple of Antarctic literary output. Early examples of adventure literature include William Kingston's *At the South Pole; or, the Adventures of Richard Pengelly, Mariner* (1877) and G. Stables' *In the Great White Land: A Tale of the Antarctic Ocean* (1903). From the 1930s to the 1950s science fiction stories involving individuals armed with suitably impressive technology proved very popular with boys. Examples include C. Farrell and H. Colson's *Jack Swift and His Rocket Ship* (1934) and V. Appleton's *Tom Swift and His Atomic Earth Blaster* (1954). In more recent years younger children have been deluged with a plethora of "penguin stories" including Joyce Holland's *Bessie, the Messy Penguin* (1967), A. Wood's *Little Penguin's Tale* (1989), and Tim Weare's *I'm a Little Penguin* (2002).

Written the year before Robert Rhodes mapped the east coast of Kerguelen, Samuel Taylor Coleridge's poem "The Rime of the Ancient Mariner" (1798) is one of the earliest and perhaps most famous examples of Antarctic poetry. It was followed by a dearth of poetical output in the nineteenth century that was balanced only by the more prolific twentieth century. A steady trickle of Antarctic poetry followed the beginnings of 1901 expeditions by the Swedish (under Nordenskjöld), Germans (under Drygalski), and English (under Scott). Poetry focussed on aspects of Antarctic exploration, its difficulties (including scurvy), its history, and more generally on the qualities of the Antarctic itself. Examples (much of them published by the *Bulletin*) are W. T. Goodge's "The Value of Knowledge" (1909), Rose de Boheme's [Agnes Rose-Soley's] "The Joys of Antarctica" (1912), Iford's [Charles Hayward's] "Vitamin C" (1937), J. E. G. Channon's "Mawson to Queensland: South" (1960), and Mary Dilworth's "Air Disaster Antarctica" (1993).

Like Antarctic fiction, the region's poetry was sometimes written to coincide with popular interest in Antarctic expeditions and was occasionally penned by the explorers themselves musing on their own endeavours. Examples are Veritas' [Ernest Shackleton] "Midwinter Night," Nemo's [Ernest Shackleton] "Erebus," and Lapis Linguae's [Eric Marshall] "Southward Bound," all in *Aurora Australis* (1908), which took as their subject matter the British Antarctic *(Nimrod)* Expedition (1907–1909). Another example of an explorer writing poetry is Douglas Mawson's "The Silence Calling" (published posthumously 1977).

R. J. Cassidy published "The Southern Sacrifice" in 1912, the same year as Scott's ill-fated attempt to reach the South Pole, while Dorothy Porter published "Wilson's Diary" (1982) and "Oates' Diary" (1989). There has been a rediscovery of the Antarctic and Antarctic themes and a move towards epic poetry of considerable length. Examples include C. B. Orsman's *South: An Antarctic Journey* (1996) and Melinda Mueller's *What the Ice Gets: Shackleton's Antarctic Expedition 1914–1916 (A Poem)* (2000).

Drama focused on the Antarctic, although scant, is currently on the increase. The nineteenth century witnessed only one known Antarctic play, titled *South Polar Expedition,* which was performed in Hobart, Tasmania on 3 May 1841 and was possibly timed to coincide with the homeward-bound American Exploring Expedition (1838–1841). In the early twentieth century B. Espinasse published *Australis; or, The City of Zero* (1900) and Antarctic explorers, rather than the Antarctic, provided the raw materials for a rendition of *Ticket of Leave*. Adapted from Watts Phillips' play and performed by Gilbert Scott, Frank Wild, and Horace Buckridge, members of Scott's Discovery Expedition (1901–1904), both Scott and Buckridge played female roles. In 1941 Australian radio broadcast Stewart Douglas' *The Fire on the Snow* and only one play per decade was published in the 1970s–1990s. However, in the late twentieth and early twenty-first centuries New Hampshire witnessed *Endurance* by Louise Smith in 2000 while the London stage hosted David Young's *Antarctica* in 2001 (first performed in Canada, 1998).

FIELD CAMPS

Antarctic field camps are temporary, summer-only camps that are set up at sites remote from permanent bases or stations. Field camps have been an important part of life in Antarctica since humans first landed on the continent. Early exploration of Antarctica relied on small field parties hauling sledges loaded with all the equipment they needed for survival. The camps they set up did not look very different from a small field camp today with pyramid ("Scott") polar tents, sleeping bags, cookers, and food supplies.

Today field camps are most commonly used as a means of studying a remote site intensively, thereby eliminating the need to transport people back and forth between the camp and the permanent base, or as a jumping-off point for various scientific studies in the vicinity of the field camp. Field camps are also used by modern explorers as they travel across the continent or set up base camps to explore specific parts of the continent.

Modern field camps vary from small tent-based camps reminiscent of the early explorers to camps that might house more than fifty people and provide infrastructure for high-tech scientific studies. How these camps are supported and what they consist of depends on the distance that the camp is from the permanent base, the number of people to be supported at the camp, and the duration that the camp is to be located at the site.

The United States Antarctic Program, for example, staged a major deep-field camp in the late 1970s on the Darwin Glacier, 150 miles south of McMurdo Station. This camp was for geologic and glaciological investigations. It housed up to fifty-eight people at any one time, and three helicopters were based at the camp to transport researchers around the area. This helicopter capacity enabled the establishment of satellite camps up to 110 miles from the main camp.

In contrast to this, while attempting to cross Antarctica unassisted from November 2000 to February 2001, modern adventurers Liv Arnesen and Ann Bancroft camped in one tent for their 94-day expedition. They set up their field camp at the end of a day of hauling their sledges by ski. The sledges contained everything they needed to survive.

Field Camp Set-Up

Field camp set-up or "put-in" can be supported in a number of ways, depending on the distance the camp is from the permanent base and the terrain to be covered to reach the site. For relatively short distances over easy terrain for overland vehicles, tracked vehicles such as Hägglunds, Caterpillar tractors, and snowmobiles can be used to transport the camp cargo overland or over sea ice on sleds. This brings with it the challenges of crevasse and sea-ice-crack crossings.

Camp put-ins by air are more common for sites several hundred miles from the permanent base. Ski-equipped, fixed-wing planes are used for this purpose. Twin Otters (with payload of approximately 1000 kg) are used by the British, United States, New Zealand, and Italian Antarctic programs, for example, and Hercules LC-130s (with payload of approximately 5000 kg) are used by the United States Antarctic Program. Temporary ski-ways are often set up at the field camp to accommodate these flights.

For flights within a couple of hundred kilometres, and to sites where ski-equipped aircraft are unable to land, helicopters are the preferred mode of transport. Fuel caches situated between the permanent base and camp location are often needed to support such flights.

Ship transport can also be a means of putting a field camp in at coastal locations, and is often used by the Australian Antarctic Division, for example.

Tents/Structures

Field camp sizes can vary from small, self-sufficient camps of two people housed in tents, to larger camps accommodating fifty people or more in a variety of large semipermanent structures.

The most commonly used tent for accommodation is the Polar or Scott tent, which is a modified version of the tents used by Captain Scott in the early 1900s. This is a four-poled, double-walled, pyramidal tent with a cloth tubed entrance and canvas floor. These tents are designed to sleep, cook, and eat in with ventilation holes in the roof, and are recognised as the most resilient to the Antarctic conditions.

Modern four-season mountain tents are also used for accommodation purposes, particularly in areas that are less prone to severe Antarctic conditions, and where weight and space are an issue for transportation.

Larger semipermanent structures can serve as accommodation, kitchen and dining facilities, research, recreation, or mechanical maintenance areas. Heaters are installed in these to keep the ambient temperature above zero. Examples of such structures are Weatherhavens™, Jamesways, or Rac-Tents. These have wooden floors with framing that supports a canvas or wool covering over it and are large enough to walk around freely inside. Jamesways and Rac-Tents are constructed by adding a number of sections together, which allows for flexibility in the size of the structure that is built.

Small, curved, lightweight, fibreglass huts are called "apples." These can be flown intact into a campsite by helicopter, set up on uneven ground, used for both accommodation and cooking, and easily extended with the addition of a second "apple."

The Australian Antarctic Division has recently introduced "tank-huts" into its sub-Antarctic operations. These are polymer water tanks that have been converted into accommodation modules with the addition of internal insulation, a doorway, and windows. These can be sealed up and floated ashore to coastal field campsites with the aid of additional flotation devices.

Converted refrigerating shipping containers are often used for camps located close to a permanent base. They are insulated, and can be hauled on sledges in a convoy train across sea ice or snow and are ideal for longer-term camps. The multinational Cape Roberts Project (Australia, Germany, Italy, New Zealand, The Netherlands, United Kingdom, and United States) operated over three seasons in McMurdo Sound using a variety of converted containers for accommodation, cooking, dining, and research laboratories.

Science Facilities

Field camps supporting scientific activities often need to cater to a range of different science technologies. These may be as basic as providing the facilities for samples to be analysed by microscope in the field, or enabling the use of computers, to more sophisticated facilities for logging, analysing, and storing sediment or ice cores. As such technologies have developed, there is a growing pressure on national Antarctic programs to provide facilities to support such work in the field.

Sleeping

Field-camp personnel usually sleep on a camp stretcher and/or on insulated matting. Containers and some of the other semipermanent structures may have bunk beds built in them. One or two sleeping bags made of natural or synthetic fibres are used. This system has changed little over time.

Food and Food Preparation

Traditionally, dehydrated foods and those high in fat content such as butter and chocolate have been used in field camps. Dehydrated foods reduce the amount of cargo weight for the put-in and any subsequent transport of the camp. Prepacked ration food boxes have a specific number of person food days in them, so the required number of food boxes are taken to cover the field period, including additional amounts for emergencies. More recently, some Antarctic programs such as the New Zealand and United States programs have moved towards frozen foods to replace the often bland and repetitive dehydrated foods. Meat, fish, cheese, vegetables, and breads can all be taken into the field and kept frozen for use when required. "Freezers" can be dug in the snow to protect the foods from the sun and potential thawing. Although this shift does bring some variability into the diet, cargo weights are increased and there is a higher risk of the food's spoiling before it is eaten.

Food preparation depends on the size of the camp and the amenities that are available. In smaller camps made up of a few Polar tents, cooking is undertaken in the tents using small primus stoves. In the larger camps, Coleman stoves, gas burners, and even microwaves, electric stoves, and ovens are used.

Water-making is key at any field camp. Depending on the site, water can be sourced by melting glacier ice (which yields a higher water content per unit of volume compared to snow), snow, surface sea ice, or naturally occurring melt streams off glaciers or snow patches.

Waste

There has been a big shift in the methods of waste disposal from field camps. Until the 1990s field waste was often burnt or buried on site. Many programs now ban the burning of waste in the field and waste is returned to the permanent base for disposal. On the polar plateau, human waste is still buried in the snow and ice, but on ice-free land, the return of human waste to the permanent station is encouraged and often enforced by legislation.

Communication

The most common form of communication from the field is High Frequency (HF) radio. In the 1950s and 1960s Morse code was used to communicate over the low-powered HF systems, as Morse could penetrate the static better than voice. As technology developed in the 1970s there was a shift away from Morse towards voice communication. A difficulty that continues to plague HF communications is solar flare activity, which disrupts the radio waves. This is particularly troublesome as field camps are usually required to make contact with the main base on a daily basis. Failure to make contact results in the initiation of search-and-rescue procedures. In many instances the use of satellite telecommunications has overcome this difficulty as these are not disrupted by solar activity. However, a good sight of the northern skyline is necessary, as communication is reliant on satellite coverage, which is often hard to obtain in the higher latitudes. Portable satellite phones and relatively small base stations mean that HF can be backed up by satellite communications if needed.

Very High Frequency (VHF) radio contact is mostly used for line-of-sight communications. VHF repeaters broaden VHF networks to cover large areas not in the line of sight and can make VHF more effective than HF communications. Such a repeater network is used in the Dry Valleys area of Victoria Land, where the network connects the New Zealand, United States, and Italian operations.

Energy Production

Power generation for small camps with limited power needs can be provided by small solar panels to recharge radio batteries, and small generators to power laptops. As camps and scientific projects grow in size and complexity, energy demands increase. These have traditionally been met by petrol or diesel generators. More recently, programs are moving towards alternative energy where possible, realising the logistical and environmental efficiencies of using less fuel. Solar power and wind energy have been used to power basic camp needs, though generator power is usually needed for backup.

Staffing

The number of field camp support staff depends on the size and purposes of the camp. If travel in potentially dangerous areas away from the camp is needed, then field safety staff members are used to ensure safe travel in these areas. Larger camps often have a camp manager, to coordinate flights, movements in and around camp, and the general smooth and safe running of the camp; a cook; and, depending on the facilities at the camp, a mechanic. Often, one person can cover the role of several of these needs.

Transport In and Around a Field Camp

The mode of transport used in the field depends largely on the purpose and permanence of a field camp. In the 1950s and 1960s some programs (for example Australian, British, and New Zealand) relied on dog teams to move their camps from site to site or to travel to areas away from a camp. A team of nine dogs could haul a sled of up to 680 kg. Travelling at an average speed of four miles per hour, the dogs proved to be useful crevasse probes in treacherous glaciated terrain.

Snowmobiles came into use in the mid-1960s and slowly replaced the dog teams, although they initially travelled only marginally faster and had difficulties going uphill. Early snowmobiles often needed to be accompanied by a mechanic as they were so unreliable. Since the late 1960s, advances in technology have now made snowmobiles a much more reliable and faster form of transport in the field.

Other vehicles used in the field include all-terrain vehicles (Quad bikes) and tracked vehicles such as Hägglunds, which are used by the New Zealand, Norwegian, Swedish, and United States programs.

Navigation

Methods for early navigation around field camps depended on where in Antarctica the camp was situated. At sites on the Antarctic Peninsula a magnetic compass could be used with relative accuracy. However, at other sites, such as those in the Transantarctic Mountains, this method was hampered by the fact that the geographic South Pole was in one direction and the South Magnetic Pole in another. In this case, theodolites, sun compasses, or sextants were employed, which used the angle of the sun and time of day to determine location.

The more recent advent of satellite Global Positioning Systems (GPS) in the 1980s revolutionised polar navigation. Although they were costly and cumbersome when first developed, accurate, handheld GPS units are now the norm.

Safety

Safety at field camps is paramount, as they are often located at remote sites where immediate assistance is not possible. Camp personnel receive first-aid training. National Antarctic programs have safety protocols in place for various operations such as linked snowmobile travel, walking/skiing over crevassed terrain, making scheduled radio contact with the permanent base, and procedures for calling for emergency assistance. Survival bags are deployed for travel away from the camp. These contain emergency food and shelter.

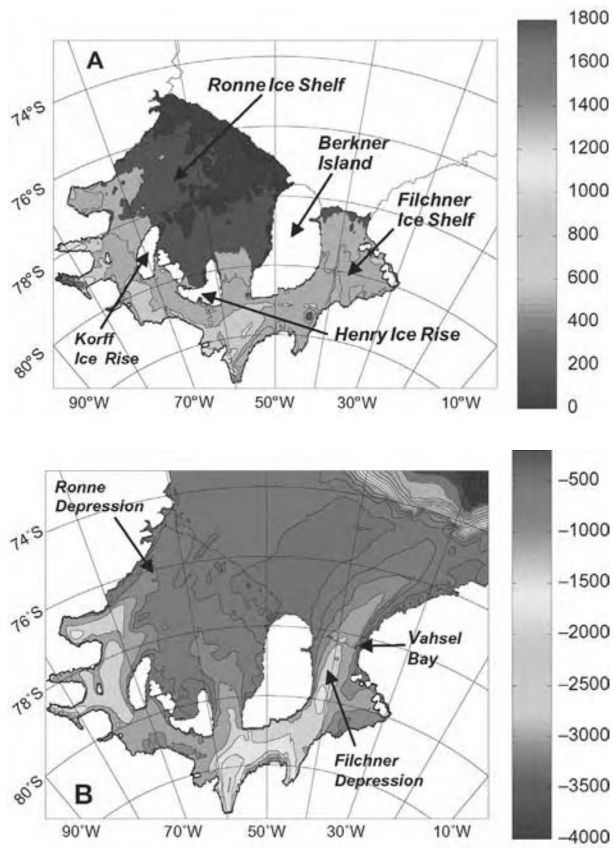
FILCHNER-RONNE ICE SHELF

Filchner-Ronne Ice Shelf (FRIS), situated in the southern Weddell Sea, is the largest body of floating ice on the planet, containing nearly 350,000 km^3 of ice. Although it is slightly smaller in area than its Ross Sea counterpart, Ross Ice Shelf, its average thickness is more then 50% greater. The separate names of Filchner Ice Shelf and Ronne Ice Shelf are generally applied to the regions lying to the east and west, respectively, of Berkner Island. However, there is no clear glaciological distinction between the two.

FRIS is fed by the flow of ice from grounded portions of the ice sheet, snowfall on its upper surface, and freezing of seawater to its base. The majority of the inflow is carried from the Antarctic ice sheet via nine fast-flowing ice streams. A much smaller proportion comes from the Antarctic Peninsula and regions of grounded ice, known as ice rises, enclosed within the ice shelf. Together these sources make up about two-thirds of the input. The vast majority of the remainder comes from accumulation. Basal freezing makes only a small contribution to the net balance of the ice shelf, because most of the frozen-on ice is melted off again before it reaches the ice front. Net melting (the amount by which basal melting exceeds basal freezing overall) removes about half of the ice that flows in from the grounded ice sheet (i.e., about one-third of the total input). Calving of icebergs from the ice front accounts for the remaining two-thirds of the mass loss. The icebergs comprise a roughly 50/50 split between ice derived from the grounded ice sheet and that derived from surface accumulation on the ice shelf.

Near the inland margin the ice is around 2 km thick in some places. The thickness gradually declines towards the ice front, where it ranges from 150 to 500 m. The structure of the ice shelf varies laterally. The fast-flowing ice streams produce thick tongues of ice, while thin ice forms between them in the wake of promontories of grounded ice and ice rises. Melting and freezing driven by an "ice pump" mechanism removes ice from the bottom of the thick tongues and deposits it in the intervening channels of thin



Maps of Filchner-Ronne Ice Shelf and the continental shelf to the north showing (A) ice thickness and (B) seabed elevation, both in metres.

ice. In this way variations in the total ice thickness are smoothed out and layers of marine ice up to 350 m thick are formed. Marine ice accumulates by intense freezing over a limited area, and is subsequently carried downstream to form long tongues that gradually thin as a result of longitudinal stretching and basal melting.

The oceanic water column beneath the ice shelf averages around 350 m in thickness, and in places it exceeds 1 km. The areas of maximum thickness are far within the cavity over deep seabed trenches, the Ronne and Filchner Depressions, which are prominent features of the continental shelf that extend to the north of the ice front. Away from the grounding line, the area of minimum clearance between the ice base and seabed, in places only about 100 m, lies at the ice front to the east of Berkner Island.

The continental shelf beyond the ice front represents one of the most southerly parts of the open ocean. (The furthest point south attainable by a surface ship alternates between Vahsel Bay in the Weddell Sea and the Bay of Whales in the Ross Sea, dependent on the cycle of advance and calving of the fronts of FRIS and Ross Ice Shelf.) The winters are extremely cold and the sea is perennially ice covered. Much of the wintertime ice production occurs at the front of FRIS, where offshore winds and tidal motion continually remove new ice, leaving the sea exposed to the frigid air. When ice forms from seawater, most of the salt is left behind in the water. The high ice-production rates in the southern Weddell Sea thus produce very salty water that has a temperature equal to the surface freezing point. This dense water flows to the deepest parts of the continental shelf, beneath the ice shelf. The main flow into the cavity follows Ronne Depression, because the saltiest (i.e., densest) water forms at the western end of the ice front. This inflow supplies most of the heat for basal melting of the thickest ice. The resulting "ice pump" causes freezing beneath thinner ice and an outflow of Ice Shelf Water (ISW) to the east of Berkner Island in Filchner Depression. The ISW fills much of Filchner Depression and overflows at the northern end, from where it flows down the continental slope to form Antarctic Bottom Water.

Filchner Ice Shelf was the planned starting point for early attempts at traversing the Antarctic continent by expeditions led by Wilhelm Filchner (1911–1913), Ernest Shackleton (1914–1917), and Vivian Fuchs (1957–1958). The last, successful expedition was contemporaneous with oversnow traverses of both Filchner and Ronne ice shelves that formed part of the United States programme for the International Geophysical Year. Since then, mapping of ice shelf extent and thickness has been completed by airborne radar sounding and satellite remote sensing. Water column thickness beneath the ice shelf has been mapped by seismic sounding. Ice flow has been measured by ground surveys and recently by satellite remote sensing. The picture that has emerged is one of near equilibrium. The rapid changes that have been observed on other ice shelves are not seen on FRIS. This is probably because its extreme southerly location buffers it from the effect of rising air temperatures seen further to the north. While the atmosphere remains cold enough to prevent surface melting and sustain the production of sea ice at the ice front, the processes of mass gain and loss are likely to stay largely unaltered. However, to confirm this requires a greater understanding of the processes than we currently have. Recent research on FRIS has been aimed at addressing these deficiencies, primarily through studies of the inflowing ice streams and of the ocean circulation beneath the ice shelf.

FILCHNER, WILHELM

Wilhelm Filchner was born on September 13, 1877 in Munich, son of Eduard and Rosine Filchner. As a teenager he enrolled in the Munich Cadet Corps, the first step in a military career. Having gained official Russian approval, in 1903 he undertook his first expedition: a solo trip on horseback across the Pamir Mountains from Osh in the Fergana Basin to Murgab, then back via Kasgar in Sinkiang.

This led in turn to his first scientific expedition, to map the upper course of the Ma-Qu (Huange He) in western China for the first time. Now with the rank of lieutenant, he set off for China in the fall of 1903 and returned home early in 1905, having accomplished his mission, despite some terrifying encounters with the hostile Ngolok tribe. Thereafter he worked at the Trigonometrical Department of the Prussian Land Survey, instructing route-surveying courses for officers posted to the German colonies.

In the light of endeavors by Belgium, France, Britain, Japan, Sweden, and Australia in exploring Antarctica, Filchner was motivated to plan his own Antarctic expedition. With the support of his superiors in the German Army, he proposed crossing the Antarctic Ice Sheet from the Weddell Sea to the Ross Sea, using sledges drawn by ponies. In preparation for this expedition, he mounted a small practice expedition to Svalbard in the summer of 1910.

The expedition headed south in 1911, entering the Weddell Sea in December of that year. Due to bad luck and serious opposition from the captain of the expedition vessel, *Deutschland,* Filchner was unable to establish a foothold on the continent. *Deutschland* became beset in the ice of the Weddell Sea early in 1912 and spent the winter adrift. Fortunately she emerged unscathed. Positive accomplishments included the exploration of the east shore of the Weddell Sea (Luitpold Coast) and the discovery of the Filchner Ice Shelf.

With the outbreak of World War I, Filchner spent some time on the Western Front, then was transferred to the Intelligence Service of the German Admiralty and was appointed head of the Naval Intelligence Service in Norway and later in The Hague.

For several years after the War, he supported himself by writing, about both Sinkiang and the Antarctic. Then, between 1926 and 1937, he mounted two major expeditions to Sinkiang and Tibet, whereby he completed impressive geomagnetic traverses of some 6500 and 3500 km, respectively, often living and traveling under extremely difficult conditions and suffering various injuries and bouts of illness. It was on this basis that he was awarded the Nationalpreis für Kunst und Wissenschaft by Adolf Hitler on January 30, 1938.

When World War II broke out in the fall of 1939, Filchner was engaged in geomagnetic surveys in Nepal, where he contracted malaria. On heading south for treatment, he was interned when he crossed into India, and spent the war years, with his daughter Erika, in the ladies' camp at Satara, near Poona.

At the end of the war Filchner opted to stay in India, settling in Poona. Finally, in 1949, ill health obliged him to return to Europe, where he settled in Zürich. He died on May 7, 1957, at the age of 79, and was buried in Enzenbuhl Cemetery in Zürich.

FILM

Antarctic film can conveniently be thought of as spanning a number of genres and fulfilling a variety of requirements, both for the filmmakers and their various audiences. Antarctic films have appeared as newsreels, pictorial expedition diaries, technical films recording discoveries (such as new land or flora and fauna), documentaries, and fictional stories about Antarctic explorers, their exploits, and their expeditions. Inevitably many Antarctic films cross these boundaries, falling into one or more categories.

In 1904 an anonymous member of the Scottish National Antarctic Expedition first made motion pictures of the Antarctic. British Antarctic explorers were quick to adopt motion picture making as an important and legitimate expedition tool as they quickly realised the power and importance of the new medium. The earliest films, like Herbert Ponting's (1870–1935) *90° South* (1914) (his film of Scott's final expedition); Frank Hurley's (1885–1962) *Dr. Mawson in the Antarctic/Home of the Blizzard* (1913) (documenting Mawson's Expedition [1911–1914]) and Hurley's *South* (1919), which chronicled Shackleton's *Endurance* Expedition (1914–1916), were extraordinary achievements. These beautifully crafted films were achieved under appalling conditions for men and equipment as the mechanisms in early hand-cranked movie cameras frequently became unworkably stiff in very low temperatures, lubricants became viscous, lenses "fogged" and "sweated," and snow somehow invaded even light-tight cameras.

The scope of these early films ranged far beyond popular entertainment, as they afforded their audiences the opportunity for vicarious participation in the process and exploits of exploration, which were often staged for the camera. Film provided a medium whereby the public was invited, at a distance, to witness and verify the priority and territorial claims of Antarctic explorers. Crucially, they also coincided with the beginning of the newsreel's heyday. Pioneered by Pathé Frères, the weekly "Pathé Journal" began in Paris in 1909/1910. It was quickly followed by their English "Animated Gazette," which was projected to an estimated audience of over two million, any one of whom could be a potential sponsor for the often cash-starved future Antarctic expedition.

By 1928 film was an indispensable tool for exploration in a year that was seminal for filmmaking in the Antarctic. While Richard E. Byrd's media-savvy expedition was closing in on the Ross Ice Shelf with cameramen Willard Van Der Veer and Joseph Rucker of Paramount News, Sir George Hubert Wilkins and Carl Ben Eielson were filming undiscovered land on their historic flight, the first to utilise film and the aeroplane to facilitate territorial discovery in the Antarctic. While Antarctic filmmaking variously served the purposes of documentary record, publicity vehicle, and cartographical aide-memoir, the versatility of the medium prompted a rueful Byrd to "regret" that on his 1925 expedition he had "paid little attention to motion pictures" or to "Donahue, of Pathé" to whom he had not "give[n] much time and attention."

In the post-WW II era film acquired a strategic value for military planners with films like *The Secret Land* (1948), which chronicled the US Navy's strategic Operation High Jump. By the 1940s the Antarctic was also providing imaginative material for the film industry with films like Charles Frend's 1948 *Scott of the Antarctic,* a dramatic reconstruction of Scott's last expedition scored by Ralph Vaughn Williams. In more recent years *Mr. Forbush and the Penguins* (1971) and *Conquest of the South Pole* (1988) have perpetuated the image of Antarctica as an escape from everyday life, while documentaries on Antarctic discovery like *Icebound (100 Years of Antarctic Discovery)* (1994) and a plethora of documentaries and films on Shackleton continue to explore the myth of the Antarctic explorer.

FIN WHALE

The fin whale is order Cetacea, suborder Mysticeti (meaning moustache, which refers to baleen plates), family Balaenopteridae, and genus and species *Balaenoptera physalus* (Linnaeus 1758). Other common names used include "finback," "finner whale," "razorback," and "common rorqual." Despite the prevalence of references to "fin," it is interesting to note that the dorsal fin of the fin whale is less pronounced than that of the sei *(B. borealis)* or the Bryde's *(B. edeni)* whale.

General Appearance and Size

Fin whales are the second longest of the great whales. In the Southern Hemisphere, females average about 21–22 m in length and weigh around 60–80 tonnes. Females are generally about 5% longer than males. The largest animals can reach up to 26 m.

The slender fin whale has a narrower head than the blue *(B. musculus)* whale, with a single well-defined head ridge running to the paired blowholes. The fin whale can be identified by its asymmetrically coloured head. The dark grey colour characteristic of the rest of the dorsal surface reaches down further on the left-hand side than the right. The right-hand side, including the lip, is a creamy white colour. This is also true of the front 20%–30% of the baleen plates. The skin shows little mottling (although it is sometimes covered in pale oval scars thought to be caused by lampreys or remoras). The ventral surface is white. The dorsal fin is falcate and set about three-quarters back on the body. Fin whales are rorquals and have 55–100 ventral grooves that run from the lower jaw to the umbilicus and that allow the mouth to expand when feeding. They have 350–400 triangular baleen plates hanging from the upper jaw on each side (about 0.7 m in length and 0.3 m at the widest part), spaced 1–3 cm apart, used in filtering krill. The flippers reach about 15% of body length and are dark grey on top and white underneath, as are the broad flukes.

In Antarctic waters, all or portions of the body may have a dark yellow-green to brown sheen from the presence of diatoms.

Distribution and Migration

Fin whales are found throughout the Southern Hemisphere (and, indeed, the Northern Hemisphere). They migrate between subtropical breeding areas (although the location of the breeding grounds is unknown) and their Antarctic feeding grounds, which appear to be related to the Polar Front, most fin whales being found between around 55°–62° S (i.e., just south of the Polar Front). Like the other large whales, fin whales rarely feed outside the Antarctic, and so in the 4 months (December to March) they spend in the Antarctic they must store energy in their blubber to last them for the migration to and from the breeding grounds as well as the time spent on the breeding grounds. Although detailed information on population structure is lacking, there are probably at least six separate populations of fin whales in the Southern Hemisphere.

Life History and Behaviour

Fin whales can live to be 100 years old. They reach sexual maturity at around 20 m (females) and 19 m (males) when they are 8–10 years old. The gestation period is thought to be around 11 months; newborn calves weigh 1–1.5 tonnes and measure around 6 m. They are weaned at about 6 months, by which time they have reached 11–12 m. There is some evidence that pregnancy rates increased and animals reached sexual maturity earlier as a result of whaling, perhaps as more food per individual became available.

Little is known about the social structure of fin whales. They are usually seen as single animals or in small groups of two to seven, although larger concentrations (up to fifty animals) are known in areas of high prey density. Their primary prey is a species of krill, *Euphausia vallentini*. Fin whales can engulf vast quantities of water and prey with their ventral grooves fully distended and eat up to 1–2 tonnes of krill per day. Fin whales typically dive for around 8–12 minutes and to depths of 100–200 m when feeding. Fin whales are relatively fast swimmers, with normal travelling speeds of around 4–5 knots with short bursts of as much as 18 knots occurring if chased.

Conservation/Status

Reflecting their size, fin whales were the second most preferred target of commercial whalers in the Antarctic after blue whales. About 682,000 were killed south of 40° S between 1904 and 1975, with over half of these killed between 1947 and 1961. They have been protected in the Southern Hemisphere since 1976.

Although still at very low population levels (perhaps less than 10% of their original numbers), there is some evidence that fin whales are recovering in some areas. A recent study estimated their numbers south of 60° S in the Antarctic to be at least 5500 in 1996.

Aside from man, the main predator of fin whales is the killer whale, *Orcinus orca,* which has been known to take adults as well as calves. Possible interspecific competition has been postulated with other baleen whales. The effect of climate change on stocks of krill and hence fin whales is unknown.

FINLAND: ANTARCTIC PROGRAM

Finland started active research in the Antarctic in 1988 when the research station Aboa was established. Aboa is situated in Queen Maud Land, about 130 km inland from the Weddell Sea on the nunatak Basen in the Vestfjella Mountains. Aboa is occupied only during the Antarctic summer. The Swedish research station Wasa is located 200 m from Aboa and the stations cooperate in research and logistics.

The Antarctic organizations in Finland are divided under several ministries. The Ministry for Foreign Affairs is responsible for handling issues related to the Antarctic Treaty System. The Ministry of Environment is involved in the Committee for Environmental Protection (CEP) and permissions. The Ministry of Education leads the Coordination Committee for Antarctic Research, the purpose of which is to promote the cooperation of different authorities, to establish the priorities for Finnish Antarctic research and to supervise the logistics of expeditions. The Academy of Finland (the Research Councils) is mainly responsible for the financing of Antarctic research projects, although some governmental research institutes have projects funded by their budgets. The logistical support is provided by the Finnish Antarctic Research Program (FINNARP), hosted by the Finnish Institute of Marine Research.

The scientific National Committee for Polar Regions Research (National SCAR Committee) deals with both Arctic and Antarctic research. There has been close cooperation with several other countries, including Argentina, Norway, Russia, South Africa, and Sweden. A number of Finnish projects have contributed to large-scale international programmes and several projects expect to participate in the International Polar Year 2007/2008 programmes.

The Antarctic research in Finland had started already prior to the establishment of the Aboa station (i.e., the Institutes of Meteorology of Finland and Argentina established a cooperation in ozone research in 1987). The first Finnish Antarctic expedition visited Aboa during the southern summer of 1989/1990 and during the 1990s the research activity expanded and became more diversified. The enlargement and development of Aboa become necessary, and from 2002–2004 more working and accommodation space was built, including more energy-saving and environmentally friendly facilities and new power supplies for all-year automated instruments.

The main activities of the Finnish Antarctic research and the field expeditions are concentrated in Queen Maud Land and the Weddell Sea. The main research fields are oceanography and marine biology, meteorological studies, geology, geophysics, and geodynamics. Current research projects include a geochemical and isotopic project on lithospheric evolution of Dronning Maud Land and hydrogeological research; paleoclimate studies on Antarctic Blue Ice Fields; glacial history and paleoceanography; seasonal snow studies in Antarctica; Antarctic UV and ozone monitoring and mesoscale atmospheric studies; sources, transformation, and characteristics of Antarctic aerosol; air–sea–ice interaction in the Antarctic Seas; and GPS and absolute gravity measurements for geodynamics studies.

Institutes participating in the Antarctic research include several departments and research units in the University of Helsinki, University of Oulu, University of Lapland, Finnish Institute of Marine Research, Finnish Meteorological Institute, Finnish Geodetic Institute, and Geological Survey of Finland.

FIRN COMPACTION

Firn compaction, or firnification, is the process by which an initial loose aggregation of snow particles compacts into solid glacial ice. Firn is snow that has survived at least one complete annual cycle, for example, along the northern part of the Antarctic Peninsula, implying persistence through a melt season. Freeze–thaw processes enhance firn compaction rates. Most of the high vast Antarctic polar plateau, however, is a dry snow zone, where no melting occurs, so firnification there is a subtle progression over many years and hundreds of metres through the snowpack.

Snowflakes deposited on the surface have a variety of forms depending on the atmospheric conditions under which they grew. Temperature determines geometry, while humidity dictates size. In cold, dry Antarctic air, snowflakes are mostly simple needles, columns, and plates, with occasional classic stellar dendrites (star-shaped with fern-like branching). These pack loosely together, so a layer of freshly fallen snow formed in calm conditions has a bulk density of only 25% that of water. Within a few days of settling, surface winds jostle neighbours into a close-packed arrangement of fine-grained old snow.

Snow is an excellent insulator, so temperatures a few metres down in the pack are practically independent of the daily and seasonal variations taking place at the surface. Firnification is therefore sometimes called equitemperature metamorphism. In the initial stages it is dominated by vapour transport through the process of sublimation (from or to a solid directly to or from a vapour, without melt). This rearranges the original snow particles, minimising the ratio of surface area to volume, by redistributing molecules from one part of a crystal to another. The process results in an assemblage of rounded grains, the larger of which grow at the expense of the smaller ones. Continued settling, wind compaction, and initial bonding together of rounded grains increases bulk densities relatively rapidly to around 55% that of water, at depths between 10 and 30 m.

As more snow accumulates, the added weight applies, increasing overburden pressure to the layers below. This results in individual crystals slowly deforming and sintering together to gradually reduce the interconnected air channels between them into discrete bubbles. When most pores have been confined to bubbles in the ice matrix, the density has reached 83% that of water, and transformation to glacier ice is complete. This level is called the firn–ice transition, and in Antarctica it occurs at depths ranging from 50 m near the coast to 120 m far inland. Surface air, which mixes freely through the firn, cannot penetrate beyond this depth. Further compression of glacier ice at great depth increases the air pressure in the bubbles, reducing their volume, eventually squeezing the bubbles into the ice crystal lattice, with final densities of 92% that of water.

Firnification rates depend on many factors. In Antarctica they are influenced by high winds accelerating initial compaction stages, but dominated by very low temperatures and minimal accumulation (snowfall), which result in protracted densification that may see complete transformation to glacial ice taking well over 1000 years (e.g., Vostok).

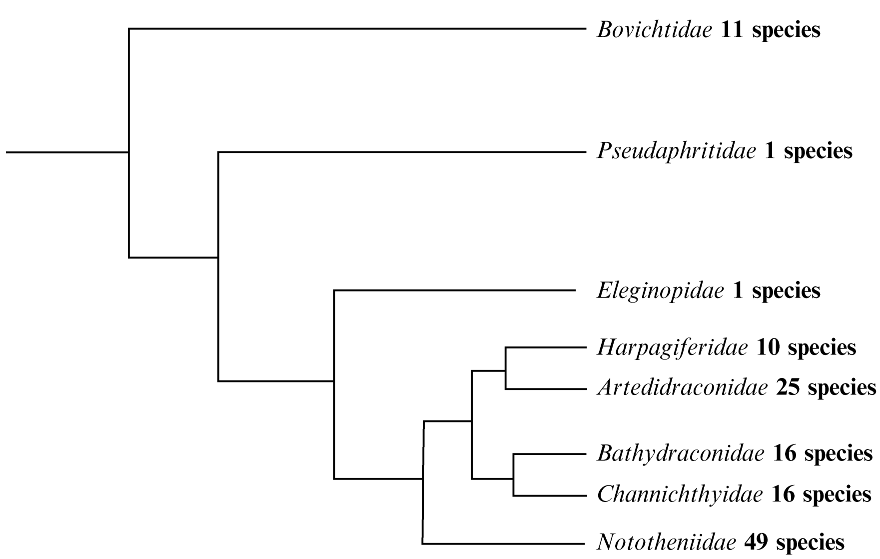
FISH: OVERVIEW

During the past 40 million years, on the Antarctic shelf there has been a nearly complete replacement of the cosmopolitan temperate ichthyofauna (fish) from the late Eocene by the highly endemic (up to 97%), cold-adapted modern fauna. The suborder Notothenioidei (order Perciformes) is dominant in species number and biomass, and to date is the most thoroughly characterised fish group of the world.

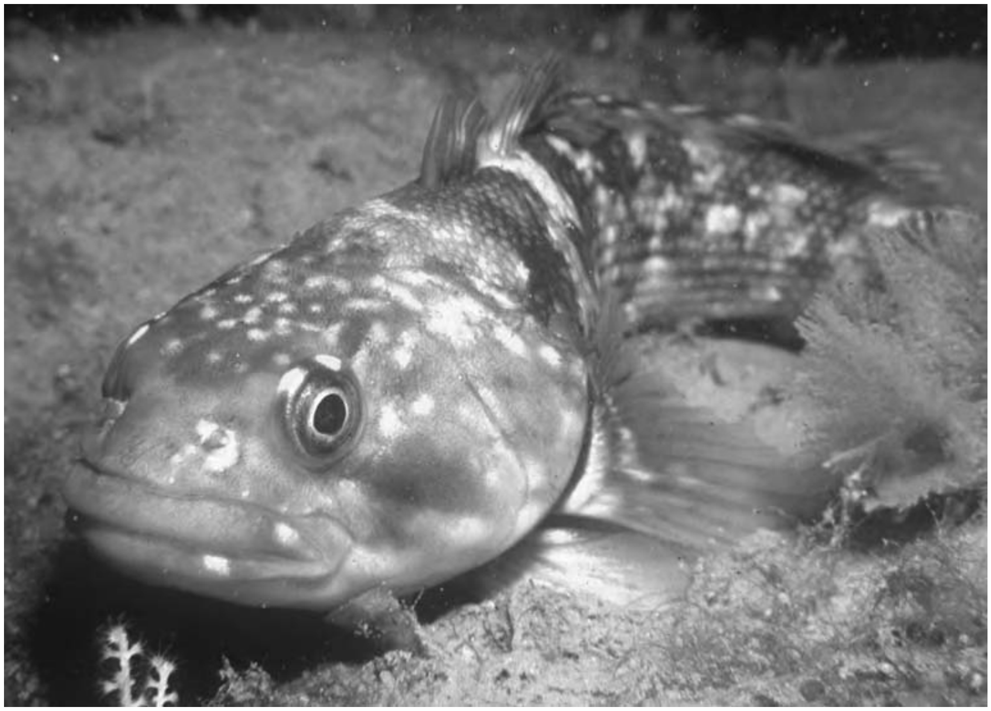
During the progressive geographic isolation, the physiology of Antarctic fish became gradually adapted to the cooling of the habitat. Thanks to adaptation, they are comfortable only in the cold, where their metabolism works best. Antarctic fish are stenothermal, such that raising the water temperature just a few degrees centigrade can cause their death. Coastal Antarctic waters, where survival of temperate fishes would be impossible due to freezing, are at –1.87°C, the equilibrium temperature of seawater and ice, for much of the year. The Polar Front has become a natural barrier to migration in both directions, fulfilling an essential role for evolution in isolation. The capacity to adapt is variable. Highly stenothermal organisms may not tolerate temperature changes of 1°C–2°C. Arctic fish, however, have adapted to survive over a wider thermal range.

In recent years, studies of the evolutionary history of Antarctic fish have envisaged coordination and stimulation of research on evolution in response to climate change, gradually extending to the Arctic scenario. During the Cenozoic, tectonic and oceanographic events played a key role in delimiting the two polar ecosystems and in influencing the evolution of their faunas. The Antarctic has been isolated and cold longer than the Arctic, with ice-sheet development preceding that in the Arctic by at least 10 million years. Although Antarctica and the Arctic have high latitudes and cold climates in common, the two regions are more dissimilar than similar. Due to the Polar Front, the climatic features of the Antarctic waters are more extreme and constant than those of the Arctic.

The modern polar faunas have lower taxonomic diversity than at low latitudes, possibly resulting from lower evolutionary rates at the poles. However, they differ in age, endemism, taxonomy, zoogeographic distinctiveness, and range of physiological tolerance to various environmental parameters. There are



Notothenioid phylogeny at the family level.



Nototheniid, *N. rossii,* sitting on the sea bed at a water depth of 10 m. (Courtesy of David K. Barnes.)
