advantages in using organisms from both poles in evolutionary studies. Some fish families (e.g., Zoarcidae and Liparidae) are represented in both polar oceans; however, hypotheses of adaptation to a common environmental parameter are better supported when a feature can be compared in distantly related taxa from both habitats, allowing examination of convergent/parallel evolutionary trends. Pertinent examples include the convergent evolution of the identical antifreeze glycoproteins of southern notothenioids and northern cods, and the recently found divergence of Arctic hemoglobins from those of Antarctic notothenioids (see following discussion).

Example 1: Antifreeze Compounds

The biosynthesis of antifreeze (glyco)proteins and peptides (AFGPs, AFPs), which allows polar fish to tolerate temperatures as low as –1.9°C, is a most intriguing evolutionary adaptation, and meets the criteria for a "key innovation." Antarctic fish must rely on this adaptation throughout the year, whereas in Arctic fish, biosynthesis of AF(G)Ps occurs only in the coldest winter months. Most of our knowledge on freezing avoidance comes from more than three decades of studies by Arthur L. DeVries's team.

In Antarctic notothenioids, the AFGP gene evolved from the gene of an enzyme (a trypsinogen-like protease), which provided the front and tail of the AFGP gene (Cheng 1998). The finding in the notothenioid genome of (i) a chimeric AFGP-protease gene intermediate, (ii) a protease gene still bearing the incipient coding element, and (iii) independent AFGP genes reveals a fascinating case of "evolution in action." The genome of a phylogenetically unrelated Arctic fish, the polar cod *Boreogadus saida* (family Gadidae), contains AFGP genes that encode nearly identical proteins. This would suggest a common ancestry. On the contrary, the genes of the two fish groups are not homologous, and hence have not followed the same evolutionary pathway. Assuming an endogenous, yet unknown genetic origin, the cod AFGP genes have evolved from a different, not trypsinogen-like, genomic locus. An example of convergent evolution has thus been discovered.

Example 2: Oxygen Transport

There has been a major evolutionary pressure for fish to adapt and modify the functional features of haemoglobin (Hb). Located in the blood erythrocytes, Hb has two pairs of identical α and β globins; its structure is indicated as $\alpha_2\beta_2$. Each globin contains the heme group, whose Fe++ ion binds oxygen during respiration. Oxygen is carried along capillaries by one or more Hbs, and released to tissues according to the metabolic needs.

Antarctic fishes show adaptive reductions in Hb content/multiplicity and erythrocyte number, which counterbalance the higher demand of energy for circulation caused by increased blood viscosity produced by subzero temperatures of sea water. Low temperatures reduce the metabolic demand for oxygen while increasing its solubility in the blood, so that more oxygen can be carried in physical solution, and less needs to be bound to Hb.

One notothenioid family (the only known adult vertebrates showing such an astonishing adaptation) has abolished Hb as oxygen carrier. The colourless blood of the "icefishes" (family Channichthyidae) lacks Hb and erythrocytes. Compensatory adaptations enhancing oxygen delivery include large gills, scaleless and highly vascularised skin, large capillary diameter, and a large increase in cardiac output and blood volume. They maintain normal metabolic function by carrying oxygen physically dissolved in the blood. Icefishes retain a small, inactive portion of adult α-globin gene(s) and no detectable β-globin gene(s) as a result of a single deletion in the ancestral channichthyid genome, which removed almost the entire notothenioid globin-gene complex. Why have Channichthyidae taken such a radical course, leaving the other families with only partial Hb reduction? The physiological role of Hb in oxygen transport in temperate and tropical fish is undisputed; however, does Hb remain vital for adequate oxygen transport in the Antarctic red-blooded families, or is it a redundant vestigial relict? The answers were found by reversibly "poisoning" Hb of the red-blooded nototheniid *Trematomus bernacchii* with carbon monoxide. This gas causes death to organisms (such as any temperate fish) whose lives depend on oxygen, because it replaces oxygen in Hb, blocking transport. However, no signs of distress, even during enforced exercise, were observed in the experimental fish *(T. bernacchii)*. The survival of *T. bernacchii* despite Hb incapacitation, leaves little doubt that, in the cold, stable environment of the Antarctic seas, routine oxygen delivery is possible also in the absence of functional Hb. Similar to icefish, red-blooded Antarctic fish can carry routinely needed oxygen dissolved in the blood.

The capacity of fish to colonise a large variety of habitats is strictly related to the molecular and functional differences encountered in their Hbs. Seven of the eight notothenioid families are red blooded. Most are sluggish bottom dwellers and show reduced Hb multiplicity, consisting of a single Hb (95%–100% of the total). Multiplicity is considered to be linked to lifestyle and environment variability; that is, in highly variable environments active fishes need a higher number of Hbs. The lifestyles of three species (active, cryopelagic *Trematomus newnesi* and *Pagothenia borchgrevinki;* and *Pleuragramma antarcticum,* a pelagic, migratory fish) are different, and their oxygen-transport systems are adjusted to each lifestyle. Multiplicity is higher (three to five functionally distinct Hbs).

Several notothenioids thrive in non-Antarctic waters, and provide important evolutionary information. Eleven out of twelve species of Bovichtidae and Pseudaphritidae, the most primitive families, live in temperate waters. *Pseudaphritis urvillii,* common in Australian rivers, has never developed cold adaptation; however, the amino-acid sequences reveal higher identity with Hbs of Antarctic notothenioids than with any temperate fish, but at the low limit of the percentage range. This argues in favour of a common origin within notothenioids, but also suggests divergence during early cooling, before the event that gave origin to AFGPs.

Some haematological parameters (high erythrocite number and Hb content) of non-Antarctic *Notothenia angustata* favour oxygen transport in a temperate environment; but Hb multiplicity and structural/functional features closely resemble those of Antarctic notothenioids. *N. angustata* appeared well before the Polar Front. However, at the end of the Miocene (5 Ma), the Polar Front moved northwards up to 39° S, the latitude of northern New Zealand, facilitating migration. The genome contains silent antifreeze genes, which can be activated by acclimation to low temperatures, indicating that—unlike *P. urvillii*—*N. angustata* was cold adapted prior to migration to temperate latitudes.

Arctic fish Hbs are increasingly becoming familiar. The benthic spotted wolffish *Anarhichas minor* (family Anarhicadidae) and three Gadidae (the benthic Arctic cod *Arctogadus glacialis,* the pelagic and migratory polar cod *Boreogadus saida,* and Atlantic cod *Gadus morhua*) all have Hb systems whose structural and functional features are remarkably different from those of the phyletically unrelated Antarctic species. They all have three Hbs, probably in response to the need to optimally adapt to the Arctic waters.

Example 3: Molecular Evolution

Investigation of individual genes using molecular methods is a powerful new aid in evolutionary biology and ecology. Molecular phylogeny is also essential for studying evolution, using protein (e.g., Hb) and nucleic-acid sequences, and chromosome change.

The amino-acid sequences of Hbs of polar and temperate fish have been analysed by means of computer programmes. A phylogenetic tree shows that *P. urvillii* and *Cottoperca gobio* (family Bovichtidae) diverged before the formation of the Polar Front, and that temperate *N. angustata* Hb groups with Antarctic nototheniids, supporting the hypothesis that it was cold adapted prior to migration.

The most important indication from molecular phylogeny is the divergence of Arctic Hbs from notothenioid Hbs. The constant physicochemical conditions of the Antarctic seas are matched by clear grouping, whereas Arctic Hbs occupy scattered positions between Antarctic and temperate groups, in keeping with the variability in the latitudinal gradient in which the Arctic species live, and their often active, pelagic, and migratory lifestyles. Distinct evolutionary pathways of the respiratory system have been driven by the need to adapt to different environmental constraints. It is not surprising that the Arctic ichthyofauna, which is not dominated by a single, taxonomically uniform group, has high phylogenetic diversity.

Future Perspectives

Antarctica is not widely considered one of the notable evolutionary sites (e.g., the East African Great Lakes, Lake Baikal, the Galapagos), perhaps because research has emphasised aspects of extreme biology rather than unifying principles of evolutionary biology. In order to survive, Antarctic organisms had to overcome strong constraints. Uniquely adapted to an extreme, isolated, and constant environment, the biota is highly susceptible to changes. In a world attuned to changes in global climate and to threats of loss of biodiversity and depletion of fisheries, the study of adaptations will provide invaluable clues to the organism response to environmental changes, particularly human induced (global warming and increased UV due to ozone depletion). Antarctic fish have been and will continue to be a key element in investigating and probably establishing the Southern Ocean as a centre of evolution.

Climate change can affect every aspect of an organism's biology, from cellular physiology and biochemistry to food web and habitat. Coping with changes in enzyme activity and DNA damage, organisms evolve phenotypic responses (occurring within the lifetime and including enzyme activation/inhibition and induction/repression of gene regulation), and genotypic responses (occurring over a much longer timescale through selection of beneficial mutations). Arising through errors in DNA replication, genotypic responses may be accelerated by increased UV radiation, which places additional demands on DNA repair, giving greater opportunity for errors.

In summary, it is necessary to study evolutionary processes in response to selection pressures associated with global change (in collaboration with the physical sciences community), evolutionary response across the molecule-to-species range of organisation (utilising molecular and biochemical techniques integrated with taxonomy, physiology, ecology, ethology, and morphology), changes in the physical environment that have driven evolution over geological time (in collaboration with the palaeosciences community), and statistical and molecular genetic approaches to analyse the biodiversity of the modern polar fauna and flora. Antarctic/Arctic comparisons are important, because the differences in the two polar environments are differently reflected in global climate changes. Accordingly, studies on their ecosystems are likely to provide answers to different questions, often complementary to one another.

The role of the polar habitats in global climate changes has awakened great interest for the evolutionary biology of its organisms. Great difficulties are to be expected in tackling the topic of evolution. However, in the fertile scenario of polar biological research, this is an exciting challenge.

FISHERIES AND MANAGEMENT

Interest in fishing in the Antarctic was first shown by the Soviet Union in the early 1960s, and by 1966/1967 the USSR had established a fishery for the marbled rockcod, *Notothenia rossii,* around the sub-Antarctic island of South Georgia. This fishery peaked in 1969/1970 with a reported catch of 400,000 tonnes, but by the 1971/1972 split year the fishery was severely depleted. In 1971 the fleet turned its attention to a new sub-Antarctic fishing ground, at Kerguelen Islands in the Indian Ocean. The fishery for rockcod lasted longer at Kerguelen than at South Georgia, but by the 1980s this stock too had been severely depleted.

Fisheries for a second species, mackerel icefish *(Champsocephalus gunnari),* also developed in the early 1970s, at both Kerguelen and South Georgia. Catches were highly variable from year to year, and icefish stocks declined severely in the 1990s, for reasons that seem not to be due to fishing. At South Georgia there has been a sufficient recovery of icefish for a small, tightly regulated fishery to take place since the late 1990s. In the mid-1990s a fishery for icefish developed at Heard Island and McDonald Islands, south of Kerguelen but on the same plateau. In 2003, Australia, Chile, the Republic of Korea, and the UK fished for icefish.

In addition to the two primary species, rockcod and icefish, fisheries in the 1970s expanded to take other species—*Notothenia squamifrons, Patagonotothen guntheri, Pseudochynichthys georgianus, Chaenocephalus aceratus,* and *Chaenodraco wilsoni*—from South Georgia and Kerguelen, and from other areas such as the Antarctic peninsula, the South Orkneys, and the Indian Ocean sector close to the continent. None of these areas or species proved to be sufficiently productive to sustain major fisheries and most are now closed. The Soviet Union was joined by other countries, so that by 1977/1978, Bulgaria, Chile, the German Democratic Republic, Japan, and Poland were also catching fish in Antarctic waters.

The next major fishery to develop was for krill *(Euphausia superba)*. The great abundance of Antarctic krill, the primary food of the baleen whales, had been known about since the early twentieth century. Part of the Soviet Union's exploration from the early 1960s was directed at finding methods of catching and processing krill, but catches remained small until a permanent krill fishery was established in the Southern Ocean in 1972. Full-scale operations were underway in 1973 when a Japanese fleet also started fishing. Both nations were producing krill products for human consumption, as whole canned tails, whole frozen krill, or krill paste. Catches of krill by the Soviet fleet in Antarctic waters increased rapidly in the late 1970s, and a number of additional countries also started fishing, notably Poland, Chile, and the Republic of Korea. Catches of krill reached a peak of 528,201 tonnes in 1981/1982 and have since declined. Initially the decline was due to processing difficulties, since krill have high levels of fluoride in their shells, and most krill caught today are processed either into fish-meal principally as an aquaculture feed or frozen for use as bait in sport fishing.

Early Soviet research had identified a number of areas of high productivity and krill abundance around Antarctica. However, only the three areas in the South Atlantic (the South Shetlands, South Orkneys, and South Georgia) have proven to have krill in swarms dense enough and in predictable areas for sufficient periods of the year to make fishing economic. The final decline in krill catches came with the breakup of the Soviet Union. In 1989/1990 the Soviet Union took 326,000 tonnes of krill, and by 1993/1994 this had dropped to 13,000 tonnes, taken by ex-Soviet vessels now flagged to Ukraine. Current fishing nations are Japan, Korea, Poland, Ukraine, and the US.

In the 1990s a new type of fishery developed. Fishing had previously been carried out using trawl nets, either pulled along the sea floor (for rockcod and icefish) or in mid-water (for krill and sometimes for icefish). The new method used long lines with baited hooks attached, set on the sea floor to catch Patagonian toothfish, *Dissostichus eleginoides*. These fish are large and live in deep water, from 500 to 2000 m depth. They had been largely inaccessible to trawls, although some had been reported as by-catch in the fisheries for icefish during the 1980s. Once again fishing started around South Georgia and Kerguelen, but by the late 1990s this species was being caught around Prince Edward and Marion, Crozet, and Heard and McDonald Islands. A longline fishery for a closely related species, Antarctic toothfish, *Dissostichus mawsoni,* also started in the late 1990s in the Ross Sea. With the development of toothfish fisheries in the 1990s the number of fishing states rapidly increased. In 2003, Australia, Chile, France, Japan, New Zealand, Republic of Korea, Russian Federation, South Africa, Spain, the UK, and Uruguay all fished for toothfish.

Toothfish turned out to be very good quality fish, achieving a high market price. This high value, and the remote location of most of the fisheries, attracted large numbers of unlicensed fishing vessels. In the early 1990s, illegal, unregulated, and unreported (IUU) fishing, as it is called, took place around South Georgia, but from 1996 most IUU vessels moved to the Indian Ocean, fishing around Prince Edward and Marion, Crozet, Kerguelen, and Heard and McDonald islands.

Currently the only substantial fisheries in the Antarctic are Patagonian toothfish around several sub-Antarctic islands; Antarctic toothfish in the Ross Sea; mackerel icefish at South Georgia and Heard and McDonald Islands; and krill around the Antarctic Peninsula, the South Orkney Islands, and South Georgia.

When fishing started, in the late 1960s, there was very little legislation governing the areas where fishing took place in the Antarctic. In the early 1980s, two important international legislative instruments were agreed to that were to change this. In 1982 the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) came into force, with a remit to manage fishing in the Antarctic. Also in 1982 the United Nations Convention on the Law of the Sea (UNCLOS) was signed, with wide-ranging implications for fisheries worldwide. By 1992, when conservation measures for all krill stocks were agreed to by CCAMLR, all Antarctic fisheries were controlled.

CCAMLR's boundaries were defined to follow the Antarctic Convergence, where cold Antarctic water meets warmer northern water, because it is roughly the limit of Antarctic and sub-Antarctic ecosystems. Within this area several sub-Antarctic islands are under state sovereignty—South Georgia (UK), Bouvet Island (Norway), Prince Edward and Marion Islands (South Africa), Crozet and Kerguelen Islands (France), and Heard and McDonald Islands (Australia). Under the agreement of UNCLOS, these states can, and do, control activities within 200 nm of the islands—their EEZ or maritime zone. All these islands are north of 60° S. South of 60° S, Antarctic Treaty states have agreed to withhold from any activities that would exert their claims to territorial sovereignty, and since this includes the enforcement of 200-nm maritime zones, none of the waters south of 60° S are under state sovereignty. All waters outside areas of state sovereignty (the vast majority of Antarctic waters both north and south of 60° S) are termed "high seas waters," and come under the exclusive competence of CCAMLR with respect to fishing except with respect to whales and seals, which have their own conventions and are excluded from CCAMLR with respect to harvesting.

Although states have the right to deviate from the advice of CCAMLR within their sovereign sub-Antarctic island waters, in practice they generally implement CCAMLR decisions and recommendations. On the high seas within CCAMLR waters, CCAMLR members have the obligation to control the activities of their vessels in compliance with CCAMLR conservation measures, and the right to inspect vessels of another member. Nonparties (states that have not acceded to the convention and are not members of CCAMLR) are not bound by the provisions of CCAMLR. Nevertheless, although they have a legal right to fish, it is a feature of UNCLOS and later agreements, such as the UN Agreement on Conservation and Management of Straddling Fish Stocks and Highly Migratory Fish Stocks, that they should not do so if this undermines the conservation activities of CCAMLR.

CCAMLR meets every October in Hobart, Australia—the location of the CCAMLR Secretariat—to agree on measures that should be implemented to conserve fish stocks. These may range from stock-specific measures, such as setting of catch limits, closed areas, and mesh sizes, to global measures, such as the toothfish Catch Document Scheme and lists of IUU vessels. The primary decision-making body, the Commission, is advised by a Scientific Committee and a Standing Committee on Implementation and Compliance (SCIC). These committees are themselves advised by specialist groups. The Scientific Committee receives advice on appropriate catch levels and other management measures, for finfish, crab, and squid, from the Fish Stock Assessment Working Group (WG-FSA). The Working Group on Ecosystem Monitoring and Management (WG-EMM) provides advice on krill catch levels and the state of the Southern Ocean ecosystem. SCIC analyses compliance by fishing vessels and the status of IUU fishing.

CCAMLR takes an "ecosystem approach" to managing all its resources—fish, squid, crabs, or krill. Fishing is undertaken in such a manner that it minimises the impact on nontarget species (the target species is the fish that the fisherman is looking for). For instance, albatross and petrels may be caught on longline hooks and drowned, but in CCAMLR, mitigation measures have been in place since the early 1990s that have reduced the number of birds killed in most Antarctic fisheries to negligible levels. There are limits on the quantity of nontarget species of fish and other animals that can be caught in all CCAMLR fisheries, to minimise the impact of fisheries on their populations.

The state of Antarctic fisheries is assessed using a variety of models, but in all cases catch limits are set to minimise the risk that the size of the stock will decrease to levels where the production of young fish might be impaired. Furthermore, depending on the place that a target species has within the Antarctic ecosystem, the fishery is managed so that there are sufficient animals left after fishing to supply predators with the food they need to survive. For instance, very many animals depend on krill—whales, birds, seals, fish, squid—so catch limits are set sufficiently conservatively to ensure that even after fishing, 75% of the original stock is still there for predators to eat. Toothfish are higher up the food chain, and fewer animals depend on them, so the appropriate level chosen by CCAMLR is to preserve 50% of the original stock.

Even with these conservative catch limits, the krill stock is so large that the catch limit is also large. The latest survey in the Atlantic (in 2000) showed that there were about 44 million tonnes of krill, and the relevant catch limit for the Atlantic is about 4 million tonnes. The catch limit for the Indian Ocean is 1 million tonnes. These figures are far in excess of the current catches of krill. Nevertheless, CCAMLR has a specific responsibility with respect to krill because it is such a key component of the Antarctic ecosystem. It has therefore developed the CCAMLR Ecosystem Monitoring Programme (CEMP), which is set up to monitor krill predators, to detect changes in their annual performance, and to determine whether these changes are due to natural causes or to the ecosystem effects of fishing. Up to fifteen indicators of performance are monitored for seven bird and seal species at sixteen sites around the Antarctic. The indicators range from small scale (foraging behaviour) to large scale (population size).

In an effort to combat IUU fishing, CCAMLR has put in place a Catch Document Scheme, in which each consignment of toothfish must be accompanied by a document stating that the toothfish were caught legally, and where and when they were caught, which stays with the consignment from the point of landing to the final point of import to a wholesaler. These documents are not available to IUU operators. CCAMLR has also developed a "black list" of vessels known to be involved in IUU fishing. Members with coastal state jurisdiction around sub-Antarctic islands have arrested, prosecuted, and sometimes sunk a large number of IUU vessels over the last 10 years.

CCAMLR also closely controls the development of new and exploratory fisheries, so that sufficient information is acquired about them before they are allowed to become large. The fishery for toothfish in the Ross Sea is currently an exploratory fishery. There are also exploratory fisheries for crabs and squid at South Georgia, but there is relatively little commercial interest in these at the present.

CCAMLR has a system of international scientific observation in which scientists from one member state can observe the fishing activities and measurements from the catch of another member. The data generated through this system are essential for the management of the fishery. All fishing vessels, except those involved in the krill fishery, must carry observers and operate a satellite monitoring system. Many fishing vessels also assist with scientific research.

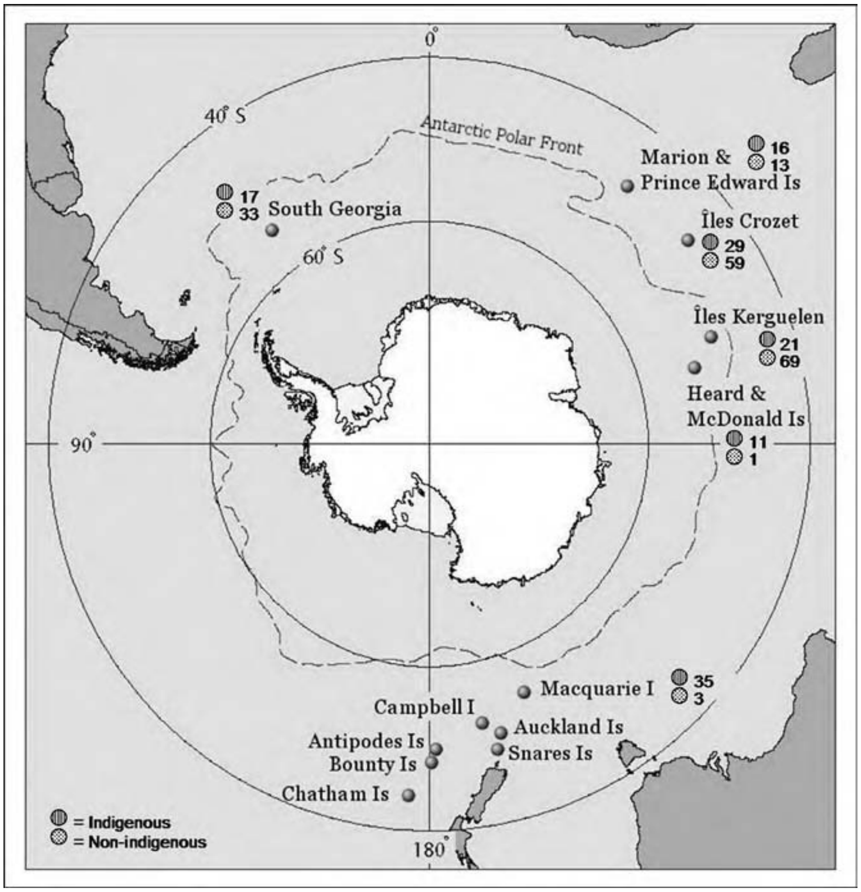
FLOWERING PLANTS

The history of flowering plants (angiosperms) in Antarctica is one of interaction between evolution, plate tectonics, long distance dispersal, and climate change. Well before the evolution of angiosperms, Antarctica was part of the supercontinent Gondwana, along with the current Southern Hemisphere continents and other land masses such as New Zealand, Madagascar, and India. Angiosperms had probably evolved in equatorial regions before the initiation of the Gondwanan breakup, some 180 Ma. Rapid expansion of angiosperms, however, corresponded with major phases in Gondwana's fragmentation. Some have suggested that intra-Gondwanan rift systems and newly created sea margins may have acted as corridors for dispersal of early angiosperms. Climate at the time was moist and cool and the high-latitude areas experienced extreme seasonal fluctuations in day length.

The interconnectedness or nearness of Gondwanan landmasses during the Cretaceous (144–65 Ma) coincided with evolutionary diversification in birds,



The number of native and nonnative angiosperm species recorded across the Antarctic region. (Indigenous numbers on top, nonindigenous numbers on bottom.) (Image source: The Australian Antarctic Division 2005.)

mammals, and angiosperms. The central position of Antarctica meant that it formed either the centre of, or the conduit for radiation of, many angiosperm lineages, including many fundamentally important Southern Hemisphere plant groups, such as the Myrtaceae and Proteaceae families and the iconic Southern Hemisphere genus *Nothofagus*. Gondwanan linkages through *Nothofagus* can be traced through extant species in South America and Australia, as well as through fossil remains in Antarctica.

The major angiosperm taxonomic order, Poales, appears to have evolved in what is now South America. Two major lineages developed; the sedges and rushes group (including Cyperaceae and Juncaceae), originating in west Gondwana (either South America or South Africa), and the grass group (Poaceae), originating in east Gondwana (Australia). This illustrates a significant point; as both groups are widely dispersed in all Gondwanan land masses today, but Africa had rifted apart early during angiosperm evolutionary time, over-ocean dispersal must have been an important biogeographic process.

The Cretaceous Antarctic environment included warm coastal areas, cooler interiors, and high carbon dioxide levels. To cope with the low angle of light, forests consisted of widely spaced, conical trees with vertically oriented leaves. Other more open vegetation types included coastal heaths, grasslands, and, with elevation, tundra and alpine zones. Fossil evidence from the Antarctic Peninsula indicates vegetation similar to present-day, cool Southern Hemisphere forests. Only plants adapted to winter darkness survived. For perennial plants, evolution selected for taxa in which carbon gain through summer photosynthesis was greater than carbon loss through respiration during winter. Some Southern Hemisphere extant tree species still possess the ability to survive long periods of darkness.

As India moved northward (132–43 Ma), it left a trail of underwater Gondwanan remnants, around which ocean sediments accumulated. This in association with volcanic activity created the mainly marine Kerguelen Plateau. The mid- to late Tertiary (25–5 Ma) saw coastal scrub-type vegetation, with ferns, grasses, and daisies on Heard Island as well as conifers on Îles Kerguelen.

By the middle of the Tertiary (38 Ma), all southern land masses had rifted apart from Antarctica. Once isolated from common ancestry, their angiosperm floras began to diverge towards unique floras. A circumpolar current flowing easterly around the Southern Ocean established between 35 and 28 Ma and Antarctica began to cool. With ice formation, habitats were lost, the treeline lowered, and ultimately, by 2.5 Ma, ice sheets had extended to the edge of the continental shelf of Antarctica and angiosperm-dominated plant communities had died out. Most plant species on the Kerguelen Plateau islands were also extirpated by glaciation; however, the regional endemic, the Kerguelen cabbage, *Pringlea antiscorbutica,* and the Kerguelen endemic cushion plant *Lyallia kerguelensis* may have survived in ice-free refugia.

Over the last one million years, the Earth has undergone cyclical cooling and warming. During this time, most sub-Antarctic islands were formed and colonized by plants through long distance, over-ocean dispersal. Today, sub-Antarctic islands experience cool, wet, and windy conditions and are clothed in treeless tundra. Major plant communities include tussock grasslands, herbfields, mires, and fellfields of scattered cushion plants and mosses. Long summer days and nutrient enrichment from marine animals provide conditions for high productivity on protected coastal areas. Fossil evidence from peats that accumulate on sub-Antarctic islands indicates that modern plant communities have been present for at least the last 10,000 years.

Currently there have been only fifty-five native angiosperm species from seventeen families found on the sub-Antarctic islands, two species from maritime Antarctica, and none from continental Antarctica. Important genera such as *Poa, Luzula,* and *Agrostis* also occur in Arctic communities. Some species have linkages with southern South America, and a considerable proportion of Macquarie Island's flora has affinities with the cool, temperate Campbell and Auckland islands, as well as New Zealand. The sub-Antarctic islands appear to be influenced by the same range of factors that influence ecology and biogeography elsewhere in the world. Vegetation complexity decreases with decreasing ambient temperatures, and variation in angiosperm flora size has been explained by island size, climate, and distance from neighbours. Similar reasons have been used to explain why only two species, a small grass, *Deschampsia antarctica,* and a small cushion plant, *Colobanthus quitensis,* have successfully colonized areas in the maritime Antarctic.

Two major issues concern Antarctic flora in the twenty-first century: global climate change, and the impact of nonindigenous (alien) invasive species introduced through human activities. The recent local colonization and rapid expansion of populations along the Antarctic Peninsula of *D. antarctica* and *C. quitensis* have been attributed to substantial warming in the region. Elsewhere, current research is documenting changes in the relative competitive ability of species due to different inherent responses to environmental change.

One hundred eight nonindigenous species from twelve families have been recorded from the Antarctic region. The impact of these species has been either direct or indirect and includes substantial loss of local biodiversity and changes to ecosystem processes. Climate change has been predicted to exacerbate the impact of nonindigenous species in the region due to more positive responses to changing environmental conditions compared with native species.

FOOD WEB, FRESHWATER

The term food web describes the interrelationships between organisms living in an ecosystem. In lakes, there are two food webs that are linked in terms of the flow of materials like essential nutrients (phosphorus and nitrogen) required for photosynthesis and carbon (a basic biological building block). These are the bottom community, known as the benthos, and the organisms that inhabit the water column, termed the plankton. The ice-free areas of Antarctica, mostly situated on its margins, carry an extraordinary array of lakes that range from freshwater to hypersaline (as much as six times seawater).

Antarctic lakes are usually extremely unproductive due to their low temperatures, low nutrient inputs from the surrounding land, and ice cover, which limit the amount of light energy that can enter the water column to drive the fundamental biological process of photosynthesis. Only the most physiologically robust organisms can survive under these conditions. Microorganisms (bacteria, algae, and single-celled creatures [the Protozoa]) are extremely adept at living in difficult environments and consequently, continental Antarctic lakes are dominated by communities of microorganisms, with few animals and no fish. The food webs are very simple, and there is low species diversity. The radiant energy of the sun is captured by the phytoplankton, which is mainly composed of flagellated protozoa that contain photosynthetic pigments (e.g., cryptophytes, *Pyraminmonas, Chlamydomonas*). In some lakes, photosynthesis is also carried out by ciliated protozoa (e.g., *Mesodinium rubrum, Strombidium*) that contain either symbiotic algae, or plant-pigment-containing organelles called plastids, that they sequester from their algal or flagellate prey and use for photosynthesis. During the process of photosynthesis, the photosynthetic organisms (the phytoplankton) exude some of the material they manufacture into the surrounding water as dissolved organic carbon. This provides a food substrate for the bacteria, which grow, and in turn are fed upon by colourless flagellated and ciliated protozoa. Many of the photosynthetic flagellates also feed on bacteria as a means of augmenting the energy they derive from photosynthesis, especially when the light levels are very low. This is called mixotrophy or mixed nutrition, because it involves a combination of photosynthesis and heterotrophy (animal-like nutrition). In the most southerly, extreme lakes of the McMurdo Dry Valleys, mixotrophic flagellates, particularly cryptophytes, are very common and there is evidence to suggest that during the winter they feed on bacteria and become progressively more dependent on photosynthesis towards summer. Thus one of the keys to survival is nutritional versatility, and mixotrophy is common in protozoan phytoplankton across all Antarctic lakes, but is more predominant in the most extreme systems.

The animals of Antarctic lake plankton are few and extremely adaptable. In the marine derived saline lakes of the Vestfold Hills, for example, the marine microcrustacean (a copepod) *Paralabidocera antarctica* is found feeding on phytoplankton and protozoan plankton. It is the only animal survivor from the seawater that was trapped when the land rose up (isostatic uplift), forming the lakes after the last glaciation. The coastal freshwater and slightly brackish lakes contain a single water flea, *Daphniopsis studeri* (a microcrustacean), that is endemic to Antarctica and its eastern sub-Antarctic islands. These crustaceans appear to remain active all year round, unlike their lower-latitude relatives, which enter resting stages during winter. The Antarctic summer is too short to allow growth from a resting egg to maturity, so these animals have to be ready to reproduce as soon as the summer arrives, enabling their young to grow and build up fat reserves to survive the following winter. Other animals found in the plankton are microscopic rotifers that feed on bacteria, algae, and flagellates. In the extreme Dry Valley lakes, rotifers (species of *Philodina*) are the only animals encountered in the plankton in low numbers. The planktonic animals have no predators, so despite their slow life cycles and low numbers of offspring they can survive in these extremely cold inhospitable waters.

The benthic communities of Antarctic lakes are usually associated with so-called algal mats. These are made up from filamentous Cyanobacteria (blue-green algae), diatoms (algae), and flagellated photosynthetic protozoa. These mats offer a much richer environment than the plankton and provide a habitat for rotifers and many more species of ciliated protozoan, for example, species of *Euplotes, Metopus, Stylonychia,* and microscopic nematode worms. In the coastal freshwater lakes, *Daphniopsis* appears to move between the plankton and the benthic mats to feed. While no crustaceans have ever been recorded in the plankton of the Dry Valley lakes, a copepod was once found in a benthic sample.

Viruses have been described in Antarctic lakes and the marine environment. Viruses are not able to reproduce themselves but must parasitise an animal or plant or a bacterial cell and make that host cell produce more viruses. The virus may continue living in the host cell without causing its destruction, and is passed on during the reproductive cycle of the host to its progeny. Alternatively the virus may cause the destruction of the host cell and the liberation of viruses into the water. Viruses play an important role in aquatic food webs because they parasitise and destroy bacteria and phytoplankton cells. This has the effect of short-circuiting the carbon cycle by destroying these cells before they can be eaten by another organism. Along with bacteria, larger viruses are exploited as food by colourless flagellates. In addition, viruses play a role in transferring genetic material between populations of bacteria in aquatic environments. Viruses are very abundant in Antarctic lakes and their many roles are currently under investigation.

The microorganisms of Antarctica's lakes have attracted considerable attention from the biotechnology industry because they contain bioactive molecules such as low-temperatures enzymes, pharmaceuticals, and antifreeze proteins. A single drop of water is sufficient to set up cultures for such bio-prospecting research, allowing the biological resources of Antarctic lakes to be exploited with virtually no environmental impact.

FOOD WEB, MARINE

Food webs are topological descriptions of a given community and are typically based on system-specific knowledge of feeding relationships. Only when many interrelated feeding relationships can be quantified to build up detailed food webs can we begin to understand ecosystems. "Who eats whom" appears to be the most central organizing concept in ecology. Therefore, assuming that the emergent behaviour of an ecosystem is, at least partly, dependent on the properties and behaviour of the entities it is composed of, food web characterization is required as an initial step in understanding an ecosystem.

The marine Antarctic ecosystem is taxonomically diverse, structurally complex, and quite variable in time and space. It is composed of interconnected, functionally distinct hydrographic and biogeochemical subsystems, including the open ocean, frontal regions, the shelf-slope waters, the sea ice, and marginal ice zones. The major physical determinant of spatial and temporal changes in the structure and functioning of the marine ecosystem is the annual advance and retreat of the sea ice. The seasonal timing of these events affects life histories of species at every trophic level. However, present knowledge of trophic linkages and energy flow patterns in Antarctic marine communities and ecosystems is still fragmentary. Due to (1) the openness of marine systems and (2) the orders of magnitude in size across the species in marine systems (diatoms vs. whales), the structure of marine food webs is different from that of terrestrial or freshwater ecosystems. Early impressions of the marine Antarctic were seemingly simple food chains leading from phytoplankton to krill *(Euphausia superba)* and further to whales (e.g., minke, *Balaenoptera acutorostrata*). But the system, consisting of many subsystems (e.g., the pelagic microbial loop, nanophytoplankton and picophytoplankton communities, sea-ice communities, and extremely diverse benthic communities on the shelf and slope), is much more complex. Moreover, in the Antarctic, the number of species with extremely numerous feeding links increases the complexity of the Antarctic marine food web. Due to its complexity, the identification of the food web structure or even the construction of a balanced trophic model is a challenging task.

Given the complexity of the system, there is need for a critical evaluation of the tools used to analyze food-web structure. A number of different techniques have been proven useful to provide information on trophic relationships at a variety of organizational scales. These approaches include gut-content analysis, feeding experiments, the use of fatty-acid biomarkers, and stable isotope tracers.

The isotope approach can help to disentangle food web processes at two different scales. Organic substances and living organisms in an ecosystem possess specific levels of stable isotope ratios because a consumer's tissue reflects the composition of its diet. Hence, $\delta^{13}C$ and $\delta^{15}N$ signatures serve as proxies of the trophic distance of an organism from the primary food source of the corresponding food chain. $\delta^{13}C$ signatures are commonly used as carbon source tracers, whereas $\delta^{15}N$ values are a helpful tool for detecting the trophic position and therefore the trophic hierarchy of the system. The stable isotope analysis of the food-web structure of the Antarctic shelf system has revealed that the benthic part of the food web is more complex than the pelagic one.

Pelagic consumers of the Antarctic are mainly dominated by copepods, krill, squids, and pelagic nototheniid fish species (e.g., *Pleuragramma antarcticum*). The benthic part of the food web is more complex, which is due to the high taxon richness and high diversity of feeding types (e.g., some groups, such as the echinoids, feed at more than one trophic level). Benthic fish and invertebrate scavenger–predators, like the nemertean *Parborlasia corrugatus,* are at the top of the food chain. Interestingly, seals, which are supposed to be among the top predators, occupy intermediate trophic levels only. The distance from phytoplankton to pelagic top predators (seals) is about 3.8 trophic levels, whereas the distance to benthic top predators is about 4.6 trophic levels.

Possible explanations for such complexity involve dimensionality of habitats (i.e., three-dimensional habitats, like the Antarctic benthos, may support longer chains than two-dimensional habitats) and species richness (i.e., chains, should be longer in communities supporting larger numbers of species).

Food-web structure and strength of trophic linkages within the functional groups determine the communities' response to and their ability to recover from disturbances. For example, environmental changes apparently affect Antarctic krill, *Euphausia superba,* and its predators. A decline in sea-ice extent at the Antarctic Peninsula has lead to a krill-stock decline and therefore affects associated predators like penguins and whales due to the given mismatch in food supply.

However, trophic decoupling (mismatch in food supply) will have critical consequences in Antarctic marine systems, especially if key species are affected. Therefore, understanding of food-web structure and of ecosystem functioning is necessary for a more efficient approach to resource management and endangered species conservation.

FOSSILS, INVERTEBRATE

Antarctica has not always been a frozen wasteland. Over geological time the continent, as part of Gondwana, has moved across the globe by plate-tectonic processes, in and out of climatic zones from tropical to polar, and this is reflected in the fossil record, preserved in the sedimentary rocks. In Antarctica, invertebrate fossils are known from the Lower Cambrian onwards and from every geological epoch other than the Silurian, for which no sedimentary rocks have yet been identified (Cooper and Shergold 1991; Crame 1989; Thomson 1991). For the most part they are of marine origin, but there are also rare occurrences of freshwater and terrestrial species. See the table for a simple distribution of invertebrate fossils in Antarctica.

Fauna of Early to Late Cambrian age occur in sedimentary rock sequences scattered through the Transantarctic and Ellsworth mountains. Limestones contain very diverse and varied trilobite faunas, together with conodonts (the jaw apparatus of some tiny marine animal), early molluscs, and brachiopods. The extinct sponge-like archaeocyaths are present in some Early and Middle Cambrian fauna and, more remarkably, in Upper Cambrian limestone of the Ellsworth Mountains (Webers et al. 1992). The Cambrian sequences were deposited in shallow-water environments, and the presence of limestone suggests both warm water and a much lower latitude than the present day. In the main, the trilobite faunas show the closest affinities with those of Australia and the Australo-Sinian Province.

Rocks of Ordovician age are poorly represented but fossils of this age are known from two areas. In the Robertson Bay Group of northern Victoria Land, limestone blocks within a shale–sandstone-conglomerate sequence contain a few trilobites and varied assemblages of conodonts of the earliest Ordovician age. Whereas those fossils have been reworked, trace fossils and body impressions of possible phyllocarid crustaceans in fine- to medium-grained sandstones of the shallow-water Blaiklock Glacier Group, Shackleton Range, represent an *in situ* assemblage (Thomson and Weber 1999).

Through the Transantarctic and Ellsworth mountains is an extensive and thick sequence of mainly sandstone and conglomeratic rocks, known as the Beacon Supergroup. Ranging in age from Devonian to Triassic, it encompasses rocks that record environmental changes from marine (Devonian) to glacial marine and terrestrial (Carboniferous) to ice-free and progressively warmer terrestrial conditions (Permian and Triassic). Devonian marine faunas occurring in the Ellsworth Mountains and Horlick Range include

Simplified Distribution of Antarctic Invertebrate Fossils Through Time and by Location

Geologic timescale is after Palmer and Geissman (1999).
*Age in millions of years of the boundary picks for the base of the subdivision.
†Shaded subdivisions indicate generalised occurrences of fossils of early (E), middle (M), or late (L) age and do not imply that a complete succession is present.

brachiopods, bryozoans, molluscs, and trilobites, which show faunal affinities with those of the Falkland Islands and South Africa. No invertebrate fossils are known from the Carboniferous of the Transantarctic Mountains, where the rocks record an extensive glaciation that covered not only Antarctica, but also large areas of South America, southern Africa, India, and Australia. Whereas the Permian rocks are more famous for their flora, there are isolated records of insects and, more commonly, conchostracans (bivalved ‘‘shrimp’’) and even freshwater bivalves. The Triassic sequences of the Transantarctic Mountains are of terrestrial origin and notable for their vertebrate fauna; no records of any invertebrate fossils have yet been published from them.

By contrast, the Mount King Formation of eastern Alexander Island contains limited but varied fauna of the mid-Carboniferous to possible earliest Permian age. These include bryozoans, brachiopods, crinoids, and a variety of molluscs (Kelley et al. 2001). It is possible that the enclosing rocks are exotic and became attached to Antarctica by the process of accretion at the proto-Pacific margin; faunal affinities are with Argentina and eastern Australia. Likewise, we have to look to the Antarctic Peninsula for the only evidence of Triassic invertebrate fauna in

Antarctica. Chert from within the Greywacke Shale Formation of the South Orkney Islands contains Triassic radiolarians and the Legoupil Formation of the northwestern Antarctic Peninsula, a bivalve fauna of New Zealand and Japanese affinity.

Jurassic strata are widespread in the Antarctic Peninsula. Early and Middle Jurassic sequences are patchy, but those of the Late Jurassic are more complete. All marine fauna are dominated by molluscs, notably ammonites. Localised Early Jurassic fauna in Alexander Island come from an accretionary complex and could be exotic; all other fauna are *in situ*. Freshwater plant-bearing shales at the northern Antarctic Peninsula contain bivalves and rare beetle remains. Middle Jurassic fauna occur in the South Shetland Islands and eastern Ellsworth Land, and Late Jurassic fauna are both varied (dominated by ammonites, belemnites, and bivalves, but also with brachiopods, echinoderms, and crustaceans) and widespread; faunal affinities are generally with those of Patagonia, New Zealand, Indonesia, and the Himalayan region.

The macrofauna of the Cretaceous are also mollusc dominated and show a mixture of regional and more cosmopolitan affinities. Fossils are locally numerous and varied, including corals, bryozoans, brachiopods, molluscs, echinoderms, crustaceans, and serpulid worms. By piecing together the fossil records from Alexander Island, South Shetland Islands, and James Ross Island area, an almost "complete" Cretaceous faunal succession has emerged. Preservation of many Late Cretaceous species is excellent (e.g., ammonites [Macellari 1986] and crustaceans [Feldmann et al. 1993]). Foraminifera (microfossils) are preserved for the first time in the Antarctic fossil record in both Cretaceous and Tertiary rocks.

Outcrops of Cenozoic (Tertiary) marine sedimentary rocks are of very restricted occurrence, being limited mainly to King George and Seymour Islands in the northern Antarctic Peninsula region, but this is outweighed by the variety and quality of preservation of the fossils (Gazdzicki 1987; Stillwell and Zinsmeister 1992). Ammonites were extinct but the dominant forms are still molluscs, with gastropods appearing in large numbers for the first time. The fauna as a whole are even more varied, with corals, bryozoans, brachiopods, echinoderms, and crustaceans, locally in abundance. Although there are some similarities with fauna from New Zealand and South America, the fauna generally reflect the isolation of Antarctica. Fossiliferous erratics in McMurdo Sound indicate that Tertiary sequences may be present there somewhere beneath the ice.

Quaternary fossils, mainly bivalves, are even more scattered but may be found almost anywhere around Antarctica where there are raised beach deposits. However, a remarkable find of molluscs, bryozoans, and serpulid worms in a borehole off Cape Roberts (Taviani et al. 1998) suggests that more discoveries await. But perhaps the most exciting discovery would be that of fossiliferous Silurian sedimentary rocks and, even more, that of graptolites, a group unknown from Antarctica.

FOSSILS, PLANT

Although Antarctica is now a land of snow and ice, for most of its past it was covered in lush vegetation. Forests thrived on the continent, even though it was situated over the South Pole. The fossilised remains of this vegetation are now preserved as permineralised logs and tree stumps, as impressions of leaves and flowers, and as microscopic pollen preserved in the rock strata. Using these plant fossils, it is possible to reconstruct the composition of these ancient forests and decipher the climate signal stored in them to understand how Antarctica's climate has changed over millions of years.

The oldest fossil plants in Antarctica are of Permian age (~250 million years old) from a sequence of rocks called the Beacon Supergroup in the Transantarctic Mountains. The strata are composed of sandstones (formerly sand that was once deposited in river beds), and coal seams that originated as peat swamps. Fossil tree stumps can be found in their original growth positions within coal seams, along with tree trunks and leaf imprints. Large oval fossil leaves called *Glossopteris* are very common, representing a type of tree that is now extinct. *Glossopteris* leaves are famous Antarctic fossils, since Scott and his party collected samples from the Beardmore Glacier region during their ill-fated trip to the South Pole. The leaves are also found in South America, southern Africa, and Australia, and are important evidence that these lands were once joined together as the great southern continent of Gondwana.

Evidence from the rocks indicates that *Glossopteris* trees were well adapted to living in cool wet climates that prevailed in Antarctica in the Late Permian, after the melting of the great Gondwanan ice sheets. However, by the end of the Permian (~245 Ma), Antarctic climates had warmed up and *Glossopteris* become extinct, and in the following Triassic period the vegetation was dominated by plants with thick waxy leaves that could tolerate dry conditions. The fern *Dicroidium* was especially common in Antarctica at this time.

Forests continued to cover Antarctica in the Jurassic, but as Gondwana broke up about 180 Ma, volcanic eruptions spewed lava over the land surface, trapping the trees in floods of lava. The vegetation survived, and until about 100 Ma, a simple flora of conifer trees, ferns, and the cycad-like fossils, called bennetites, thrived in a warm climate. One of the first significant fossil plant localities discovered in Antarctica is the Early-Middle Jurassic Mount Flora fossil assemblage, near Hope Bay at the tip of the Antarctic Peninsula. It was discovered by geologist Johann Gunnar Andersson during the Swedish South Polar Expedition (1901–1904) and remains of exceptional scientific importance today.

Some of the most spectacular fossil forests in Antarctica are preserved within mid-Cretaceous (100-million-year-old) rocks on Alexander Island, on the west side of the Antarctic Peninsula. Hundreds of fossil trees and shrubs are preserved in their positions of growth, buried within sandstones that were deposited during catastrophic floods from volcanic uplands. Studies of the spacing of the stumps and plant types illustrate that these forests were as dense as any normal temperate forests that grow in low latitudes today, even though the Alexander Island forests grew in latitudes as high as 70° S. At this latitude it is thought that the plants tolerated the extreme polar light regime by becoming dormant in the long dark winters and flourishing during the summer days of midnight sun.

The first appearance of fossils of flowering plants (angiosperms) during the Late Cretaceous marked a change in Antarctic vegetation. Fossil floras from the South Shetland Islands and the eastern side of the Antarctic Peninsula (from James Ross Island and Seymour Island in particular) are dominated by leaves of flowering trees. Many fossil leaves are similar to those of families that live in subtropical climates today, indicating that warm, wet climates extended southward to cover Antarctica in much warmer global climates. Quantitative analysis of physical features of the leaves can be used to estimate the climate in which the trees grew, for the Late Cretaceous mean annual temperatures of about 19°C prevailed, with warm, frost-free winters.

Subtropical floras grew in warm climates on the volcanic arc of the Antarctic Peninsula for millions of years, surviving the environmental catastrophe that saw the extinction of the dinosaurs 65 Ma at the end of the Cretaceous period. A younger flora, about 60 million years old, from the Palaeocene epoch, was discovered on Seymour Island by Otto Nordenskjöld while his party was abandoned due to shipwrecks during the Swedish South Polar Expedition (1901–1904). The leaves were first described by Dusén in 1908, and recognised as ancestors of the temperate vegetation living today in South America and Australia.

Fossil plants of Eocene age (~55–40 Ma) hold vital clues to a major change in climate at that time. The warm-loving types disappeared, replaced instead by trees that were tolerant of cool climates. In particular, the southern beech *Nothofagus* became most common in Antarctic forests, along with the "monkey puzzle" conifer *Araucaria*. Leaf analysis suggests that by 40 Ma, mean annual temperatures had dropped to around 10°C, with winter temperatures below freezing.

Geological evidence from other regions of Antarctica suggests that ice sheets were well developed on the continent by this time, marking a major change from greenhouse to icehouse climates.

The onset of glaciation and cold climates led to the demise of Antarctic vegetation. Plant macrofossils are rare from rocks younger than 40 million years old, but fossil pollen shows that tundra vegetation was present, with small bushes of *Nothofagus,* mosses, and rare conifers. In the Beardmore Glacier region of the Transantarctic Mountains, a unique flora of dwarf *Nothofagus* bushes, cushion plants, and mosses is preserved sandwiched between glacial deposits. Preserved in their growth positions, these plants grew only 300 miles from the South Pole and indicate a short burst of climatic warmth and glacial retreat during the icehouse world. These fossils heralded the end of Antarctica's ancient forests as the glacial landscape took over. Will forests return in the future as our climate warms?

FOSSILS, VERTEBRATE

Since the discovery of the first Triassic terrestrial vertebrate fossil from Antarctica in 1967, three significant Mesozoic faunas have been identified and described from the southern Transantarctic Mountains in areas approximately 500–600 miles from the Geographic South Pole. Early Triassic (245 Ma) vertebrates occur at numerous localities in exposures near the Beardmore and Shackleton Glaciers. An early Middle Triassic (225 Ma) assemblage has been described from two localities in the Gordon Valley discovered in 1985–1986 and more recently (2003) from Fremouw Peak; both of these sites are in the Beardmore Glacier region. Finally, an Early Jurassic dinosaur fauna was found in 1990–1991 on Mt. Kirkpatrick near the Beardmore Glacier.

The Early Triassic fossil vertebrates occur at numerous levels in fine- to medium-grained fluvial sediments of the lower Fremouw Formation. The fauna of the lower Fremouw have been the most extensively collected and studied of the three fauna from the southern Transantarctic Mountains. This fauna includes a diverse assemblage, consisting of the therapsid reptiles *Lystrosaurus murrayi, Lystrosaurus curvatus, Lystrosaurus mcCaigi, Myosaurus gracilis, Thrinaxodon liorhinus, Eriolacerta parva, Peadeosaurus parvus, and Rhigosaurus glacials*. *Lystrosaurus* is a very common Early Triassic dicynodont known from a number of other Gondwana continents in addition to Antarctica. *Myosaurus* is a very small, rare dicynodont known only from South Africa and Antarctica. The dicynodonts are a common group of herbivores in the Late Permian and Triassic periods worldwide. *Thrinaxodon* is a weasel-sized carnivorous cynodont that also occurs in South Africa. *Eriolacerta, Peadeosaurus,* and *Rhigosaurus* are all small scaloposaurids, a group that is typical of the Late Permian in South Africa.

Occurring with the therapsids in lower Fremouw Formation are the prolacertid *Prolacerta broomi,* the procolophonid *Procolophon trigoniceps,* the temnospondyls *Austrobrachyops jenseni* and *Cryobatrachus kitchingi,* and an indeterminate rhytidosteid. Prolacertids are a primitive group related to modern lizards, and procolophonids were small and lizard-like but not closely related to lizards. The temnospondyls were a fairly diverse group of extinct semiaquatic amphibians during the Permian and Triassic ranging in length from less than a meter to the size of a large crocodilian. All three of the Early Triassic temnospondyls from Antarctica are relatively small.

The Middle Triassic fauna from the upper Fremouw Formation of Antarctica again include therapsids and temnospondyls; however, they are generally much larger than most of the Early Triassic forms. A large kannemeyerid dicynodont occurs along with the large cynodont *Cynognathus,* a more derived indeterminate cynodont, and a gomphodont that shares some features with the Middle Triassic traversodontids. Gomphodonts were medium-sized herbivores related to the cynodonts. The temnospondyls from the upper part of the Fremouw Formation include two very large capitosaurs, with skull lengths of nearly 1 m.

The youngest vertebrate fauna from the southern Transantarctic Mountains were collected from the Hanson Formation on Mt. Kirkpatrick near the Beardmore Glacier at an elevation of about 4000 m. This Early Jurassic assemblage includes the partial skeleton of *Cryolophosaurus ellioti,* a 7-m-long carnivorous theropod dinosaur unique to Antarctica. The name means "frozen crested reptile" in reference to its polar occurrence and the unusual bony display crest on top of the skull. Teeth of small scavenging theropods, partial remains of a plateosaurid prosauropod, a tooth from a tritylodont, and the humerus of a pterosaur were also recovered from the same locality. A new locality in the same formation was discovered in 2003 on Mt. Kirkpatrick. To date, this new site has yielded remains of a true sauropod, with much of the material still under study. Sauropods are the large, long-necked, long-tailed herbivores such as *Apatosaurus* and *Brachiosaurus* known from the Jurassic on other continents. Prosauropods were a group of generally small animals that resembled the true sauropods and may be related to them. The tritylodonts represent the last of the therapsids and were rather beaver-like in appearance and habits. Pterosaurs are the flying reptiles that coexisted with the dinosaurs during the Mesozoic.

In addition to the vertebrate fauna from the southern Transantarctic Mountains, several other fauna are known from other regions of Antarctica. In 1999 a short reconnaissance expedition to Southern Victoria Land in the northern part of the same range near McMurdo Station led to the discovery of a few bone fragments from the Upper Triassic Lashly Formation. Consequently, there are now terrestrial vertebrates of four different ages from the Transantarctic Mountains. However, exposures of Upper Triassic rocks in Southern Victoria Land are not extensive and the fossils are extremely fragmentary. Only a single dicynodont tusk and some indeterminate small limb pieces were recovered.

On the other side of the continent, Late Cretaceous (70 million years old) vertebrates have been found on several islands near the Antarctic Peninsula. Skeletons of plesiosaurs and mosasaurs occur in shallow marine deposits on these islands. Plesiosaurs are extinct marine reptiles with long serpentine necks that coexisted with the dinosaurs in the Mesozoic. Mosasaurs are extinct marine reptiles that are closely related to modern lizards. Both plesiosaurs and mosasaurs were carnivorous.

In addition to the marine animals, the Cretaceous deposits have produced a few fragmentary dinosaurs. These include a nodosaurid, a small hypsilophodontid, a single tooth from a hadrosaur, and a small theropod. The nodosaurs are a group of armoured herbivores related to the ankylosaurs. Hypsilophodontids are small herbivorous ornithopod dinosaurs and hadrosaurs are the larger herbivorous "duck-billed" dinosaurs.

The only non-Mesozoic Antarctic fossil vertebrates were also collected from the Antarctic Peninsula region. These specimens include only a few fragmentary jaw specimens of a small Eocene-age marsupial mammal. This find supports the theory that marsupials originally migrated from South America across Antarctica to reach Australia.

Other than the terrestrial fauna described already, the only additional Antarctic vertebrate fossils come from two bony fish fauna from Devonian deposits in the Horlick Mountains near the southern portion of the Transantarctic Mountains and from Middle Jurassic lake interbeds near the Beardmore Glacier.

Since 98% of Antarctica is covered with glacial ice, the potential for future fossil vertebrate discoveries is limited. By far the most likely place new finds will be made is in the extensive early- to middle-Mesozoic deposits of the Southern Transantarctic Mountains.

FOYN, SVEND

Svend Foyn (July 9, 1809–November 11, 1894) was a Norwegian sealing and whaling entrepreneur whose method of whaling became the model for the industry as it developed in the Northern Hemisphere and later in Antarctic waters.

Foyn was born in the town of Tønsberg, a busy shipping port. He went to sea as a boy on family-owned vessels. He was a captain at 24, and worked in the timber trade—a favoured trade in Norway in the heyday of the sailing-ship era. However, in 1844 his career took a new turn, when he went on a sealing voyage to the Arctic. After returning home, he built his first sealer—a sailing vessel with an auxiliary steam engine. It became a model of design. Foyn built more vessels, and so did other merchants. Arctic sealing became a new maritime growth industry in the region.

Foyn's entrepreneurial skills led him into yet another industry. He felt that the competition in sealing, due to its large expansion, had become too intense. In his years in northern Norway and the Arctic, he had observed the abundance of rorquals—blue whales, fin whales, and humpback whales. At that stage in the history of whaling they had not been heavily exploited. While sperm whales and right whales could be caught by traditional methods, employing rowboats, and hand-held harpoons and lances, the powerful, fast-swimming rorquals were beyond reach of these tools. New methods had to be developed to chase them successfully. Foyn put his inventive energy into this work, and in the early 1860s he put into practice a method of whaling that dramatically altered the further development of the entire industry. The two most important components of this new concept were the harpoon cannon and the steam catcher boat. Several other Norwegian and American inventors had worked on the development of whale cannon, but Foyn brought the ideas together in a practical solution in his cannon with an explosive grenade harpoon. The whaling vessel of his design, *Spes & Fides*—94 feet (29 m), and schooner-rigged with a steam engine—was built in 1863. It was large and powerful enough to handle the strong, fast rorquals. A third important element in his whaling enterprise was a land-based processing plant, a shore station. He built one in Vadsø, Finnmark, in 1870.

Foyn was able to protect his entire system of whaling by patents, so for all intents and purposes, he had a monopoly until 1881. At that point, businessmen in Tønsberg and the neighbour town Sandefjord were anxious to enter the business. A new industry was created and expanded throughout the 1880s and 1890s.

In the early 1890s, the whaling community in Norway and elsewhere started to consider the Antarctic as having potential whaling grounds. Foyn was about to retire, but, when approached by his younger relative Henrik J. Bull, he paid for an expedition in search of whales. Foyn bought a former sealing vessel that was refitted and named *Antarctic*. The expedition was away from 1893 to 1895. Foyn died while it was down south, and thus was not able to see its results, nor the next phase of the development of the whaling industry: Antarctic whaling.

The entirety of Svend Foyn's own career was associated with the Northern Hemisphere. Nevertheless, he played a major role in the development of Antarctic whaling. First, the whaling concept he developed—shore stations with small, powerful, cannon-equipped steamers—was adopted at South Georgia and elsewhere beginning in 1904. Many of those Norwegian Antarctic whaling pioneers had their first experience at Finnmark. Second, the expedition Foyn funded, which included Carsten Borchgrevink, was not only a significant adventure of the early Heroic Age of Antarctic exploration, but also was the necessary background to the growth of the Antarctic whaling industry. The ship in that expedition—*Antarctic*—even made a second famous journey, carrying Otto Nordenskjöld's Swedish expedition of 1901.

For all his life, Foyn was a very religious man. He was married twice, but left no children. His large fortune was given to missionary concerns.

FRANCE: ANTARCTIC PROGRAM

The Institut Polaire Français Paul-Emile Victor (IPEV) is commissioned by the French government to organize the research activities in the Antarctic and sub-Antarctic French Territories, where extreme climatic environmental conditions require specific technologies. IPEV was created in January 2002 as a successor to the Institut Français pour la Recherche et la Technologie Polaires (IFRTP), created 10 years before to take over the scientific research activities conducted by the Expéditions Polaires Françaises (EPF) since 1947 in the Antarctic (Terre Adélie), and by the Mission de Recherche du Territoire des Terres Australes et Antarctiques Françaises (TAAF) since 1956 in the sub-Antarctic French Territories (South Indian Ocean islands: Kerguelen, Crozet, Saint-Paul, Amsterdam).

In its capacity of funding agency, IPEV coordinates, supports, and implements national and international scientific and technological research programs in the Antarctic and sub-Antarctic regions; selects and supports specific scientific and technological operations in the Antarctic; organizes and promotes scientific expeditions; and contributes to international scientific and technological planning by maintaining regular and close communications with similar foreign polar organizations.

IPEV also organizes research cruises on board *Astrolabe* and *Marion Dufresne,* the Antarctic and sub-Antarctic French Islands supply vessels, and contributes to the development of large European oceanographic programs.

The research programs supported by IPEV are relevant to Earth and planetary sciences, atmospheric sciences, glaciology, oceanography, marine and terrestrial life sciences, and human biology and medicine, and include many multidisciplinary approaches. In addition to the permanent observatory activities and the basic field operations involving many disciplines—like geology, seismology, geomagnetism, geodesy, glaciology, oceanography, meteorology, aeronomy, astronomy, astrophysics, biology, and medicine, run by major French universities (Aix-Marseille II et III, Besançon, Bordeaux 1, Boulogne-sur-Mer, Grenoble 1, Lyon I, Montpellier II, Nice-Sophia, Orléans, Paris VI, Rennes I, Saint-Etienne, Strasbourg 1, Versailles) and large research organizations (CEA, CNRS, ENSG, EOST Strasbourg, EPHE, IREMER, IPG Paris, MNHN)—IPEV contributes to the promotion of the International Polar Year program (IPY +50) and adheres to the five new international programs recently identified by SCAR: "Antarctic Climate Evolution" (ACE), "Antarctica and the Global Climate System" (AGCS), "Evolution and Biodiversity in the Antactic" (EBA), "Interhemispheric Conjugacy Effects in Solar-Terrestrial and Aeronomy Research" (ICESTAR), and "Subglacial Antarctic Lake Environments" (SALE).

IPEV corresponds to a "Groupement d'Intérêt Public" in which the Ministry of National Education and Research and the Centre National de la Recherche Scientifique (CNRS) are the leading partners. Other government bodies and public or private organizations like the Foreign Office, the Terres Australes et Antarctiques Françaises (TAAF), the Commissariat à l'Energie Atomique (CEA), the Institut Français de Recherche pour l'Exploitation de la Mer (IFREMER), the Centre National d'Etudes Spatiales (CNES), the Méteo-France and the Expéditions Polaires Françaises (EPF), are also associated with IPEV but at a lower level.

As the national polar funding agency, IPEV directly supports the activities of the Comité National Français des Recherches Arctiques et Antarctiques (CNFRA), founded at the time of the International Geophysical Year (1957–1958) by the French Academy to promote polar research programs. The main purpose of CNFRA is to provide a forum for French scientists involved in Antarctic research to discuss their field operations and plans and to promote collaboration between them. CNFRA is also the official French representative on the Scientific Committee on Antarctic Research (SCAR), an international body established in 1958 by the International Council of Scientific Unions (ICSU), in charge of the coordination of scientific activity in the Antarctic.

All the partners of the French Polar Institute (IFRTP-IPEV) listed above are members of the board of directors, chaired between 1992 and 1998 by Claude Lorius (IFRTP) and now by Jean Jouzel (IPEV). A Science Council with disciplinary representation, acting as an advisory and expert group, was established in 1992 and successively chaired by Roland Schlich (1992–1997) and Yvon Le Maho (1998–2001). In 2002 this council was replaced by a "Science and Technology Program Council" chaired by Edouard Bard.

The director of the French Polar Institute is elected by the board of directors. Between 1992 and 1997 IFRTP was headed by Roger Gendrin (CNRS) and now IPEV is headed by Gérard Jugie (CNRS).

The annual budget of the French Polar Institute is about 30 million with a permanent staff of about 50 engineers and technicians (not including the additional staff recruited on a time basis to staff the annual expeditions and summer season campaigns). Most of the funds are provided by the Ministry of Research and the Centre National de la Recherche Scientifique (CNRS); these resources are mainly devoted (90%) to run the Antarctic and sub-Antarctic science activities and the corresponding logistics.

FRANCE: INSTITUT POLAIRE FRANÇAIS PAUL-EMILE VICTOR (IPEV) AND TERRES AUSTRALES ET ANTARTIQUES FRANÇAISES (TAAF)

Two French organizations are in charge of the Southern French Territories, the sub-Antarctic Îles Kerguelen, Îles Crozet, Île Amsterdam, and Île St. Paul, and Terre Adélie, in Antarctica:

Terres Australes et Antarctiques Françaises (TAAF) is the official representative of the French government. The organization is responsible for national sovereignty and has powers to enforce law and order. It issues permits required by the Protocol on Environmental Protection to the Antarctic Treaty and authorizations to access protected areas. The budget of 26 million per year is provided by the Ministry of Overseas Territories and by external resources (fisheries, tourism, tax for ship registration, philately).

The French Polar Institute *Paul-Emile Victor* (IPEV) is a support agency for research in polar and subpolar regions. Originally created in 1992, IPEV has the status of Public Interest Group (Groupement d'Intérêt Public, GIP). The partners of this GIP are the following: French Ministry for Research, French Ministry of Foreign Affairs, National Centre for Scientific Research (CNRS), French Atomic Energy Commission (CEA), French Research Institute for Exploitation of the Sea (Ifremer), French Meteorological Agency (Météo-France), French Space Agency (CNES), French Austral and Antarctic Territories (TAAF), and French Polar Expeditions. The missions of IPEV are to provide the legal framework and the human, logistic, technical, and financial means for the development of French research in the Arctic, sub-Antarctic, and Antarctic. In this context, IPEV (1) supports and implements national and international scientific programs; (2) organises scientific expeditions; and (3) builds and maintains infrastructure and equipment in support of research. IPEV also organises marine science expeditions on board the vessels it operates.

The resources allocated to scientific, technical, and logistic activities in the field represent more than 90% of IPEV's annual budget. These include capital expenditure for scientific equipment, infrastructure, and vehicles as well as operating costs such as the charter and operation of vessels and salaries and travel expenses to and from the polar regions for field personnel.

Some sixty research programs covering all disciplines are selected every year by IPEV on the recommendation of its council on polar scientific and technological programs. A large proportion of these programs are based on field activities in the southern polar regions: Terre Adélie and Dôme C in the Antarctic, and Îles Kerguelen, Îles Crozet, and Île Amsterdam in the sub-Antarctic. In the Arctic, programs are carried out in summer in Svalbard using the research support infrastructure managed by IPEV at the international scientific station of Ny-Alesund. A Memory of Understanding was recently signed with the Alfred Wegener Institute (AWI) in order to gather the logistics facilities of the two organizations at Ny-Alesund.

In the Southern Indian Ocean, TAAF operates three sub-Antarctic research stations at Îles Kerguelen, Îles Crozet, and Île Amsterdam. They are serviced by *Marion Dufresne,* a multipurpose vessel chartered for resupply operations. Every year, four voyages of *Marion Dufresne* out of La Réunion Island in the Indian Ocean carry personnel and supplies to the stations.

The research station in Îles Crozet has operated since 1964. The station accommodates around twenty staff over winter. The research station in Îles Kerguelen was first established in 1951, and saw a significant development during the International Geophysical Year (1957–1958). The station accommodates about sixty staff over winter. The research station in Île Amsterdam has operated since 1950, and accommodates about twenty staff over winter.

In Terre Adélie, IPEV operates the Dumont d'Urville Station, located in a rocky archipelago on the edge of the Antarctic continent, which is only accessible by sea during summer in the southern hemisphere, the austral summer, from mid-December to mid-March. The supply vessel, *L' Astrolabe,* makes five return voyages between Hobart in Tasmania and Dumont d'Urville over the summer. IPEV manages the entire operation of the station and the support to its research programs. The station accommodates around thirty staff in winter and about one hundred staff in summer.

IPEV operates also with its Italian partner (PNRA) the new French–Italian research station Concordia, at Dôme C, at about 3200 m altitude and at 1100 km from DDU and 1200 km from Mario Zuchelli Station, at Terra Nova Bay (Italian research station). Concordia can accommodate sixteen persons over winter, researchers, technicians, a doctor, and a chef, living a totally self-sufficient life for 9 months. The first wintering-over started in February 2005 with thirteen staff.

Surface convoys composed of heavy tractors, trailers, and sleds and known as "traverses" operate between Dumont d'Urville and Dôme C to deliver all equipment for the construction and operation of Concordia station and the conduct of its research programs. Three traverses are usually organized each year. An annex station, Cape Prud'homme, located on the Antarctic continent off Dumont d'Urville, supports the organisation of the surface convoys.

IPEV and TAAF assist the French Ministry of Foreign Affairs in the Antarctic Treaty System. IPEV chairs the Council of Managers of National Antarctic Programs (COMNAP) during the 2005–2007 period and the European Polar Board as well. It participates also in the Europolar Consortium, gathering twenty-five Ministries, Funding Agencies, and National Polar RTD Authorities from nineteen European countries in order to pave the way for a "European Polar Entity."

FRENCH ANTARCTIC *(FRANÇAIS)* EXPEDITION (1903–1905)

Jean-Baptiste Charcot's 1903–1905 expedition in *Français* is one of the least-known expeditions of the Heroic Age of Antarctic exploration. Charcot's father had died in 1893, leaving an inheritance that enabled Charcot's long-maturing ideas for travel and exploration to be achievable. He commissioned the construction of *Français,* to be rigged as a three-masted schooner, from the well-known firm of Gauthier in Le Havre. The specification provided for the best materials to be used, and Charcot took advice from Adrien de Gerlache with regard to the equipping of the ship. His original intention was to travel north but, on news reaching Europe that Otto Nordenskjöld in *Antarctic* was overdue and presumably in difficulties, he redirected his attention southwards.

Charcot was fortunate in being able to secure additional support from Paul Pléneau, a wealthy engineer, and from various official French bodies and the newspaper *Le Matin,* the proprietor of which was his brother-in-law. The expedition also had the support of the French government. In addition to providing aid for the Nordenskjöld search effort, Charcot's plans included the exploration of the west coast of the Antarctic Peninsula as far south as Adelaide and Alexander Islands, discovered by John Biscoe and Fabian von Bellingshausen, respectively. A full research programme was to be undertaken and several officers with scientific interests were on board.

A tragic accident delayed departure, but *Français* finally left Le Havre on August 27, 1903, with Pléneau and de Gerlache as members of the expedition.

However, on arrival in Brazil, and to Charcot's disappointment, de Gerlache left the expedition. Upon reaching Buenos Aires, news was received of the rescue of Nordenskjöld and his men, enabling Charcot to proceed with an exploratory expedition, unhampered by humanitarian considerations. *Français* left Buenos Aires on December 23, and ventured into the Drake Passage from Tierra del Fuego on January 27, 1904. After a rapid voyage, she arrived in the South Shetland Islands on February 1, and proceeded southwest, passing along the coasts of the Palmer Archipelago. On February 5, the boiler pipes ruptured and serious engine problems were experienced but, despite this difficulty, Charcot pressed on to Flanders Bay where repairs were made. However, constant problems with the engines—which had been purchased secondhand due to decreasing funds—were experienced throughout the rest of the voyage.

On February 19, *Français* reached Wiencke Island and an inlet that Charcot named Port Lockroy after Edouard Lockroy, the Vice-President of the Chamber of Deputies and a great supporter of the expedition. Continuing southwards, and despite further engine problems, *Français* passed latitude 65° S, where he searched for a suitable wintering site. He determined that an inlet on Booth Island was adequate for the purpose.

Nowhere is Charcot's natural skill as an explorer revealed more clearly than in the methods he adopted with regard to this wintering. The *Français* expedition was one of the best equipped of all the expeditions of the first 2 decades of the twentieth century, and Charcot had taken careful notice of the problems experienced by de Gerlache during the *Belgica* expedition. *Français* carried material for the construction of buildings for the accommodation of scientific instruments, and the most careful preparations had been made for the welfare of the crew. These included the provision for each man of as much privacy as possible and of varied, and good, food and drink. Lectures were given and discussion groups were held to combat boredom. Whenever conditions permitted, groups went ashore for scientific and recreational purposes.

In spring, on November 24, a whaleboat expedition set forth with the aim of reaching Petermann Island and surveying a large portion of the Graham Land coast. Despite very considerable difficulties arising from the presence of large ice masses in the narrow channels of the area, and from snow blindness, the trip was a success, and much accurate mapping was achieved.

With the approach of summer, and the clearing of ice from the bay by the winds, *Français* was able to set sail and continued southwards, rounding the Biscoe Islands and passing inland of Adelaide Island. On January 13, 1905, Alexander Island was sighted, but shortly thereafter *Français* struck a submerged rock. The ship was badly holed and made water fast, necessitating the use of the crew to power the pumps, the engines still being inefficient. In addition, the weather was deteriorating, so Charcot had no option but to head northwards in an attempt to reach appropriate shelter in which repairs could be effected. Eventually *Français* reached Wiencke Island after a voyage of 16 days—during which the pumps were continually manned. Repairs took 10 days, after which Charcot continued north, arriving at Smith Island on February 15, and eventually Puerto Madryn and Buenos Aires.

In Buenos Aires the ship was examined in dry dock and the extent of the damage, which was considerable, was fully revealed. She was sold to the government of Argentina, and the members of the expedition returned to France aboard a passenger vessel, taking with them some seventy-five boxes of scientific specimens, records, and charts.

Despite the continual problems that were experienced with the engines, and the accident, the results of the *Français* expedition were most impressive. More than 600 miles of difficult coast had been charted, and the scientific results were the most detailed to have yet been secured from the area of the Antarctic Peninsula. The expedition also established Charcot's high rank as an explorer. In addition to his extremely good planning, he had demonstrated excellent leadership in serious difficulties. He had succeeded in the most difficult task of maintaining morale throughout the expedition. An appreciative French government paid for the publication of the scientific results, which totaled eighteen volumes.

FRENCH ANTARCTIC *(POURQUOI PAS?)* EXPEDITION (1908–1910)

Stimulated by the success of his earlier expedition aboard *Français,* Jean-Baptiste Charcot resolved on continuing the exploration of the Antarctic Peninsula. He intended to study the area "in all branches of science" and "to verify, complete and expand" the work done on the earlier expedition. One of the aims of the *Français* expedition had been to determine whether Antarctica was a continent or a group of ice-covered islands. The achievement of this had been frustrated when *Français* struck a rock in January 1905, necessitating a return northwards due to a continual flow of water entering the ship. Charcot regarded these goals as unfinished business to be resolved by a second expedition.

Charcot submitted his plan to the Academy of Sciences and secured its approval and this, together with the approval of various other official French organisations, made the endorsement of the government itself, and its financial backing, almost inevitable. Charcot was thus able to secure substantial funding, so that the expedition was lavishly equipped, certainly more so than most of those of the Heroic Age of Antarctic exploration.

Français had been sold to the Argentine government, and Charcot determined, after various attempts to purchase a whaler, to commission another vessel from the same shipbuilder, Gauthier of Le Havre, that had constructed his earlier ship. The new vessel was the fourth one that he had owned with the name *Pourquoi Pas?*. She was launched on May 18, 1908, a three-masted barque constructed to the highest standards. She was immensely strong, with very close ribs and several layers of planking, and came equipped with a powerful 450-hp engine, which was installed as a result of *Français*'s having been so underpowered.

The expedition left Le Havre on August 15, 1908, and of the twenty-two members of the expedition, no fewer than eight had served aboard *Français,* a clear indication of Charcot's ability as a leader. Proceeding via Rio de Janeiro and Buenos Aires, the ship left Punta Arenas on December 16, and after a rapid transit of the Drake Passage (Charcot seems to have been extremely fortunate in his navigations in that notorious area) it arrived at Smith Island 6 days later. They sailed directly to Deception Island, where Norwegian whalers were already established, and on December 29 reached Booth Island and the bay in which *Français* had wintered in 1904. On January 1, 1909, Charcot discovered a wonderfully sheltered harbour, on nearby Petermann Island, which he named Port Circumcision. Almost immediately, Charcot set off by boat to explore the coastline to the east of Petermann Island, but uncharacteristically, insufficient supplies were taken, and in suddenly deteriorating weather and rapidly forming ice, the situation quickly became serious. Only after 3 full days away did the party eventually reach the ship. This incident seems to have been one of Charcot's very few lapses in planning.

Soon after this, *Pourquoi Pas?* ran firmly aground. Fortunately, she floated off on the next high tide, but it was necessary to delay the progress of the expedition until the extent of the damage could be estimated. Although there was significant damage, the ship was strong enough that it was agreed the damage was not serious enough to hinder the continuation of the voyage. In mid-January a detailed examination and mapping of Adelaide Island was carried out, and they discovered a large gulf that was named Marguerite Bay after Charcot's second wife. They then approached to within 2 miles of the coast of Alexander Island before, short of coal, and with increasing ice, the ship returned to Port Circumcision to winter.

Charcot followed the same principles that had proven so successful on his previous expedition. Huts were built ashore for the scientific instruments and were lit by electricity. The narrow entrance of the harbour was secured by steel hawsers to prevent the ingress of icebergs, and the ship was roofed over with canvas. But it was his care for his men that most marked Charcot as a leader, and all possible measures, including the publication of a daily newspaper, were taken to prevent the onset of boredom and the inevitable consequent demoralisation.

Exploratory journeys away from the ship were made in September and October, and, after these, the ship left the harbour in November. She headed for Deception Island in order to replenish coal stocks. The opportunity was taken for a thorough survey of the condition of the exterior of the hull by a diver from the Norwegian whalers active there. The damage from the grounding turned out to have been severe but, despite this, Charcot determined to again head south. Hoping to reach Hope Bay, they were halted by ice, but did land the first two men ever on Bridgeman Island. They then visited Admiralty Bay at King George Island before returning to Deception. Turning back south on January 6, 1910, they made directly for Alexander Island, from offshore of which

Charcot was delighted to sight land to the southwest. This new island was ultimately named Charcot Island in honour of the explorer's father.

Charcot now headed west hoping to link his discoveries with those made by previous explorers. However, he was frustrated in his desire to explore the coastal areas as thoroughly as he wished to because of large amounts of sea ice. Nevertheless, on January 14, they spied Peter I Øy, the first time it had been sighted since Fabian von Bellingshausen's expedition almost 90 years earlier. Charcot then followed the coast westwards as far as 124° W. On January 22, Charcot decided that the work of the expedition had been completed and determined to return to South America. *Pourquoi Pas?* arrived at Punta Arenas on February 11, following which she underwent extensive repairs before proceeding to Rouen, which was reached on June 5.

The *Pourquoi Pas?* expedition confirmed Charcot's status as an explorer of the highest rank. The results were most impressive. In addition to the charting of some 1,250 miles of coastline in the difficult waters to the west of the Antarctic Peninsula, a very large amount of new scientific data had been secured—ultimately filling 28 volumes of scientific reports. Meanwhile, Charcot had maintained morale at the same high levels as those that had been evident on his earlier expedition, and despite the huge difficulties caused by the grounding of the ship, the programme of work had not been seriously affected. Charcot's aims in his expeditions were always modest. He himself noted that the Antarctic Peninsula, selected as the scene of his efforts, meant an approach to the South Pole was unlikely. More satisfying for Charcot was sailing his own vessel in unknown waters and facilitating research by scientific colleagues on board.

It is noteworthy that two of the sites in Antarctica most frequently visited by tourists, Port Lockroy and Port Circumcision, are closely associated with Charcot, and it is a matter for regret that so many go there without ever hearing his name.

FRENCH NAVAL (*ASTROLABE* AND *ZÉLÉE*) EXPEDITION (1837–1840)

Jules-Sébastien-César Dumont d'Urville made three voyages to the Pacific. The third was especially notable for its contribution to the exploration of the Antarctic.

Astrolabe, under the direct command of Dumont d'Urville, departed France in September 1837 accompanied by *Zélée,* commanded by Charles-Hector Jacquinot (1796–1879). Dumont d'Urville was one of France's experts on the Pacific, and the instruction, issued in August, that stated, "You will extend your exploration towards the Pole as far as the polar ice will permit" looks like an ill-considered afterthought. But in fact, the French had always been interested in the discoveries made by James Weddell, who had reached 74°15′ S. His account had been published in 1825, and this was the first occasion France had to emulate his achievements.

The French ships left the Straits of Magellan on 9 January 1840, the first drift ice was seen on the 13th, and icebergs were encountered from 15 January. Compared to Weddell's voyage, the French had a hard time of it, and on the 21st they met with a great barrier of ice, called *La banquise,* which during this season was to prevent them from sailing any farther south than 62°21′ S.

Dumont d'Urville's descriptions of the polar terrain have few rivals. When he wrote of "a new world unfolding before our eyes, but a world that is inert, mournful and silent, where everything threatens man with annihilation" (Rosenman 339), the style was self-conscious and romantic, but it also indicated the quickly earned respect he had for such a formidable environment. His words were complemented by the sketches of the artists on board, Ernest Goupil (1814–1840), who later died in Hobart, and Louis Le Breton (1818–1866).

The two ships soon became caught in the ice. Dumont d'Urville lamented "the tragic prospect of seeing my two crews forced to seek precarious shelter on the icebergs surrounding us, there awaiting, in despair and horror, an end to their pitiful existence"

(Rosenman 341), while, in fact, the men seem to have enjoyed the chance to skylark. Le Breton's painting of this, "The corvettes *Astrolabe* and *Zélée* caught in the ice, February 1838" (1841, Musée des Beaux-Arts, Quimper, France), is the best visual representation of Antarctic conditions in the prephotography era. In poor sea conditions, the expedition persisted for nearly 2 months. It was, wrote the commander, "a complete failure."

After being rebuffed by the ice, with many of the crew sick, the expedition sailed for Chile, then the more familiar waters of the Pacific, where the next 18 months were spent. The French had now resolved to make a second voyage to the Antarctic, via Hobart in Van Diemen's Land (Tasmania), which they reached on 12 December 1839. A week elapsed before Dumont d'Urville was able to meet the Governor of the English colony, Sir John Franklin (1786–1847). Franklin was, arguably, the world's foremost Arctic explorer, but the French commander was somewhat circumspect in recounting what advice Sir John may have conveyed.

The French left Hobart on New Year's Day, 1840. Dumont d'Urville's intentions were twofold. He wanted to "push down well south of Tasmania and determine under which parallel I would encounter pack ice" and "there was one important discovery yet to be made; the position of the magnetic pole."

On the 20th the crossing of the Antarctic Circle was celebrated, and late the following day Terre Adélie was claimed and named after the commander's wife, Adèle.

Returning to Hobart, on 29 January, 1840, a curious incident occurred that illuminates the tensions that existed between competing exploring nations. Dumont d' Urville was aware that the United States Exploring Expedition, under the command of Charles Wilkes, was in the region. That afternoon *Astrolabe* was approached by USS *Porpoise,* under the command of Lt. Cadwalader Ringgold, but before any communication took place, *Porpoise* tacked away. There had been a mutual misunderstanding, but it was a prickly breach of etiquette, and both later sought to excuse themselves. "We had not the slightest interest in keeping secret the results of our operation and the discoveries we had nearly paid for with our lives," claimed Dumont d'Urville (487), while Wilkes later wrote, "By refusing to allow any communication with him, he not only committed a wanton violation of all proper feeling, but a breach of the courtesy due from one nation to another" (Wilkes, vol. 11, p. 344).

Hobart was reached on 17 February 1840. A sketch by Aimé Desbois of the act of possession was given to Lady Franklin (now held in the Allport Library and Museum of Fine Arts, Hobart). The expedition returned to Toulon on 6 November 1840. Dumont d'Urville was killed in a railway accident, but his brilliant publication *Voyage au Pôle Sud et dans l'Océanie* was his legacy. France continued to venerate his memory by naming its contemporary Antarctic station, established in 1956, Dumont d'Urville.

The areas visited by Dumont d'Urville were not more fully explored until Douglas Mawson's Australasian Antarctic Expedition (1911–1914). And nearly 100 years elapsed before the limits of Terre Adélie—between Wilkes Land and George V Land—were formally defined as "The islands and territories situated south of the 60° parallel of south latitude and between the 136° and 142° meridians of longitude east of Greenwich."

FUCHS, VIVIAN

Sir Vivian Fuchs was a British Antarctic explorer who led the first expedition to cross Antarctica, and served for more than 20 years as director of Britain's national Antarctic program.

Vivian Ernest Fuchs was born on February 11, 1908, the only child of a prosperous German father and Anglo-Australian mother. During World War I his father was interned and his income severely curtailed, leaving young Fuchs to be brought up in genteel poverty by his partly disabled mother. The return of peace brought reunion to the family and the gradual restoration of its fortunes. Fuchs attended Brighton College as a boarder, and in 1926–1930 was an undergraduate at St. John's College, Cambridge, where he read geology and natural history. His first expedition was with a summer vacation climbing party in East Greenland, organized by his geology tutor, J. M. Wordie, who had served in Sir Ernest Shackleton's *Endurance* expedition of 1914–1917. Later he met Louis Leakey and E. Barton

Worthington, with whom he was to serve as a field geologist on three African expeditions—to the East African Lakes (1930–1931), to Olduvai Gorge (1931–1932), and to Njorowa Gorge (1933). Now interested in both geology and anthropology, he subsequently led his own African expeditions to Lake Rudolf in 1934 and Lake Rukwa in 1937–1938.

In 1933 Fuchs married his cousin, Joyce Connell, who shared his interest in travel and adventure. In 1936 the couple settled in Barton Road, Cambridge, which remained their home base throughout their lives. In the same year Cambridge University awarded him a Ph.D. With World War II looming, in 1938 he joined the Territorial Army, and in 1939 was commissioned in the Cambridgeshire Regiment. He saw wartime service in West Africa in 1942–1943 and, after undertaking a staff course, served from 1944 with the Second Army in Europe, where he was mentioned in dispatches. He ended the war as a town major in Civil Affairs in Plön, Schleswig-Holstein.

Released from the army in 1946, Fuchs returned to a growing family (Hilary, born 1936, and Peter, born 1940). Hoping to continue working as a field geologist, he sought to join the Falkland Islands Dependencies Survey (FIDS), an expedition of seven bases in the British (South American) sector of Antarctica. Originally "Operation Tabarin," a wartime naval operation, FIDS had recently been taken over by an unprepared and reluctant Colonial Office. To his surprise, Fuchs was invited to join as expedition leader, and was briefed by the controlling committee to develop a scientific field programme that would help to justify the continuing operation of bases in Antarctica.

Between early 1948 and 1950 Fuchs led the survey from Base E, Stonington Island, Marguerite Bay, where he quickly acquired skills of dog-driving and ice-craft. Frustrated in his original plans by the non-arrival of a promised aircraft, he nevertheless led a year's vigorous programme of sledging and surveying in southern Marguerite Bay and George VI Sound. In early 1949, when he and his ten companions were due for relief, persistent sea ice prevented the resupply ship *John Biscoe* from entering Marguerite Bay. "The Lost Eleven," as they became known to the outside world, completed a further involuntary year, in which Fuchs continued to supervise by radio the work at the other bases, and led extensive geology-oriented sledging journeys southward from Base E.

On his return to Britain in early 1950, Fuchs was retained by the Survey to establish and direct the FIDS Scientific Bureau—essentially to develop a long-term programme of scientific research that could be maintained from an increasing number of permanent stations in the British sector—on the Antarctic Peninsula, the South Orkney Islands, South Shetland Islands, and South Georgia. However, during his stay on Stonington Island, Fuchs had begun to plan an expedition, previously attempted by Wilhelm Filchner in 1911 and Ernest Shackleton in 1914, to cross Antarctica from the Weddell Sea to the Ross Sea. As this was well beyond anything that could be done within the remit of FIDS, in April 1955 he took leave from the Scientific Bureau to plan and set up his own Commonwealth Trans-Antarctic Expedition. Although opposed by almost the entire UK polar establishment, he gained support from the Treasury, the Royal Geographical Society, the governments of New Zealand, Australia, and South Africa, and private subscriptions.

Leaving Britain in November 1955, he established Shackleton Base on the Weddell Sea coast, leaving a wintering party to complete the base. In the following spring he returned to explore inland and set up an advance base (South Ice) by air 450 km inland. After wintering at Shackleton in 1957, he began the crossing. Using dog teams, Muskeg tractors, Sno-Cats, and aircraft, he and his party crossed the continent from Shackleton to Amundsen-Scott, the recently established US scientific station at the South Pole. There the team was met by a New Zealand support party led by Sir Edmund Hillary, and returned with them to Scott Base in McMurdo Sound.

On returning to London in 1958, Fuchs was knighted, and the following year he returned to FIDS as director. He continued to develop and increase the scientific efficiency and output of an expanding Survey, touring the stations every second or third year. From 1961, when Britain joined the Antarctic Treaty, FIDS was renamed the British Antarctic Survey (BAS), and from 1967, still under his direction, it was taken under the wing of the recently formed Natural Environment Research Council. Sir Vivian retired from the directorship in 1973.

In 1974 Fuchs was appointed FRS. Through a long retirement, with membership in many learned societies, he remained active in an advisory capacity in polar, geographic, and scientific affairs. In 1982–1984 he was appointed president of the Royal Geographical Society, an organization that had supported both his African and his Antarctic expeditions, and awarded him two of its most prestigious medals. He wrote a history of FIDS and BAS *(Of Ice and Men)*, and later his autobiography *(A Time to Speak)*. Widowed in 1990, he later married Eleanor Honnywill. He died on November 11, 1999.

FUNGI

The kingdom Fungi is a large, diverse group ranging from simple yeast cells to complex fruiting bodies (typical mushrooms and bracket fungi), and in some cases to diffuse colonial organisations that may exist over wide areas. Approximately eighty thousand species of fungi have been named, and it has been suggested that more than one million species may be currently undetected or undescribed. While the most evident Antarctic fungi are those forming lichens with symbiotic photosynthetic cyanobacteria and algae, only the nonlichenized fungi are considered here.

At least 870 species of fungi have been reported from within the Antarctic Polar Front. Possibly the most southerly record for a true "mushroom" is a probable *Gallerina* species on Léonie Island (67°36′ S). In general, macrofungi and most basidiomycetes are confined to the sub-Antarctic and the Antarctic Peninsula. Microfungi, particularly ascomycetes and zygomycetes, and yeasts have been isolated from all Antarctic areas. There is little evidence for endemism, and less than 10% of the species reported have been described as new, while many have also been recorded from Arctic and mountain regions, suggesting that species are more associated with particular environments than with geographical regions. There is considerable uncertainty over which fungi are indigenous to the Antarctic. Some reports have suggested that species have been introduced by human activity, but there are comparatively few background assessments to demonstrate this. Viable fungal propagules have been reported from sea and fresh water, soil, air, and ice-core samples, and these may provide a continual source for colonisation.

The function of fungi within Antarctic ecosystems remains largely unknown. Plant pathogens have been identified from the sub-Antarctic, as have nematode and other invertebrate pathogens, parasites, and predators, and a small number of potentially pathogenic species have been isolated from birds. Similar species and associations have been reported from maritime and continental Antarctica. Some fungi form mycorrhizal associations with plants, and although this has been observed in the sub-Antarctic, there has been debate as to whether mycorrhizas occur further south. Recent studies have identified novel potentially mycorrhizal associations on the Antarctic Peninsula between the ascomycete fungus *Hymenoscyphus ericae* and the liverwort *Cephaloziella exiliflora,* and between the zygomycete *Glomus antarcticum* and the grass *Deschampsia antarctica*.

Many fungi may be present in the Antarctic as transient or dormant propagules, while some that are usually associated with specific hosts in other regions may have adapted to alternative lifestyles. One example is the ascomycete *Lecanicillium lecanii*. This is normally an insect pathogen, but in Antarctica it has been isolated together with bacteria and algae from mineral crusts.

There is little information regarding Antarctic marine fungi. Some baiting experiments have been conducted in coastal waters, and yeasts have been isolated from the open ocean, but few, if any, true marine fungi have been reported.

A major constraint to the identification of fungi is that less than 20% of known species have been isolated and grown in pure culture, and of these, many require specific isolation conditions and media. New molecular studies suggest that there may be many more fungi present in the Antarctic environment, although further consideration will need to be given to their ecological role.

G

GENE FLOW

Gene flow is a process occurring between two or more populations of a species and is defined as the movement of genes from the gene pool of one population to the gene pool of another population. The movement of genes between populations may occur through the migration of individuals (or zygotes), or through the movement of gametes.

The most important genetic effect of gene flow is the homogenization of the genetic composition of different populations, which tend to be genetically more similar to each other along with the increase of gene flow. By homogenizing gene frequencies across populations, gene flow counteracts their differentiation by random genetic drift and, in some cases, selection.

When gene flow is determined by moving individuals, it exerts its effects only if the migrating individuals will eventually reproduce in the new population, therefore introducing their genes into the new gene pool. Individuals may actively move from one population to the other, and highly mobile species have higher levels of gene flow. However, they can also be passively transported by other animals or by physical agents (such as water currents or winds). Passive transport is also responsible for the migration of seeds and spores, as well as pollen grains in terrestrial plants or gametes in marine animals and plants, which also contribute to the enhancement of gene flow.

In population genetics, gene flow can be estimated using direct or indirect methods. Direct methods are based on the release and recapture of marked individuals. Indirect methods are much more widely used and are based on the assessment of gene frequencies in different populations and the estimate of gene flow from levels of interpopulation differentiation.

Levels of gene flow play an important role in speciation, as new species arise only when gene flow is insufficient to counteract the differentiation between allopatric populations. Therefore, a prerequisite for speciation is the interruption (by any method) of gene flow between populations.

Antarctic soil invertebrates, such as springtails, mites, and nematodes, show a fragmented distribution, resulting in isolation between populations being enhanced by the presence of large areas of soil where survival is impossible. Therefore, gene flow might be strongly reduced, and populations tend to have higher levels of genetic differentiation compared to those observed in related species inhabiting temperate habitats. Due to the low vagility of these organisms, active migration between populations is negligible, although moderate levels of passive transport may be determined by wind or soil trapped in the feet of birds. The reduction of gene flow determined by the peculiar environmental conditions of Antarctic soils may provide suitable conditions to promote speciation.

Passive dispersal of propagules by means of wind or water flowing in small streams might guarantee higher levels of gene flow in moss species, which appear to be genetically more homogeneous than soil invertebrates.

Interestingly, significant levels of genetic differentiation have been found also in marine organisms, such as krill, suggesting that interruption or reduction of gene flow can be caused by marine currents.

GENTOO PENGUIN

The gentoo penguin *Pygoscelis papua* is a tall penguin that weighs approximately 5–5.5 kg. It is black dorsally with white underparts. The head is black with a prominent triangle of white feathers above each eye. The iris is brown and there is a white ring around the eye. The bill (with black culmen and tip), legs, and feet are orange to red.

Gentoo penguins walk with their flippers raised behind the body. The birds wade into water until their flippers are half-submerged, then swim. On return, they porpoise towards their breeding locality, survey it, and then swim quickly ashore. On icy coasts, they leap out of water onto the ice.

Distribution

The gentoo penguin occurs in sub-Antarctic and Antarctic waters, usually between about latitudes 45° and 65° S. It is one of three penguins in the genus *Pygoscelis*. It has a more northerly distribution than the other two species, the Adélie *P. adeliae* and chinstrap *P. antartica* penguins, although there is some overlap in breeding ranges in the South Atlantic region.

The gentoo penguin breeds on ice-free ground at the Antarctic Peninsula, and at Antarctic and sub-Antarctic island groups in the Atlantic (Falkland, South Shetland, South Orkney, South Georgia, South Sandwich), Indian (Prince Edward, Crozet, Kerguelen, Heard), and Pacific (Macquarie) Oceans. A few pairs breed in the Beagle Channel at the southern tip of South America.

Annual Cycle

Some adult birds remain near their colonies throughout the year unless ice conditions force them to move to ice-free areas offshore. However, numbers at colonies during the nonbreeding period are much reduced and birds may be absent from the colony for up to 5.5 months after moult. At southern localities, birds disperse from their colonies in autumn after moult. Upon return to colonies, birds may fast for a short period (1–5 days). The courtship period (from pair formation to clutch completion) lasts about 25 days.

Laying is earliest at the northern localities, commencing about mid-June and peaking in late June or July, and progressively later southwards. At the South Orkney Islands and the Antarctic Peninsula, laying occurs in November. At the northernmost localities, the laying period extends over 5 months, although more than 80% of pairs initiate laying within a period of 3 weeks. South of the Polar Front, laying is more synchronous. At South Georgia, 95% of clutches are begun within a period of about 2 weeks.

Both birds feed regularly during courtship and incubation, although the female may go to sea for 1–3 days between the laying of eggs, leaving the male alone. Incubation is by both parents, starts in earnest once the second egg is laid, and takes 35–36 days. The fledging period lasts 74–100 days. Chicks are normally fed each day and their mass increases approximately linearly during the first 70 days after hatching.

Birds moult annually at the conclusion of breeding. They leave breeding localities to fatten up at sea for 10 days to 2 months before moulting ashore. They replace all their feathers during a fast of about 20 days.

Breeding and Survival

Gentoo penguins are monogamous, with often long-lasting pair bonds. They breed in small to large colonies; nests may be more than 1 m apart. There is usually fidelity to nest sites, but locations of colonies may be changed between years. Nesting areas are flat or gently sloping. Nests are scraped-out hollows, built with stones, shells, bones, feathers, and vegetation; nesting materials are sometimes stolen from neighboring nests. The male initiates nest construction, which the female continues, after pair formation, with material brought by the male.

Gentoo penguins normally lay clutches of two similarly sized eggs, with the interval between laying 3–4 days. At northern localities, if clutches are lost they may be replaced 1–2 months later. The first chick to hatch is noticeably larger than the second. At colonies on the Antarctic Peninsula, both chicks may fledge. At the northernmost breeding localities, it is rare for more than one chick to survive, and breeding success is typically lower than at localities farther south.

Gentoo penguins may breed when 2 years old, but usually will not do so until 3 years. When food is scarce, or following severe winters, mortality may increase, substantial numbers of birds may not breed, fidelity to mates may decrease, and breeding may be delayed. At Marion Island, delayed onset of breeding led to high mortality being inflicted on eggs and small chicks by returning sub-Antarctic skuas *Catharacta lonnbergi*. Annual survival of adults is about 85%, and of birds in their first year 27%–59%.

Food and Feeding

Gentoo penguins feed during the day, catching prey by pursuit diving. At South Georgia, Antarctic krill *Euphausia superba* is their main prey, but fish are also eaten. Most krill is caught on dives shallower than 54 m, whereas most fish are taken at 54–134 m. At northern localities, crustaceans and cephalopods are eaten, but benthic and midwater fish dominate the diet. While breeding, gentoo penguins have a maximum foraging range of about 100 km, but they usually feed much closer to breeding localities than this.

Population Size

The overall population of gentoo penguins is thought to be about 317,000 pairs, of which approximately 25% occur at the Antarctic Peninsula and 75% at sub-Antarctic islands. The largest populations are at the Falkland Islands (115,000 pairs) and South Georgia (105,000 pairs).

Conservation Status

The gentoo penguin is classified as Lower Risk/Near Threatened on the Red List of IUCN (The World Conservation Union). Most populations around the Antarctic Peninsula have increased. However, populations at several sub-Antarctic localities have decreased. That at Bird Island, South Georgia decreased by 20% from about 1985–2005 and that at Marion Island by 40% from 1994–2005. The latter decrease likely resulted from scarcity of food, thought attributable to climate change. At South Georgia, when krill was scarce, meal size, rates of provisioning of offspring, and breeding success decreased by 90%. At the Falkland Islands, there was a decrease from about 110,000 pairs in the 1980s to 65,000 in the mid-1990s, followed by a recovery to present levels equivalent to those of the 1980s.

GEOLOGICAL EVOLUTION AND STRUCTURE OF ANTARCTICA

Like all other continents, Antarctica has "very old" cores or nuclei, generally called cratons, that are roughly surrounded by successively younger (mountain) belts. These belts are the products of plate-tectonic events such as the subduction of oceanic crust beneath continental crust and/or the collision of two former separate continents. More precisely, these mountains belts, or "orogens," are the products of convergent plate-tectonic movements and form at or near the margin of (former) plates. These convergent movements are complemented by divergent plate-tectonic movements that divide continents, forming rifts, grabens, and finally oceans.

Therefore, it is reasonable to discuss together the geological structure and evolution of Antarctica chronologically from the oldest to the youngest.

Continental nuclei or cratons are those parts of the continents that are older than 1500 million years; the "younger" Antarctic mountains belts (orogens) are as follows:

- 1300 to 900 Ma: the orogens of Grenvillian age,
- 600 to 500 Ma: the Ross and the Pan-African orogens,
- 250 to 200 Ma: the Ellsworth or Weddell Orogen,
- 150 to 90 Ma: the Antarctic Andean Orogen,
- 50 Ma to recent: the plate-tectonically active part of Antarctica.

In contrast to all other continents, Antarctica and its rocks, and thus its geological structure and history, are more than 99% covered by ice, which is up to 4700 m thick. This means that geological knowledge of Antarctica is based on less than 1% of the continental area. This 1% has not been fully investigated everywhere, but about half of the 99% has been surveyed remotely by geophysical techniques, mainly by aeromagnetic and gravimetric surveys. Therefore, our understanding of Antarctica's geological structure and history will change and improve in the future.

The Antarctic Cratons

Until the early 1980s, the "East Antarctic Shield" was assumed to be a single and uniform Antarctic craton, but this term is incorrect for two reasons:

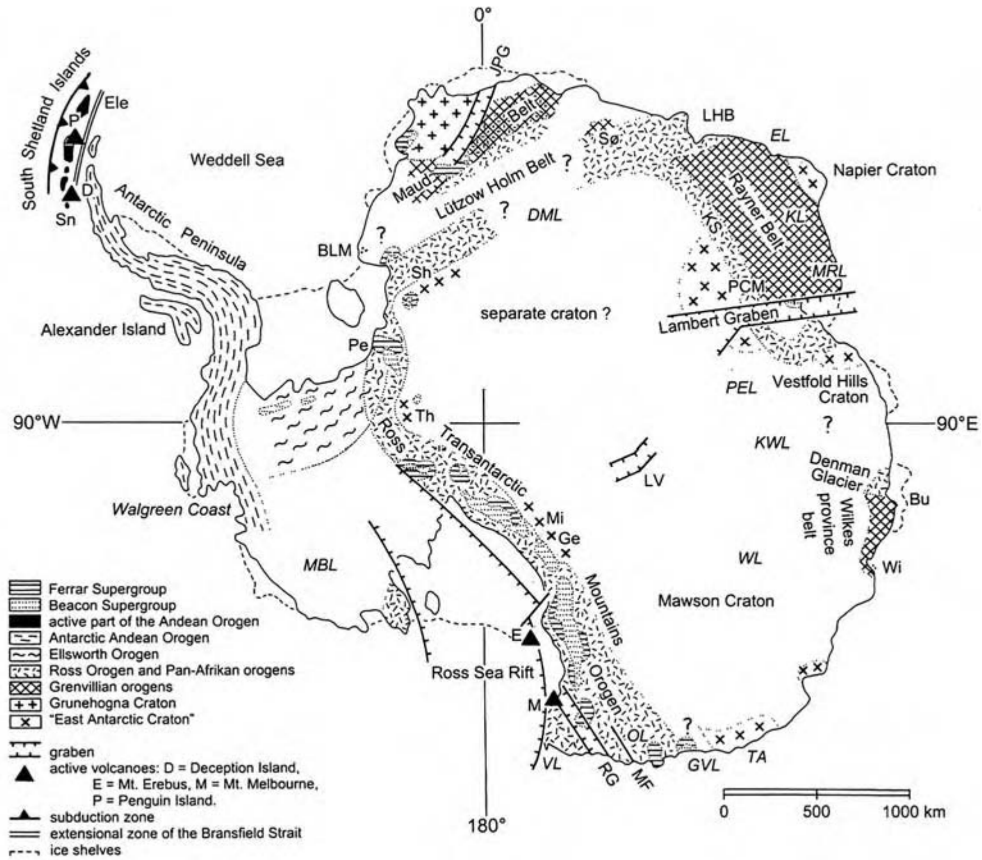
1. A craton comprises two parts: a basement and an undeformed, relatively young cover. That part of the craton where the older basement crops out is called the "shield" and that part where undeformed sedimentary rocks cover the basement is called the "platform." Even if East Antarctica was one uniform craton, it would be a "platform" with some minor "shields," as it is covered, for the most part, at least, by the "rock" ice!
2. East Antarctica comprises several cratons, at least two of which are widely accepted: the Grunehogna Craton and the East Antarctic Craton *sensu stricto* (that is, in the strictest sense).

The Grunehogna Craton

The small Grunehogna Craton (sometimes also called the Maudheim Craton) comprises westernmost Dronning Maud Land. There, sediments older than 1000 million years are flat-lying and undeformed. The even older (around 3000 million years) basement crops out only at Annandagstoppane (c. 6° W, 72°30′ S), where it is correctly termed a "shield."

The East Antarctic Craton Sensu Stricto

The larger of the Antarctic cratons, the East Antarctic Craton *sensu stricto,* occupies the larger part of East Antarctica beyond the Transantarctic Mountains (i.e., west of the Transantarctic Mountains in Victoria Land, south of them in their central and southern sections, and east of them at their "Atlantic end" at the Pensacola Mountains). The East Antarctic Craton emerges from beneath the East Antarctic ice sheet in



The geological structure of Antarctica. Land, MBL: Marie Byrd Land, MRL: Mac.Robertson Land, OL: Oates Land, PEL: Princess Elizabeth Land, TA: Terre Adélie, VL: Victoria Land, WL: Wilkes Land.

only a few places, that is, the southern Shackleton Range, the eastern Thiel Mountains, the Miller and Geologists ranges of the central Transantarctic Mountains and near the continental margin in Enderby Land, in the southern Prince Charles Mountains, in the Vestfold Hills, in Wilkes Land, in Terre Adélie, and in George V Land. The exposed basement of the craton (shield) consists of high-grade metamorphic rocks, such as gneiss and granulite complexes, which yield radiometric ages from more than 1500 million years to more than 3500 million years (Enderby Land). Occasionally, the basement is more or less covered by platform sediments. An almost-flat-lying sequence of sedimentary rocks of Neoproterozoic, Cambrian, or Ordovician age occurs in the Thiel Mountains. In the southern Shackleton Range, relics of internally undeformed Neoproterozoic sediments with an autochthonous Neoproterozoic regolith at their base cover locally the 1600-million-year-old crystalline basement complex. In George V Land, the boundary to the next-youngest unit, the Ross Orogen, is not clear and is still debated. Here the cratonic basement ("shield": up to 2440-million-year-old granulites, gneisses, and related rocks) borders abruptly much younger granites (c. 500 million years old) to the east in the form of a shear zone.

Parts of Enderby, Kemp, and Mac.Robertson lands have been separated from the East Antarctic Craton and attributed to younger orogenic belts, that is, the Grenvillian and Pan-African belts (in the broadest sense) (Boger et al. 2001; 2002; Boger and Miller 2004; Fitzsimons 2000a), so that northern Enderby Land is considered to be a separate craton (Napier Complex).

The same could happen farther east, when the southern extensions of the Grenvillian and Pan-African orogenic belts in the Denman Glacier region, at Bunger Hills and on the Windmill Islands (Wilkes Land) (Fitzsimons 2000a, b) under the ice sheet, are known more precisely. Then the Vestfold Hills, together with the major parts of Princess Elizabeth and Kaiser Wilhelm II lands, may also be regarded as a separate craton.

Thus, in the next few years, the East Antarctic Craton could change its configuration drastically and appear to be an accumulation of several much smaller cratons, which may be

- the already accepted Grunehogna Craton, which is actually a fragment of the African Kalahari Craton
- the Napier Craton, which is actually a fragment of Dwarhai Craton in India
- the Vestfold Hills Craton
- the Mawson Craton (Fitzsimons 2000a, 2003), possibly comprising the Miller and Geology ranges of the central Transantarctic Mountains, the shield areas of eastern Wilkes Land, Terre Adélie, George V Land, and their Australian counterpart, the Gawler Craton
- a craton comprising the southern Prince Charles Mountains, the southern Shackleton Range, and perhaps the eastern Thiel Mountains

The relationships between the Mawson Craton, the Vestfold Hills Craton, the southern Shackleton Range, and the southern Prince Charles Mountains are totally unknown and wide open to speculation. Furthermore, the cratonic areas could even be subdivided if, for example, the 1600- to 1700-million-year-old orogens can be separated.

The Orogenic Belts of Grenvillian Age

Although Grenvillian strictly means an orogeny at 1100 Ma in eastern North America, Grenvillian in the broader sense is used in the geodynamic and Antarctic literature to refer to the event that resulted in the formation of the supercontinent Rodinia in Mesoproterozoic/Neoproterozoic times (i.e., about 1300 to 900 Ma). Whereas the Pre-Rodinian oceanic crust has been consumed by this process, at least parts of the Pre-Rodinian continents have survived in the cratons. The evidence for this event is the orogenic mountain belts at the former plate margins. In Antarctica, there are three (Fitzsimons 2000a):

1. It is generally accepted that the Maud Belt of Dronning Maud Land is the trace of the welding together of the Grunehogna Craton and the Shackleton Range/southern Prince Charles Mountains craton. It extends from western to central Dronning Maud Land and includes Heimefrontfjella, Kirwanveggen, H.U. Sverdrupfjella, Mühlig-Hoffman-Gebirge, Wohlthatmassivet, Schirmacheroasen, and possibly parts of the Sør Rondane.
2. The Rayner Belt (Yoshida and Kizaki 1983) in Enderby, Kemp, and Mac.Robertson lands connects the cratons of the Napier Complex and the southern Prince Charles Mountains and has been identified in the northern Prince Charles Mountains and the Rayner Complex (Boger et al. 2002).
3. The Wilkes province belt (Fitzsimons 2000a) of Wilkes Land occurs in the Bunger Hills and Windmill Islands and merges the Vestfold Hills and the Mawson cratons.

As their structures (polyphase folding), metamorphism (gneisses, granulites), and magmatism (granitoids) somewhat resemble those in the cratons, those areas that formed during the Grenvillian orogeny have been included in the cratons.

In the late 1980s and early 1990s, the Antarctic Grenvillian orogen was assumed to be a very long, single event, following the Antarctic coast as a 250-km-wide strip from Coats Land in the west to George V Land in the east. This has also occasionally been called the "Circum East Antarctic Mobile Belt" (Yoshida 1992). Such an extension is incorrect for Terre Adélie and George V Land and is unproven for Coats Land. There the only outcrops are three small groups of nunataks called Littlewood, Bertrab, and Moltke nunataks. The Littlewood and Bertrab nunataks consist of rhyolite and granophyre yielding an age of 1100 million years (Storey et al. 1994), but they are absolutely undeformed. However, an orogen cannot be inferred just from the existence of rhyolites of the right age. The Moltke nunataks could prove crucial but, unfortunately, they have been inaccessible since their discovery in 1911–1912 because of overhanging ice masses. However, some fearless explorers collected a few samples and confirmed that there is no rhyolite, but the structural and age data are still missing (Kleinschmidt 2002).

The Ross Orogen

Roughly 750 Ma, Rodinia started to disintegrate, and oceans opened between the numerous fragments. Also, the area of present-day East Antarctica was broken apart (West Antarctica did not exist at that time). The southern prolongation of the Mozambique Ocean opened between the Grunehogna Craton and the rest of East Antarctica as shown by relics of this ocean (ophiolite) in the northern Shackleton Range. Presumably, there was a branch of this ocean in the area of southern Enderby Land extending from the Prince Charles Mountains towards Princess Elizabeth Land. At about the same time, the edge of the Palaeo-Pacific Ocean formed in the general area of the present Transantarctic Mountains. Subduction of the Palaeo-Pacific beneath East Antarctica resulted in the Ross Orogen around 600 to 500 Ma. Therefore, the Ross Orogen *sensu stricto* is restricted to the Transantarctic Mountains (Stump 1995) and extends from northern Victoria Land at the Pacific end up to the Pensacola Mountains at the Atlantic end. Westernmost Marie Byrd Land (Edward VII Peninsula) has to be included within the same orogenic belt, as it separated only much later, towards the end of the Cretaceous.

The Ross Orogen is characterized by folds, thrusts, metamorphism, granitoids, terranes, and flysch- and molasse-type sediments. Remarkable thrusts have been reported from Oates Land that could be traced into the Australian continuation of the Ross Orogen, the Delamerian Orogen (Flöttmann et al. 1993). The systematic distribution of high- and low-pressure types of metamorphism (Talarico et al. 2004) and of S- and I-type granitoids (e.g., Vetter and Tessensohn 1987) led to the model of East Antarctic–ward subduction of the Palaeo-Pacific. In northern Victoria Land, the Ross Orogen comprises three so-called terranes: high- to medium-grade metamorphic rocks and granite dominate the Wilson Terrane to the west; the low-grade turbiditic Robertson Bay Terrane lies to the east; and the low-grade and volcanic-rich Bowers Terrane lies between these two. These terranes are considered to be allochthonous or just a related island arc (Bowers Terrane) and an accretionary wedge (Robertson Bay Terrane). All results indicate that the Ross Orogen is subduction dominated (Andean-type) with a partly oblique and partly orthogonal compressional regime.

The Other Orogens of Pan-African Age

Three orogenic belts formed at about the same time as the Ross Orogen during the Pan-African period of 600 to 500 Ma:

1. The belt of the Shackleton Range–Dronning Maud Land–southern Sør Rondane–Lützow-Holmbukta region. Jacobs et al. (1998) proposed the name "East Antarctic Orogen" or "East Antarctic Belt," while Fitzsimons (2000b) proposed the more appropriate "Lützow-Holm Belt."
2. The belt of the southern Prince Charles Mountains–Grove Mountains was called the "Kuunga Suture" (Boger et al. 2002).
3. The Denman Glacier region (Fitzsimons 2000b).

However, the exact extent of these orogens is uncertain because of their predominant ice cover, which is particularly true of the Denman Glacier belt.

The Lützow-Holm Belt is characterized by extensive thrust and nappe tectonics (Shackleton Range), by widespread and distinct late-orogenic collapse structures (Shackleton Range), by thick molasse formations (Blaiklock Glacier Group, Shackleton Range, Urfjell Group, Dronning Maud Land), and by syn- and post-orogenic magmatism (Dronning Maud Land) (Paech 2004). Therefore, these Antarctic portions, formed during the late Neoproterozoic to Cambrian, show typical characteristics of a collisional orogen.

The three belts indicate the amalgamation of West Gondwana (South America, Africa, and Grunehogna Craton) and East Gondwana (India, Australia, and main East Antarctica). As proposed by Boger et al. (2001, 2002), Gondwana's amalgamation may have taken place in two stages, the first before 550 Ma and the second after 550 Ma. The first step is merging West Gondwana and "Indo-Antarctica" (i.e., India and the northern Prince Charles Mountains plus the Napier Complex) manifested as the Mozambique Belt and as its Antarctic prolongation, the Lützow-Holm Belt. The second stage is adding the rest of East Gondwana (i.e., the rest of East Antarctica and Australia), and thus producing the Kuunga Suture. This idea could explain the discrepancy within the Lützow-Holm Belt and its "double-track": in Dronning Maud Land it is mainly older than 550 million years and thus part of the first stage. The Shackleton Range belongs to the second stage (<550 million years old). Thus, the existence of an old alien element between both "tracks," consisting of the Bertrab, Littlewood, and Moltke nunataks in southern Coats Land, is perfectly explicable, maybe as an exotic terrane or maybe a mini-craton.

The relation of the Denman Glacier belt, which is interpreted as a prolongation of the Leeuwin Complex of the Pinjarra Orogen in Australia, is still unclear.

During the Lifetime of Gondwana

The Pan-African orogenies led to the formation of the supercontinent Gondwana, existing from c. 500 Ma until 180 Ma. Its central part, that is, its keystone, was (East) Antarctica. Evidence for the existence of Gondwana's huge landmass is shown by the terrestrial sedimentary rocks that, in Antarctica, are collectively termed the "Beacon Supergroup," unconformably overlying the older formations of the cratons, and the Grenvillian and Pan-African orogenies.

The Beacon Supergroup occurs in the Transantarctic Mountains (Victoria Land, central Transantarctic Mountains, Pensacola Mountains), George V Land, the eastern edge of the Shackleton Range, north and south of the Shackleton Range (the Theron Mountains and Whichaway Nunataks respectively), western Dronning Maud Land, the Ellsworth Mountains, and Mac.Robertson Land (Lambert Glacier area). The main rock types are fluvial sandstones, indicating a predominantly terrestrial environment, that were deposited from Devonian through to Triassic times. The most conspicuous strata are Permo-Carboniferous tillites and diamictites combined with striations and Permian coal measures. These indicate a rather rapid climatic change from an ice age to dense woodlands, from cold conditions to humid conditions and mild temperatures (e.g., Collinson et al. 1994).

The Beacon Supergroup corresponds to the (lower) Gondwanan strata of India and South America, to the Karoo Supergroup of southern Africa, and to the Permo-Triassic analogues of Australia.

Gondwana Breakup

The disintegration of Gondwana started with rifting of the Gondwanan crust around 200 to 180 Ma. This initial rifting led to an intense Gondwana-wide Jurassic volcanism (c. 180 Ma), called the Ferrar Supergroup in Antarctica. These subalkaline, basic volcanic rocks are widespread in western Dronning Maud Land, in the vicinity of the Shackleton Range (Theron Mountains), throughout the Transantarctic Mountains from Pensacola Mountains to northern Victoria Land, and in George V Land.

The rocks of the Ferrar Supergroup form extensive flood basalt sheets (e.g., Kirkpatrick Basalt) or (more frequently) they occur as horizontal or subhorizontal sills (Ferrar Dolerites) intruded into older rock sequences (basement, Beacon Sandstone) where they can attain a thickness of a few hundred metres.

Although their chemistry is not an alkaline type, they are generally regarded as an indication of crustal extension (i.e., of Gondwana's decay) (Elliot 1992). However, they are also discussed in relation to the subduction processes of the Ellsworth Orogen.

The breakup of Gondwana, actually the separation of New Zealand from Marie Byrd Land, in the Cretaceous (some 100 Ma), is also accompanied by magmatism. Anorogenic A-type granites, the so-called "Byrd Coast Granites," formed on both Gondwanan fragments. The end of the Gondwana decay, and the consequent final isolation of Antarctica, was the opening of the strait between Victoria Land and Tasmania c. 35 Ma and of the Drake Passage between the Antarctic Peninsula and South America c. 25 to 20 Ma.

The Ellsworth or Weddell Orogen

The Pacific margin of Antarctica has existed since the formation of Gondwana and it was also the Pacific margin of Gondwana throughout Gondwana's existence. At this margin, the next growth zone of Antarctica, after the Ross Orogen, was added some 250 to 200 Ma. This is the Ellsworth Orogen, sometimes called the Weddell Orogen, or in a larger context the Gondwanides Orogen, which includes its continuation to southern Africa (Cape Fold Belt) and to South America (Sierra de la Ventana Fold Belt). The Ellsworth Orogen extends from the Ellsworth Mountains to the Pensacola Mountains and includes the Whitmore Mountains to the south. The chain of the Ellsworth–Pensacola Mountains represents the fold belt, while the Whitmore Mountains represent the magmatic arc of an Andean-type orogen. It merges with the Ross Orogen in the Pensacola Mountains, where it partly overprints the older structures of Ross age.

The Ellsworth Orogen trends noticeably obliquely to the Palaeo-Pacific margin of Antarctica indicated by the Ross Orogen. This obliqueness is due to secondary rotation, as demonstrated by palaeo-magnetic investigations by Funaki et al. (1991) and confirmed by Randall et al. (2004).

The Antarctic Andean Orogen

The orogen of the Antarctic Andes occupies the entire Antarctic Peninsula southward to the Walgreen Coast. It formed mainly in three stages: (1) Late Jurassic through Early Cretaceous (150–140 Ma), (2) Mid-Cretaceous (c. 105 Ma), and (3) Tertiary (c. 50 Ma to recent), and it is partly still active (e.g., Birkenmajer 1994; Vaughan and Storey 1997).

Thus, it represents the youngest growth zone of the continent. The Antarctic Andes are a typical subduction orogen, like the South American Andes, with extensive orogenic magmatism in the form of granitic plutonism and volcanism. In detail, the deformation and metamorphism is very complicated because it is polyphase. Folding and thrust tectonics are reported mainly from the southern peninsula (Palmer Land, Alexander Island) and from the extreme north (Trinity Peninsula and eastern South Shetland Islands). The distribution of types and degrees of related metamorphism(s) is also heterogeneous (A. Wendt, personal communication), including high-pressure metamorphism with blueschists characteristic of subduction complexes (e.g., on Elephant Island) (Trouw et al. 1991).

The Plate-Tectonically Active Parts of Antarctica

The plate-tectonically youngest, and the only plate-tectonically active, part of Antarctica is situated northwest of the Antarctic Peninsula in the South Shetland Islands (from Snow Island in the southwest to Elephant Island in the northeast) and along Bransfield Strait. Northwest of the South Shetland Islands a small section of the Pacific ocean floor, called the Drake Plate, was, and possibly still is, being subducted at the South Shetland Trench beneath the Antarctic Plate. (The Drake Plate is the remnant of the older, but largely subducted, Phoenix Plate.) Related, mainly andesitic, volcanism forms the island arc of the South Shetland Islands. Almost all of these volcanoes are extinct but Penguin Island erupted less than 100 years ago. Parts of the South Shetland Islands (part of Livingston Island and Elephant Island) belong, like the Antarctic Peninsula itself, to earlier stages of the Antarctic Andean Orogen and consist of strongly deformed Jurassic trench sediments.

Bransfield Strait is located southeast of the subduction-related volcanic island arc and forms an active extensional basin accompanied by tholeiitic volcanism, partly submarine, partly as an active island volcano (Deception Island) (Smellie et al. 2002). Bransfield Strait is often regarded as a classic example of a back-arc basin, but recently this has been disputed (Gonzáles-Casado 2000).

Major Fault Systems

The constructive aspect of the geologic development of Antarctica contrasts with the destructive aspect: Antarctica's structure is cut by relatively young extensional faulting. Particularly large and conspicuous fracture zones are as follows:

- The Lambert Graben or Lambert Rift (East Antarctica)
- The West Antarctic Rift System and its major part, the Ross Sea Rift (Pacific sector)
- The graben of Jutulstraumen and Penckmulde (occasionally called the Jutul–Penck Graben [Atlantic] sector)
- The Rennick Graben, the major element of a strike-slip fault system in Victoria and Oates lands

The Lambert Graben developed in the East Antarctic Craton and is filled by sediments of the Permo-Triassic Beacon Supergroup. Faulting began during the early Palaeozoic, reached its peak during the Permian, and continued into the Early Cretaceous (Hofmann 1996). Vostok Subglacial Lake possibly belongs to the same rift system, although it is somewhat offset. The continuation of the Lambert Graben is the Indian Mahanadi Rift southwest of Calcutta in the state of Orissa (Hofmann 1996), filled with sediment of the same type and age as the Lambert Graben. In the reconstruction of the Gondwanan India–Antarctica fit, these graben systems coincide with reconstructions of Archaean to Early Proterozoic elements of Rodinia. This means that the relationship between Antarctica and India during Rodinian and Gondwanan times did not differ substantially.

The Ross Sea Rift is extremely wide (about 1000 km). Its subsidence started during the late Mesozoic (about 140 Ma), reached its main activity in the Early Tertiary (about 40 Ma), and produced an enormous relief at its western shoulder. The difference in altitude between the Transantarctic Mountains and the Ross Sea floor exceeds 14 km. The crustal extension is combined with alkaline, intracontinental volcanism, which is still active at Mount Erebus (3794 m) and Mount Melbourne (2732 m), both located in Victoria Land.

The Jutul–Penck Graben of western Dronning Maud Land probably originated around 140 Ma or a little later (Jacobs and Lisker 1999). The graben marks the boundary of the Grunehogna Craton to the southeast and thus it is following a much older geological structure. A possible continuation of the Jutul–Penck Graben into the still-active East African rift system is under discussion (Graham and Hunter 1991). This is not unlikely because parts of the East African rift system were already active during the Jurassic (Ring and Betzler 1993).

The strike-slip fault system of Victoria and Oates lands trends obliquely to the Ross Sea Rift and is cut by it. It still shows certain activity, demonstrated by earthquakes in 1952, 1974, and 1998, the last two of which were located in the main element of the system, the Rennick Graben. This graben contains down-faulted volcanic rocks of the Ferrar Supergroup and sedimentary rocks of the Beacon Supergroup, which have been spectacularly folded and squeezed onto the graben shoulders. This proves alternating dextral transpression and transtension (with the formation of pull-apart basins), as parts of a complicated strike-slip system (Rossetti et al. 2003). The 1954 earthquake occurred some 120 km to the west at the parallel structure of the Matusevich Glacier. There is an ongoing discussion as to whether this strike-slip fault system constitutes the continuation of the oceanic fracture zones between Australia and Antarctica (e.g., the Tasman Fracture Zone) into the continental crust of Antarctica.

GEOMAGNETIC FIELD

The Earth's magnetic field—the geomagnetic field—is produced mainly by an internal dynamo source but extends many Earth radii into space. The field is dipolar but the positions of the magnetic poles do not coincide with the geographic poles. Furthermore, the intensity and direction of the field vary with time. In addition to the dynamo source, the field measured at the surface includes contributions due to magnetic sources and electric currents in the Earth's crust, and external sources arising from currents in the ionized part of the atmosphere (the ionosphere) and charged particles reaching Earth from space. Knowledge of the geomagnetic field has advanced greatly during the spaceflight era but is still far from complete.

Discovery and Measurement of the Geomagnetic Field

The nature of the geomagnetic field was first clearly described in 1600 by William Gilbert, court physician to Queen Elizabeth I of England. In what is often regarded as the first true work of modern science, Gilbert used a series of experiments to establish that the Earth is magnetized and possesses magnetic poles. The total strength of this field is around 0.066 milliTesla (mT) near the poles and 0.024 mT near the equator. By comparison, a small bar magnet produces a field on the order of 10 mT.

Although magnetic compasses had probably been used as navigational aids since the twelfth century, the fact that the direction in which a compass points deviates from true (geographic) North by an amount that depends on location was first clearly reported by Christopher Columbus in 1492. This angle of deviation is called the magnetic declination. Knowledge of the declination is important for navigation. The first declination chart of the Earth was developed by Edmund Halley in 1702.

At low and middle latitudes the declination is generally just a few degrees. However, in the polar regions declination can be very large, so the compass needle may point in quite a different direction from poleward. For example, at the Australian Antarctic station Davis, the declination in April 2003 was 78°31′ W, and increasing westerly by about 8′ per year.

Observatories for systematically measuring the geomagnetic field strength and direction were established in the 1840s. Today a global network of magnetic observatories continually monitors the geomagnetic field, contributing data to the World Data Centers for Geomagnetism in Copenhagen, Edinburgh, Kyoto, and Mumbai. Data from these centers are freely accessible and largely online. About eighty observatories around the globe also provide data with 1-minute timing via the International Real-Time Magnetic Observatory network, known as INTERMAGNET. At each of these observatories the geomagnetic field is measured each 5 seconds with a resolution of 0.1 nanoTesla (nT) and an absolute accuracy of 5 nT.

The geomagnetic field is described in terms of its total intensity F and the horizontal intensity H, both measured in nT, the inclination or dip angle I (the angle between the horizontal and the total field direction, in degrees), and the declination D, in degrees. It is also common to describe the field in terms of its intensity in the true north, east, and vertical directions (called X, Y, Z), all measured in nT.

The strength and direction of the geomagnetic field vary over periods from millions of years to fractions of a second. In general, variations with periods longer than about a day are of internal origin. The short-period variations of external origin are a thousand to a million times smaller in amplitude than the main internal field. The magnetic field produced by common objects such as a belt buckle or screwdriver will be of intensity comparable to these rapid variations. Thus, magnetic observatories are constructed from nonmagnetic materials and need to be located a good distance away from sources of electrical or magnetic noise. Two types of instruments are usually used to measure the geomagnetic field. Absolute instruments measure the components of the main background field (F, H, I, and D) in terms of basic physical units. In addition, variometers measure the field's variation from the undisturbed state. Some magnetometers combine both functions with GPS-synchronized digital sampling.

The Dipolar Nature of the Field

A mathematical description of the geomagnetic field was first provided by Carl Gauss in 1839. He recognized that the internal source of the main magnetic field could be represented by a small tilted bar magnet at the geodetic center of the Earth. The resultant field is dipolar and the dipole axis is tilted by about 11° with respect to the Earth's geographic rotation axis. Such a dipole accounts for about 80% of the geomagnetic field at the surface. Gauss also calculated the positions where the best-fitting dipole axis cuts the Earth's surface. These locations are the geomagnetic poles. Vostok Station in Antarctica is located near the South Geomagnetic Pole. Strictly speaking, this is a north pole, because it attracts the south pole of magnets (such as compass needles).

The positions of the actual magnetic poles (or dip poles), where a compass needle stands vertically, depend on local effects in the crust and do not coincide with the geomagnetic poles. The resultant nondipole field accounts for 10%–25% of the field measured at the surface. The dip-pole locations are not readily calculated and therefore measuring their locations was an important goal for early explorers.

The position of the North Magnetic (dip) Pole was discovered by James Clark Ross on June 1, 1831, at 70°05′ N, 96°46′ W. The South Magnetic Pole was first approached in an epic man-hauled sledge journey by T. W. Edgeworth David, Douglas Mawson, and Alistair Mackay, from Ernest Shackleton's British Antarctic Expedition, on January 16, 1909. At that time the pole was located at 71°36′ S, 152°0′ E, over 190 miles (300 km) into the interior of the Antarctic plateau.

In December 2000 the magnetic dip pole was relocated (Barton 2002) by the ship *Sir Hubert Wilkins* at 64°40′ S, 138°01′ E, about 150 miles (240 km) offshore from the French base Dumont D'Urville. It is estimated that since 1841 the South Magnetic Pole has drifted 1300 km, at an average speed of 8.2 km/yr. It is currently drifting northwest at around 4 km/yr. This type of slow field change is called secular variation. For this reason magnetic charts need to be updated periodically. For example, the declination at London, England changed gradually from 11.5° E in 1576 to 24° W in 1823, and is now about 6° W.

Internal Source of the Geomagnetic Field: Dynamo Theory

Magnetic fields are produced by the motion of charges, such as electrons moving in a wire. In the case of the Earth this occurs in the outer core. The continents and ocean floors form the crust of the Earth. Seismic observations show that the underlying mantle extends to about 1800 miles (2900 km) in depth, below which lies the outer core. This encloses the inner core, another 1375 miles (2200 km) further down and about 810 miles (1300 km) in radius. The outer core comprises mostly liquid iron, about 4% nickel and 10% lighter elements, while the inner core is denser and of solid metal. The inner core is produced by solidification of outer-core material as the Earth cools, and is gradually growing in size.

Conditions in the inner core are extreme. The density is about four times that of the crust, and the temperature is similar to that at the surface of the Sun, around 6400°C. The heat in the core remains from when the Earth was formed, and is also provided by radioactive decay processes. Liquid iron deep in the outer core is heated and rises upward toward the mantle, where it cools and then sinks. This convection process is similar to the circulation of water in a saucepan heated on a stovetop. The resultant loss of heat from the deep outer core also causes heavier elements to solidify at the boundary between the inner and outer core. This releases latent heat, further contributing to turbulent convection in the outer core.

The inner part of the outer core rotates faster than the outer part. The linear rotation speed of fluid rising through the outer core under convection is slower than the linear rotation speed higher up. The rising fluid thus imposes drag in the larger radius part of the outer core. The resultant differential rotation of the conducting fluid produces a self-excited dynamo, generating an electric current and hence the main dipole field. Nondipole regional anomalies probably arise from eddy circulations in the outer core.

Secular Variation

The geomagnetic field is locked to fluid motions of the core. This means that the secular variation is directly related to processes in the dynamo source, and that understanding of the Earth's interior requires detailed knowledge of the secular variation (e.g., Jackson et al. 2000). Several factors may influence the dynamo process, including changes in the Earth's rotation rate and changes in the mass distribution at the Earth's surface due to ice ages or a major asteroid impact. It has been suggested that the secular variation exhibits periods of roughly 8000 and 400 years (Yukutake 1973), although many factors may influence the data and analysis (Barton 1983). On a time scale of millions of years, movement of the magnetic poles appears to be linked with large-scale tectonic processes such as continental drift.

The strength of the main geomagnetic field is described by the Earth's dipole moment, in units of Amp m^2. This has steadily decreased by about 20% over the last 400 years (Barton 1989). The significance of this is not clear. However, it is well established that the geomagnetic field completely reverses direction from time to time. The last such reversal was about 780,000 years ago, referred to as the Brunhes-Matuyama reversal. Short-duration decreases in the dipole moment have occurred more recently.

Evidence of magnetic reversals occurs in the pattern of alternating magnetic polarities seen in solidified lava along the sea floor. These patterns arise from the cooling of hot magma as the continental plates spread out away from midocean ridges. The cooling magma carries with it magnetization characteristic of the ambient magnetic field. Since the sea floor spreads at a more or less constant rate, this pattern provides a timeline of the field polarity. The discovery of these magnetic patterns was invaluable to the theory of plate tectonics.

Reversals occurred on average each 750,000 years 50 Ma, but by 10 Ma this rate had decreased to about 200,000 years. The geomagnetic field appears to have no long-term preference for either polarity.

Occasionally there may be a sudden (on the order of a year) change in the general trend of secular variation. Such changes are called magnetic jerks. Recent jerks occurred in 1925, 1969, 1978, and 1992. They are unpredictable and their cause is unknown.

The Crustal Field

The contribution to the observable geomagnetic field arising from magnetic materials in the Earth's crust is often called the anomaly field. This field varies on all spatial scales and is mapped with ground-based, marine, aeromagnetic, and satellite surveys. Such activity has two practical applications. First, magnetic charts including crustal contributions are necessary for precise navigation. Second, magnetic surveys delineating the crustal field provide vital information to the geophysical exploration community that is concerned with locating and exploiting mineral deposits. Surveys of this nature can be contaminated by short-period field variations of external origin.

High-precision measurements of the geomagnetic field from spacecraft missions such as Oersted and Champ provide detailed data on the crustal field, and allow the surface-level field to be extrapolated to the core–mantle boundary. This provides important information to mathematical and laboratory-based models that try to mimic and predict the complex turbulent convection processes in the core that drive the dynamo field. The most sophisticated of these models are able to simulate geomagnetic field reversals, although it is not possible to say with what accuracy.

Models of the Geomagnetic Field

While it is relatively easy to describe the geomagnetic field in terms of a centered dipole, this is a poor approximation to the actual field. A significant improvement is gained by using an eccentric axis dipole, based on a tilted dipole source displaced about 325 miles (520 km) from the Earth's center, toward the Philippines.

The most widely used model of the geomagnetic field is the International Geomagnetic Reference Field (IGRF). This is based on a multipole expansion using a series of mathematical functions, spherical harmonics that characterize the physical properties of the observed field. The IGRF includes data on the secular variation and crustal contributions obtained from ground-based and spacecraft observations, and is updated at five yearly epochs. The location of the IGRF magnetic pole is very close to the actual measured dip pole.

Since the distribution of magnetic observatories is concentrated in the industrialized countries, and because of the locations of the magnetic poles, observations from the polar regions are particularly important to such geomagnetic field models. Historical data are also vital for retrospectively defining the past field.

The Corrected Geomagnetic coordinate system (CGM) is a derivation of the IGRF but more accurately represents the field line paths following by moving charged particles. The joint French/Italian Antarctic station, Concordia (also called Dome C), which opened in December 1997, is located at 75°17′ S, 123°63′ E, 3220 m above sea level, 950 km from the coast, and very near the CGM pole. Part of the reason for establishing a station at this challenging location is that at this great height above the continental crust, magnetic measurements are unaffected by contributions from crustal anomalies. In addition to being near the CGM pole, this makes Concordia an ideal location to study geomagnetism.

Because of the offset of the dipole field, the surface magnetic field strength reaches a minimum in the Atlantic Ocean just off the southeast coast of Brazil. This is called the South Atlantic Magnetic Anomaly (SAA). Since the motion of charged particles arriving from space is usually directed along magnetic field lines, such particles reach their lowest altitudes near the SAA. This can result in high radiation doses that may affect humans and damage spacecraft in near-Earth orbits that traverse the SAA. Such spacecraft suffer the greatest number of radiation-induced operational anomalies near the SAA, and the International Space Station incorporates extra shielding to protect the crew against the enhanced radiation experienced there.

External Contributions to the Field

Measurements from magnetic observatories show systematic seasonal and diurnal variations that are due to motions of the upper atmosphere driven by the variation in solar radiation with time and latitude and the gravitational pull of the sun and moon. This results in winds and tidal forces that drive motions of charged particles in the ionosphere, usually around 65 miles (105 km) in altitude. The resultant electric currents cause a quiet day variation in the ground-level magnetic field.

These ionospheric currents also give rise to currents within the conducting layers of the Earth. The precise magnitude and direction of these currents depends on the electrical conductivity profile. The quiet-time diurnal ionospheric currents thus form a convenient source for mapping the conductivity profile of the Earth.

In the polar regions there is an additional ionospheric current system that produces larger magnetic variations on time scales of an hour or so. Called the auroral electrojet, this is an intense westward electric current in the ionosphere that is associated with active auroral displays. It produces strong magnetic variations. The polar geomagnetic field lines stretch from the Earth's surface a long distance into space—typically 10 Earth radii on the day side and much further on the night side. The enclosed volume is called the magnetosphere and contains significant populations of charged particles. The geomagnetic field lines provide a conduit to the ionosphere for these particles. The most energetic such particles are cosmic rays, mostly protons accelerated from the Sun and other stars. There is good reason, therefore, to locate cosmic ray observatories in Antarctica. One such observatory is at Australia's Mawson station.

A large population of energetic charged particles orbits the Earth in the Van Allen radiation belts. The motion of these particles Earthward produces field-aligned currents that drive the auroral electrojet. The existence of these field-aligned currents was first proposed by the Norwegian scientist Kristian Olaf Birkeland in 1908, and therefore they are often called Birkeland currents. In a series of remarkable experiments, Birkeland constructed a terrella—a small magnetized sphere representing a model of the Earth in space—and created artificial auroras around its magnetic poles using electron beams. He thus demonstrated that auroras are caused by electrically charged particles traveling Earthward along magnetic-field lines and energizing gas molecules in the polar atmosphere. He also reasoned that these energetic electrons affect the geomagnetic field, thus causing polar magnetic storms. Norway honors Birkeland on its 200-kroner banknote.

The existence of Birkeland currents was only proven in 1974 by observations from the Triad spacecraft, which was carrying suitably sensitive magnetometers over the polar ionosphere. These currents have important consequences apart from characterizing the location of auroras. Spacecraft in low-Earth orbit use magnetometers for attitude control, by determining their orientation with respect to the main geomagnetic field. However, as such a spacecraft passes over the polar regions, the magnetic fields produced by the Birkeland currents may be sufficient to affect the spacecraft's altitude-control system. Magnetometer data from networks of communications satellites can be used to map the precise location and size of the Birkeland current systems.

The South Magnetic Pole is located a considerable distance from the geographic South Pole. This has an interesting effect. During summer the polar ionosphere is continually sunlit. This produces enhanced ionization at relatively low magnetic latitudes over the Antarctic Peninsula. Ionospheric winds are then able to drive charged particles up the geomagnetic field lines, resulting in an anomalously high particle density on those field lines compared to other longitudes.

Geomagnetic Disturbances

In addition to secular variation, the magnetic poles also move on relatively short time scales. During measurements from *Sir Hubert Wilkins* over December 21–22, 2000, the South Magnetic Pole was initially about 360 km from its expected position, and moving at 17 km/hr. The pole then moved to the predicted position and settled down to a small elliptical path close to the IGRF pole. Such short-period motions are due to external contributions to the geomagnetic field associated with the effect of the solar wind on the magnetosphere, including magnetic storms and ULF pulsations.

During the International Polar Year in 1932 a system was developed to characterize the level of disturbance of the geomagnetic field due to these external effects. This is based on indices describing the level of disturbance each three hours, called K indices. The K indices from typically 12 observatories around the globe are averaged to produce the 3-hourly planetary magnetic activity index, Kp. Today this is the most widely used measure of geomagnetic disturbance.

Magnetic storms produce a variety of effects on terrestrial and space-borne systems. These phenomena are collectively termed space weather. For example, the petroleum industry uses the geomagnetic field to guide directional drilling toward oil reservoirs. Typical accuracies required are 0.1° in direction and 50 nT in total intensity. This requires knowledge of the crustal field, daily variations, and space weather effects such as magnetic storms.

GEOPOLITICS OF THE ANTARCTIC

In considering the nature of Antarctic geopolitics over the past century, four particular dimensions stand out: (1) territorial ambitions, which relate to the quest by states to demonstrate sovereignty over Antarctic lands; (2) spatial considerations, which refer to the crucial impact of how the Antarctic environment affects the aspirations of states; (3) strategic designs, which reflect attempts by governments to exercise calculated objectives in the Antarctic; and (4) resource acquisition, which concerns the greater importance felt by states to secure access to Antarctic natural resources. Taken in combination, these considerations have shaped national geopolitics in the Antarctic, so much so that they pushed an evolutionary trend in state behavior in the region from bilateral rivalry and conflict up until the mid-1950s to the progressive codification since then of peaceful cooperation through a special multilateral regime.

National geopolitical rivalries in the Antarctic aroused controversy over territorial ambitions throughout the last century. Before its discovery in the early nineteenth century, the continent was uninhabited and belonged to no one. No universally accepted treaties or legal principles governed activities in the Antarctic or defined jurisdiction over that continent's territory and resources. Antarctica was considered *terra nullius,* literally no man's land, a frozen ice-covered continent at the bottom of the world. Beginning in the early twentieth century, however, seven governments progressively asserted pie-shaped claims to Antarctica as portions of their own national territory. While these claims to Antarctica persist today, they are not recognized by any government other than that of the claimants themselves. Consequently, these claims carry salient geopolitical implications for the legal status of the continent and its circumpolar waters.

The United Kingdom was the first government to assert a claim to the Antarctic continent. Known officially as the British Antarctic Territory, the United Kingdom's claim was made in 1908 and goes south of 60° S between meridians 20° and 80° W to the South Pole. The area covers some 700,000 square miles on the continent, including "Graham's Land" on the Antarctic Peninsula. The UK claim also encompasses important island groups in the Southern Ocean, namely the South Orkneys, South Shetlands, South Georgia, and the South Sandwich group. In the case of South Georgia, the establishment of a local government and the collection of taxes are made a fundamental part of the claim. While not formally a geographical part of the Antarctic, the Falkland Islands prominently figure to geopolitics in the region. British sovereignty over the islands has been disputed by Argentina since the 1820s. In April 1982 Argentina invaded "Las Malvinas" and other British territories in the South Atlantic (South Georgia and the South Sandwich Islands), igniting war with the UK. By June the British had won the conflict and established control over all the island groups in the region. The UK claim to Antarctica rests mainly upon the exploits of British explorers in the circumpolar seas. Captain James Cook visited these waters in January 1775 and claimed South Georgia in the name of King George III. He also discovered the South Sandwich Islands group. In 1819, William Smith discovered the South Shetland Islands and claimed them for Great Britain. One of the earliest sightings of the Antarctic mainland was made in 1820 by Edward Bransfield, a Royal Navy officer. The South Orkney Islands were claimed in 1821 for the British Crown by George Powell. During 1841–1843, Sir James Clark Ross circumnavigated the continent, charted some 500 miles of coastline along Victoria Land, and discovered Ross Island, as well as the northern edge of the Ross Ice Shelf. In January 1843, Sir Ross landed on Palmer Peninsula and claimed Ross Island and all "contiguous lands" for the British Crown.

British claims to administer legal title in the Antarctic were first set out in a King's Letters Patent of 1908. This royal proclamation formally established the Falkland Islands Dependencies, consisting of the Falkland Islands, South Georgia, the South Orkneys, the South Shetlands, the South Sandwich group, and Graham's Land on the continent. In March 1917 a second Letters Patent was issued to elucidate Great Britain's claim. This decree included all islands and territories between 20° and 50° W situated south of 50° S, as well as all islands and territories between 50° and 80° W situated south of 58° S. When depicted today on a map, the geopolitical implications of the British claim become stark: The UK claim overlaps in substantial part with contending claims of sovereignty made by Chile in 1940 and Argentina in 1945 to the Antarctic Peninsula, an area that possibly contains petroleum, natural gas, and mineral deposits. It bears remembering that not only do the United Kingdom and Argentina share contentious claims over the Antarctic Peninsula, they also dispute the ownership of several sub-Antarctic islands and went to war when Argentina invaded South Georgia and the Falkland Islands in 1982.

New Zealand's claim to Antarctica, known as the Ross Dependency, covers 175,000 square miles and runs south of 60° S between 160° E and 150° W, extending to the South Pole. By an Order-in-Council in 1923, this wedge of Antarctica was entrusted by the United Kingdom to New Zealand. The subsequent legal grounds posited by New Zealand for its claim rest in discoveries by the British explorer Admiral James Clark Ross in 1841, as well as expeditions by Robert Scott and Earnest Shackleton between 1901 and 1909. Further legitimacy for New Zealand's claim supposedly flows from the title originally asserted by Great Britain (Logan 1979).

France claims the smallest portion of the continent, a 150,000-square-mile wedge called Terre Adélie. The

French claim runs between 136° and 142° E, extending to the South Pole. The French sector in fact bisects the Australian claim. The legal ground for the French claim is discovery, particularly the voyage of Dumont d'Urville in 1840. While considerable weight is given to d'Urville's discoveries in the region, he never set foot on the continent. The French exercise uncontested sovereignty over some islands in the Antarctic Ocean, namely Kerguelen, Crozet, Amsterdam, and St. Paul. These islands, along with the Adelie Land on the continent, were administered by the Governor General of Madagascar until 1955. Since then, the French Southern and Antarctic Territories have been administered by the Terres Australes et Antarctiques de France (TAAF) in Reunion, as a part of the Ministre d'Outre Mers.

Australia has the largest claim to the continent. With an area of 2.4 million square miles, the Australian Antarctic Territory covers the region south of 60° S between 45° and 160° E, running to the South Pole, except for the wedge claimed by France. Australia in effect claims two large sectors on the continent. Australia states two main legal grounds in support of its Antarctic claims. The first consists of the acts of discovery made by British and Australian explorers, especially that of Captain Cook's circumpolar voyage in 1770–1775, which is buttressed by the expedition in 1910–1911 of Sir Douglas Mawson. The second is that Australian nationals have established a continuous occupation in Antarctica, characterized by administrative acts and civil control. Australia's sectors were originally part of the British claim made in 1908. Australia requested that the United Kingdom declare a sovereign claim to the Antarctic mainland on its behalf. This was done in 1933 by a British Order-in-Council that transferred title to Australia and entered into effect in 1936. Australia contends that, in legal terms, its claim rests on effective occupation of the continent since then (Morgan 1996).

Norway claims a part of Antarctica known as Dronning Maud Land. The Norwegian claim includes the Antarctic mainland, running from the Falkland Islands Dependencies in the west at 20° W to the Australian Antarctic Territory in the east at 45° E. Covering an area of 1.2 million square miles, the Norwegian claim was declared by royal decree in 1939. The immediate catalyst for Norway's decree stemmed from geopolitical concerns about reports that Nazi Germany intended to stake a claim in the Antarctic. The legal basis for Norway's claim to title, however, rests on "geographical work done," ostensibly during the expedition by Roald Amundsen during 1910–1912, which had no relationship to Dronning Maud Land. Norway's claim differs from other claims to the Antarctic in that it relies less on discovery than on actual occupation and historical use of the circumpolar seas by national whaling fleets. It is also distinguished from other claims by its having neither a defined northern nor a defined southern terminus. Paradoxically, Amundsen, the first man to reach the South Pole, had in fact laid claim to the polar plateau in December 1911 for King Haakon VII of Norway. That precise basis was never legally articulated or formally acknowledged by the Norwegian Government. Norway's decision not to allow its claim to terminate at the South Pole was prompted by a pragmatic geopolitical consideration: if this Antarctic claim were acknowledged, it would imply formal substantiation of Norway's validation of using sectors as permissible means for demarcating polar territory. Such a circumstance would undercut Norway's legal position for claims it made to territory in the Arctic, which were originally contested by the Soviet Union (now Russia). In the Arctic, Russia continues to assert a sector claim to Spitsburgen in the Svalbard archipelago such that it geographically disadvantages a Norwegian claim to the same territory. To admit the validity of using the sector device anywhere would be tantamount to admitting the validity of the contentious Soviet (Russian) claim. Consequently, Norway's proclamation of sovereignty in the Antarctic was judiciously calculated to avoid asserting a sector-shaped claim there in order to safeguard its geostrategic and legal interests in the Arctic.

The claim by Chile to its "Territorio Chileno Antartico" extends from 53° to 90° W, terminating at the South Pole. While Chile has not officially declared the endpoint for its northern baseline, cartographers generally place it at 60° S, an action that has not provoked any formal protest by the Chilean Government. One wonders why this has been the case, since Chile's claim was made prior to the Antarctic Treaty in 1959 and would naturally converge at the South Pole. Chile's claim covers some 500,000 square miles. Prior to 1940, Chile expressed scant interest in the south polar region. It was then, however, that President Aquirre Cerda issued an executive decree that the Chilean Antarctic was comprised "by all lands, islands, islets, reefs, pack-ice, etc. known and to be discovered, and their respective territorial sea, lying within the limit" of the above sector coordinates. It is significant to realize that Chile's claim overlaps those of Argentina and the United Kingdom, both of whom could present evidence of prior historical assertions to title. It was not until 1947 that Chile established a permanent base in the South Shetlands, which provides the earliest demonstrable support for what might be considered Chile's "effective occupation" in the Antarctic.

The legal foundation for Chile's claim substantially reflects that of Argentina. Contemporary title is said to have been transferred to Chile by the 1493 Papal *Inter Caetera,* as supplemented by the 1494 Treaty of Tordesillas between Spain and Portugal. Chile alleges that it also inherited lawful claim to title to Antarctic territory upon its independence from Spain in 1810 *(uti possidetis)*. Chile, like Argentina, contends that privileged legal positions stem from its geologic contiguity and geographic proximity to the Antarctic. Chile additionally contends that effective occupation of the continent has been demonstrated, although only since 1947. It was then that the Chilean government began undertaking special administrative deeds intended to shore up the lawfulness of its sovereignty assertions to the continent. It is important to underscore the geopolitical implications that flow from Chile's assertion to title in the Antarctic. For one, its claim to territory on the Antarctic Peninsula overlaps those of the United Kingdom and Argentina. For another, Chile's historical relationship to Argentina since 1880 at times has been hostile and tense. Third, Chile is the sole claimant whose initial assertion in 1940 included sovereign rights to a territorial sea, although it has not openly exercised such offshore jurisdiction since then (Child 1985; Pinochet de la Barra 1955).

The last claim to title in the Antarctic was made by Argentina in the mid-1940s. This claim, known as "Antartida Argentina," extends south of 60° S, from 25° to 74° W, and dovetails at the South Pole. Argentina's claim encompasses some 550,000 square miles and includes territory in the Antarctic Peninsula, as well as several islands, among them the South Orkneys, the South Shetlands, South Georgia, and the South Sandwich group.

Argentina's Antarctic claim was initially asserted by Juan Peron and first appeared on special maps published by the government in December 1946. Argentina alleges that four legal pillars support its south polar claims. First, Argentina contends that it has performed since February 1904 uninterrupted maintenance of the Laurie Island weather station in the South Orkneys, an action that purportedly demonstrates adequate effective occupation to meet the requirements for territorial sovereignty in the entire region. Certainly Argentina has sought to underline its claims in the Antarctic by periodically performing symbolic acts intended to validate administration of its polar territory. Such acts include depositing special plaques, designating postmasters, coroners, and local magistrates for the region, issuing special postage stamps commemorating Argentina's claimed territories, arranging to have children born there, and even declaring a national "Antarctic" holiday (Fraga 1979).

A second pillar of legal support is Argentina's contention that, under the doctrine of *uti possidetis juris,* valid lawful title to Antarctic territories was transferred to Argentina when it separated from Spain. Like Chile, Argentina argues that historical support for this legal contention flows from the Papal Bull *Inter Caetera* of 1493 and the Treaty of Tordesillas of 1494. Under these arrangements, Pope Alexander VI divided up the Western Hemisphere between Spain and Portugal. Spain was given the entire world west of the 46th meridian, extending from pole to pole. Thus, Argentina maintains that it succeeded to this legal title to Antarctic lands upon its independence from Spain in 1816. Modern international law, however, attaches no legal credibility to papal edicts issued 500 years ago as justification for making a claim of sovereign title to territory.

Propinquity, or geographical proximity, supplies a third pillar for Argentina's claims. The geographical fact that Argentina (along with Chile) is nearest to Antarctica supposedly confers to that state a special and unique right to claim territory on the continent. A fourth pillar used by Argentina to support its claims is geological affinity with the Antarctic region. This line of reasoning argues that the Andes Mountains form a continuous geomorphological chain stretching from South America, under the Southern Ocean, to the Antarctic continent. As a consequence, Argentina should be given preferential priority to claims made to geologically attached areas. In sum, Argentina's claims appear to be couched in legal supposition, but in fact are grounded in geopolitical nuance (Joyner and Ewing 1991).

Geopolitical spatial considerations impact heavily on the lawfulness of claims made to Antarctica. That is, environmental conditions tend to confuse the lawful acquisition of sovereign rights to Antarctica. First, there is the geophysical fact that a mantle of ice nearly 3 miles thick in some places overlays the continent. This condition makes Antarctica's environment extraordinarily harsh and hazardous compared to other continents. The overwhelming presence of ice, aggravated by persistent severe weather conditions, impairs the possibility of establishing effective occupation through permanent settlement on the continent, the critical requirement in modern international law for confirming sovereignty over a territory. Second, the legal status of claims in the Antarctic is susceptible to doubt on account of the inability of claimant governments to perfect their claims to title. Discovery of lands is not sufficient to claim sovereign title to territory. Modern international law requires that a claimant secure physical possession and maintain continuous performance of governing acts to indicate the legitimate authority of the claimant state over that territory. Title must be perfected through effective occupation within an undefined, but "reasonable time." Third, claimant governments have not been able to demonstrate through permanent settlement authoritative political, economic, and civil ties to the continent; consequently, they have not been able to generate international recognition that their claims to title are legitimate. In sum, it is not possible to affirm in a compelling manner that permanent settlement giving rise to effective occupation of the continent has been demonstrated authoritatively by any claimant. Colonists from states do not live permanently in the Antarctic; scientists and logistical personnel from many nationalities work there temporarily (Joyner 1991).

Assertion to title in Antarctica highlights the geopolitical notion of sector claims. As officially depicted on maps, claimed areas to the Antarctic continent resemble pie slices that are demarcated by two meridian lines that converge in an apex at the South Pole. Five of the seven claims assert the same baseline of latitude, namely 60° S. The United Kingdom's claim is earmarked by a step-shaped baseline, with a lower rung fixed at latitude 58° S and the upper edge set at 50° S. Norway's claim has designated neither a latitudinal baseline, nor official government acknowledgment that the claim formally terminates at the South Pole. The so-called sector "principle" that purportedly supports these wedge-shaped claims originated in a statement in the Canadian Senate on February 20, 1907 when Senator N. P. Poirier recommended that Canada officially declare possession of the lands and islands lying between the extremes of its northern coast and the North Pole. While the Canadian government did not immediately take up Poirier's suggestion for the Arctic, the British government did so in the Antarctic through its Letters Patent of March 28, 1917. Yet the fatal flaw with the sector device is the inherent contravention of established practical legal norms. What legal basis exists for their extension? Sector claims advanced in the south polar region allegedly rest on specific points where discovery occurred, as well as on combinations of historical appropriation, geographical propinquity, and alleged acts of administration. Yet three of the seven claims—those by Argentina, Chile, and the United Kingdom—overlap substantially, thereby subjecting the entire Antarctica Peninsula and the Weddell Sea area to contradictory zones of jurisdiction. This situation demonstrates the specious validity of the sector claim as a legitimate device of delimitation, largely because of its geopolitical qualities and mechanistic attributes. In sum, resort to a sector claim may be considered a convenient geopolitical device employed by some governments to rationalize their national policy positions in the polar regions, but such a device is not considered a legitimate construct under modern international law. The status of claims made to the continent presents legal implications for any claims made to territorial rights in circumpolar Antarctic seas. For one, Antarctica is a continent without any internationally recognized state. The logical assumption is that because no recognized state exists on the continent, no zones of jurisdiction may be extended seaward from Antarctica. If territoriality cannot be projected from the continent to include territorial waters or other offshore zones, the logical conclusion follows that high seas extend up to the edge of the continental land or ice shelves. In this regard, it is noteworthy that no claimant government has suggested it claims within its wedge all waters northward from the continent's edge to 60° S, although Chile in its 1940 decree intimated such a claim to territorial waters, but never acted on that presumption (Joyner 1991).

Another important realization is that establishment of offshore jurisdictional zones first requires designation of a baseline from which the breadth of these zones can be measured. Unlike other continents, Antarctica is covered by an immense ice sheet that feeds into huge ice shelves along the margins. These ice shelves are either floating or locally grounded. Since the ice sheet is constantly moving seaward, massive pieces frequently calve off the continent into the ocean. Thus the Antarctic "shoreline" is constantly changing. In addition, Antarctica is surrounded by seasonal accumulations of fast ice and pack ice that can grow out in the winter to cover 7.3 million square miles of the Southern Ocean. These natural occurrences severely complicate the ability to delimit according to international legal techniques regarding standard baselines for setting offshore jurisdiction. This notwithstanding, Australia has officially declared that it controls a 200-mile exclusive economic zone offshore of its Antarctic territory. Moreover, in November 2004, Australia submitted official documents to the UN Commission on the Limits of the Continental Shelf that indicated that it claimed special rights to the continental shelf protruding from Antarctica into the circumpolar seas. Interestingly, it is the only claimant state to do this.

Geopolitical strategic designs figure heavily into some states' rationales for an Antarctic presence. This is especially true for Latin American attitudes, especially in Argentina and Chile, toward the polar south. Latin American geopolitical thought toward Antarctica views present policy in terms of future expectations. Argentine geopolitical thinkers view their country as a "Tri-Continental nation." Sovereignty is viewed as encompassing territory (1) on the

South American continent; (2) in "Insular Argentina," consisting of several island groups (namely, the Malvinas/Falklands, South Orkneys, South Sandwich Islands, and South Georgia); and (3) in Antarctic Argentina. All of these are linked together by the "Argentine Sea," that is, waters in the South Atlantic and Southern Ocean. For Argentina, the key to national greatness lies in the ability to resist external challenges to this vital geopolitical space through control of these territories and vital circumpolar waterways. Thus, Argentina's post–World War II policy toward Antarctica was highlighted by a geopolitical nationalism that perceived threatening competitors, namely Chile and the United Kingdom, vying for Argentina's critical space in the polar south (Fraga 1979). More recently, however, the internationalization of the circumpolar region under the Antarctic Treaty System has moderated the intensity of Argentina's geopolitical nationalism in favor of multilateral cooperation. Argentine policy now accepts creation of an Antarctic "zone of peace," the expansion of scientific exchange and collaboration, the exercise of inspection rights, and regular participation in annual Antarctic Treaty Consultative Party meetings. In 2004, the Antarctic Treaty Secretariat was opened in Buenos Aires, an important symbolic achievement for Argentina's role in the Antarctic Treaty Consultative Party group. Even so, Argentina has not abandoned its core geopolitical idea of maintaining national claims to territories in its Tri-Continental area (Child 1988; Dodds 1997; Joyner and Ewing 1991).

Chile's geopolitical approach to Antarctica is guided by geographical proximity. As the state closest to Antarctica, Chile has geopolitical perceptions that share the concept of tri-continentalism. For Chile, there are its territory on the South American mainland, certain island territories in circumpolar waters, and the Antarctic continental sector, all of which are united by "the Chilean Sea." In this regard, Chile pursues twin goals of maintaining national territorial sovereignty and articulating maritime rights in the Antarctic, not only historically in negotiations with Argentina and the United Kingdom, but also in legal proclamations and vigorous base-building in the region. Chilean geopolitical thinkers emphasize Chilean sovereignty throughout its tri-continental space. In addition, Chilean geopolitical thought places great emphasis on maritime rights, especially the notion that Chile is the guardian of three geostrategically salient southern passages: the Beagle Channel, the Strait of Magellan, and the Drake Passage. Since entry into force of the Antarctic Treaty in 1961, Chile has pursued a two-pronged strategy toward the Antarctic. On the one hand, Chile actively participates in and supports Antarctic Treaty institutions, but on the other hand, Chile pushes policies that seem to reinforce Chilean claims and place Chilean nationals as leaders in both scientific bodies and political institutions in the Antarctic Treaty System (Child 1988; Dodds 1997).

The Cold War ushered more geopolitics into Antarctic affairs. By the late 1940s, concern was mounting among US policymakers over the Soviet Union's emerging interest in Antarctica. Prompted by events in Eastern Europe, the United States became wary about Soviet intentions—not only their desire to exert more influence internationally, but also the possibility that Moscow might view Antarctica as geostrategically important. US policy embraced the objective of dissuading the Soviet Union from attempting to establish a territorial claim on the continent. In June 1948, US policy toward the Antarctic was officially set out in PPS-31, a strategic plan by the Policy Planning Staff of the Joint Chiefs of Staff. This paper acknowledged that while securing a claim to Antarctica was not critical to US interests, denying the Soviets access to the continent was. The United States was particularly concerned that the Soviet Union might set up bases in the unclaimed portion of the continent, where the United States had established in the 1930s and 1940s a firm legal basis for its own claim.

During the Korean War, the anti-Soviet theme became fixed in US Antarctic policy. Both states increasingly turned their attention to both poles, as serious concern surfaced that East–West rivalry, with its inherent tensions, might generate Cold War politics in Antarctica. Such a development could complicate geopolitical problems over sovereignty and, more ominously, possibly precipitate an arms race, leading to testing and implantation of nuclear weapons on the Cold Continent. It would be prudent to avoid such geopolitical circumstances.

By the mid-1950s, US policy had softened as the opportunity for Soviet involvement in Antarctic affairs was opened by preparations for the International Geophysical Year (IGY). This occasion marked the Soviets' first international involvement in Antarctic affairs. Still, Australia remained sensitive about Soviet geopolitical intentions with the establishment in 1956 of Mirnyy Station on the coast of its sector claim and the concern that it might become a submarine facility that threatened shipping lanes in the Indian Ocean. Even so, Soviet participation in the IGY from July 1957 through December 1958 demonstrated the Soviet commitment to scientific interests and opportunities for cooperative research. The launch of Sputnik on October 4, 1957 supplied the strongest motivation for the United States to seek post-IGY conference negotiations. Other important geopolitical developments occurring during the IGY included the Soviets' establishing major scientific stations in each of the claimed sectors and the United States' construction of its Amundsen–Scott station at the South Pole, the very point where all the claimed sectors (except for Norway's) converge.

The highly productive multilateral scientific cooperation during the 1957/1958 IGY prompted participating governments to believe that such cooperation should be preserved diplomatically in a legally binding arrangement. At the invitation of the United States, delegates from the twelve participating states in the IGY (the seven claimant states, plus five nonclaimant states active in Antarctic affairs, the United States, the Soviet Union, Japan, Belgium, and South Africa) convened periodically from May 1958 through November 1958 in meetings intended to negotiate a treaty for the Antarctic. This agreement was completed on December 1, 1959. The Soviets contributed two very critical ingredients that impacted these negotiations. First, they argued for a system of unanimity voting, which eventually became adopted as a consensus arrangement; second, they suggested that the Antarctic Convergence be made the boundary for the treaty's northernmost jurisdictional reach. This biologically based suggestion was overridden in favor of a Chilean proposal to use the 60° S mark as a more convenient geopolitical mark. Important for Antarctic geopolitics, the Soviets accepted a treaty provision for unannounced, onsite, or aerial inspections for violations by one party of another party's polar stations, ships, or personnel. In the spirit of international cooperation, the Soviet Union also accepted the insertion of provisions that demilitarized and denuclearized the treaty area and preserved the region for peaceful uses only (i.e., mainly for science). Finally, the Soviets accepted Article IV, which provides for claimant states to retain their claims, while at the same time permitting nonclaimant states to persist in not recognizing those claims. While often criticized for being legally ambiguous, Article IV effectively shelved any intentions the Soviets (or the Americans) harbored for asserting national claims to the continent throughout the life of the Antarctic Treaty (Joyner 1989).

Geopolitical concerns implicit in states' claims to sovereignty on the continent were alleviated by successful negotiation of the Antarctic Treaty in 1959. The key to reaching a desirable outcome was Article IV in the treaty. This provision is the "flexi-glue" that allows the Treaty to function, as it provides a political context in which all parties can cooperate in Antarctic affairs, while at the same time allowing governments to agree to disagree on where, when, how, and if sovereignty can be lawfully acquired by states in the polar south. Through Article IV, disagreement over the legitimate status of the claims was negotiated into legal limbo among Antarctic Treaty parties. It is essential to understand that all the claimant states were original parties to the Antarctic Treaty and were therefore included in this cooperative relationship. Likewise, the five nonclaimant IGY participants were original parties. For all these governments, and the thirty-three other governments that became parties thereafter, the legal legerdemain of Article IV sets aside disputes over sovereignty for the sake of international cooperation, at least for the duration of the Treaty (Joyner 1991, 1998).

Concern over the geopolitics of resource acquisition, which could lead to environmental degradation, has dominated the Antarctic Treaty parties' attention since the agreement entered into force in 1961. In 1964, at the behest of SCAR, the parties adopted special measures to conserve Antarctic flora and fauna on the continent (see Agreed Measures for the Conservation of Antarctic Flora and Fauna). These rules restricted access by nationals of treaty parties to certain places on the continent. In 1972, when reports surfaced that the Soviets might resume seal hunting in the region, a special convention was negotiated to protect Antarctic seals. Increased harvesting of krill and fish by the Soviets and Japanese in the 1970s prompted the treaty parties in 1980 to create a special regime to protect and conserve marine resources living in the Southern Ocean. This regime, which extends beyond the treaty area northward to the Antarctic Convergence (Antarctic Polar Front) around 55° S, oversees and regulates the harvesting of Antarctic marine life. The commission established by the living marine resource conservation regime provides the principal forum for setting catch ceilings and establishing no-fishing zones, not only for krill but also for finfish. This body also serves as the principal multilateral forum for monitoring unreported, unregulated, and illegal fishing in the Southern Ocean. It does not attempt to regulate whaling, however, since that responsibility falls to another multilateral forum, the International Whaling Commission (Joyner 1998; Rothwell 1996).

International geopolitics affecting the south polar area intensified during the 1980s. During this decade, the Antarctic Treaty parties negotiated a special regime to regulate the exploration for and exploitation of minerals in and around Antarctica, if ever those possibilities should occur. These special negotiations sparked international debate and condemnation in the UN General Assembly about the ownership of Antarctic mineral rights. Led by Malaysia's objections, developing countries asserted that these special negotiations amounted to a grab for Antarctic mineral resources by rich, developed states. While the treaty parties produced in 1988 a draft text for an Antarctic mineral treaty, Australia, France, and New Zealand declined to support the agreement, thereby precluding its possible ratification (Joyner 1996). The Antarctic Treaty parties then reversed course in 1990 to negotiate a protocol to the 1959 agreement that provides comprehensive environmental protection in the region (the Protocol on Environmental Protection to the Antarctic Treaty). This environmental protection protocol was completed in 1991 and entered into force in 1998. Importantly, it prohibits mineral exploitation and drilling activities in the Antarctic for at least 55 years, and goes far to strengthen resource conservation and environmental protection regulations throughout the Antarctic (Joyner 1998). In 2005, the treaty parties adopted a special annex to the protocol that elaborates a liability regime for persons who do damage to the Antarctic environment.

National geopolitics throughout the twentieth century furnished great incentives for developing international legal rules and acceptable policies for cooperative interstate activities in the Antarctic. The 1959 Antarctic Treaty and its constellation of associated agreements now furnish the principal regulatory regime for institutionalizing legal governance and international oversight of activities in the Antarctic. At the same time, they diminish concern for national geopolitical ambitions by the states most interested in the Antarctic. But if the past is prologue, the negotiation of new legal instruments will be necessary to deal with new geopolitical concerns and the onset of disturbing natural processes. Chief among the foreseeable challenges are increasing numbers of illegal fishers in the Southern Ocean, the persistent depletion of atmospheric ozone above the continent, the escalating numbers of tourists visiting the Antarctic Peninsula region, and increasingly grave worries that persistent global warming is causing the retreat of Antarctic glaciers and disintegration of the continent's ice shelves. Importantly, the subordination of national geopolitical ambitions to international legal rules will be necessary, but not sufficient, to reverse these problems. It should be noted, however, that beyond the Antarctic Treaty System, international legal agreements have been negotiated to address these challenges. The 1987 Montreal Protocol to the Vienna Convention on the Protection of the Ozone Layer regulates efforts to reverse ozone depletion and the 1997 Kyoto Protocol to the Climate Change Convention, for all its faults, deals with global warming. Neither of these instruments requires any geopolitical changes in the Antarctic. The question of tourism is being treated slowly through site guidelines and considerations of port state jurisdiction, adopted and enforced by the Antarctic Treaty parties. This, too, does not pose any basic change in the Antarctic geopolitical situation. Perhaps of greater interest, the Convention on Biological Diversity cannot be applied to marine life in the circumpolar Antarctic, which may prove to be a serious oversight given that the United States remains the principal nonratifying state blocking discussion of this need. The critical ingredient remains the ability and willingness of state governments to adopt and enforce regulations that compel their citizens to abide by these rules.

GEOSPACE, OBSERVING FROM ANTARCTICA

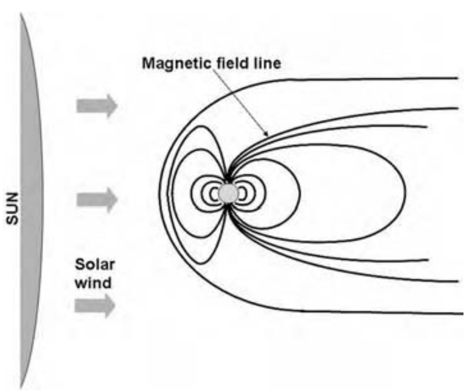
The Importance of Geospace

Geospace is the Earth's environment at the edge of space. It is primarily a vast expanse of nearly vacuous, plasma-dominated atmosphere cocooned by Earth's magnetic field. The atmosphere as most people know it, and as seen as a hazy glow in photographs taken of the edge of Earth by the space shuttle, extends from the ground up to around 100 km in altitude. Above this, however, geospace extends out to 60,000 km on the sunward side of Earth and stretches elongated on the night side to over 500,000 km—farther away than the moon, which is about 400,000 km away. Geospace is shaped like a tadpole—a stream of energetic electrons and protons from the sun, called the solar wind, flows around Earth at around 400 km per second, deforming Earth's magnetic field, which would otherwise be like that of a bar magnet, and stretching it out away from the sun. Even though geospace is so huge, if you could take all the plasma in geospace down to Earth's surface, to normal atmospheric pressure, it would all fit inside a large football stadium. Even though geospace is so empty, it is of increasing importance.

Geospace is Earth's first line of defence against matter and radiation from space; it absorbs the very short-wavelength, high-energy radiation (extreme ultraviolet) from the Sun; deflects and traps energetic electrically charged particles, preventing them from reaching the ground; and burns up meteors and space debris at the edge of the atmosphere. Geospace is the environment containing some of the major technological advances of the modern era: it is home to satellites used for communications, GPS positioning, earth observation, and military surveillance, and it is where astronauts live and work. Geospace is the closest natural plasma environment; it acts as a laboratory to understand the plasma processes that control 99.9% of the universe, and that are required to harness power from atomic fusion. Geospace poses major hazards both for space vehicles and for technology at Earth's surface; energetic particles destroy and debilitate satellites, huge electric currents generated in the aurora can put electricity power grids out of action and corrode oil pipe lines in the Arctic, and charged particles accelerated towards Earth by geospace processes can exceed the safe radiation dose for aircraft passengers at cruising altitude. Understanding these hazards and the processes that cause them is important for maintaining the continuity of satellite services and for the safety of humans and their environment on Earth. There is a growing recognition of this societal relevance, and the variability and dramatic day-to-day changes that can occur in geospace are referred to as space weather. Space weather is primarily driven by violent eruptions on the Sun related to the presence of sunspots; these dark spots, as large as ten times the diameter of Earth, frequently erupt on the Sun's surface. Sunspot magnetic fields can become unstable and their field lines can burst, hurling billions of tons of magnetised gas from the Sun's surface into space. This coronal mass ejection can hurtle towards Earth, energising the solar wind and pumping energy into geospace as it flows around it. This sparks geomagnetic storms, which can deflect compass needles by several degrees. These storms generate auroras when energetic electrons that are accelerated along Earth's magnetic field into the upper atmosphere excite oxygen and nitrogen atoms so that they emit light. Different auroral colours are characteristic of the excitation of different gases.

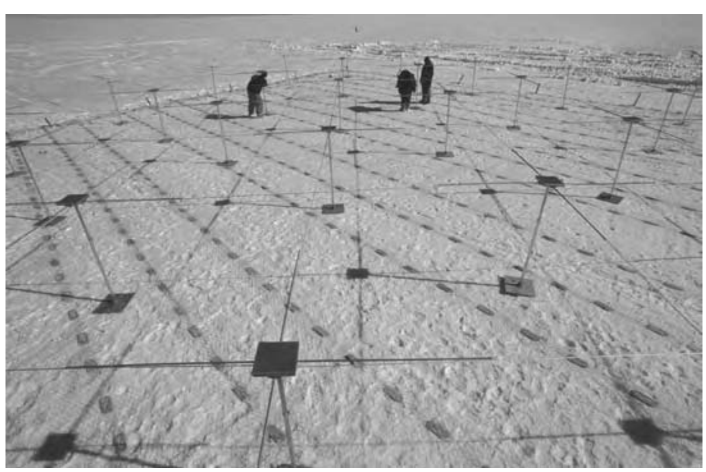
Geospace from the Ground

It is difficult to investigate geospace from satellites for several reasons. First, it is so vast that several satellites travelling in formation are required to get any real perspective on the changing environment. Secondly, satellites are always travelling rapidly across the geospace environment, so temporal and spatial changes cannot be distinguished from one another. Thirdly, the plasma is so tenuous that it is technically difficult to measure it. Observations from the ground, however, have a number of advantages over those from satellites. Plasma motion is restrained by the Earth's magnetic field—because there are almost no collisions between particles in this rarefied region and because charged particles will naturally gyrate around the magnetic field lines, any particle will remain on the same field line all the time, travelling along it rather than crossing it. Thus the plasma travels along a similar field-line geometry to that which would be mapped out by iron filings scattered around a bar magnet in the laboratory. The magnetic field lines are packed much closer together at the Earth's surface and then spread out as they extend into space. The ionosphere, between 100 and 300 km in altitude, acts like a television tube to processes going on throughout geospace. Processes that occur on the field lines many thousands of kilometres above the ground generate signatures in the ionosphere and, because the field lines in the ionosphere are much closer together than those where the processes are occurring, the picture is in miniature. A process occurring over a 5000-km-square region of geospace can typically be focussed down to a region just 200 km square in the ionosphere. This effect is accentuated in the polar regions because, as with a bar magnet, the majority of field lines enter the magnet (in our case the solid Earth) near the poles. Thus ground-based observations in either the Antarctic or the Arctic enable the study of processes in more than 90% of the volume of geospace—some million billion (1,000,000,000,000,000) cubic kilometres.



A schematic cross-section of the distortion of Earth's magnetic field by the solar wind.

The Arctic poses problems since it comprises an ocean surrounded by separated land masses. Thus sensors can only be positioned at selective longitudes, and hence time zones. Similarly sampling can only be made of part of geospace because of the physical difficulty of placing sensors at the higher latitudes. In contrast, Antarctica is a pole-centred land mass surrounded by ocean and without political boundaries. This allows the positioning of instruments at high latitude and all longitudes, giving greater coverage. As noted previously, plasma processes, which are driven primarily by the action of the solar wind, are spatially organised by the magnetic field configuration because plasma particles remain constrained to the same field line. However, processes driven by the



The antenna array of an imaging riometer at the British Antarctic Survey research station at Halley (76° S, 27° W), Antarctica.

direct action of solar radiation together with those driven by processes in the neutral atmosphere are configured by the geographic coordinate system. The geographic pole and the geomagnetic poles are offset from each other both in the Northern Hemisphere and the Southern Hemisphere. This offset allows scientists to determine whether phenomena observed in geospace are oriented in geographic coordinates or geomagnetic coordinates and hence, what the driving mechanism is—solar radiation or solar wind. In the Antarctic the offset is some 5° larger than in the Arctic and so it is easier to distinguish between the drivers from observations in the Antarctic. Thus, Antarctica is the best place on Earth for observing geospace.

Ground-based measurements from Antarctica have played a key role in understanding geospace since 1957 when the first coordinated measurements were made as part of the International Geophysical Year. Since then there have been major developments in instrument techniques that have enabled the continuous monitoring of geospace conditions from the ground; this information is used both for scientific research and to help generate forecasts of space weather. These forecasts are used for damage limitation to spacecraft, to minimise radiation exposure of astronauts and aircraft, to predict loss of terrestrial radio communications, to ensure the accuracy of magnetically guided oil drills, and to make estimates of the insurance liability regarding space technology. Many different instruments are used to remotely sense geospace from Antarctica, each with its own strengths and weaknesses; taken together, and in combination with satellite information, they allow the study of how matter and radiation from the Sun interact with the Earth system.

Geospace Observation Techniques

One of the simplest techniques is the magnetometer. This measures extremely small variations in the strength of the geomagnetic field. The strength of this field at the ground is some 35,000 nT (dependent upon location). During geomagnetic storms this can typically vary by 500 nT because of both (1) the distortion to the field produced by the strength and direction of magnetisation of the solar wind and (2) a doughnut-shaped ring of current created in geospace above the equator by electrons energised in the storm. Using an array of magnetometers hundreds of kilometres apart, the distortion that Earth's field has gone through during the storm can be reconstructed. As noted above, plasma is constrained to the field lines and so this reconstruction also defines where the plasma has moved to. While most of the plasma in the solar wind flows around geospace as if it were an obstacle in a stream, if the magnetic field within the solar wind is directed southwards, then it is able to connect with the Earth's magnetic field in a process called reconnection and plasma from the solar wind can penetrate geospace on the sunward side, enhancing the storm effect. The complex magnetometer variations during a storm allow the study of this reconnection process. Like a bar magnet, the field lines very near the poles extend a long distance away, but those nearer the middle of the magnet (i.e., Earth's equator) loop symmetrically from one half of the magnet to the other. These latter "closed" field lines resonate like the strings on a guitar but with resonant periods of a few tens of seconds. The resonant frequency is dependent upon the length of the field line and the density of the plasma through which it passes and can therefore be used to map the plasma charge density within geospace. A more complicated procedure using pairs of magnetometers to study these resonances additionally enables the mass density to be determined. Arrays of magnetometers, typically spaced a few hundred kilometres apart, are now being deployed across Antarctica to provide data throughout the majority of geospace. Many of these operate autonomously using wind and solar power; these are visited once a year by aircraft for maintenance and to download data.

A more sensitive version of the magnetometer with a very fast time resolution is designed to detect oscillations with periods of a few tenths of a second. These are generated by the gyration of protons around the Earth's field lines. Additionally, oscillations with periods of just a few seconds are generated by interactions between particles and waves and can be directly transmitted from the solar wind itself. Again, these data hold information about the plasma environment of geospace and ground-based magnetometers can provide continual measurement from a fixed location.

Latitudinal plasma density profiles through the equator can also be determined from Antarctica using naturally occurring Very Low Frequency (VLF) radio waves. There is almost no lightning in Antarctica. However, transient VLF radio spikes can be generated by lightning in the Northern Hemisphere and travel along Earth's field lines to the Antarctic. As they do so, they are dispersed—each radio frequency travels at a different velocity—and so by the time they are received by a VLF radio receiver in the Antarctic they can be heard as a whistling noise. These are called "whistlers" and their individual musical characteristics depend upon the electron density at the point farthest from Earth along the field line along which they travelled. Thus whistlers can be used to map the electron density in the equatorial plane. In addition to signals generated by lightning, artificially generated VLF waves from transmitters designed for submarine communications can also be detected after they have travelled both along the field line and around the Earth's surface to Antarctica. Measuring the difference between the radio waves taking these two different signal paths enables geospace to be observed expanding and contracting with time. It also allows the measurement of the depletion of the radiation belts, where energetic electrons can be trapped for many days, which occurs during geomagnetic storms and which precipitates high-energy electrons into the atmosphere between 50 and 100 km in altitude and changes its chemistry to produce ozone-depleting nitric oxide.

The amount of electrically charged particle precipitation generated by geomagnetic storms is measured using riometers. These instruments operate on the simple principle of using cosmic radio noise as a reference source, and measuring the changes in the strength of that on the ground. Absorption of the cosmic radio noise maximises at about 85 km in altitude, where the product of collision frequency and electron concentration, and hence removal of energy from electrons excited by the cosmic radio noise, maximises. Riometers run continuously and respond almost instantly to the electron precipitation. Imaging riometers have an array of antennae producing beams pointing in several different directions; these allow a map of the precipitation pattern to be generated, for physical boundaries within geospace to be tracked, and for drifting plasma structures to be investigated.

An alternative method of mapping the precipitation from geospace, and hence understanding space weather, is to use optical imagers. These have the disadvantage compared to riometers that they can only operate in darkness and in cloudless conditions, but they provide much finer resolution image and information on the energies of the particles. Precipitating electrons in Antarctica generate the aurora australis—the undulating curtains and radiant beams present in the aurora reflect the configuration and motion of the geomagnetic field along which the electrons travel. Different energy electrons penetrate to different depths in the atmosphere where there is a different molecular composition and hence a different-coloured emission is generated. Thus lower-energy particles lose their energy at higher altitude and produce a characteristic red glow from oxygen atoms; higher-energy particles penetrate to levels where nitrogen dominates and densities are sufficiently high that oxygen emissions are limited, so that a blue-crimson colour is generated. By using a variety of colour filters and an extremely sensitive digital camera it is possible to estimate the relative strength of different-colour light emissions, hence the relative strength of the energy dissipation at different altitudes, and thus the energy of the precipitating particles.

VLF signals propagating in the waveguide between the ionosphere and ground can provide information on the spatial size of precipitation patches. These patches perturb the VLF signal paths, changing the amplitude and phase of the signal. If sufficient transmitters and receivers exist that many listening paths cross, the pattern of perturbations in the different paths allows the size of the precipitation patch to be deduced. Recent work using Antarctic receivers has shown these precipitation patches, a consequence of lightning in the Northern Hemisphere, to be much larger than previously thought, meaning that lightning plays a significant role in emptying particles from geospace.

In the early years of Antarctic measurements, ionospheric sounders (ionosondes) were a key instrument for studying geospace. These reflect vertically transmitted radio waves off the ionosphere to determine its altitude and electron concentration, analogous to the way that ships use sound waves to echo-sound the bottom of the ocean. Later advances in ionosonde technique allowed spatial information and the velocity of ionospheric features to be determined. Because changes in the ionosphere often reflect changes in geospace higher up the field line, these studies provided basic information on geospace boundaries and electric fields. However, the spatial extent of the information was limited, covering a 600-km circle above each instrument, and the complexity of the instrument meant that it could only be operated at a fully resourced scientific base. A significant advance was achieved with the advent of high-frequency over-the-horizon radars. These transmit radio pulses horizontally so that, given the curvature of the Earth, they intercept the ionosphere at several hundred kilometres' distance from the radar, and are capable of sensing radio backscatter from ionospheric irregularities over an area of more than a million square kilometres. By measuring small changes in the frequency of the returned pulses caused by Doppler shift (similar to that experienced when the tone of a police siren changes with the relative speed of the police vehicle) it is possible to measure the speed of the irregularities as they are swept around by the ionospheric convection. This convection maps directly to electric fields in farthest geospace and, by having several similar radars around Antarctica, the ionospheric convection over most of the southern polar cap can be measured on a daily basis. There are currently five of these radar antenna arrays in Antarctica, covering the ionosphere above most of the continent; these are part of the international bipolar SuperDARN (super Dual Auroral Radar Network) system, which has fifteen radar arrays in total.

X-rays produced by the aurora in geospace cannot be measured from the ground because the X-rays are absorbed by the atmosphere and do not reach Earth's surface. As a consequence, Japan and the United States have launched huge helium-filled stratospheric balloons, some 5000 cubic metres in volume, with instrumentation on board to measure these X-rays from the stratosphere, where they are above 98% of the atmosphere. The prevailing stratospheric winds mean the balloons circumnavigate Antarctica, and the constant 24-hour summer daylight allows the balloons' electronics to be powered by solar panels. This constant sunlight also maintains a balloon at a stable temperature, which helps it maintain altitude without extreme fluctuations between night and day. Such balloons have also measured the electric field between geospace and the ground. This field is part of a global electric circuit, driven by thunderstorm activity in the tropics and by the electric field created across the polar regions when geospace interacts with the solar wind.

To reliably detect these weak currents and electric fields in this global circuit from the ground, a high, dry observation site is required. Antarctica is probably the best location in the world to make ground-based measurement of this global circuit and the influence that geospace processes have on it. Several nations are collaborating to develop an array of instruments on the Antarctic plateau; field mills will measure the vertical electric field and polished metal spheres will be suspended above the surface to measure the air–Earth current. This research may have relevance to global climate change; one scientifically controversial possibility is that changes in the global circuit could cause changes to global cloud cover, and hence climate. This collaborative work is promoted under the umbrella of the International Polar Year of 2007–2008, 50 years on from the International Geophysical Year, when the first coordinated geospace measurements from Antarctica were made.

Summary

The basic discovery and exploration phase of geospace is now largely complete. There is still much to be learnt, however, about the plasma process of reconnection, the statistical nature of geomagnetic storm occurrence, radiation belt precipitation processes, and the links between geospace, the lower atmosphere, and climate. Geospace is so vast and there are so many interacting electrodynamic processes that measurement using a single instrument and a single site can provide virtually no new information. Multiply instrumented sites and spatially distributed arrays of identical sensors are essential for major scientific progress to be made. Antarctica offers these opportunities through the advantageous geophysical locations of its research stations, the pole-centred land mass available for deployment of arrays, and the unfettered international cooperation that is traditional amongst Antarctic operators. Antarctic geospace measurements are likely to remain a key component of space weather research in the years to come.

GERMAN SOUTH POLAR *(DEUTSCHLAND)* EXPEDITION (1911–1912)

On December 14, 1911, when Roald Amundsen and his four companions reached the South Pole, *Deutschland,* the vessel of the Second German South Polar Expedition, led by Lieutenant Wilhelm Filchner, was encountering the first ice in the Weddell Sea. Filchner had earlier established his reputation as an adventurer and explorer by his solo trip across the Pamirs in 1900 and by his expedition to map the headwaters of the Huang-He in western China in 1903–1905.

It was a time when Antarctic expeditions by the Belgians, British, Swedes, French, and Scots had caught the imagination of the world. While Germany had already entered the field with Erich von Drygalsksi's First German South Polar Expedition of 1901–1903, that expedition had barely set foot on the continent and could boast of no heroic adventures. Hence, Filchner decided to mount an expedition whereby this situation might be rectified. He obtained the patronage of Prinzregent Luitpold of Bavaria and also the support of his superiors in the German Army.

Filchner's aims were entirely scientific, and he had no plans to try to reach the Pole. He suspected that East and West Antarctica were two separate landmasses, joined by the Antarctic Ice Cap, and proposed to test this hypothesis by crossing from the Weddell Sea to the Ross Sea, using horse-drawn sledges.

The expedition vessel, *Deutschland,* was a former whaler, a wooden, bark-rigged vessel with an auxiliary steam engine. Filchner was pressured to find a German captain and, despite some misgivings on his part (and even warnings), the captain chosen was naval officer Richard Vahsel, who had been second officer on Drygalski's *Gauss*. The German naval authorities authorized *Deutschland* to fly the Imperial Naval flag. This was to be the source of serious problems for Filchner, since it meant a divided command.

Filchner assembled an impressive group of scientists. Fully aware of his own (and his colleagues') lack of experience regarding ice and snow, he and five companions travelled to Svalbard in the summer of 1910 on a practice expedition. They made a pioneer traverse of Spitsbergen, traveling on glaciers, from the head of Isfjorden to Storfjorden and back.

Deutschland sailed from Bremerhaven with the main expedition in early May 1911. Having called at Buenos Aires (where the expedition's Greenland dogs were embarked) and Montevideo, it reached Grytviken in South Georgia on October 21. Here Captain Carl Larsen, manager of the whaling station at Grytviken, put his yacht, *Undine,* at Filchner's disposal, to survey the coasts of South Georgia, while *Deutschland* surveyed the northern islands of the South Sandwich Islands.

Having embarked the expedition's twelve Manchurian ponies, *Deutschland* put to sea from Grytviken, bound for the Weddell Sea, on December 11, 1911. It entered the pack ice on December 14 and for over a month fought its way slowly south, emerging into open water on January 29, 1912. On the next day, ice-covered land, the southern continuation of Coats Land, was sighted to the southeast and was named Prinzregent Luitpold Land.

On January 31, at 77°44′ S, the ship's further progress was blocked by the front of an extensive ice shelf stretching from the ice cap westwards to the horizon. Later named the Filchner Ice Shelf, along with the Ronne Ice Shelf farther west, it forms the southern limit of the Weddell Sea. The angle between ice shelf and ice cap was named Vahsel Bay, after the captain.

In that angle lay a tabular iceberg that had broken away from the ice shelf but still abutted against it. With an assurance from the expedition's ice expert, Paul Bjørvik, relayed by Captain Vahsel, that there was little chance of the iceberg's breaking away, Filchner decided to erect his base hut on its surface, since it offered a suitable landing site. Offloading of equipment and supplies began on February 9; by the evening of February 17, the shell of the hut was complete and a large amount of stores and equipment had been landed. But on the night of February 17–18, with a high spring tide, the iceberg broke adrift and began floating out to sea, followed by a minor armada of other tabular bergs. In the midst of this crisis Filchner learned that Bjørvik had warned the captain against this choice of a site for the base camp.

Work began to salvage as much as possible, and ultimately only the shell of the hut, one and a half tonnes of coal, five sledges, and some food had to be abandoned. Undeterred, Filchner set about establishing a second base camp on the ice cap, east of Vahsel Bay, and by the evening of February 28 had made all the preparations. But new ice began to form the next morning, and on March 2 Captain Vahsel insisted that to prevent his ship from becoming beset, it must leave immediately. *Deutschland* managed to make some progress north, but by March 15 was solidly beset, and a winter adrift in the ice of the Weddell Sea had begun. An array of buildings and instrument shelters was erected on the ice around the ship and a comprehensive program of scientific work began. In late June, when the ship was fairly close to the alleged position of "Morrell Land," reported by the American Benjamin Morrell in 1823, Filchner and two companions made a week-long sledge trip to the alleged location of this landmass and proved that it did not exist.

On August 8, Captain Vahsel, who had been sick for some time, died of syphilis and was buried at sea. Possibly his bizarre decisions about the landing may be attributed to the neurological side effects of the terminal stages of the disease.

As the ice began to break up, the ship managed to free itself on November 26 and got under way under the command of the first officer, Wilhelm Lorenz. By December 19 they were back at Grytviken.

Despite having fallen far short of Filchner's goals, the expedition had made some useful contributions to both geographical exploration (the surveys of South Georgia and the South Sandwich Islands, the discovery of Luitpold Land and the Filchner Ice Shelf, and the removal of "Morrell Land" from the map) and to meteorology and geomagnetic studies on the basis of the work during the ice drift.

GERMAN SOUTH POLAR *(GAUSS)* EXPEDITION (1901–1903)

The noted German scientist Georg von Neumayer (1826–1909) began promoting the dispatch of a German expedition to Antarctica as early as 1865, but it was not until three decades later that he finally succeeded in setting up a German Commission for South Polar Exploration, of which he became chairman.

During the Sixth International Geographical Congress—held in London in 1895 under the presidency of Clements Markham—a resolution was passed that the exploration of the Antarctic regions was the greatest piece of geographical exploration still to be undertaken. Neumayer finally had the opportunity to push forward the plan of a German expedition. However, it was not until February 19, 1898 that the geographer Erich von Drygalski (1865–1949) was elected leader of the expedition. He had already gained polar experience by leading two expeditions to Greenland (1891 and 1892–1893). Now the responsibility changed from the Commission to Drygalski. Nevertheless, he was bound to Neumayer's travel route via Îles Kerguelen.

In April 1899, the expedition was financially secured by an Imperial internal budget, to be administered by the Ministry of the Interior. During the Seventh International Geographical Congress—held in Berlin in 1899 under the presidency of Ferdinand Freiherr von Richthofen (1833–1905)—Markham defined the fields of work of the German and British expeditions. He divided Antarctica into four quadrants starting at the 0° Greenwich meridian. According to the British tradition of exploration, he assigned the Ross and Victoria quadrants to Britain and the Weddell and Enderby quadrants to Germany.

Drygalski proposed a collaboration with the British expedition and recommended the organisation of simultaneous observations during the expeditions and at suitable locations outside the Antarctic. Magnetic term days were defined on the first and fifteenth of each month from February 1, 1902 until February 15, 1903. Meteorological observations were to be made from October 1, 1901 until March 31, 1903, including on all merchant and navy ships sailing on a route south of 30° S. When a French expedition under Jean-Baptiste Charcot (1867–1936) followed in 1903, the international cooperation was expanded until March 31, 1904.

The Imperial Admiralty was involved in the planning of the expedition, but only two of the seamen came from the navy. The building of the first German polar research vessel, *Gauss,* was taken over by the Nautical Division of the Reich Marine Office at Howaldt Warf in Kiel. *Gauss* was to serve as the flagship of German science, with an iron-free area for magnetic investigations on the ocean and a body similar to the Norwegian *Fram*.

Drygalski became an official representative of the Ministry of the Interior, and the expedition was allowed to sail under the official flag of the Ministry. A special decree allowed the ship's commander, Hans Ruser (1863–1930), the right to refuse Drygalski's orders only in cases where he perceived an immediate threat to life and property aboard.

The instructions given by Emperor Wilhelm II were rather general, referring only to a few fundamental questions and leaving the freedom of action that Drygalski desired. The program followed Alexander von Humboldt's (1769–1859) ideas of comprehensive investigation of an unknown area concerning the three elements—earth, water, and air—and the living world. Due to this, geology, geography, earth-magnetism, oceanography, meteorology, and biology played major roles. Five officers, five scientists, and twenty-two seamen were aboard. Drygalski and biologist Ernst Vanhöffen (1858–1918) had already wintered together at Greenland 9 years before, and the Norwegian ice pilot Paul Bjørvik (1857–1932) was a very experienced Arctic veteran.

On August 11, 1901, *Gauss* set sail at Kiel for an unknown destination near 90° E, far to the south. A base station not being influenced by Antarctica was established at Observatory Bay on Île Kerguelen. Unfortunately, on February 22, 1902, *Gauss* was beset by ice close to the Antarctic Circle at 66°2′ S, 89°38′ E, 85 km off the Antarctic coast. The expedition members were lucky that the ice was not drifting, so they could establish a fixed winter station on sea ice 385 m above sea bottom. They discovered the ice-covered coast of Kaiser Wilhelm II Land and an ice-free extinct volcano, which they named Gaussberg. After 50 weeks of captivity, the ship finally came free on February 8,

1903. Drygalski tried in vain to approach higher latitudes west of their wintering place to give an answer to the unsolved problem of the existence of a coastal connection between Kemp Land and Enderby Land or of a drift that would take them into the Weddell Sea. But a second attempt to go south was not allowed by the Ministry of the Interior, because the budget was already exhausted. So the expedition was forced to sail home as soon as possible, arriving at Kiel on November 25, 1903.

The welcome for the returning expedition was not overwhelming, because Emperor Wilhelm II had been disappointed in their results, as Robert Falcon Scott had established a farthest south of 82°17′ S on the concurrent British National Antarctic Expedition. In early 1900, Antarctica had become a playground of politics, and many believed the goal there was to set the flag as far south as possible. Being trapped at the Antarctic Circle was seen as a national failure, when geographical achievements were considered much more valuable than thoroughly measured scientific data, which had to be analysed and published over a period of decades (three in this case). To avoid costs for maintenance, *Gauss* was sold for 75,000 Canadian dollars and used under its new name *Arctic* for the Canadian Coast Guard by Joseph E. Bernier (1852–1934).

Despite the political controversies, data of the collaboration were exchanged and synoptic charts plotted for meteorology and magnetism. Nine hundred thirteen daily synoptic weather charts were produced in Germany, which were processed to thirty maps of monthly means and several other quarterly, seasonal, and yearly charts. Geographical investigations indicated that Antarctica was a big continent covered by ice. The mean height of the continent was assessed as 2000 m $\pm$ 200 m. Data of the magnetic field of the Earth improved the charts of the southern seas. The biological collection of 4030 species was outstanding, and 1470 species were described for the first time. The most striking result of the expedition indicated a stratification of four different water layers in the southern Indian Ocean. All results were published in a process extending until 1929, filling twenty volumes and two atlases. Retrospectively, Drygalski's expedition was labelled "universitas antarctica."

The German initiative of a scientific cooperation in Antarctica became a model for further research, which culminated in the International Geophysical Year of 1957–1958.

GERMAN SOUTH POLAR *(SCHWABENLAND)* EXPEDITION (1938–1939)

When agriculture had to be rebuilt in Germany following World War I, sperm oil became the most important raw material for the production of margarine and soaps. During the early years of the Third Reich, the Fat Plan was designed to solve the need for fats, but it was not successful and was ultimately replaced by the New Plan, which promoted an increase of home-grown fat production. One of the issues that had to be resolved to do this was decreasing German dependence on foreign sperm oil. Germany was the second largest importer of Norwegian sperm oil—about 200,000 tons per year—which caused a tremendous outflow of capital. To resolve this problem, a German whaling fleet was set up and put to sea during the austral summer of 1937–1938.

Helmuth Wohlthat (1893–1952) was totally familiar with the need for fat and with the problems of foreign exchange when he became ministerial director for special employment under the Representative of the Four-Year Plan, Hermann Göring (1893–1946).

Following the return of the whaling fleet in spring 1938, Wohlthat initiated the third German Antarctic expedition, the goal of which was to establish self-sufficiency in sperm oil within the outlines of Göring's Four-Year Plan. The main part of the expedition plan was to occupy a position on the Antarctic coast, where a secure base for German whaling could be established. At the time, on the return journey, secret military problems concerning the future establishment of a naval base on the island of Trinidad, or Martin Vaz northwest of Rio de Janeiro, could also be resolved. Thus, with this expedition, German Antarctic exploration was launched again, although it was driven by economic and political aspects during the Third Reich, rather than by pure scientific research.

Alfred Ritscher (1879–1963) was the only possible leader for the expedition. He was captain and aircraft pilot, after having already gained polar experience during the Schröder-Stranz expedition to Spitsbergen in 1912. He was released from the high command of the German Navy so that in an extremely short time he could prepare the expedition with two Dornier-10-t-Wal seaplanes, *Boreas* and *Passat,* aboard the catapult ship *Schwabenland.*

On December 17, 1938, the expedition left Hamburg. The ship traveled south along the Greenwich meridian, reaching the belt of pack ice around the Antarctic coast on January 19, 1939. However, the region between Coats Land in the West and 45° E—which included the area in which the Germans hoped to carry out their mission—had been put under Norwegian sovereignty through a royal decree five days previous. Nevertheless, by February 6, 1939, six reconnaissance flights and eight flights for photogrammetric surveys of the region east of the Weddell Sea between 6° W and 18° E had been performed. This gave the Germans the data for the construction of a map of Neuschwabenland on the scale 1:1,500,000.

Altogether 350,000 km^2 of uncharted territory were carefully covered by aerial survey and a further 600,000 km^2 were seen as well. The expedition discovered Neuschwabenland, with its ice-free mountain ranges of up to 3000 m in height in the Wohlthat Mountains, including the spectacular Schirmacheroasen (in recent decades one of the centers of German Antarctic scientific research). Later that year, the outbreak of World War II stopped all further attempts to continue exploration or research related to the establishment of an Antarctic base and the securing of German whaling.

GERMANY: ANTARCTIC PROGRAM

Germany has been a consultative party to the Antarctic Treaty since 1981 and maintains a long-term commitment to scientific research in Antarctica. The Alfred Wegener Institute for Polar and Marine Research (AWI), as the national coordinator, enables Germany to maintain this role from its research and long-term monitoring and survey activities. It provides the main mobile and stationary infrastructure for Antarctic research, and maintains the permanent German presence in Antarctica. AWI closely cooperates with national Antarctic programmes of the consultative parties and provides members to the related international organizations within the Antarctic Treaty System. In addition to AWI, the Federal Institute for Geosciences and Natural Resources (BGR), the German Aerospace Centre (DLR), and the Federal Agency for Cartography and Geodesy (BKG) perform long-term research activities in Antarctica.

The research and supply vessel RV *Polarstern,* commissioned in 1982, is the major research tool for German marine polar activities. The advanced scientific and technical equipment and ability to navigate in heavy ice conditions in almost all regions of the Arctic and Antarctic oceans make it a leading platform of the international polar research fleet. It provides ideal working conditions for biological, geological, geophysical, glaciological, chemical, oceanographic, and meteorological research. Nine scientific laboratories, hydroacoustic sounding systems, winches, fiberoptic networks, and data-acquisition systems are installed. Refrigerated rooms and aquaria permit the transport of samples and living marine fauna. Facilities such as flight control, hangar, helideck, and refuelling facilities are available for two helicopters (BO 105 CBS 5) used for sea-ice reconnaissance, transport of personnel, and scientific observations. The weather station provides forecast information and satellite imagery on sea-ice distributions. Hydroacoustic navigation aids have been installed to deploy remotely controlled underwater vehicles. The overall length is 118 m and maximum beam 25 m. Displacement and draught are 17,300 tons and 11.2 m, respectively. Propulsion is performed by 4 diesel engines providing approximately 14,000 KW. The maximum speed is 16 knots. Bow and stern thrusters assist to manoeuvre the ship, if required for special observations or for unloading operations at the ice shelf margin. The overall capacity is 124 persons with 38 to 44 berths for crew. About fifty to seventy scientists can be accommodated and provided with working facilities on board. RV *Polarstern* is managed by AWI and spends approximately 320 days at sea each year. By 2006 the vessel had completed twenty-three Antarctic expeditions and twenty-one Arctic expeditions with two visits to the North Pole, in September 1991 and January 2001, respectively. Antarctic cruises have gone to the Weddell, Bellingshausen, and Amundsen seas as well as waters around the Antarctic Peninsula and Weddell Sea, where the supply of Neumayer Station is a yearly task.

The Neumayer station (70°39′ S, 08°15′ W, 40 m a.s.l.) is the permanently occupied German research station located at the Eckström ice shelf of Atka Bay. The station was commissioned in 1992 and replaced the original Georg von Neumayer station commissioned in 1981. Since that time scientific observatories have been continuously operated for meteorology, atmospheric chemistry, and geomagnetic and seismological data. These long-term records are routinely fed into the respective international networks. Neumayer station provides highly recognized contributions to climate research, in particular studies of the ozone layer and to investigations of the regional present-day tectonic and seismic activity. In 2003 one of the four Infrasound Arrays in Antarctica was installed at the station as part of the global International Monitoring System (IMS) of the Comprehensive Test Ban Treaty Organisation (CTBTO) controlling the adherence of the Comprehensive Nuclear Test Ban Treaty. The Neumayer station is constructed on ice. The central facility is a steel tube system consisting of two main tubes (eastern tube 82 m in length, western tube 92 m), a 92-m-long cross tube, and a garage for polar vehicles. The tubes' diameters are between 8 and 8.4 m. The gross area within the tubes is about 3400 square meters. Founded on ice, the current Neumayer station has a finite lifetime of about 15 years. It will have to be replaced by a new station in 2008, in order to continue long-term scientific observations and commitments.

The wintering staff consists of four scientists, three technicians, a cook, and a physician. During the Antarctic summer season about thirty to fifty scientists and technicians are temporarily at the station. Neumayer is the operational base for scientific and supply aircraft missions and deep-field traverses. The Dornier 228-101 aircraft *Polar 2* (commissioned in 1983) is regularly operated in Antarctica during the summer season. The combined wheel and ski gear enables take-off and landing at gravel strips and even unprepared snow surfaces. The slow flight speed makes it an effective tool for airborne geophysical and glaciological survey missions as well as meteorological and air chemistry studies.

The polar vehicle fleet is composed of "Pisten-Bully" tracked vehicles specially adapted to withstand the stress of pulling sledges for heavy loads and sundry other equipment necessary to ensure optimal working conditions for scientists as well as their personal safety. They are equipped with GPS navigation and appropriate communication equipment and can operate year-round, allowing serving of deep-field observatory installations. Every summer season the Kohnen station (75° S, 00° E, 2892 m a.s.l.), the first German summer base on the Antarctic inland ice plateau of Dronning Maud Land, is also supplied by the vehicle fleet. The distance between Neumayer and Kohnen is 470 miles (757 km). Depending on weather conditions a traverse takes 9 to 14 days. The Kohnen Station was established in 2000 primarily as the second base for deep ice-core drilling in the frame of the European Project on Ice Coring in Antarctica (EPICA). In the course of six summer seasons a 2780-m ice core was drilled. About 400,000 years of climate history could be studied from this ice core. Kohnen Station will serve at least for the next decade for a number of summer-only investigations. It consists of a 32-m-long and 8-m-wide platform on steel pillars where 11 prefabricated container modules are mounted. Up to twenty individuals can be accommodated (see http://www.awi-bremerhaven.de/Polar/Kohnen/index.html).

Further research facilities of the German Antarctic program were established in cooperation with other national programs. The Dallmann Laboratory is operated as an annex station at the Argentinian Jubany station at King George Island (62°14′ S, 58°14′ W, 15 m a.s.l.). It was established in 1994 as an international laboratory funded by the Instituto Antartico Argentino (IAA), The Netherlands Council of Earth and Life Sciences (NWO), and AWI. Since then about twenty-five to thirty-five scientists have been working there each summer season. Besides special laboratories for marine-biological work, scuba diving facilities are available (see http://www.awi-bremerhaven.de/Polar/dallmann.html). The German Antarctic Receiving Station (GARS) is an annex station at the Chilean station General Bernardo O'Higgins (63°19′ S; 57°54′ W). Since October 1991 GARS has been cooperatively operated and managed by the German Aerospace Center (DLR) and the Instituto Antartico Chileno (INACH). GARS is part of the international ground segment for remote sensing in the southern hemisphere. The station is an important European research platform for acquisition, precision processing, and cataloguing of satellite data. The station has its own specially constructed radio-telescope with a 9-m-diameter mirror for reception of satellite data and performance of geodetic surveys using Very Long Baseline Interferometry (VLBI). Up to fifteen scientists can be accommodated. The station is only occupied about 120 days per year.

Antarctic research in Germany has a long tradition. The historical record features famous names as Johann and Georg Forster, who participated on the expedition of James Cook aboard the ships *Resolution* and *Adventure,* but also Eduard Dallmann, Erich von Drygalski, Wilhelm Filchner, and Alfred Ritscher as expedition leaders and scientists. Modern international Antarctic research commenced with the International Geophysical Year (IGY) of 1957–1958, following which both German governments began Antarctic activities. After 1959 guest scientists from East Germany stayed for wintering and worked in the field at several Russian Antarctic stations. Likewise, scientists from West Germany joined US expeditions.

In 1974 the Antarctic Treaty was signed by East Germany. It received consultative status in 1988. The first permanently occupied Research Base—later named Georg Forster Station—was established in the Schirmacher Oasis in 1976. At that time the construction concept was pioneering. Prefabricated container modules serving as laboratories, power plants, and accommodations were carried on sledges over a distance of 120 km into the Schirmacher Oasis and assembled as a research base within 6 weeks. Since then the station has been permanently occupied and operated—as an annex to the Russian Novolazarevskaya Station until 1987 and then as a German Antarctic station until 1993. Long-term studies of magnetospheric–ionospheric processes, geophysical investigations, biological studies, and sea-ice observations using satellite imaging were performed. In 1985 the station became known to the international scientific community when the vertical extension of the ozone hole in the southern polar stratosphere was first recorded by regular balloon-borne ozone observations. These regular ozone measurements were performed until 1992 and continued at Neumayer station afterwards.

In West Germany, the first marine-biological expeditions were performed in 1975–1976 and 1977–1978. The Antarctic Research Programme of the Federal Republic of Germany was established in 1978 and the Antarctic Treaty was signed in 1979. BGR performed the first terrestrial expedition (GANOVEX I) into North Victoria Land in 1979–1980. Germany received consultative status in 1982 after the foundation of AWI in 1980, construction of the permanently occupied research station Georg von Neumayer in 1981, and commissioning of *Polarstern* in 1982. The budget for AWI's Antarctic research, including personnel, operations, and investment, increased from 39 million Euros in 2000 to about 49 million Euros in 2005. AWI has also been successful in applying for funding from the European Union. The annual budgets are about 2 million Euros for BGR and about 1.5 million Euros for DLR/BKG Antarctic activities. Project funding of about 3 million Euros is via the DFG within the framework of applications for the Priority Program Antarctic Research or via the normal funding channels. DFG funding is of great importance, as it enables the participation of a number of university working groups on the complex marine and terrestrial Antarctic expeditions. Altogether about 250 to 300 German scientists and technicians work in Antarctica every year. Scientific objectives and logistical performance of all German Antarctic operations by ship, aircraft, and land vehicles, as well as works at stations and in the field, are in line with the international regulations of the Antarctic Treaty System. A national environmental protection act (AUG) is in force according to the Protocol on Environmental Protection to the Antarctic Treaty, which requires the approval of all research activities in Antarctica by the Federal Environmental Agency.

GIGANTISM

Polar Gigantism in Antarctic Benthos

Scientists on turn-of-the-twentieth-century voyages to Antarctica marvelled over isopods the size of a human hand and sea spiders (pycnogonids) even larger. Modern visitors may occasionally observe the sea surface from boats and see ctenophores (comb-jellies) up to 0.5 m long, despite being only a few cells thick. Several benthic invertebrate groups tend towards larger sizes at high latitudes. Polar gigantism has been described for several marine Antarctic taxa including Porifera, Nematoda, Nemertea, Ascidiacea, Polychaeta, and Pycnogonida, as well as many crustaceans (Cirripeda, Ostracoda, Copepoda, Isopoda, and Amphipoda). Polar dwarfism has also been described, but only for gastropods, bivalves, and fish. Low temperature and its effects on growth have long been the most widely quoted factors in explaining polar gigantism. However, a thorough study of crustacean Amphipods recently showed oxygen to be a key factor.

This work was based on length measurements of over 2000 species of benthic amphipods, divided over sixteen geographical localities from the tropics to the poles. Furthermore, the study included fresh (Lake Baikal), brackish (Caspian Sea), and high-altitude (Lake Titicaca) waters, allowing the decoupling of temperature and oxygen concentration.

Analysing size spectra of these sixteen amphipod fauna showed that, with increased oxygen concentration, size increased slightly in small species, more in mid-size species, and maximally in the largest species. The hypothesis for explaining this relationship is based on two physiological factors. First, amphipods lack an efficient blood-pigment and carry oxygen around the body in dissolved form. Secondly, surface:volume ratio decreases with increasing size. At some point, an upper threshold is reached, where the respiratory surface limits further oxygen supply for the volume of metabolically active tissues. Therefore, oxygen availability acts not as a selection pressure on size, but as a ceiling limiting the maximum potential size amphipods can reach.

The relationship has been observed across taxonomic levels, from order to species. These results suggest that each species has an optimum size, which is closely linked to metabolic cost. Both of these are limited by the amount of oxygen available in the environment.

A similar trend linking size and oxygen has been demonstrated in nematodes and deep-sea gastropods. A latitudinal cline in maximum size was described for caridean shrimps and brachyuran crabs, but no firm conclusions were drawn. However, oxygen availability was probably important. The close relationship between oxygen concentration and maximum size remains unexplored in other taxa. The best Antarctic candidates are pycnogonids, certain crustaceans (isopods, mysids, and pelagic copepods), nemerteans, and freshwater mites. However, recent work has shown that generations of flies grown in reduced oxygen get smaller.

Oxygen availability is also important in setting upper temperature limits for survival in marine species. Furthermore, poor aerobic capacities cause Antarctic benthic species to lose the ability to do work with very small incremental changes in temperature, and interestingly, the largest animals are the first ones affected. An important future consequence for the limitation of size and temperature tolerance related to oxygen is that global warming is likely to have more dramatic consequences for Antarctic marine animals than fauna from other latitudes, and the largest species are possibly the most vulnerable.

GLACIAL GEOLOGY

Glacial geology is the study of sediments and landforms produced by glaciers as they flow over the Earth's surface. The processes that lead to the creation of glacial sediments and landforms can be divided into erosion, transportation, and deposition.

The principal forms of glacial erosion are (1) plucking, which occurs when blocks of material are pulled from the bed of a glacier when water freezes, and (2) abrasion, which is caused by mechanical wear of the glacier bed by rock particles held within ice at the bottom of the glacier. In Antarctica it is thought that the rates of glacial erosion are considerably lower than in other glaciated environments, partly because most ice flows very slowly and partly because of the low temperature of the ice. The exceptions to this are the ice streams that flow at considerably high velocities and are warmer than the surrounding ice. One of the contemporary debates concerning erosion processes concerns whether cold glaciers (those with beds well below the freezing point) are capable of basal erosion. Research in the Northern Hemisphere has suggested that cold glaciers may preserve landscapes rather than erode them (Kleman and Borgstrom 1994). Studies of glaciers in Antarctica with basal temperatures around –18°C show that such cold-based glaciers can deform and erode their beds (Atkins et al. 2002; Fitzsimons et al. 1999). This is most likely where glaciers rest on frozen sand and gravel, which can be eroded by plucking and incorporated in the base of glaciers. In Antarctica there are few of the classical features of glacial erosion that are associated with temperate mountainous environments. The absence of such landforms is in large measure due to the fact that most of Antarctica remains heavily glaciated and the eroded landforms lie beneath the modern ice sheets. In addition those parts of the periphery of Antarctica that were glaciated have a subdued topography, such as the east Antarctic coastal oases in the Vestfold, Larsemann, and Bunger Hills, because they were completely inundated by ice.

Material that is eroded by glaciers can be transported in three positions: on top of the glacier (supraglacial), within the glacier (englacial), and close to the bed of a glacier (subglacial). In Antarctica it is very rare for material to be transported in a supraglacial position because so little rock protrudes from the glaciers. The exceptions are nunataks, which are isolated peaks that rise above the ice surface. Where this occurs it is possible that debris from the nunatak will be transported on the glacier surface in a line that extends downstream from the rock outcrop. In Antarctic glaciers, the bulk of debris is transported close to the beds of glaciers. Ice that is adjacent to the glacier bed is often characterised by relatively high concentrations of debris (typically 10% by volume) carried in a layered zone up to a few metres thick. This basal ice forms at the glacier bed through a combination of thermal and mechanical processes that link the glacier to its bed. These thermal and mechanical processes result in several characteristics, including layers and/or lenses of debris entrained from the bed, deformation structures including folds and faults, relatively high solute concentrations, and unusual gas compositions that distinguish the ice from ice that has formed solely by the firnification of snow at the glacier surface. Because of its position close to the glacier bed, basal ice is an important component in the rheological behaviour of glaciers. The basal zones of glaciers are generally only visible at terrestrial (on land) glacier margins, although occasionally icebergs with prominent black and white layers that are characteristic of basal ice are sighted in the Southern Ocean.

Material transported by glaciers is deposited by several processes, including lodgement, melt, and sublimation. Lodgement is a process that occurs beneath flowing ice where particles held within the ice are dragged along the bed until the drag exceeds the forward motion of the ice, at which time the particle is deposited. Deposition by melting occurs where relatively warm conditions are found at glacier margins, beneath relatively fast-flowing glaciers and beneath ice that comes into contact with water. The main product of melting of debris-bearing ice is an unsorted or poorly sorted deposit that is referred to as a till or diamict. The particularly cold and dry nature of the climate in Antarctica means that melting is much less important than in glacial environments in lower latitudes. For example, in the Dry Valleys, sublimation (the direct transfer of ice into water vapour without a liquid phase) is thought to constitute from 40% to 80% of total ice loss by glaciers (Lewis et al. 1998). Because of the importance of the process of sublimation, it has been argued that the landforms and sediments produced by glaciers are different from those produced in Arctic and temperate environments (Shaw 1977), although Fitzsimons (2003) has argued that landforms and sediments associated with polar continental glacier margins such as Antarctica are not fundamentally different from other glaciated environments on earth. In the more northerly parts of Antarctica, such as the coastal oases and Antarctic Peninsula, melting becomes more important because of the warmer temperatures, and when debris is released it often slumps, slides, and flows because it becomes saturated. Where material transported and deposited by glaciers becomes concentrated, distinctive landforms called moraines form. The most prominent moraines in Antarctica occur in the coastal oases such as the Vestfold, Bunger, and Larsemann hills or in ice-free areas such as the McMurdo Dry Valleys. In these locations, end moraines record the former positions of glacier margins. In the case of the coastal oases, the moraines are a few thousand years old, whereas in the Dry Valleys the landforms may rest relatively undisturbed for several million years. Two contemporary problems that have occupied glacial geologists are the behaviour of the Antarctic ice sheets during the last glacial maximum (20,000 years before present) and the initiation of glaciation in Antarctica. Evidence from the McMurdo Dry Valleys indicates that during the last glacial maximum the Ross Ice Sheet thickened, advanced into the valley forming Glacial Lake Washburn, and deposited the Ross Sea Drift. The Ross Sea Drift consists of numerous small moraines and eskers that form narrow sinuous ridges deposited by streams that formed within or under the melting ice (Denton and Marchant 2000). Other prominent landforms in this area are lake shorelines that record the level of the now-drained Glacial Lake Washburn, and perched deltas that record the positions of streams that flowed into the lake.

Another focus of research in glacial geology in Antarctica has been understanding the origin of the ice sheets and ice-sheet behaviour over the last 35 million years. The Cape Roberts Project was a cooperative venture between seven countries—Australia, Britain, Germany, Italy, the Netherlands, New Zealand, and the United States of America. It was designed to investigate the early history of the East Antarctic ice sheet and the West Antarctic Rift System by coring sedimentary strata at 77° S, at the edge of the present ice sheet close to the Transantarctic Mountains. The cores provide a 1500-m record of climate and mountain/basin history for the period from 34 to 17 Ma. They show that this sector of East Antarctica had a cool temperate to periglacial climate with low woodland vegetation from 34 to 24 Ma, at which time mountain glaciers and possibly inland ice sheets were releasing icebergs to the Ross Sea. The cores also show that the period from 17 to 24 million years before present was cooler, allowing a low-growing sparse tundra on the adjacent mountains, along with periods of more extensive grounded ice. And finally, they show that the Transantarctic Mountains had achieved most of their present height by 34 Ma (Nash et al. 2001). The Cape Roberts Project has been succeeded by the ANDRILL project, which is focussed on reconstructing 35 million years of ice-sheet behaviour at the Antarctic continental margin.

The lack of ice-free land in Antarctica means that most products of glacial erosion and transportation are deposited into the ocean surrounding Antarctica. The vast bulk of this glaciomarine material is deposited close to the position at which the ice begins to float (the grounding line), where it forms subaqueous (underwater) moraines and fans. Fine suspended sediment may be transported into deeper water together with debris flows, which are sediment–water mixtures that flow under the influence of gravity. The other main form of transportation of debris into deeper water occurs where outlet glaciers containing debris produce icebergs that subsequently melt, resulting in the release of debris into the ocean (Anderson et al. 1980). The deposit produced by this process is known as ice-rafted debris and it consists of fine marine sediment with occasional coarse particles up to the sizes of boulders.

Ice-free areas that are adjacent to, but not covered by, glaciers are often referred to as periglacial areas and are characterised by low temperatures and permanently frozen ground (permafrost) that has a thin surface layer (an active layer) that may thaw during the short summer period. These areas are covered by cold desert soils that often show signs of long periods of weathering, some chemical alteration, and biological colonization and are often associated with very stable landscapes that have not been significantly disturbed for millions of years (Campbell and Claridge 1987).

GLACIERS AND ICE STREAMS

Glacier ice is the largest reservoir of fresh water on Earth. About 90% of that reservoir is located in Antarctica, in the east and west Antarctic ice sheets, and in ice caps and glaciers on the Antarctic Peninsula.

Glaciers typically form in mountain valleys where snow persists throughout the summer. Over time, the accumulated snow compacts under the weight of snow above it, becomes more dense, and turns into glacier ice. Gravity, which forces a sloping ice surface to spread out over time, causes the glacier to flow downhill towards lower elevations. When more mass is gained by snow accumulation than is lost to melting, sublimation (a phase change directly from solid to vapor), or, in some locations, iceberg calving, the glacier grows larger. When more mass is lost than gained, the glacier retreats. Mountain glaciers may coalesce at high altitudes to form small ice caps or large ice sheets. Cycles of glacier growth and retreat are controlled by the environment and by glacier flow.

The rate at which glacier ice flows depends on its geometry and on the characteristics of the bed over which the ice moves. Steeper surface slope and greater thickness tend to produce faster ice flow. The effects of basal conditions are more complex. Rigid bedrock surfaces resist glacier flow more readily than do weak unconsolidated sediments. Meltwater at the interface between the base of the ice and the underlying material is another important factor. Both soft sediments and large basal water pressures tend to enhance ice flow, in a group of processes called basal sliding. Together, these characteristics of the ice and the bed over which it flows produce a wide range of glacier flow styles.

According to the physical laws of motion, the forces acting on a steadily moving body, such as a glacier, must balance. Glacier ice is put in motion by a gravitational driving force that is the product of ice surface slope, thickness, density, and the acceleration due to gravity. The driving force is resisted, or balanced, by drag forces wherever the glacier ice must push past another material, such as the bed beneath the ice, valley walls, and obstacles in the path of the flowing ice, and by longitudinal pushes and pulls within the ice. The application of a driving stress causes ice to deform, flowing like a viscous fluid. The deformation rate depends on temperature; warmer ice responds more rapidly than colder ice.

The relative importance of the various resistive forces determines the style with which a particular glacier's ice flows. Where the basal drag is large, ice deforms by vertical shearing, an internal deformation of the ice crystals much like the shearing of a stack of cards when a traction is applied to its upper surface. This is the style of ice flow observed in most mountain valley glaciers, in the interiors of ice sheets, and in some ice streams. That flow may be enhanced by basal sliding. Where basal drag is small, due to the presence of a weak substrate or high-pressure water, the vertical shearing is also small and the ice moves mainly by sliding and spreading on the lubricating layer. This style of flow is observed in ice streams and in the floating ice shelves that form where glaciers flow to the coast and float on the ocean surface.

Ice Stream Classification

Fast-flowing ice streams are the pathways through which the large ice sheets in Antarctica and Greenland discharge most of the ice accumulated in their interiors. There is considerable evidence that these features were also important parts of the Northern Hemisphere's ice sheets of the Ice Ages. Ice streams today are classified into several types, depending on the physical processes responsible for their fast flow.

Ice streams move tens to hundreds of times faster than the ice sheets through which they flow. Several physical processes responsible for such fast flow have been identified, leading to a range of ice-stream types. Traditionally, the term ice stream was reserved for features unique to the West Antarctic Ice Sheet but it has been expanded to include other very fast-flowing features. The range of ice-stream types lies between two "end members," the ice streams of West Antarctica, for example, Whillans Ice Stream, and the isbrae of Greenland, for example, Jakobshavns Isbrae.

West Antarctic–type ice streams are wide (tens of kilometers) and relatively thin ($\sim$1000 m) features that flow within subtle troughs in the underlying bed topography. They have small surface slopes but flow quickly because weak, water-saturated sediments (called glacial till) within those troughs lubricate the contact between the ice and bedrock. The importance of the weak till is twofold: first, it retards the drainage of basal meltwater, leading to high basal water pressures; and second, water saturation weakens the till, allowing it to deform rapidly as the moving ice pushes over its surface, reducing the basal drag force on the ice. Thus, despite small gravitational driving stresses, West Antarctic–type ice streams flow at speeds of hundreds of meters per year. The gravitational driving stress is taken up primarily by drag in narrow (1000 m or less) "shear margins" at the sides of the ice stream. The flow of the most studied of the these features, Whillans Ice Stream, increases from 200 m per year at its upstream onset to about 600 m per year at its downstream end, where it flows into the adjoining ice shelf.

At the other end of the spectrum, isbrae-type ice streams are narrow ($\sim$10 km) and very thick (1000 to 2000 m or more), with large surface slopes. The resulting large driving stresses yield very rapid ice flow, more than 1000 m per year, in some cases without the benefit of basal sliding. Isbrae are thicker than the surrounding ice sheet because they occupy deep bedrock channels. Isbrae-type ice streams are found in East Antarctica, for example, the Shiraze and Jutulstraumen Glaciers. The large outlet glaciers of the Amundsen Sea Embayment may also be of this type.

West Antarctic Ice Streams

The interior of the West Antarctic Ice Sheet (WAIS) flows slowly over rough bedrock. Downstream, the ice is channeled into a network of fast-flowing tributaries and ice streams, which are separated by slow-flowing ice ridges. While the interstream ridges are frozen to the bed, there is ample meltwater at the interface between an ice stream and its bed. Seismic reflection studies have shown that a soft till layer exists in the shallow troughs beneath many of the WAIS ice streams. This till has been sampled in several locations by drilling through the ice on the Whilans and Kamb Ice Streams and was found to consist largely of marine clays. These clays must have been deposited before the WAIS formed, when the region was an open seaway.

The ice streams of the Ross Sea embayment region of West Antarctica have long been the subjects of intense scientific study because their fast flow may make the ice-sheet system vulnerable to rapid change. As the thick ice sheet flows toward the coast, it eventually thins to the point where buoyancy forces it to float on the ocean surface. The transition between ice resting on bedrock and floating ice is called the grounding line. At the grounding line, the water stored on land in the grounded ice sheet returns to the sea and makes a contribution to sea level. When the balance of ice stored in the ice sheet and ice discharged across the grounding line favors storage, sea level drops. When the balance favors discharge, sea level rises. If the ice streams are capable of rapid changes in discharge rate, the WAIS may be capable of causing rapid changes in sea level.

There is substantial evidence that the Ross ice streams are capable of significant changes in flow rate over time scales of tens to a few hundreds of years. Kamb Ice Stream (KIS) is currently quiescent, discharging ice across the grounding line at a rate of 10 m a^{-1} or less. One hundred fifty years ago it was flowing at more than 350 m per year. The 150-year age for shut-down is measured by the accumulation of snow on the top of cracks that formed on the ice stream surface when it was flowing rapidly. Distortions to internal layers of the ice indicate that the shut-down was rapid, occurring over only a few decades. The cause of KIS shut-down is under investigation and is thought to be related to changes in the water content of the marine clays and in the availability of meltwater at the interface between the ice and clay. Other processes, such as changes in ice stream width, may also be important. The downstream part of Whillans Ice Stream has decelerated at a rate of about 5.5 m per year since the mid-1970s. Together, these changes mean the ice sheet is storing more ice than it is discharging, but it is not yet possible to predict if the trend toward deceleration will continue in the future.

The Weddell Sea sector of the WAIS is drained by ice streams with characteristics that lie between the West Antarctic ice stream and isbrae types described above. Gravitational driving stresses are similar to those in the Ross ice streams but speeds are generally slower. The largest of these ice streams in terms of volume of ice discharge, Rutford and Institute, reach speeds of about 400 m per year at the grounding line. There is no evidence that their flow has been as variable as that of the Ross ice streams.

West Antarctic Isbrae

The WAIS also discharges ice into the Amundsen Sea, predominantly through the Pine Island and Thwaites Glaciers. The characteristics of these ice streams lie near the isbrae end of the range. They flow through deep bedrock channels, have large driving stresses, and attain speeds up to 2500 m per year at their downstream ends. The Amundsen Sea sector is the least studied of the three major regions of the WAIS but the data that do exist indicate that significant change has taken place since the 1970s, inspiring many new research projects. This region is often cited as the most likely to experience large change on human time scales.

Discharge from the Amundsen Sea sector of the WAIS is strongly out of balance, with an estimated 60% more ice lost than gained in recent years. This imbalance is characterized by thinning in the upstream parts of the glaciers and acceleration of flow in the downstream reaches. Velocity of the largest Amundsen ice stream, Pine Island Glacier, has been measured via satellite since the mid-1970s. That monitoring reveals two phases of acceleration, from 1974 to 1987 and 1994 to the present, separated by about 7 years of steady flow. The magnitude of this acceleration, 22% over the entire period, is sufficient to explain thinning inferred from satellite-observed lowering of the glacier surface.

Unlike the Ross and Weddell ice streams, which terminate in large ice shelves, the Amundsen ice stream's grounding lines are close to the open ocean. These marine termini are vulnerable to rapid melting by warming ocean water. The bed beneath Pine Island Glacier slopes down toward the interior of the ice sheet, another possible source of instability; as the grounding line begins to retreat from a steady position, the thicker ice upstream from the old grounding line position floats. Once floating, the ice experiences less basal drag than it did while grounded, and its flow rate will increase. Faster flow will cause the ice to thin, allowing ice still farther upstream to unground. Because the glacier bed deepens upstream, the cycle of floating, accelerating, thinning, and continued ungrounding may not stop. This hypothetical process is often called the marine ice sheet instability. The exact cause of Pine Island and Thwaites Glacier acceleration is not yet known but it is likely that processes acting at the seaward termini of glaciers are important.

East Antarctic Isbrae

A number of large outlet glaciers with thicknesses of more than 1000 m and large driving stresses drain the East Antarctic Ice Sheet. The largest of these is the Lambert Glacier, in the Indian Ocean sector of East Antarctica. Over much of its course, the Lambert Glacier flows at speeds of 400 to 800 m per year. It discharges into the Amery Ice Shelf. Unlike the major isbrae of West Antarctica, the Lambert Glacier is observed to be slowly thickening. Other notable East Antarctic isbrae are the Shirase Glacier, which attains a maximum speed of 2300 m per year, and the Totten Glacier and Ninnis Glacier, both of which attain maximum speeds of about 900 m per year. Overall, East Antarctic isbrae appear to be near steady state, with their seaward fronts both advancing and retreating over the last several decades of observation and new ice accumulation nearly balancing ice discharge.

Antarctic Glaciers

Mountain and outlet glaciers form a relatively small proportion of the ice mass on Antarctica. The majority of these glaciers can be grouped into two categories, those draining ice from the large ice sheets of East and West Antarctica and those on the Antarctic Peninsula. Outlet glaciers move ice through mountain ranges at the edges of the large ice sheets. On the Antarctic Peninsula, ice accumulates in high ice caps and descends toward the coast through mountain valleys.

One of the most unusual environments in Antarctica is the McMurdo Dry Valleys. Most valley floors are glacier free but many small glaciers are found on the ridges flanking the valleys. Most of these glaciers flow only partway down the valley sides, but several, like the Commonwealth and Canada Glaciers in the lower Taylor Valley, extend onto the valley floors. Because the ice is thin and very cold, these glaciers flow slowly due to vertical shearing, at rates of a few meters per year. These glaciers are very old; the Meserve Glacier in Wright Valley has existed for at least 3.4 million years.

The Antarctic Peninsula (AP) is one of the fastest-warming regions on Earth. Along with that warming, its glaciers are also changing. A comprehensive study of glacier terminus locations around the coast of the AP found that 87% of the 244 glaciers mapped have retreated over the last 50 years and that the retreat rate has increased over recent years. Relatively little is known about the thickness and flow of AP glaciers. Where they have been measured, speeds at the grounding lines of large glaciers are on the order of 500 to 1000 m per year. Of particular interest is the response of glaciers that flowed into the Larsen A and B ice shelves on the eastern side of the Peninsula. The Larsen A and B disintegrated in 1995 and 2002, respectively, and since those events, the glaciers that flowed into them have accelerated.

GLOBAL OCEAN MONITORING PROGRAMS IN THE SOUTHERN OCEAN

In order to be able to respond to the threat of climate change, information is needed about how the climate system works. The ocean stores immense amounts of heat and the greenhouse gas carbon dioxide, and moves both of them slowly around the world, thus influencing climate both regionally and globally. During that slow cycling, ocean waters move through the Southern Ocean, bringing climate signals from elsewhere and taking away the climatic imprint of the Antarctic region. Understanding the role of the Antarctic region in the climate system, as the basis for predicting the timing, magnitude, and direction of future change, therefore requires monitoring the physical properties of the Southern Ocean. That monitoring takes place through the fast-developing Global Ocean Observing System (GOOS), which is the ocean component of the Global Climate Observing System (GCOS).

The GOOS is broadly envisioned to resemble today's global meteorological observation and prediction network: the World Weather Watch (WWW) of the World Meteorological Organisation (WMO). Like the WWW, the GOOS will be supported by national governments and implemented through the contributions of national agencies, organisations, and industries, with the assistance of bodies involved in the national and international management and distribution of data. The development of the GOOS is led by the United Nations through the Intergovernmental Oceanographic Commission (IOC).

The GOOS embraces observations made from ships, buoys, floats, and satellites. The data are fed into advanced numerical models that are capable of producing forecasts of ocean weather and climate. Much of the GOOS is now being implemented through national activities carried out under the umbrella of the Joint WMO/IOC Technical Commission for Oceanography and Marine Meteorology (JCOMM). This includes programmes that are active in the Southern Ocean as well as elsewhere, such as the following:

1. The Voluntary Observing Ship (VOS) programme, which measures the properties of the upper ocean and the lower atmosphere; a subset of these data is collected to the higher standards required for climate observations, through the climate subset of the VOS, known as VOS-Clim.
2. The Global Sea Level Observing System (GLOSS), which uses tide gauges and the global positioning system (GPS) to measure the height of sea level around Antarctica and its offshore islands, and uses bottom pressure recorders to measure the height of sea level above the deep sea floor in the Southern Ocean.
3. The International Programme for Antarctic Buoys (IPAB), which deploys buoys that drift with the currents at the ocean surface, or on the sea ice, and collects data on the properties of the surface water and lower atmosphere.
4. The Argo float programme, which deploys instrumented floats that move through the ocean at a depth of 2000 m, ascending every 10 days or so to collect a vertical profile of temperature and salinity that is sent back to base via satellite when a float reaches the surface, upon which the float repeats the cycle.
5. The reference buoy network of stations at which measurements are collected of ocean properties through the water column at the same site several times a year to provide a picture of change with time.
6. Observations made of the ocean surface by remote sensing from satellites using instruments of various kinds that can measure changes in ocean surface height (by altimetry), sea-surface temperature (by radiometry), sea-surface roughness (by scatterometry), sea-ice cover (by passive microwave), and ocean colour.

On the global scale, the GOOS was 50% operational in 2005, and is intended to be fully operational by 2010. However, monitoring the Southern Ocean presents a formidable challenge, because it is so geographically remote, such a harsh environment to work in—especially in the southern winter—and so far away from major oceanographic centers and shipping lines. Much more effort than is available at present will be needed to make the GOOS fully operational there. Until that effort is made, the Southern Ocean will represent a gap in the knowledge required to predict climate change accurately.

GONDWANA

Gondwana is one of two giant landmasses that encompassed all the Earth's land areas until about 160 Ma. Gondwana was an amalgamation of what we know today as South America, Africa, Madagascar, India, and Australasia, all grouped around Antarctica. Parts of south and southeast Asia were probably also included. The other supercontinent was Laurasia, made up of North America, Europe, and most of Asia. During the earlier phase of their existence, these two landmasses were in contact and together constituted a supercontinent, known as Pangea. The "Pacific Ocean" was far larger than it is today, and there was a deep oceanic embayment between Laurasia and Gondwana, known as Tethys, which later extended between Europe and Africa and through "Central" America into the eastern Pacific.

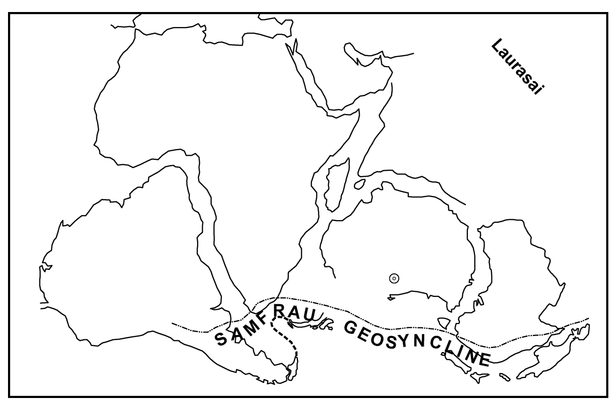
The best early review and argument for the existence of Gondwana is the classic work by Alexander Du Toit (1937). Building upon the theories put forward by the German meteorologist and Arctic researcher Alfred Wegener (1915), Du Toit amassed a wealth of argument for the previous existence of Gondwana. Apart from the obvious geographical argument (notably the jigsaw-puzzle fit of some continents, especially across the Atlantic), there was the geological correspondence of major rock formations across oceans. Furthermore, palaeoclimatological, palaeontological, and biological data for individual continents made much more sense if it were supposed that continents had once been much closer together. From the very outset, Du Toit stressed the vital role of Antarctica, as the key piece in understanding the construction of Gondwana. Later, understanding Antarctica's position would also be crucial to the elucidation of breakup and dispersal mechanisms for marine biota (Thomson and Vaughan 2005).

To many geologists and biologists, the previous existence of Gondwana made a great deal of sense, providing a very neat explanation for the occurrence of similar rock formations and ancient plants and animals in what are now widely disparate landmasses, separated by thousands of miles of deep ocean. A geological map of Gondwana compiled by Campbell Craddock (1970) in the Antarctic Folio, published by the American Geographical Society, drew graphic attention to apparent geological continuities and similarities between Antarctica and other continental pieces of the original Gondwana:

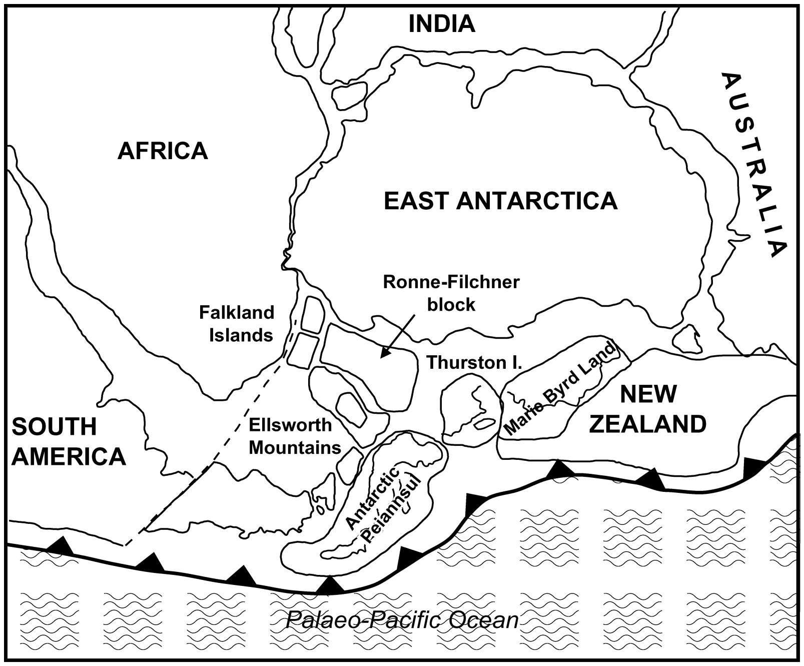
- Cratonic areas of southern Africa, India, East Antarctica, and Australia
- Fold belts of southeastern Australia and northern Victoria Land
- Ellsworth Mountains and the Cape Fold Belt of South Africa
- Antarctic Peninsula and Pacific Marie Byrd Land with South American Andes and New Zealand

These issues were addressed and argued by various authors at the International Symposium on Antarctic Geology and Geophysics in Madison, Wisconsin in 1977, and widely elsewhere. They have also formed the focus of several international, intercontinental geological field studies.

In the upper Palaeozoic and lowest Mesozoic (Trias) sequences of South America, southern Africa, Madagascar, India, Australia, and Antarctica there is a basic stratigraphical succession that, whilst not everywhere identical, nevertheless shows a remarkable



Reconstruction of Gondwana in the Palaeozoic, simplified and redrawn from DuToit (1937). After many years of argument, the basic pattern has changed remarkably little, apart from our more detailed understanding of complexities on the palaeo-Pacific margin. We now know that DuToit's SAMFRAU (South America, South Africa, and Australia) geosyncline includes rocks of ages other than Palaeozoic. His reconstruction is distorted, principally because he maintained a link between South America and the Antarctic Peninsula via the Scotia arc (a Cenozoic structure).



Modern reconstruction of Gondwana for the early Jurassic (about 190 Ma) showing the palaeo-Pacific margin as a jigsaw of continental fragments. In particular, note the position of the Falkland Islands. The area that is now the Weddell Sea is almost entirely occupied by the Ellsworth Mountain and Ronne-Filchner blocks. The toothed line represents a subducting margin to the palaeo-Pacific Ocean. (Simplified from Thomson and Vaughan 2005, fig. 14.)

degree of commonality. Key units are a Carboniferous–Lower Permian glacial sequence (commonly resting on an erosion surface), Permian sedimentary rocks with a *Glossopteris* flora (e.g., Plumstead 1962) and locally well-developed coals, and a Triassic terrestrial sequence with floras characterized by *Thinnfeldia/Dicroidium* and with similar amphibian and reptilian vertebrate faunas (e.g., Colbert 1982).

Sequences of Late Carboniferous and Permian glacial deposits (about 338–256 Ma) locally resting on scratched pavements are found in Brazil and Argentina, southern Africa, the Indian subcontinent, the Malaysian region, Australia, and Antarctica. Plotted on a modern map of the world, the occurrences make little sense; they are not only widely dispersed, but many occur in areas that today experience tropical climates. Plotted on a map of Gondwana, however, they come together as the vestiges of one glaciation, centred more or less on Antarctica, with ice sheets radiating out into once-contiguous landmasses. The distribution of the postglacial Permian *Glossopteris* flora in the rocks of South America, southern Africa, Madagascar, India, Australasia, Antarctica, and even Anatolia also makes more sense if it is viewed as a Gondwanan vegetation (which also achieved some incursion into southern Laurasia). Whilst critics might argue that plants may achieve distribution by wind or sea, the distances involved are huge. For land animals, the problem of dispersal is even greater and contiguous land is a prerequisite for almost all. Thus the discovery of a varied Triassic vertebrate fauna of amphibians and reptiles (typified by the reptile *Lystrosaurus*) in the Transantarctic Mountains, many of which were known also from South Africa and India, but unlikely candidates for transoceanic migrations, provided a clinching argument for the existence of Gondwana for most palaeobiologists.

Nevertheless, however attractive it may have been to some, the concept of Gondwana came in for stiff criticism, not least from those who were unable to find a mechanism for the subsequent breakup and dispersal of the supercontinent (Le Grand 1988). It also posed headaches for believers. Reconstructions that otherwise satisfied the known geological constraints of the day all too often ended up with the Antarctic Peninsula overlapping southern South America or the Falkland Plateau, and the Ellsworth Mountains of Antarctica with their typical Gondwanan geology set at an anomalous structural angle to related sequences in the Transantarctic Mountains. Madagascar oscillated between a position tucked in south of the horn of Africa and an alternate location tucked into the coastal embayment of Mozambique.

The dilemma of the Antarctic Peninsula was encapsulated in a paper by Ian Dalziel and David

Elliot (1982), but help was at hand if Antarctica was not viewed as a rigid entity through geological time. The concept of West and East Antarctica as separate tectonic units, and the west made up of several discrete microcontinental blocks, each with its own movement history, made it possible to solve the Gondwana puzzle in terms of all external constraints without the embarrassing inconveniences of overlaps and strange tectonic orientations. It even turned out that the Falkland Islands came from somewhere adjacent to Natal and had been rotated by approximately 180° in the process (Curtis and Hyam 1998). Likewise, the Ellsworth Mountains are now generally believed to have rotated counterclockwise from a position closer to the Weddell Sea coast of East Antarctica. Currently favoured reconstructions of Gondwana depict the peninsula lying west of southern Chile, and West Antarctica a compact mass of fragments that have very different relative positions today.

As important as the previous existence of Gondwana are the mechanism of its breakup and the dispersal history of the ensuing fragments. Breakup began about 180 Ma in the area between the southeastern margin of Africa and northwestern Dronning Maud Land, probably when heating and doming of the crust in response to a hot plume of molten rock rising from the mantle caused the crust first to fracture and then to spread apart (Storey 1995). From about 165 Ma, the region between the two became an expanding ocean with arms radiating out to become the South Atlantic and the Indian oceans. Freed of its attachment to Antarctica, India moved rapidly northward to collide with Asia, forming the Himalayan chain in the collision zone. The last remaining connections between Antarctica and fragments of old Gondwana were those between the Antarctic Peninsula and southern South America, and between Australia and northern Victoria Land. Severance of these two land connections 32.5 and 31 Ma, respectively, broke down barriers to marine connections and made possible the development of a deep-water Antarctic Circumpolar Current (Thomson 2004), which isolated the continent physically and climatologically.

Yet, even as Gondwana was breaking up, it still had an important role to play in the distribution of terrestrial plants and animals. The southern beech, today restricted to southern South America and Australasia, is known as fossils from the late Cretaceous of Antarctica (approximately 75 Ma) but not at all from South Africa or India. It thus seems that these plants developed after Africa and India had separated from their Gondwana neighbours. Widespread throughout the Americas in the geological past and probably originating from there in the late Cretaceous, marsupial, or pouched, mammals are today best known from Australia, with a fossil record that extends back to the late Oligocene. They are, however, unknown from Africa, India, and even New Zealand, all of which had separated from the rest of Gondwana in the Late Jurassic and mid Cretaceous. It thus appears that the previous existence of Gondwana can best explain the distribution of plants and animals in our world today and that Antarctica played a key role as a migration path.

GOUGH ISLAND

Gough Island has been described as the most important seabird island in the world. It lies in the mid South Atlantic at 40°21′ S, 9°53′ W and forms part of the United Kingdom Overseas Territory of Tristan da Cunha. The island was discovered in 1505 by Portuguese sailors, although an 1804 visit by a sealing gang was the first confirmed landing.

Gough Island covers 6400 ha and is roughly rectangular in shape. It is a volcanic island, about three million years old, with the last eruption occurring 130,000 years ago. The island is mountainous with steep coastal cliffs. With the exception of a low-lying area in the south, the land rises steeply to a central plateau above 500 m, with the highest point, Edinburgh Peak, at 910 m. There are numerous offshore islets and rocks within 1 km of the island. Gough's climate is cold-temperate, with strong prevailing westerly winds, a mean annual precipitation of 3154 mm, and a mean monthly temperature between 8.9°C in August and 14.5°C in February. Snow can fall in the interior, but rarely at sea level.

In 1976 Gough Island and its territorial waters out to three nautical miles were declared a wildlife reserve. A management plan was adopted in 1993. In 1997 the island was renamed the Gough Island Nature Reserve and its boundaries extended out to 12 nautical miles. Gough Island and its territorial waters were designated a World Heritage Natural Site in 1995. Another island in the Tristan da Cunha Group, Inaccessible, was added to form the Gough and Inaccessible Islands World Heritage Site in 2004.

Gough supports an altitudinal succession of vegetation types, from coastal tussock grassland through to lowland fernbush, up to an altitude of 500 m, where highland vegetation of wet heath, peat bog, feldmark, and montane rock communities occur. The flora on Gough Island is typical of southern cold-temperate oceanic islands, with relatively low species diversity, and a predominance of ferns, lichens, and bryophytes, although two tree species occur. Currently, 281 plant species are recognized on Gough, of which 12 are endemic and 24 introduced. The range of most alien plants is limited to disturbed areas and only four species are widespread.

The indigenous invertebrate fauna is characterized by relatively low species diversity, typical of Southern Ocean islands. Over 100 free-living species have been recorded, but due to inadequate sampling and taxonomic study of many taxa, the true number of species is likely to be much greater. There is a large number of introduced invertebrates.

There are twenty breeding seabird species totalling millions of pairs (mainly members of the Procellariiformes—albatrosses and petrels) and two endemic land bird species (the flightless Gough moorhen *Gallinula comeri* and the Gough bunting *Rowettia goughensis*). The seabirds play an important role in the island's terrestrial ecology through the importation of large quantities of marine-derived nutrients, mainly in the form of guano. Virtually the entire world population of the endangered Tristan albatross *Diomedea dabbenena* and the vulnerable Atlantic petrel *Pterodroma incerta* breed on Gough Island. Also breeding is the world's largest population of the endangered sooty albatross *Phoebetria fusca,* second-largest population of the endangered Atlantic yellow-nosed albatross *Thalassarche chlororhynchos,* over 100,000 pairs of the vulnerable rockhopper penguin *Eudyptes chrysocome,* and millions of burrowing petrels, notably the great shearwater *Puffinus gravis*.

Two native mammal species breed on the island, the sub-Antarctic fur seal *Arctocephalus tropicalis* and the southern elephant seal *Mirounga leonina*. Both species were hunted extensively during the nineteenth century and almost driven to local extinction. Only the fur seals have since recovered, and currently some 200,000 are found on the island. The elephant seal population remains small with only ten to fifteen pups born each year.

The only alien mammal currently occurring on Gough Island is the house mouse *Mus musculus,* likely to have been accidentally introduced by sealers, sometime in the early nineteenth century. Mice are now ubiquitous on the island, with densities reaching at least 224 individuals/ha. They have evolved a larger body size than elsewhere, perhaps due to a combination of reduced temperature, extended longevity, and low predation, together with a high energetic content of food, especially avian material.

The inshore waters of Gough support a fishery for the Tristan rock lobster *Jasus tristani*. The marine life is little known, although a number of species of fish occur in abundance within the surrounding kelp beds. Southern right whales *Eubalaena australis* occasionally visit.

The South African Weather Service and the South African National Antarctic Programme (SANAP) of the Department of Environment Affairs and Tourism have maintained a small meteorological station on

Gough Island under agreement with the Tristan Government since 1956. Located on the coastal cliff above Transvaal Bay, it is the island's only standing human construction. The station supports an annually rotated staff of at least six people.

There has been considerable scientific interest in the islands since the late 1700s. The Gough Island Scientific Survey undertook the first multidisciplinary study of Gough Island over a period of 6 months in 1955/1956. It conducted inventories of the island's fauna and flora, as well as studies of its geology and palaeontology, and produced the first map. More recently there have been multiyear investigations of the island's fauna (invertebrates, threatened birds, and the introduced mouse), conducted by both South African and United Kingdom scientists.

Unexpectedly, in the first few years of the new millennium it was discovered that the house mouse was preying upon chicks of the winter-breeding Tristan albatross and Atlantic petrel, literally eating them alive over a period of several nights. Modelling the birds' consequently lowered breeding success suggests that both species are at risk of extirpation (the albatross also being adversely affected by fishery-related mortality while at sea). Research is now being conducted to assess how the mice can be eradicated, most probably by dropping poison bait from helicopters over the whole island in a single operation. Such an exercise, whereas theoretically feasible, will be hugely expensive and thus a test of political will to fund.

GREENPEACE

Greenpeace is a nonprofit international environmental organization. Greenpeace's trademark tactics combine nonviolent direct action and "bearing witness"—a form of active–passive resistance originated in the Quaker traditions of some of the organization's earlier activists, which involves protesting injustices by being present to observe them. Greenpeace used these approaches to bring the plight of the Antarctic region to the public's attention, and to promote its protection as a wilderness region, in particular through opposing mining, whaling, and unsustainable fishing.

Greenpeace was founded in Vancouver, Canada, in 1971. A broad range of people converged in Vancouver at the time—hippies, peaceniks, radical ecologists, Quakers, Vietnam War draft dodgers. Vancouver was also the largest city closest to Amchitka Island in the Aleutians, where the US Atomic Energy Commission was planning to conduct a 5-megaton nuclear weapon test, the largest in US military history. The testing program generated concerns about the effect of underground nuclear explosions in a seismically active area, and substantial public opposition. The "Don't Make a Wave Committee" was created to oppose the testing, and some of its members attempted to reach the test grounds in a wooden halibut fishing boat, the *Phyllis Cormack,* to "bear witness"—and to report back. This committee later became Greenpeace, a combination of words—coined by Bill Darnell—that links concern for the earth and opposition to nuclear arms. Robert Hunter created the concept of reaching to public consciousness through dramatic images of environmental abuse—what was called the "Media Mind Bomb." David McTaggart, who in 1972 led Greenpeace's second protest voyage to oppose French nuclear testing in the South Pacific, convinced several loosely connected groups to form Greenpeace International in 1979 (Brown and May 1989).

It was McTaggart who directed the attention of Greenpeace to Antarctica. In 1978 Jim Barnes had set up the Antarctic and Southern Ocean Coalition (ASOC) as an international coalition to protect Antarctica, and he persuaded McTaggart that

Greenpeace should support the World Park Antarctica campaign. The World Park concept was based on the protection of the Antarctic wilderness values and wildlife; and in the maintenance of Antarctica as a zone of peace, free of all weapons, and devoted to international scientific cooperation. The exact legal form of the concept was not spelt out—it could be enacted through existing legal entities such as the Antarctic Treaty System, or through the mechanisms of the World Heritage Convention (Brown and May 1989).

The initiation of negotiations by the Antarctic Treaty States for a convention to open the continent for minerals exploitation was the trigger for Greenpeace's involvement, which began in 1983. Initially, the Antarctic campaign involved working to enhance the efforts of ASOC, and lobbying at Antarctic Treaty meetings and at the wider community of states in the United Nations (whose General Assembly discussed annually the "question of Antarctica"). Greenpeace conducted protests in the capital cities of Antarctic Treaty Parties, and delayed the departure of vessels leaving to Antarctica to conduct oil research. Later, Greenpeace took its protest to Antarctica itself to further increase pressure on Antarctic Treaty Parties (Brown and May 1989; Rigg 1995).

The first Greenpeace Antarctic expedition, in 1985–1986, departed from Lyttelton, New Zealand, intending to build a base at Ross Island. Operating a base would provide Greenpeace with direct Antarctic experience and thus the capacity to speak with credibility with Antarctic Treaty Parties. However, ice conditions prevented the expedition from reaching its destination. The base was built and tested in New Zealand during the austral winter, and Greenpeace tried again the following summer, anchoring off Cape Evans on January 25, 1987. By February 13 the base—a prefabricated green hut—had been completed. World Park Base (77°38′ S, 166°24′ E) was located 200 yards to the northeast of the hut from Robert Falcon Scott's last expedition, at a site previously occupied by the base camp of a private expedition. Its purpose was to monitor human activities in the surrounding area (particularly McMurdo Station, 18 miles away); carry out a modest program of scientific research; and draw public attention to the future of the continent, in particular to generate opposition to the minerals convention. World Park Base operated year-round with a crew of four (both men and women) and was supplied annually by Greenpeace ships. World Park Base pioneered environmentally friendly approaches to Antarctic operations—such as the removal of all waste and the use of alternative energy (Brown and May 1989; Greenpeace 1994; Roura 2004).

Other Greenpeace Antarctic Expedition actions included blocking temporarily the construction of an airstrip at the French base Dumont D'Urville (of particular concern because it involved dynamiting several small islands rich in bird life); and protesting poor waste and fuel management practices—for instance, by depositing trash from McMurdo's dump at the station's administration building. In the Southern Ocean, Greenpeace disrupted the "scientific" killing of minke whales and unsustainable fishing activities. From 1987–1988 Greenpeace began conducting unofficial review visits to Antarctic stations, focusing on their environmental performance. (The reception for Greenpeace activists during these "inspections" ranged from being invited to lunch to being assigned an unwanted military escort.) Between 1987–1988 and 2001 Greenpeace visited, and reported on, over 160 sites or facilities, mostly in the Antarctic Peninsula and Victoria Land (ASOC & UNEP 2003).

Action on the ice and in the Southern Ocean was tightly coupled with media work, political lobbying, and technical engagement in specialized fora—with feedback both ways, and through the ASOC network. Images from Greenpeace's direct actions went around the world, and documentation from the expeditions was provided to Antarctic Treaty Consultative Meetings, meetings of the Convention for the Conservation of Antarctic Marine Living Resources, or the International Whaling Commission.

Greenpeace's methods were criticized as "confrontational" by some of the targets of its activism (e.g., Browne 1990). Some have speculated that there exist links between the high-profile public campaign for the protection of the Antarctic and the growth of Antarctic tourism (e.g., Hemmings 1997).

Following NGO efforts, Australia and France rejected the minerals convention, CRAMRA, and as more nations also decided not to ratify the convention, it was ultimately abandoned in favor of the 1991 Protocol on Environmental Protection to the Antarctic Treaty, with its 50-year moratorium on mineral resource activities. World Park Base was entirely removed in 1991–1992, after the signature of the Protocol. The removal included environmental remediation, and a monitoring program that lasted until 1995–1996 (Roura 2004). Between 1991 and 1998 Greenpeace lobbied in most Antarctic Treaty states and internationally for the ratification and implementation of the Protocol. In the mid-1990s, Greenpeace began to focus on the impacts on the Antarctic environment resulting from global (rather than local) activities, and began documenting the emerging effects of climate change in the region (Dalziell 1996), such as the collapse of the Larsen Ice Shelf. Since the late 1990s Greenpeace has been focusing on the increasing threat of Southern Ocean fishery collapse, in response to illegal, unregulated, and unreported fishing.

Greenpeace's Antarctic campaign helped to generate public interest in the protection of Antarctica, which in turn catalyzed changes in Antarctic policy on the part of the Antarctic Treaty nations. Consequently, environmental protection became one of the pillars of the Antarctic Treaty System (e.g., Bastmeijer 2003). Greenpeace's Antarctic presence strengthened the case for environmental NGOs gaining expert status at the Antarctic Treaty Consultative Meetings, which ASOC was granted in 1991. (Before then, the meetings were conducted behind closed doors, and activists could only gain access to delegates at coffee breaks. However, a parallel application for expert status by Greenpeace itself was rejected.) Greenpeace claims as a victory the establishment of the Southern Ocean Whale Sanctuary, approved by the International Whaling Commission in 1994. Greenpeace's support for Antarctic research resulted in several publications in peer-reviewed scientific journals.

At its peak the Antarctic campaign costs reached several million US dollars annually. Greenpeace funds its activities primarily with the voluntary donations of individual supporters, supplemented with grant support from foundations. Its funding policy is designed to ensure complete independence from all governments, corporations, and political parties. Presently Greenpeace, whose international headquarters are in Amsterdam, The Netherlands, has a presence in forty countries across the Americas, Asia, Europe, and the Pacific, and a fleet of ships that includes two ice-class vessels. Some of Greenpeace's current campaigns, including campaigns to stop climate change, stop whaling, and save the oceans, involve activities in the Antarctic Treaty Area and adjacent regions—as well as in the Arctic.

GREY-HEADED ALBATROSS

The grey-headed albatross *(Thalassarche chrysostoma)* is a medium-sized albatross weighing between 3 and 5 kg, with a wingspan of over 2 m. Adults are distinguished by a combination of a grey head with a white crescent just behind the eye, a black bill with narrow, bright yellow ridges, and a mostly white underwing with a broad black leading edge.

Grey-headed albatrosses are a globally threatened species classified as vulnerable because of an estimated decrease of 48% over 3 generations (90 years). If the major population decreases observed at some sites are shown to be occurring elsewhere in the species range, it is projected that the conservation status of the species will be relisted as endangered.

Grey-headed albatrosses breed in Chile and at six sub-Antarctic island groups in the Southern Ocean. The annual breeding population is estimated to be 92,300 pairs, equivalent to a total of about 250,000 mature individuals. The population at South Georgia is the largest across the species range and accounts for 56% of the global population. Other large populations occur at Isla Diego Ramirez in Chile, Marion and Prince Edward Islands, the Campbell Islands, and a small population on Macquarie Island.

Grey-headed albatrosses are essentially biennial breeders with a breeding season that extends over 8 months. They typically breed on tussock slopes and cliff terraces, sometimes in association with other albatross species. Breeding adults return to the colonies in early September to early October with males returning about a week ahead of the females. Both adults share the 10-week incubation period, the eggs hatching in December and early January. The chicks are brooded for 3 to 4 weeks after hatching, and chicks fledge at about 20 weeks of age. Typically successful breeders depart the colonies when chicks fledge in late April and May.

Juvenile grey-headed albatrosses generally return to their breeding island when they are 6 to 7 years of age, and breed when 10 to 14 years. The life history of grey-headed albatrosses is well studied at South Georgia, where, over the last 2 decades, the Bird Island population has decreased at an annual rate of 1.4%–1.8%. This population decrease is mainly a result of decreases in juvenile survival rate (from 35% to 5% recruitment) and reduced survival rates of adults (95% to 93%).

Grey-headed albatrosses have an oceanic distribution and are found in sub-Antarctic and Antarctic waters between 46° and 64° S during summers and between 39° and 51° S during the winter months. Satellite tracking of breeding adults from South Georgia showed regular use of core feeding areas in the Antarctic Polar Frontal Zone (APFZ), which is likely an area of predicable aggregations of prey associated with mesoscale oceanographic features. Breeding birds also make extensive use of shelf waters, the reliance of different feeding habitats varying among years. During the 18-month nonbreeding-period season, grey-headed albatrosses from South Georgia undertake a circumpolar migration, one bird recorded as completing the trip in just 46 days. Grey-headed albatrosses have distinct migration strategies, with some individuals exploiting the same key staging areas in successive winters.

Grey-headed albatrosses obtain their prey by surface seizing, and also by diving to depths of 6 m. Most foraging occurs during daylight hours, and a combination of squid, fish, and krill is most commonly consumed, the relative proportions of prey varying with foraging habitat. Grey-headed albatrosses also scavenge offal and discards from fishing boats, and as a result they are vulnerable to being hooked and drowned on longlines as they scavenge on the baited lines. Mortality of grey-headed albatrosses in longline fisheries has been identified as a major cause of the population decrease. In the absence of adoption of effective changes to fishing practices it is projected that such decreases will continue into the future.

GROWTH

Growth in Antarctic marine cold-blooded species is slow. This has been known for more than 25 years. Generally, growth rates are slowed by around two to five times compared to temperate species. A few studies have reported fast growth in Antarctica for some sponges (Dayton et al. 1974), ascidians (Rauschert 1991), and bryozoans (Barnes 1995). However, the fast rates here are only as fast as slow rates elsewhere, and when the whole range of growth is viewed, it is generally depressed at high latitudes. A typical example is the brachiopod *Liothyrella uva,* which takes around 50 years to reach maximum size. This was verified by linking enhanced ^{14}C levels in shells to periods of increased ^{14}C following nuclear bomb tests (Peck and Brey 1996). Growth is often estimated from growth rings, and these, too, show great age in Antarctic species. Seasonal variations in isotopes in shells have also been used to show that rings are laid down annually in the bivalve *L. elliptica* (Brey and Mackensen 1997).

Studies showing faster growth rates in some species, along with relatively fast summer growth in pelagic invertebrates, have been used to argue that low temperature itself cannot constrain growth, and that growth is limited by seasonally restricted food supplies. This argument still continues, with some species exhibiting highly seasonal periods of growth (e.g., the urchin *S. neumayeri*) (Brockington 2001), whereas others that feed seasonally appear to grow more evenly throughout the year (e.g., the bivalve *Y. eightsi*) (Peck et al. 2000). Both of these have been viewed as supporting seasonal growth limitation, the former through cessation of growth in winter, and the latter through the spreading of growth effort through the year to optimise efficiency of use of stored reserves. Some studies have shown slow growth in the presence of unlimited food resources in adults (e.g., the amphipod *Waldeckia obesa,* which might live to 8 years). However, possibly the best support for temperature limitation of growth comes through analyses of larval development, where Hoegh-Guldberg and Pearse (1995) showed that development in feeding and nonfeeding larval types was similarly slowed at low temperatures. It is also interesting that development in protected embryonic forms is markedly slowed in Antarctic species, which has been well demonstrated in molluscs (Hain 1991) and amphipods (Sainte Marie 1991). Both temperature and seasonality probably place restrictions on growth in different parts of the life cycle.

There is recent evidence showing that proteins may be less stable and more difficult to synthesise at low temperatures (Fraser et al. 2002). This is one mechanism where low temperature might limit growth.

Slow growth at polar latitudes comes with extended lifetimes and deferred maturity. Where studies exist, all show extended longevity in Antarctic species. Thus, Antarctic sea urchins, brachiopods, and bivalve molluscs all live for more than 50 years, and the starfish *O. validus* has been estimated to live more than 100 years. Data for sponges is even more extreme, with some age estimates for Antarctic species in the hundreds, and possibly in excess of 1000 years (Gatti 2002). Cold-water species also exhibit deferred maturity. They do not begin to reproduce until much later than warmer-water relatives, and their rates of gamete maturation also take much longer than warmer-water species. All of these slowed biological rates are likely to make Antarctic marine species vulnerable in a changing environment, because their responses will be slower than lower-latitude relatives.

H

HANSSEN, HELMER

Helmer Julius Hanssen participated on Roald Amundsen's first three polar expeditions and was in the five-man group that reached the South Pole on December 14, 1911.

Helmer Hanssen was born in Andøy, northern Norway, on September 24, 1870, and followed a traditional pattern of farm work and fishing from an early age. Small whale and seal hunting in the Arctic, his certificate as ship's mate, and participation on Henry J. Pearson's expedition to Novaya Zemlya in 1897 gave him a good foundation for polar expedition work. When Pearson's expedition was about to start from Sandefjord in Norway, Hanssen met Roald Amundsen, who was preparing to leave with the Belgian Antarctic Expedition in *Belgica*. After more years as a sealer and ship's mate, Hanssen joined Amundsen's *Gjøa* expedition through the Northwest Passage, 1903–1906, after being recommended by a mutual acquaintance. Thereafter followed an 18-year-long association with Amundsen. On the *Gjøa* expedition Hanssen learned dogsled driving, which was to be his particular expertise on the South Pole expedition.

After *Gjøa*'s return, Hanssen worked as a customs officer in Tromsø, northern Norway, but was given leave to participate on the Amundsen expedition that went to the Antarctic in 1910–1912. With his skill at dog-driving, he was a natural choice for the Pole party, and he drove the leading sledge the entire way, except for the very last part, when he let Amundsen ski in front to be the first to reach the Pole. Hanssen's experience regarding dogs, sledge travel, clothing, igloo building, and food on long journeys had been acquired in close contact with the Inuit on King William Island during the *Gjøa* expedition, but he seems also to have had a natural talent for work with dogs, and he boasted that he almost never had to use the whip. Without a doubt, he was a key person on the South Pole expedition, and he contributed greatly to the success of the sledge journey.

Hanssen participated as skipper on Amundsen's next expedition, in *Maud* through the Northeast Passage, 1918–1920, but his relationship with Amundsen turned sour during this frustrating, ice-struck voyage, and he was dismissed when *Maud* reached Nome, Alaska. During the last winter on board, Hanssen had made a rigorous sledging journey for Amundsen from the expedition's winter harbour at Ayon Island to the nearest functioning telegraph station at Anadyr by the Bering Strait and back, a distance of c. 4000 km that took six and a half months. After his dismissal in Nome, Hanssen had to take work in industrial gold digging to earn money for his ticket home.

Hanssen participated as dog driver on the Oxford University Spitsbergen Expedition in 1924 and crossed Nordaustlandet with the expedition leader George Binney. In 1926 he assisted a German film expedition in Svalbard and Northeast Greenland. On this trip he met the American polar explorer Richard E. Byrd, but declined to join him on a new Antarctic expedition. The rest of his working life was spent in Tromsø, where he died on August 2, 1956.

HEALTH CARE AND MEDICINE

No Antarctic-specific ailment or disease has been diagnosed. Humans going south are transient visitors and, as many are highly mobile, diseases contracted in tropical or temperate areas may occur in Antarctica, consistent with the age and sex of the individual. Health care is therefore the practice of medicine in Antarctica, as varied as that practice is, and not a specialty of Antarctic-specific disease states.

Each group, whether national research, tourist, or adventure seeking, has assessed the risks and developed health care in response to the perceived needs. Multidisciplinary medical teams and elaborate medical suites and equipment contrast with no medical staff and basic materiel. National programs have chosen different models, civilian, military, contract, or, within the national organization, a combination of these. Determining factors include the degree of physical isolation, medical logistics capabilities (especially the ability to provide medevac by ship or aircraft), and the number and skills of the medically trained staff. Traditional tourist vessels with older passengers have different needs from those catering to the younger, more adventurous visitors.

As a number of wintering Antarctic medical services have an evidence base of decades, operating with no prospect of timely evacuation, preventive medicine has become the cornerstone of the service. Judicious planning has seen the assessment of the risk–benefit of every potential procedure, with a service that is not unrealistic in what should be provided or the ultimate outcome. Preventive principles are reflected in predeparture medical screenings including psychological and/or psychiatric assessment, training of medical staff, first-aid training for all personnel, medical and first-aid manuals, and prophylactic appendectomy for the physician. Screening was performed by a number of expeditions in the Heroic Era. Guidelines for such were and are variable, ranging from disqualification of candidates for specific conditions such as diabetes, asthma, and heart disease, to the granting of waivers. Physical examinations vary, but generally include laboratory investigations, electrocardiogram, chest x-ray, and blood-donor screening.

Contrary to popular belief, the environmental conditions of cold injury, hypothermia, and snow blindness are uncommon; most are experienced in accidents and recreational pursuits such as skiing and driving snowmobiles. Increased ultraviolet radiation, as a consequence of ozone depletion, has not been found to be a problem, as polar clothing covers most of the body and sunscreens and goggles are universally used.

Trauma and accidents are common, with most of a minor nature. Injuries range from lacerations, abrasions, musculoskeletal sprains and strains, and burns, to fractures and multiple trauma. Ill-defined conditions such as headaches, dyspepsia, and insomnia, endemic during the 24 hours of summer daylight, occur frequently. Dental and skin problems are also common. The latter may be *polar hands,* the presence of painful cracks in the skin of fingers, especially around nails, caused by the dry, cold environment. Diagnoses made and treated in Antarctica include appendicitis, breast, lung, and testicular cancer, gall bladder disease, gout, heart attack, hepatitis, intracranial bleeding, kidney stones, malaria, peptic ulcer, pneumonia, amoebic dysentery, scurvy, hypervitaminosis A, and mental and behavioral disorders.

Over a thousand persons have died in Antarctica, but the mortality rate is low when compared with more densely populated regions. The majority perished in two disasters. In September 1819 the Spanish warship *San Telmo* was wrecked on Livingston Island, drowning hundreds of officers, crew, and military personnel. A crash of an Air New Zealand flight into Mount Erebus killed 257 tourists in November 1979. Deaths in the Heroic Era contrast with recent fatalities: three skydivers, a young woman on a yacht from complications of diabetes, and a number of tourists from heart attacks. Deaths on national expeditions have resulted from carbon monoxide poisoning, burns, falls into crevasses, drowning, multiple trauma, hypothermia, alcohol poisoning, cerebral hemorrhage, perforated gastric ulcer, appendicitis, and heart attacks.

The medical armamentarium has evolved over the past century from simple chests to the best now having suites complete with library, examination, emergency, sterilizing, laboratory, and diagnostic equipment, patient ward, operating theater with surgical, anesthetic, orthopedic, obstetric, and dental instruments and equipment, and an extensive range of pharmaceuticals. Procedures have ranged from removal of a splinter to brain surgery.

Since the introduction of the wireless to Antarctica, medical communications have been important, from station physician to consultants outside Antarctica and to scientists in the field, where facilities and equipment are primitive. Telemedicine has been practiced in Antarctica for 40 years. Improvements have come with modern technology and the advent of satellite communications, not subject to radio *black-outs*. Data, clinical and pathology photographs taken through a microscope, x-rays, ultrasound images, and electrocardiograms are routinely sent to consultants outside Antarctica. Many doctors have access to phone, fax, e-mail, data circuits, and the World Wide Web. In addition to providing clinical and peer support, telemedicine and medical informatics provide continuing medical education, access to databases, electronic patient records, electronic journals, and inventories to remote medical staff.

Polar medicine has always had a close nexus with human biological research. International collaboration over 50 years in research, sharing diagnostic dilemmas within a SCAR medical working group, and in medevacs, together with recent initiatives within COMNAP, have improved standards of care in Antarctica. Community attitudes as well as the expectations of groups isolated on the Antarctic Continent and of their families and friends at home have also played a part, but it is unrealistic to expect the standard to be that of the world's best practice. Although highly qualified doctors have provided excellent cover, provision of a continuing service has been hampered by lack of physicians with the necessary personality and skill set to deal with the demands of practice with its isolation, confinement, and separation from colleagues. Many ethical and medico-legal issues face those providing health care. Availability of equipment and supplies, skills of staff, privacy and confidentiality, medical indemnity, status of walking blood banks, and who doctors the doctor are but a few. A physician removed his own appendix in 1961, and there have been highly publicized evacuations of doctors from the continent in the past 10 years. Many of these issues face those organizing medical services for long-duration space expeditions, Antarctica being an ideal analogue for space medicine.

Antarctica being central to research on global climate change, a much-sought-after tourist destination, and an important analogue for space, Antarctic health care and medicine continue to evolve.

HEARD ISLAND AND McDONALD ISLANDS

Heard Island is located at 53°05′ S, 73°30′ E in the southwest Indian Ocean, approximately 4350 km southwest of Australia, 4850 km southeast of South Africa, and 1650 km north of the Antarctic continent. Heard Island is broadly circular in shape, approximately 40 km east–west and 20 km north–south, and dominated by Big Ben, an active volcano of 2745 m elevation and radiating buttresses. Heard Island lies south of the Antarctic Polar Front (formerly known as the Antarctic Convergence) and 70% of the island is permanently covered in glaciers. This permanent ice cover has decreased from 79% in 1947, and is continuing.

The island has a relatively narrow coastal area, with ice-free headlands flanked by glaciers around the coastline. There are numerous rivers and streams on the island, fed by glacial melt and rainfall runoff. Four lagoons present around the coast were formed by the retreat of coastal glaciers and are believed to be more than 100 m deep. Other permanent and ephemeral lagoons of varying sizes (none large) are present. The geology of the islands is not well understood, given that most of Heard Island is permanently covered in ice. A number of different geological formations have been proposed. The active vulcanism on both Heard and McDonald Islands is rare in the sub-Antarctic.

The McDonald Islands lie approximately 40 nm to the west at 53°03′ S, 72°36′ E. Formerly three islands, volcanic activity since the 1990s has resulted in lava flows connecting Flat Island with McDonald Island, a significantly altered coastline to the joined islands, and an elevation increase to McDonald Island by as much as 100 m. The extent of McDonald Island has doubled to 2 km^2 because of this activity. The volcanic activity is believed to have destroyed all vegetation on the island, based on ship-based observations in 2002. There have been just two recorded landings on McDonald Island, the first in 1971 and the second in 1980. There were and are presently no bodies of water, permanent ice, or rivers on the McDonald Islands.

The climate for both islands is maritime, with high annual rainfall and strong winds (gusts over 65 km/hr^{-1} have been recorded with automatic weather stations on the mountain slopes). Mean annual rainfall at Atlas Cove, the station occupied for the 1947–1954 period, was 1380 mm, with some form of precipitation occurring on 75% of days. The mean air temperature at Atlas Cove for the period 1948–1954 was 1.2°C, but had increased to 2.1°C for the 1997–2000 period. Limited data prevent the determination of corresponding change in the sea-surface temperatures for the area.

The fauna and flora for the islands are generally less well developed than other sub-Antarctic islands due to the isolation, climate severity, and limited ice-free habitat. A total of twelve species of vascular plant have been recorded from the islands, and the plant community is expected to increase in extent and diversity as the glacier retreat continues and further ice-free areas are formed. The invertebrate fauna are relatively poorly known and the marine species surrounding the islands have been investigated. The seabird and seal community has received perhaps the greatest research effort during the human presence on the island. There is a rapidly increasing population of Antarctic fur seals *Arctocephalus gazella* present, and the population of southern elephant seals *Mirounga leonina* has decreased by more than half since 1947. The factor(s) behind these changes are presently unknown. The population of king penguins *Aptenodytes patagonicus* has increased since first recorded in 1947, as has the breeding population of black-browed albatross *Thalassarche melanophrys*. Few other long-term data are available.

Heard Island was discovered on 23 November 1853 by Capt John Heard on the barque *Oriental* en route between Boston and Melbourne, following the adoption of great-circle shipping routes to Australia. On 4 January 1854, Capt. William McDonald on the *Samarang* discovered the McDonald Islands. Sealing activities began on Heard Island in 1854/1855, with southern elephant seals killed for their blubber. More than 40 vessels, 62 from the US, brought oil on 79 voyages from Heard Island in the period 1854/1855–1880/1881, and almost 93,000 barrels of oil were shipped from the island.

A research station was established at Atlas Cove in the northwest of Heard Island in December 1947, and was occupied until 1955 when the station was abandoned in favour of the opening of Mawson station in the Antarctic. Sovereignty of the island was transferred from the United Kingdom to Australia coincident with the opening of the station; however, the US does not recognise this claim and there are no other claimants. The wintering parties of fourteen men undertook extensive biological, meteorological, glaciological, and atmospheric research. Several brief summer and private expeditions visited Heard Island until the mid-1980s, when research efforts on the island reemerged. Recent expeditions have examined the impact of climate change on the island's glaciers and biota, further investigated ecosystem dynamics as it relates to existing fisheries, and documented the sealers' relicts scattered around the island. Fare-paying tourists have visited the island on several occasions in the 1990s, but the unpredictable weather, relative isolation, and difficult conditions ashore have minimised the visitation to date.

The islands are listed on the Australian Federal Register of the National Estate (as of 1983) and were inscribed on the United Nations World Heritage Register in 1997. In October 2002, the islands and 65,000 km^2 of the surrounding marine area were declared a Commonwealth Reserve under Australian legislation; this is the second-largest marine reserve in the world. Consideration is presently being given to nominating the territory as a wetland of international importance under the Ramsar Convention.

HEATED GROUND

Areas of geothermal activity are unusual in the Antarctic. On the continent itself, they are limited to volcanoes in Victoria Land (Mounts Erebus, Melbourne, and Rittmann) and, possibly, unknown sites currently below ice sheets. Other sites of activity are associated with active tectonic plate boundaries in the seas of the maritime Antarctic, including the South Sandwich archipelago (all volcanic in origin, with up to ten of the major islands showing contemporary activity), Deception Island (South Shetland Islands), and Bouvetøya. Much more remote from the Antarctic continent, sub-Antarctic Marion and Heard Islands also display eruptive volcanic activity. Across these sites, a range of terrestrial and freshwater habitats are found, including areas of diffuse heated ground, fumaroles, heated pools, and geysers, which have been the focus of a very limited number of ecological studies. The existence of active submarine vents is also confirmed; although not studied, exceptional biological communities analogous to those of "black smokers" on midoceanic ridges elsewhere would be expected.

Sites of geothermal activity provide unique habitats in the Antarctic, the year-round heating and liquid water overcoming two of the major environmental constraints to life elsewhere in the region. Exceptional biological communities develop near to them. In maritime Antarctic localities these consist of lush growth of diverse mosses and liverworts, dominated by sub-Antarctic or Fuegian taxa such as *Campylopus* spp., *Ditrichum* spp., and *Cryptochila grandiflora,* otherwise unknown away from these habitats in the Antarctic. Species that are common on nonheated ground elsewhere in the Antarctic are also well represented, and basidiomycete fungi (toadstools) also show exceptional levels of abundance. Likewise, the terrestrial invertebrate fauna includes mites and springtails known elsewhere only from milder sub-Antarctic locations. The lack of higher plants (other than on Deception Island and Candlemas Island, South Sandwich Islands) distinguishes these communities from temperate, tropical, and Arctic analogues. Zonation in relation to temperature, indicative of different ecophysiological limitations across species, can be particularly well developed. Heated ground communities on the slopes of Victoria Land volcanoes are more limited, including algae and other microbial groups, and the earliest stages of development of mosses (again including *Campylopus* sp.).

Specific sites of activity, and their plant and animal communities, are transient on a timescale of years to decades. Even at active sites, the speed and magnitude of temporal variation in heating can be large, highlighting the need for physiological flexibility required of biota. Short- and long-range colonisation of new locations maintains species presence. As with newly emergent habitats elsewhere in the world (e.g., Surtsey, Krakatoa), initial colonisation is rapid. Habitats are also extremely limited in three dimensions, as temperature gradients with increasing depth are often spectacular and can reach 50°C–75°C at depths as little as 2.5 cm below the vegetation surface. Only the upper 1–2 cm of bryophytes growing in some locations will be alive, even though deeper accumulations representing growth over several years can be found. Hotter soils, approaching 100°C, and the vicinity of fumarole vents emitting superheated steam, are colonised by microbial communities.

It is clear that the presence of heat and water in these exceptional habitats allows the persistence of species that are unable to survive elsewhere in the Antarctic. While individual sites of activity and their communities are transient, areas such as the South Sandwich Islands, where island age ranges up to 3 million years, may have allowed the persistence of Antarctic species through periods of greater environmental extremes, such as those during recent Pleistocene glacial maxima. Over longer timescales, volcanism has been widespread throughout the Tertiary period in the South Shetland Islands and parts of the northern Antarctic Peninsula, giving further potential for long-term biological survival in the region.

HILLARY, EDMUND

The son of a journalist–beekeeper and a schoolteacher, Edmund Percival Hillary was born on July 20, 1919, in Auckland, New Zealand, and grew up in Tuakau, a small country town nearby. As a boy he was an avid reader of books about adventure, and his passion for climbing began at the age of sixteen, when he first saw snow, on a school trip to Mount Ruapehu (9174 feet; 2797 m). After 2 years at university he joined his father and brother Rex in the family beekeeping business, and during World War II he served in the Pacific as a navigator for the Royal New Zealand Air Force. During the 1940s he completed many successful climbs in New Zealand's Southern Alps and in 1951 travelled to the Himalayas with a New Zealand expedition. He then joined the British Everest Reconnaissance Expedition, which was led by legendary climber Eric Shipton, one of Hillary's childhood heroes. On 30 September 1951, Hillary and Shipton were the first to see a possible southern route to the summit of Mount Everest from the Khumbu Glacier.

In 1953 Edmund Hillary and fellow New Zealander George Lowe were invited to join the British Everest Expedition, led by Sir John Hunt. Eric Shipton had described Hillary as having "summit potential" and on May 29, 1953, Hillary and Tenzing Norgay reached the top of Mount Everest (29,028 feet; 8850 m). Hillary's photograph of Tenzing standing on the summit, flags fluttering from his ice-axe, became one of the defining images of the twentieth century.

The success of the climb changed Hillary's life forever—he became both an international celebrity and a local hero. He was knighted by Queen Elizabeth II, received awards and honours from many countries, and in September 1953 married Louise Rose, daughter of Jim Rose, the president of the New Zealand Alpine Club. It was to be a very happy marriage.

In May 1955 the government of New Zealand formed the Ross Sea Committee to manage New Zealand's involvement in Antarctica during the International Geophysical Year and to provide support for the Commonwealth Trans-Antarctic Expedition. Hillary was invited to lead the New Zealand part of the expedition. He met Dr. Vivian Fuchs in Britain and traveled to Antarctica with him on *Theron* in December 1955, when Shackleton Base was established.

The New Zealand party was to establish a base on the Ross Sea in Antarctica, and travel across the Ross Ice Shelf and up onto the Polar Plateau, establishing depots of fuel and food for the British crossing party. They would meet at Mount Markham, 250 miles south of Scott Base, in November 1957. Hillary viewed the depot-laying as a fairly modest requirement, and in July 1955 he wrote from London to the Ross Sea Committee: "although the journey objective of the New Zealand end must be the establishment of a dump at Mount Markham . . . the expedition should have sufficient supplies and equipment so that if organisation and time permits, or an emergency occurs, the Party could travel out as far as the South Pole" (Hillary 1999).

On New Zealand's Tasman Glacier, Hillary's team trained in skiing, dog-sledging, flying ski-planes, and working with Ferguson tractors. They arrived in Antarctica in January 1957 well-prepared and Scott Base was speedily established using prefabricated, insulated buildings. Over the winter, Hillary's engineers and mechanics adapted the five 28-horsepower Ferguson tractors for polar travel by adding full tracks, roofless canvas cabs, and tow bars. They also built a towable shelter that they called the "caboose."

The tractor party left Scott base on October 14, 1957, with three tractors and a Weasel, each towing almost eleven tons. They crossed the ice shelf and traveled up the 100-mile Skelton Glacier to arrive at their Plateau Depot on 31 October. On the Polar Plateau they established three more depots: Midway Depot, Depot 480, and Depot 700, the last of which was 500 miles from the South Pole. They had continual mechanical problems, were plagued by sastrugi and soft snow, and were regularly required to extricate tractors from crevasses. Hillary credited his engineers, Murray Ellis and Jim Bates, for keeping their small vehicles rolling in extremely difficult conditions.

Having completed the tasks required of him by 16 December, and with Fuchs' party still at South Ice, 500 miles on the other side of the South Pole, Hillary decided to press on south. At 12:30 PM on January 4, 1958, after 10 weeks of driving "like three tiny black ants across the snowfields of eternity," the New Zealand team of Hillary, Ellis, Bates, Peter Mulgrew, and Derek Wright rolled into the Pole Station. They were the first to reach the South Pole overland since Captain Robert Scott in 1912.

The British media criticized Hillary's drive to the Pole, which was construed as a race with Fuchs. But in 1961 the British *Alpine Journal* review of Hillary's book about the expedition, *No Latitude for Error,* concluded: "In this book we learn for the first time how the original concept was transcended, by Hillary's vision and thrustfulness, from a mere depot-laying chore into an ambitious and mettlesome exploit of which the New Zealanders can be justly proud" (Banks 1961). Hillary met Fuchs and the British team at the South Pole on January 20, 1958, and guided them back to Scott Base from Depot 700. Of the fifty drums of fuel the New Zealand party placed at the depots, only twenty were needed by the crossing party.

On a joint scientific and mountaineering expedition in 1961, Sir Edmund received a request from a Sherpa friend that he build a school for Sherpa children. It was the beginning of a new focus for his life. In the ensuing 40 years Hillary's Himalayan Trust has completed scores of aid projects with the Sherpa people. It has built schools, hospitals, clinics, bridges, and airstrips; repaired and rebuilt monasteries; recruited voluntary doctors; trained and equipped teachers and nurses; and provided tertiary scholarships for Sherpa youth. Louise Hillary was closely involved in all the Himalayan Trust projects and often visited Nepal, but in 1975 Louise and their daughter Belinda, then aged 16, were killed in an airplane crash at Kathmandu. Sir Edmund and his two surviving children, Sarah and Peter, took several years to recover from this personal disaster, and Hillary immersed himself in completing projects with the Sherpas who shared his loss and grief.

In 1985 Hillary was made New Zealand's High Commissioner to India, a post he held for 4 years. In 1989 he married June Mulgrew, widow of one of his Antarctic companions, Peter Mulgrew. Despite his focus on work in Nepal, Hillary has remained closely involved with Antarctica. His son Peter is a climber who has twice climbed Mount Everest and, like his father, has travelled overland to the South Pole. In 1967 Hillary led a New Zealand climbing team that made the first ascent of Mount Herschel (11,700 feet; 3566 m) in the Admiralty Range, and in November 2004 at the age of 84 he visited Antarctica to open the new Hillary Field Centre, commemorating his establishment of Scott Base in 1956.

HISTORY OF ANTARCTIC SCIENCE

Antarctic science draws on most branches of knowledge, but is also an entity in itself. This is mostly because scientists, both physical and biological, working in this remote part of the world, usually have to share common facilities. Social bonding is evident in the many Antarctic clubs, societies, and institutions, some of which have existed for many years, holding meetings and issuing publications that often cover many different topics all together.

However, a single starting point can be found in one person. In 1699 Edmund Halley, in his magnetic survey of the South Atlantic, sailed to within 200 miles of South Georgia. He saw icebergs and recorded meteorological, marine, and biological features, but did not make any great contribution to Antarctic science directly. It was his wide outlook and lasting influence that were important. His demonstration that voyages made purely for scientific purposes were well worth government support led to Captain James Cook's being sent by the British Admiralty in HMS *Endeavour* to observe from a favourable spot the transit of Venus that he, Halley, had predicted would occur in 1769. This did not add any knowledge about Antarctica, but the government's interest in obtaining information about the southern seas led to the *Endeavour* voyage's being followed up by a circumnavigation by Cook in the ships *Resolution* and

Adventure (1772–1775). This yielded precise charting of the regions up to the Antarctic ice-edge, together with observations on weather, currents, ice movements, islands and their plants, and animals. Halley's influence extended even further than this. He had made the whole world his observatory, and is justly regarded as the founder of geophysics, a science that has subsequently provided the major impetus for large-scale Antarctic investigations even up to the twenty-first century.

Following Cook there was Fabian von Bellingshausen, dispatched by Tsar Alexander I with the two ships *Vostok* and *Mirnyy* to circumnavigate the southern oceans. Bellingshausen achieved a voyage (1819–1821) that was, in H. R. Mill's words, "a masterly continuation of that of Cook, supplementing it in every particular, competing with it in none." However, his imperial master had given him little time for preparation but an enormous list of scientific tasks, and he had to sail short of naturalists. Nevertheless, Bellingshausen was first to record volcanic activity in the Antarctic, probably first to see the continental ice shelf, and an assiduous observer of meteorological and marine conditions, magnetic data, birds, seals, and whales.

Around this time many ships from the United States and Britain were searching the Peninsula region for seals, but tended to keep their movements secret and recorded little of scientific interest. James Weddell was an exception, with an enquiring and accurate mind. In 1823 he reached a latitude in what is now known as the Weddell Sea of 74°15′ S, which was to remain the farthest south in that area for nearly 90 years. He wrote a book, charting many coasts and recording magnetic data, ice situations, and distribution of fauna. The first overt American exploring expedition to the Antarctic was commanded by Benjamin Pendleton and Nathaniel Palmer and sailed in the sealing brigs *Seraph* and *Annawan* in 1829. It achieved little in its geographical objectives and only one of its "scientific corps," James Eights, made any worthwhile contribution. He collected rocks, lichens, and many marine animals and wrote five papers in professional scientific style. He discussed the transport of rocks and animals by drifting ice (anticipating Charles Darwin by 6 years), expressed clearly the modern view on the origin of ice shelves, described the geology of the South Shetlands, discovered the first Antarctic fossil, pioneered studies of Antarctic invertebrates, and provided the first scientific record of a flowering plant in Antarctica. It is extraordinary that his work was almost unknown for nearly 100 years.

Another voyage with a specific scientific object was that of HM *Chanticleer* under the command of Captain Henry Foster, FRS, to make geodetic measurements. The voyage in the South Atlantic included a stay of nearly 2 months on Deception Island in 1829. The surgeon, Dr. William Webster, was deputed to be naturalist. Besides pendulum data there were accounts of geology and geothermal events and observations on plants and animals. Around this time the British sealing firm of Enderby was sending out ships, beyond financial prudence but captained by men of education and naval experience. John Biscoe in the years 1830–1832 circumnavigated Antarctica, mostly south of Bellingshausen's track, confirming that large landmasses existed. Other Enderby men made considerable geographic discoveries but added little science, except that John Balleny's report provided Darwin with information on the transport of rock by an iceberg (1839).

In the mid-nineteenth century, science generally was developing apace and Antarctic science had a burst of activity for 6 years. Three nations were involved. In the United States, New England merchants were keen to find new sealing and whaling grounds and eventually persuaded Congress, with drawn-out argument, to support an expedition to the Pacific Ocean and the south seas. Lieutenant Charles Wilkes, with much disapproval since although he had a tendency to science he was a junior officer, was eventually put in command. His unsafe flotilla of ships was led by USS *Vincennes,* which spent a total of about 3 months in Antarctic waters during its cruise of 1838–1842.

In France the explorer and scientist Captain Dumont d'Urville was keen to go on another voyage to study Pacific ethnology and was taken aback when King Louis Phillippe readily agreed to give support, with the condition that there should first be an attempt to reach the South Pole, evidently for the glory of France. The expedition was launched in two corvettes, *Astrolabe* and *Zélée,* with dispatch and no argument (1837–1840).

After the Napoleonic wars, the Royal Navy had been left with a surplus of men and ships. Some of these had been deployed to explore the Arctic, mainly under the powerful influence of John Barrow, the Second Secretary of the Admiralty and an enthusiast for exploration, who was also able to promote an expedition south. Behind the political machinations that launched all three of these ventures were scientific plans. The power lay firstly in the Baron Alexander von Humboldt (1769–1859). He was widely travelled—he wanted to visit Antarctica himself but did not succeed—and has been described as the last complete scientist: an expert on geomagnetism, geology, and botany, a pioneer in climatology, oceanography, and biochemistry, and of techniques such as isothermal plotting, geological mapping, and numerical analysis of data. He was particularly enthusiastic about terrestrial magnetism and had himself observed the connection between auroral display and variation in horizontal magnetic intensity. He was in close contact with C. F. Gauss and W. Weber at Göttingen, the leading organizers in the field. Such was his influence that his proposal for a chain of geomagnetic observatories stretching across Russia was taken up by the authorities in St. Petersburg. The United States and Europe from Ireland to Germany already had networks of similar stations, and Humbolt realized that to complete the encircling of the Earth he had to persuade the British government to establish stations in its overseas territories. He had no difficulty with this. The Royal Society and the British Association for the Advancement of Science gave support to "the Magnetic Crusade," and the government, under Barrow's influence, was willing to equip an expedition under James Clark Ross, who had recently located the North Magnetic Pole, to make observations in the Antarctic, setting up stations in British Territories on the way (1839–1843). The two ships, HMS *Erebus* and *Terror,* were fitted to penetrate the ice and were well equipped.

The Americans and French also had magnetic observations as major objectives; both countries had contacts with Humboldt, but did not have the British Fox dip circle, which could measure declination, dip, and intensity with acceptable accuracy on a vessel at sea. The US ships provided evidence of land of continental extent within the Antarctic Circle. Their contributions to Antarctic geology and biology were slight—Wilkes left his biologists behind when he went south, deeming that there would not be much for them to do. The expedition's greatest scientist, James Dwight Dana, made observations in the Pacific that later were to contribute to the theory of plate tectonics, and it was he who described the type specimen of *Euphausia superba,* now familiar as the Antarctic krill. The French made valuable observations on meteorology and ice formations, and their reports on zoology and biology were beautifully illustrated, with crabeater seals *(Lobodon carcinophagus)* being a notable discovery.

The provision of definitive charts of magnetic determinations was a major achievement of Ross's expedition on *Erebus* and *Terror*—measurements were checked daily between the two ships. Their work enabled the Gaussian theory of the Earth's magnetic field to be revised to fit the Southern Hemisphere. Before the ships had sailed, the Royal Society had set up committees for physics, meteorology, geology and mineralogy, botany and vegetable physiology, and zoology and animal biology. Their recommendations were incorporated into an eighty-five-page booklet with some sections so useful as to be reissued for general use. Humboldt had written to the Admiralty giving many valuable suggestions, especially regarding the critical facts that seawater does not have the same point of maximum density as freshwater and that pressure on thermometers at depth distorts the readings. Unfortunately, his letter arrived after the expedition had sailed. There were no professional scientists aboard ship, it being assumed that officers would take care of the physical side and the surgeons the geology and biology. Ross himself was an expert in magnetism and had a bent towards natural history. Among the natural historians was Joseph Hooker, twenty-two when he sailed, an ardent botanist who had taken a year's course in medicine simply to enable him to voyage in foreign parts. He collected plants whenever possible, and back in England he quickly produced *Flora Antarctica* (1847)—still referred to today—but at sea he collected marine life and made drawings for Ross. He drew attention to the fact that diatoms are plants, not animals as was supposed, and that they are the primary producers of the oceans. To the present biological oceanographer, this is the greatest discovery of the nineteenth century. Information, useful when corrected as suggested by Humboldt, on physical oceanography was obtained by the officers. The discovery of the Ross Ice Shelf (or Great Ice Barrier as it was originally known), which is floating at its seaward edge, was momentous. Rocks were collected assiduously, many from crops of penguins. A book on the larger animals was published, but the material collected for Ross, planktonic and benthic, was, sadly, lost.

The scientific achievements of these three expeditions were considerable. Magnetic studies were carried out to similar programmes, and there was some exchange of information, although patriotic rivalry ran high. None undertook any land exploration.

Following this, there was an "age of averted interest" for almost 50 years. No real prospects of colonisation or commercial promise attracted any nation farther south, and scientists themselves seemed to have no wish to probe any further. After their return, both Ross and Hooker made it evident that they found no problems calling for further attention, and, rather surprisingly, said that they did not expect anyone to visit again the regions that they had penetrated. It was certainly not that science was becoming quiescent. Humboldt's efforts to advance physical geography had, however, become unfashionable, and interest in terrestrial magnetism had dwindled. A lone voice raised on behalf of the Antarctic was that of the American maritime meteorologist Matthew Maury (1869). He realised that the high southern latitudes provided the key to the weather of the Southern Hemisphere, but nothing came immediately of his efforts to organise research.

The incursion of the *Challenger* Expedition (1874) into the Antarctic yielded much from its dredging of bottom deposits about the geology of the continent and the nature of the Southern Ocean. Interest began to strengthen late in the nineteenth century. Karl Weyprecht, coleader of the Austro-Hungarian Exploring Expedition (1872–1874), gave deep thought to the general problems of polar research while beset off Franz Josef Land, concluding that detailed topography was of secondary importance, that the geographic pole did not have greater value for science than any other point at high latitude, and that decisive scientific results could only be obtained by a series of synchronous expeditions distributed all over the polar regions. He put this view before various academies without effect until it was taken up at an International Meteorological Congress in 1879, leading eventually, after he died in 1881, to the first International Polar Year (1882). Included in this was a German expedition to South Georgia for a full year. This did excellent work on meteorology, magnetics, glaciology, marine and terrestrial flora, and ornithology. Dr. Georg von Neumayer, Director of the Deutsche Seewarte at Hamburg and an enthusiastic campaigner, had given support to this, and at the Sixth International Geographical Congress, held in London in 1895, spoke at length on Antarctic science, expressing the hope for international collaboration in organising expeditions. In a later lecture to the Royal Society, he made a remarkably foresighted comment that studies of geomagnetism and atmospheric electricity would be particularly important in the Antarctic. British scientists, including Sir John Murray (of *Challenger*) and Sir Clements Markham (President of the Royal Geographical Society) strongly supported Neumayer's suggestions. Things then began to happen. Whalers made exploratory cruises south from 1892 onwards, but their attitude to science was sometimes unhelpful. The voyages of *Belgica* (1897–1899), *Valdivia* (1898–1899), and *Southern Cross* (1898–1900) all contributed useful science, but the continent itself was only marginally touched.

The Heroic Age followed. The major scientific expeditions were the German Antarctic Expedition (*Gauss,* under Erich von Drygalski, 1901–1903), the Swedish South Polar Expedition (*Antarctic,* under Otto Nordenskjöld, 1901–1904), the British National Antarctic Expedition (*Discovery,* under Robert Falcon Scott, 1901–1904), the Scottish National Antarctic Expedition (*Scotia,* under William Speirs Bruce, 1902–1904), the French Antarctic expedition (*Française,* under Jean-Baptiste Charcot, 1903–1905), the British Antarctic Expedition (*Nimrod,* under Ernest Shackleton, 1907–1909), the second French Antarctic expedition (*Pourquoi-Pas?,* under Charcot, 1908–1910), the British Antarctic expedition (*Terra Nova,* under Scott, 1910–1913), the second German South Polar Expedition (*Deutschland,* under Wilhelm Filchner, 1911–1912), the Australasian Antarctic Expedition (*Aurora,* under Douglas Mawson, 1911–1914), and the Imperial Trans-Antarctic Expedition (*Endurance,* under Shackleton, 1914–1916). All had undertaken scientific work to attract support, and most produced substantial reports, some running to ten or more weighty volumes. Even the unfortunate *Endurance* managed several worthwhile papers, although Roald Amundsen's brilliant attainment of the South Pole in 1911 produced no science of significance.

Although there had been some preliminary consultation between nations, the only major overlap of individuals on these expeditions was between Scott and Shackleton, and Shackleton and Mawson, but in the event these were of no importance scientifically. Four of the expeditions did not have established land bases for research, and only five had "well-found" laboratories ashore. Several concentrated on oceanography. In general, however, there was good spread among the sciences, from physics and chemistry to geology and biology. Comparison of the quality of the science is rather pointless; the expedition on *Scotia,* led by a scientist, produced the largest number of high-quality publications, but the bulk was specialised zoological work, whereas that on *Discovery,* although it also did much zoological work, produced beyond this reports covering a wide range, establishing basic knowledge of the continent itself. There had been questions as to whether a scientist or naval officer should be in charge of such expeditions. The bitter quarrel between Markham and the Royal Society on the subject is not a strictly scientific topic, but it is a reasonable surmise that a good naval captain, Scott, with no scientific training but an innate feeling for science was better than an eminent geologist who might have put his own subject first. At least Scott did his best to ensure on his fateful return from the Pole that the fossils collected by Edward Wilson, eventually found to include *Glossopteris*—evidence of continental drift—should reach the British Museum.

Following the Heroic Age, there was an effective step toward the organisation of polar science in the foundation of the Scott Polar Research Institute in Cambridge in 1920. Two of Scott's men, Raymond Priestley and Frank Debenham, together with Shackleton's geologist, James Wordie, set up a centre for collecting polar information. Now, in the twenty-first century, it does research on its own account and has the best polar library in the world. Heroic Age tradition still lingered on in two modest expeditions. T. W. Bagshaw and M. C. Lester wintered (1920–1922) on the Antarctic Peninsula in a hut knocked together from an old boat and some packing cases, and yet collected a prodigious amount of useful data. The British Graham Land Expedition (1934–1937) carried out some excellent science, although the biologists had to make do with a balance made from a wooden beam poised on a pebble ground to a knife edge.

There were two major advances in the period between the two World Wars. At the beginning of the century, Scandinavians had pioneered oceanography in the Arctic seas, and the expeditions just mentioned had followed this with much data about the Southern Ocean. W. Meinardus, using more than half a million measurements obtained by *Gauss,* identified the Meinardus Line, later called the Antarctic Convergence. The *Discovery* Investigations extended Antarctic oceanography, both on the physical and biological sides, working intensively in the 15 years after 1926. It came into being because whaling was developing rapidly on the South Atlantic, and the British government realised that management was necessary if the industry was not to collapse as it had done in the north. For once the civil service understood the needs of science and proposed far-reaching research with ample financial support. The results were excellent: among the outstanding scientists were George Deacon, who worked out the pattern of circulation in the Southern Ocean, and Alister Hardy, who invented the plankton recorder that was used to effect in the south and is now employed over most of the world's oceans. The other major advance was American, on three expeditions in 1928–1930, 1933–1935, and 1939–1941, led by Richard E. Byrd and financed on a substantial scale. They were not the first to use radio, mechanised surface transport, and aircraft in the Antarctic, but they were first in using these effectively and extensively. Work was carried out over wide fields, beginning a more efficient era in Antarctic science. Contributions in geology, meteorology, ionospherics, and microbiology were particularly outstanding.

The urgent demands of the Second World War produced more equipment and techniques adaptable to polar conditions. After the war, these were used on massive scale by the US, involving icebreakers, advances in meteorology, and flying techniques extending to helicopters and aerial photography. However, at this time the US interest was, frankly, military. *Operation Highjump* (1946–1947) used 4700 men, 13 ships, and 9 aircraft in the Antarctic, but produced just three scientific papers. Science began again with the Norwegian–British–Swedish Expedition of 1949–1952, a private venture that was the beginning of good international cooperation, putting well-planned science before geographical exploration. It was the first to obtain reliable systematic seismic sounding of ice thickness in Antarctica. Apart from that, some national stations were being established. The British Operation Tabarin, set up by Winston Churchill to keep an eye on the Antarctic Peninsula and surroundings, had been changed into the Falkland Islands Dependencies Survey and began scientific work. Later it was renamed, for political correctness, the British Antarctic Survey, and has become one of the outstanding organisations for Antarctic research.

The mid-twentieth century saw a momentous development, with the International Geophysical Year (IGY) set up to study ionospherics and geomagnetism with special attention to the Antarctic. Governments gave support, and there were brought together in July 1957 scientists of 64 nationalities, involving 4000 stations, 55 of these, from 12 countries, being in Antarctica. Vast amounts of data were accumulated and in the course of time led to spectacular advances in geophysics. Other important results were that it helped lead to the Antarctic Treaty, which effectively neutralised quarrels over terrestrial claims and established a continent reserved for science.

Nations were anxious to keep foot in Antarctica and carried on research there after the cessation of the IGY. The Scientific Committee on Antarctic Research was set up to advise the treaty organisation. Other subjects were quickly added to ionospherics and geomagnetism, geology being foremost but oceanography, terrestrial, and atmospheric physics and chemistry, glaciology, meteorology, biology, and medical studies being included. Subjects were, of course, brought up to date, and some led the field. An example might be ornithology. Hitherto this had been mainly for naturalists, but Antarctic birds are particularly amenable to study, being large, unafraid of man, tolerant of handling, and breeding in large numbers in accessible colonies. Sophisticated physiological and ecological techniques, such as attachment of instrument packages and satellite telemetry, enable populations and behaviour to be quantified. This work has been of worldwide value in establishing the role of seabirds in the marine ecosystem. Marine biology is, in fact, an Antarctic science with a commercial impact. Overfishing in southern waters calls for conservation. The Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR), based on sound ecology and set up by the treaty, includes stringent control measures that came into operation in 1980. Another example, largely an international operation, is ice drilling, yielding cores down to more than 3000 m. Ice samples contain air, dust, and other materials from which chemical analyses give measurements of climate at precisely determined dates extending more than 740,000 years. The cyclic processes revealed are of great value in indicating what future climatic changes may be.

A feature of Antarctic research during the last 30 years is that, as elsewhere in the modern world, it is mainly done by teams carrying out carefully planned programmes with elaborate equipment and steered by a committee via radio and satellite. Nevertheless, some of the most exciting discoveries in the last half-century have been made by chance or individuals. After 50 years of indifference since Scott found them, the Dry Valleys were opened up first to geology and then to limnology, microbiology, and exobiology by two obstinate young New Zealanders, B. C. McKelvey and P. N. Webb (1957). It cost a geologist who had not been south difficulty in persuading the US National Science Foundation that the extraordinary collection of meteorites on Antarctic ice was possibly of interest. The "ozone hole" over Antarctica in the austral spring was discovered by British Antarctic Survey atmospheric chemists persisting with a rather dated technique when satellite monitoring produced so much data that the events recorded over the Antarctic escaped notice. Such items of history are worth bearing in mind by scientists.

HOOKER, JOSEPH DALTON

Joseph Dalton Hooker was born at Halesworth, Suffolk, on June 30, 1817, the second son of William Jackson Hooker and his wife Maria Sarah. Educated at Glasgow High School and then Glasgow University, where his father was professor of botany, Hooker graduated with an MD in 1839 and managed to combine his enthusiasm for botany with travel by joining James Clark Ross's expedition to Antarctica as the botanist and assistant surgeon. During 4 years exploring the Southern Ocean, Hooker made crucial plant collections from many remote places. When *Erebus* returned in 1843, he began work on the *Botany of the Antarctic Voyage,* which eventually comprised six volumes, two each for the sub-Antarctic islands, New Zealand, and Tasmania. His father, by then director of the Royal Botanic Gardens at Kew, was unable to support him and the production of these key volumes was achieved on his pay as an assistant surgeon. He worked for 2 years for the Geological Survey, but then gained a government grant to collect plants in the Himalayas (1847–1849).

In 1851, Hooker married Frances Harriet Henslow, daughter of the professor of botany at Cambridge. They had six children, but Frances died in 1874, and 2 years later Hooker remarried to Hyacinth Symonds, with whom he had two further sons.

In 1855, Hooker was appointed assistant to his father at Kew, taking over from him as director after his father's death in 1865. He remained director until 1885. He continued to work after retirement, producing *Flora of British India* and *Handbook of the Flora of Ceylon,* as well as a book on his father and numerous scientific papers. Even his friends described Hooker as high strung and irritable, yet his capacity for hard work was well known. During his directorship, Kew consolidated its reputation as a key source for the natural materials and resources, of which perhaps the most famous was the transfer of rubber trees from Brazil to parts of the British Empire.

A very close friend of Charles Darwin, Hooker was a firm believer in evolution and pioneered phytogeography, the study of the distribution of plants. Hooker was highly regarded both by his peers and by politicians, receiving numerous honorary degrees and public honours, such as the CB in 1869, KCSI in 1877, GCSI in 1897, and the Order of Merit in 1907. The Royal Society gave him first the Royal Medal in 1854, then the Copley Medal in 1887, and finally the Darwin Medal in 1892. He received numerous prizes and awards from both British and foreign scientific societies. He died in his sleep on December 10, 1911, and was buried alongside his father at Kew Green.

HUMPBACK WHALE

Because they are active at the surface, easy to identity, and often found close to shore, humpback whales *(Megaptera novaeangliae)* are among the best known of the great whales. Surface activity is characteristic of humpback whales; they are commonly observed leaping from the water (breaching), slapping the surface with the flippers (flippering) or tail flukes (lobtailing), and lifting the head from the water (spyhopping). They are the most distinctive of the baleen whales, with flippers that extend to about a third of the body length, rounded knobs on the upper and lower jaws, and an irregular, prominently serrated trailing edge on the tail flukes. The dorsal fin is variable in shape, from tall and strongly hooked to a low, rounded lump. The dorsal surface is black, with varying degrees of white on the ventral side of the body and flukes. In some Southern Hemisphere humpbacks this white coloration extends up the flanks nearly to the dorsal fin. On diving, they regularly raise the flukes into the air. The undersides of the flukes are distinctively marked and individuals can be recognized from these natural "tags."

Humpback whales are mysticetes or baleen whales. They have no teeth, but rather use a series of horny plates called baleen, which grow from the upper gums to filter prey from the water column. Up to 400 fairly short (<1 m), dark-coloured baleen plates occur on each side of the jaw. The fringes on the inside of these plates form a thick mat for straining prey from the water. The relatively coarse fringe on humpback baleen is better suited to the capture of krill and small schooling fish than smaller zooplankton. Krill (principally *Euphausia superba*) is their preferred food in Antarctic waters; they are occasionally reported to take other invertebrates and fish, though some of this other food may be caught incidentally.

Krill form dense swarms that humpbacks take into the mouth by expanding the throat cavity. They have fourteen to twenty-two large pleats referred to as rorqual grooves that extend from the lower jaw to the navel. These allow the throat area to expand massively, engulfing krill-laden water for subsequent filtering. A wide and diverse variety of acrobatic behaviours including lunging, breaching, or lobtailing and the underwater release of bubbles are common among humpbacks during feeding and rarely observed among other baleen whales. These activities presumably concentrate prey or prevent diffusion of prey swarms. On the feeding grounds humpbacks are most often seen in clusters consisting of several small groups of one to four whales. Larger groupings are sometimes seen, particularly where food is abundant. While these whales may travel or feed together in a coordinated manner, these associations do not appear to represent social groupings and little if any group stability or coherence is observed over time.

Cosmopolitan in distribution, humpback whales are found in every major ocean basin ranging from the equator to polar waters. They occur in two distinct seasonal habitats. During the summer they are principally found in productive temperate, polar, and subpolar waters where they feed. In winter they migrate to tropical and subtropical breeding grounds for calving and mating. Thus few humpback whales occur in Antarctic waters during the winter months (May through September). However, humpbacks may well be present during every month of the year as some, particularly nonbreeders, may occasionally overwinter in the feeding grounds while others may not undertake a complete migration during some years.

Humpback whales are widespread in the productive waters from the Antarctic convergence to the ice edge. A small feeding group has also been identified along the coast of Chile, but the vast majority of Southern Hemisphere humpback whales feed in the Southern Ocean. They are found most commonly in areas where oceanographic conditions lead to exceptionally large, dense swarms of the krill on which they feed. Because the oceanographic conditions that lead to these swarms are reasonably predictable annual occurrences, humpback whales are likely to return to the same region each year. Such regular return to specific feeding areas has been documented in the Northern Hemisphere, and is thought to be widespread in humpback whales. Seven feeding areas have been proposed for the Southern Ocean. However, the boundaries between these are often obscure, with no clear gaps in whale distribution between them. Lacking detailed information on individual movements, therefore, the extent and scale of feeding-area fidelity in the Southern Ocean is not well known, and it is possible that individual humpback whales may forage over large regions of the Southern Ocean.

During the austral winter months, humpback whales leave the Antarctic and are found in one of seven low-latitude breeding grounds. It is in this region that calves are born and that mating is presumed to take place, though it has never been observed. The largest numbers of animals are found in shallow water sites near continental margins, reefs, banks, or islands. Most occur at about 20° S latitude, though along the west coast of Africa whales occur north of the equator, while the breeding area off Costa Rica, where geographical, though not seasonal, overlap with animals from the Northern Hemisphere has been shown, extends to nearly 10° N.

Because these seasonal habitats are separated by several thousand kilometres, migration is a prominent feature of humpback whale ecology. Movements of more than 8000 km by individual humpback whales from the Antarctic Peninsula to breeding areas off Central and South America are the longest documented for any mammal. Migrations have traditionally been thought to consist principally of north–south travel between feeding and breeding areas at similar longitudes, and each of the seven breeding areas has been linked with a feeding area to the south. A small number of tag returns between feeding and breeding grounds have shown substantial east–west movement, however, suggesting that animals from different breeding areas may mix on the feeding grounds. Thus, in the absence of additional data on individual movements and population genetics, the specific movement patterns and population structuring of humpback whales in the Southern Hemisphere remain speculative.

The mating system has been likened to a lek, with numerous males and females congregating in a common area and males attracting females through physical or vocal display rather than by controlling a territory. Physical display may include aggressive competition between males, while the long, complex, and highly structured song of humpback whales is produced only by males and is likely to be used as a vocal display. Social bonds do not appear to play an important role in the mating system, as neither kinship nor feeding ground affiliation has been found to influence associations on the breeding grounds. Mating is thought to be brief and no long-term bond is established between the pair. Males have no role in tending calves, and genetic tests have shown multiple calves born to the same mother to have different fathers.

Females give birth to a single calf every 2–4 years following a pregnancy lasting 11–12 months. Calves remain with the mother for about a year; the two stay in close proximity during the first summer in Antarctic waters. Calves are approximately 4–4.5 m at birth, weighing 2 tonnes. The young grow at about a half-meter each month on rich milk that contains about 45% fat. By weaning they average about 9 m. Adult humpback whales average 13–14 m in length and weigh upwards of 25 tonnes. Weight and blubber thickness vary seasonally and with reproductive condition. Humpbacks normally do not eat during migration or while on the breeding range and so must store enough blubber during the feeding season to maintain them during winter. Both males and females mature sexually at 5 years of age, continuing to grow for another 10 years or so. As in all baleen whales, females are somewhat larger than males. There are few data on life expectancy, but adult survival rates are high (0.96), and the oldest animal reported from whaling operations was 48 years of age.

Given their large size, adult humpback whales have little to fear from most predators, though calves are vulnerable to killer whales and possibly to larger sharks. A number of attacks on humpback whales by killer whales have been witnessed and visible scars from orca teeth on the flukes of many whales bear witness to further unseen attacks. These same scars, however, show that many humpbacks survive encounters with killer whales, leaving unresolved the extent and importance of predation in humpback whale ecology.

Thousands of Southern Hemisphere humpback whales were killed on the breeding range by the nineteenth-century nonmechanized whale fishery. It was not until early in the twentieth century, however, that the introduction of fast, mechanized catcher boats and deck-mounted harpoon guns opened the Southern Ocean to whaling on a scale not previously imaginable. Initially, whaling operations required a land base, and South Georgia, with secure harbours near a seemingly boundless number of whales, dominated the global industry. These technological advances also made humpback whales a primary target of the whalers, as these whales were relatively slow swimming, were often distributed near to shore, were easy to process, and yielded a large quantity of oil. During the first season of whaling at the Grytviken whaling station on South Georgia, 81% of the whales landed were humpbacks, while humpbacks accounted for 69% of total catches during the first 10 years at South Georgia. As whaling spread to other islands and the development of viable floating factories opened more remote regions to hunting, humpbacks continued to account for a disproportionate share of early catches. Whalers shifted to other species only as the more valuable humpback and blue whales declined.

The best estimates currently available suggest that in all about 200,000 humpbacks were killed in the Southern Hemisphere during the twentieth century. Catches of humpback whales peaked almost immediately after modern whaling commenced, with over 50,000 animals reported taken between 1909 and 1915. These officially reported catches may underestimate the actual number killed; as late as the 1950s, 20%–50% of the whales harpooned were not landed. Another major peak in catches occurred during the 1950s and 1960s. The extent of these takes was largely unknown at the time, as most were unreported catches made during widespread, indiscriminate whaling operations conducted by the Soviet Union. The actual catch records have only recently been made public. Between 1947 and 1972, the Soviet fleet landed well over 48,000 humpback whales in the Southern Hemisphere while reporting only 2820. About 13,000 were taken during a single season in 1959–1960.

Concerns over rapidly declining catches resulted in an end to commercial hunting of humpback whales in the Southern Hemisphere in 1963–1964, though the illegal catches continued for another decade. Because of the extent of global depletion and the uncertain extent of recovery, humpback whales are listed as vulnerable by the IUCN and trade is restricted under Appendix I of the Convention on International Trade in Endangered Species. The number of humpback whales living in Antarctic waters today is not known. The Scientific Committee of the International Whaling Commission recently presented an abundance estimate of 10,000 humpback whales south of 60° S. This is almost certainly a low estimate given the large number of whales that have been individually identified in the Southern Hemisphere. However, no better estimate is currently available.

In some areas of the Southern Hemisphere there is considerable evidence for population recovery following protection. Notably, surveys off Australia indicate dramatic increases in the number of whales migrating off both the west and east coasts. In other regions where humpback whales were formerly abundant, there is little or no evidence of recovery. Near South Georgia, for example, evidence indicates that humpbacks remain uncommon today. Because of limited shipping and fishing in the Southern Ocean, the major current causes of human-induced mortality, ship strikes and entanglement in fishing gear, are likely to be of minimal concern in Antarctic waters.

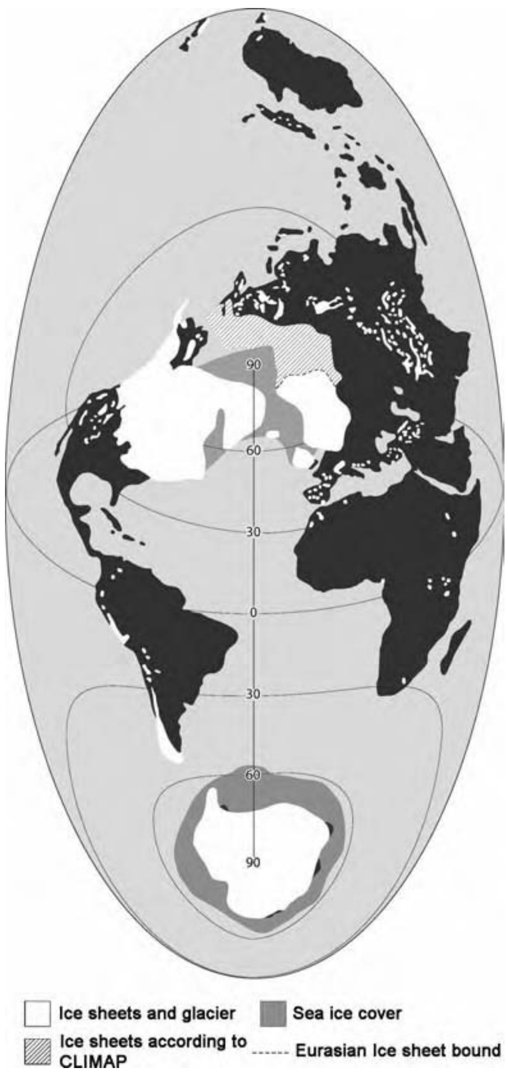
ICE AGES

The theory of ice ages, or "glacial theory," was developed in the mid-1800s by Louis Agassiz, who argued that the surface morphology of much of northern Europe and North America could be explained by processes active within glaciated environments. While his theory involved an inaccurate reconstruction of a huge single ice sheet flowing from the pole and covering much of the Northern Hemisphere, the basic principle of the theory was visionary. It was also hugely controversial. Glacial theory challenged the widely held belief that the landscape had been both created and modified by God (a theory known as diluvialism). Through scientific reasoning, however, Agassiz convinced many of the leading geologists of the time, including the Reverend Dr. William Buckland, of past glaciation. Once glacial theory had been largely accepted as a natural phenomenon, geologists began to identify the causes of ice ages.

It was twice hypothesized (by Scottish cleric James Croll in the late nineteenth century and Serbian mathematician Milutin Milankovitch in the mid-twentieth century) that changes in the Earth's orbit around the Sun would lead to reductions in the level of solar heat that, in turn, would cool the planet and result in the growth of glaciers.

While Croll was the first to propose a connection between solar inputs to the Earth and climate change, his calculations were wrong (he advocated that the last ice age occurred some 60,000 years before it actually did). His analysis was refined, however, by Milankovitch, who proposed that ice ages were forced by variation in Earth's orbit, causing changes to the amount of solar radiation received at the Earth's surface, in three ways. The first orbital variation is known as the eccentricity, or the change from an elliptical to circular orbit over a period of ~100,000 years. The second is the obliquity of the spin axis, which varies between 21.39° and 24.36° over a cycle of ~41,000 years. The third orbital change is due to the precession of the equinoxes, which affects the timing of perihelion and aphelion (the position where the Earth is closest and furthest from the Sun) with a periodicity of ~21,000 years.

On both occasions when orbital variations were proposed as the cause of ice ages, after initial recognition the idea lost favour in the scientific community. The problem is that the changes in solar input to the Earth caused by its orbital variation are so low that many found it difficult to reconcile the process with the growth and decay of huge ice sheets and the many associated changes to the physical and biological environments. Not until the 1970s was the hypothesis proven, by climate researchers looking at ocean sediments for evidence of past climate shifts. Hays, Shackleton, and Imbrie identified that shifts in the ratios of isotopes of oxygen recorded in sea-floor sediments corresponded well with the periodicities involved in Milankovitch's calculations. Although this work established the root cause of ice ages, the problem of how small changes in solar inputs lead to large changes in ice sheets and climate remained. It is thought today that solar input variations are merely a trigger for other processes acting on or near the



Ice sheets of the last glacial maximum. Note that the size of the Eurasian Ice Sheet across northern Europe and Arctic Russia is shown in both maximum (after the CLIMAP project of the 1970s) and minimum (after the QUEEN project of the 1990s) configurations. (Adapted from Broecker and Denton 1990.)

Earth's surface, which lead to positive "feedback" in the climate system. For example, small reductions in air temperature caused by solar variations lead to an increase in the snow field extent, which reduces the amount of solar energy absorbed by the Earth (as snow is quite reflective), thus further reducing air temperature. Several feedback processes have been identified, and many of them are complex and interactive. They combine to both magnify and modify the effect of Earth's orbital variations around the Sun to force huge environmental changes.

The most detailed information concerning the timing and magnitude of past ice ages comes from the deep ice cores of Greenland (for the past ice age) and Antarctica (for the past four or so ice ages). As the ratio of oxygen isotopes varies with global ice volume, by measuring this ratio in ancient ice, records of an ice age can be evaluated. Furthermore, the gas held within the former snowpack, which later densifies into ice, contains a record of atmospheric greenhouse gases, which are related to global air temperatures. Analysis of ice-core results, and their sea-floor sediment counterparts (exchange ancient calcarious organisms for ancient ice to reveal oxygen isotope ratios), has resulted in a detailed understanding of the natural climate cycles that characterise ice ages.

While ice cores have revealed how orbital variations dictate the pacing of ice ages, they have also shown that short-term climate oscillations operate around the long-term signal. For example, Greenland ice cores show temperature variations of several degrees centigrade over periods as short as a few decades. Such climate change cannot be explained by orbital forcing. Instead, the climate feedback processes that cause magnification of the orbital influence on air temperature are probably responsible. For example, as the Earth warmed during the onset of deglaciation, ice sheet decay led to enhanced fluxes of meltwater being issued to the ocean. Such was the influence of this process on the salinity of the North Atlantic that the thermohaline ocean circulation system was affected, so reducing the flow of warm water northwards and thus reversing climate warming in this region. The traditional view of climate change over a glacial cycle, involving a lengthy ($\sim$90 ka) period of cooling followed by a rapid ($\sim$10 ka) period of warming has been revised in recent years with short-term oscillations punctuating this long-term envelope.

The ultra-low rates of snow accumulation in Antarctica (being a polar desert) mean that Antarctica's subsurface ice is much older than Greenland's. Antarctic ice cores therefore provide important information about climate change extending back through several glacial cycles. The ice core at the Russian base Vostok Station goes back as far as 420,000 years (Petit et al. 1999), covering four glacial cycles, whereas a recent ice core from Dome C, drilled by the European Project for Ice Coring in Antarctica (EPICA 2004) extends this record through a further four cycles.

The time of maximum extent of the last ice sheets is known as the last glacial maximum (LGM). So much water had been taken from the ocean to form these ice masses that global sea-level was around 120 m lower than today. Clearly the cryosphere looked very different at the LGM than it does now. The greatest change was in the Northern Hemisphere, with the development of huge ice sheets over the bulk of Canada and much of the northern United States (the Laurentide ice sheet, which contributed to over 60 m in sea-level fall) and in northern Europe (the Eurasian ice sheet, which held as ice over 15 m worth of sea level). Other places also witnessed great increases in the size of ice sheets, notably in Greenland and Antarctica and across Patagonia. In Antarctica, the greatest change in the form of the current ice sheet was across West Antarctica, where both the Ross and Filchner-Ronne ice shelves became part of the grounded ice sheet that flowed in some places out to the continental margin. Numerical modelling predicts that this expansion caused sea-level reduction of 16–30 m. The bulk of this expansion occurred in West Antarctica. In East Antarctica ice growth was curtailed by the drier conditions of the last glacial cycle, which led to slight thinning in the ice sheet interior. This surface lowering was countered somewhat by growth at the ice sheet margin. The net effect of these processes was only modest enlargement of the East Antarctic Ice Sheet. Today, the processes may be reversing, as ice sheet margin retreat is more than balanced in East Antarctica by snow-driven ice-thickness increases (Davis et al. 2005).

In addition to ice sheet growth and expansion, other components of the cryosphere (sea ice and permafrost) also experienced a prolonged period of growth prior to the LGM.

Cryospheric change of this kind had a huge impact on the planet's environment. The hypsometry of several continents were changed so greatly that atmospheric airflow was affected. The ocean state was modified by both air-temperature cooling and the growth of sea-ice fields, both affecting oceanic flow. Air temperatures were, on average, around 8°C–10°C cooler. Precipitation values fell in association with this cooling. Because quite warm conditions prevailed at the equator, enhanced meridional air-temperature and atmospheric pressure gradients were set up. LGM Earth was therefore far cooler, drier, and windier than today.

Such was the level of dryness and windiness that huge levels of dust were taken up within the atmosphere and transported across much of the globe. Considerable deposits of this material, known as loess (in excess of tens of metres thick), were laid over large regions of continental interiors. The material was also deposited on the ocean. Some scientists argue that the production of plankton in the oceans was enhanced during the ice age by "iron fertilization" caused by dust deposition in the ocean. If this was the case, it may provide one of the processes by which atmospheric CO_2 is down-drawn during ice ages (although a relationship between CO_2 and air temperature has been established, the mechanisms by which CO_2 is taken or supplied to the atmosphere remain to be identified fully over glacial cycles).

The physical environment of LGM Earth had huge consequences for the distribution of plants and animals. In fact the study of plant material (such as pollen) and animal remains (such as whalebones) are critical to our understanding of ice age conditions. At the edges of formerly glaciated environments, such as the United Kingdom, ancient polar fauna and flora have subsequently been replaced by a deciduous biome. A similar story can be told for the oceans; where once cold-water plants and animals were abundant, now warmer-water varieties thrive.

The ice age also witnessed the rise to dominance of *Homo sapiens*. The oldest fossilised evidence for *Homo sapiens* is from about 130,000 years ago. Consequently the development of their population, as well as the decline of *Homo neanderthalensis,* took place during the last ice age. It is interesting to note that modern human development was able to survive and indeed thrive over a considerable period of environmental change. It is also important to acknowledge that the establishment of modern civilisation has taken place over just the last 10,000 years, during which time Earth's climate has been atypically stable.

An interesting feature of ice age Earth is that, as sea level was much lower, land bridges occurred between regions now separated by shallow sea. Importantly, such a connection was made across the Bering Strait, which, during deglaciation as the Laurentide and Cordillern ice sheets began to melt, may have encouraged humans to cross from Asia and populate the American continent.

Between the LGM and the end of the ice age, the return to the relative warmth of the modern world was punctuated by short episodes of climate cooling. The most significant of such climate reversals is known as the Younger Dryas (named after a tundral flower found in ancient sediment across several sites in northern Europe), which saw regrowth of glaciers across many parts of the Northern Hemisphere for a period of about 1000 years. The exact cause of the Younger Dryas is not well understood, but many believe it was a consequence of a shut down in the ocean flow caused by desalination of the North Atlantic by Laurentide iceberg melt. If so, the cooling would have been a phenomenon that was restricted spatially. However, some argue for evidence of the Younger Dryas across the Southern Hemisphere. Much work remains to be done in pinning down the spatial magnitude and cause of the Younger Dryas. Such work would be vital to understanding the nature of connections between processes affecting the climate of both hemispheres.

During the seventeenth, eighteenth, and nineteenth centuries air temperatures were a few degrees cooler than today, causing the widespread growth of many glaciers. This period is known as the Little Ice Age (LIA), and is characterised in history by "frost fairs" on the ice-capped River Thames in winter and in literature by a Dickensian view of Christmas weather perpetuating in Christmas cards the world over. Seldom, however, in the twentieth century did London experience snow on 25th December. Consequently the LIA was a period of rapid short-term climate change. The exact cause of the LIA is not well understood. There are several processes that theoretically can act over a period of a few hundred years, such as solar activity (not to be confused with orbital variations) and ocean circulation change. Although one of these is likely to be responsible for the LIA, much work still needs to be done to fully comprehend this climate phenomenon.

ICE–ATMOSPHERE INTERACTION AND NEAR-SURFACE PROCESSES

The climate of the Antarctic continent is famed and feared for its harshness. Being almost entirely covered by ice and snow, Antarctica is not only the coldest place on Earth, with temperatures down to 90°C below the freezing point of water, but also the windiest. With annual mean wind speeds in some coastal places reaching almost 20 m s^{-1}, it was aptly coined "The home of the blizzard" by Australian explorer Douglas Mawson nearly a century ago. It is the combination of intense cold and fierce winds that makes Antarctica such an inhospitable place for humans.

The extremely low temperatures over Antarctica are due mainly to its topography (elevations over 4 kilometers in the center) and its isolated location at the South Pole. The strong surface winds are less easily explained, however. Whereas stormy winds in the rest of the world usually arise from highly variable large-scale weather systems and synoptic pressure gradients, in Antarctica they are strongly tied to near-surface processes. Surface winds in Antarctica are not only very strong, but also very persistent in terms of direction. These winds are called katabatic winds, and originate because of intense cooling over a sloping ice surface.

Most of Antarctica is covered by a huge ice sheet. Ice itself is a deformable medium, and hence it slowly flows from the high inland towards the coast. The ice mechanics associated with this flow induce a parabolic ice surface profile, with steep outer edges and a vast central plateau exhibiting little inclination. Since katabatic winds are proportional to surface slope—the steeper, the stronger—it is not surprising to find that the coastal escarpments experience the fiercest katabatic winds.

The Katabatic Wind Pump

Katabatic winds are ultimately caused by surface air that becomes colder than the air higher up in the boundary layer. On an inclined surface this means that the air at a particular location is colder—and hence, heavier—than the air at the same elevation downslope. Gravity then forces this cold air to flow downward, and this process continues as long as the surface air is cooled. In Antarctica, this cooling goes on semipermanently, and that is why the katabatic winds only rarely cease.

The snow surface, reflecting most of the incoming sunlight because of its brightness, experiences a strong radiation deficit. More infrared or thermal radiation is emitted than solar radiation absorbed, causing the temperature of the snow surface to drop. With the surface temperature being lower than that of the overlying air, the near-surface air is stably stratified (densest near the surface, less dense higher up). This means that turbulent motions in the surface air layer will transport heat from the atmosphere towards the surface. This flux of heat eventually balances the radiation deficit of the surface, but it also cools the surface air and as such motors the katabatic flow.

Interestingly, the downward heat transport is strongly dependent on wind speed (the stronger the wind, the higher the heat transport) but also on the magnitude of the vertical temperature gradient. This temperature gradient, in turn, depends heavily on wind mixing: in stormy conditions, mixing is strong and the atmosphere will be less stably stratified. Under still conditions, mixing is virtually absent, and the surface will be much colder than the overlying air. All taken together, this means that the katabatic wind system is based on an intricate balance between surface cooling, katabatic wind forcing, and wind mixing. The coastal regions with the steepest surface slope generally experience the strongest katabatic winds. Being deflected by the Coriolis force, these katabatic winds generally blow from southeasterly directions and are strongest in winter when surface cooling is most severe.

The Surface Mass Balance

The Antarctic Ice Sheet gains ice mass through snow accumulation. Most snow falls in the coastal regions, whereas the high inland regions are as dry as a desert with only 5 cm of snow accumulation per year. There, annual precipitation occurs in a few events, when synoptic low-pressure systems manage to battle themselves onto the high plateau. Moreover, air can hold significantly less moisture when it gets colder, so when it encounters the deep-freeze conditions of the Antarctic inland most moisture has already been squeezed out.

Generally, mass loss at the surface of an ice sheet occurs through melt, sublimation and, on the local scale, wind erosion. Surface melt takes place only in some isolated coastal locations and on the Antarctic Peninsula where summer surface temperatures regularly exceed the freezing point, but averaged over the Antarctic continent, melt is insignificant. On the other hand, sublimation, the phase transition from the solid snow directly to water vapor, occurs everywhere but depends strongly on wind speed and temperature, and amounts on average to about 10% of the total accumulated snow.

The sum of all water mass fluxes to and from the snow surface is generally referred to as the surface mass balance. When positive, the surface gains mass on an annual basis because snowfall is abundant, for instance. In mild, low-lying glaciated regions, significant melting may exceed snowfall resulting in a negative surface mass balance. Over the Antarctic Ice Sheet, the surface mass balance is positive nearly everywhere. Moreover, it peaks in the coastal regions because of the precipitation distribution. In the inland reaches, the mass balance is slightly positive because of the extreme cold, causing melt to be absent and sublimation to be minimal.

The transport of snow by the winds is probably only of secondary importance to the overall mass balance of Antarctica. An interesting aspect of the persistent near-surface katabatic winds of Antarctica is that they are able to carry huge amounts of loose snow over great distances. The amount of snow transported by the wind—also known as drifting snow, or blowing snow—increases dramatically with wind speed. Hence, the strong katabatic winds are able to redistribute large amounts of the precipitated snow, with erosion and deposition patterns being largely governed by the ice sheet topography.

Blue Ice Areas

An illustrative example of the local effects induced by erosion and deposition of drifting snow is the existence of so-called blue ice areas. These are very localized regions, usually only a few square kilometers in area, where the topography has induced a surface wind field that favored continuous erosion of snow, leaving bare (blue) ice. Usually, but not exclusively, these blue ice areas are found in the wake of mountains protruding through the ice surface. Over the course of time, strong, turbulent surface winds have eroded the entire snow deck. Once the ice layer has surfaced, snow was unable to stick to the smooth ice, preventing the blue ice area from being covered by snow again.

The persistence of blue ice areas is reinforced by strong sublimation rates. Since blue ice is darker than the adjacent snow fields, heating through solar radiation is more vigorous, creating a relatively mild local climate in which the ice surface loses mass through surface sublimation. While only a tiny fraction of Antarctica is covered by blue ice, its bluish appearance makes it fairly easily recognizable from space. If climate-induced changes in temperature and wind somehow affect the size of blue ice areas, these regions may be used as an indicator of climate variations taking place over the southern continent.

Drifting and Blowing Snow

Because of the ever-persisting katabatic winds raging down Antarctica's icy slopes, blizzards, snow storms, and drifting and blowing snow are very common phenomena. Since loose surface snow is found almost everywhere on Antarctica, surface winds over about 7 m s^{-1} inevitably cause surface snow particles to become airborne. At moderate winds, individual snow particles bounce along the surface—a process called saltation—thereby ejecting more particles. When wind speeds increase further, the particles become fully detached from the surface and start to float. This state of snowdrift is usually referred to as suspension. Driven by Antarctica's persisting katabatic winds, snow particles may travel tens to hundreds of kilometers before settling down again.

Like surface snow, however, suspended snow particles are continuously subject to sublimation. Traveling downslope with the katabatic wind, turbulent updrafts are required to keep the particles afloat. These induce a turbulent moisture flux, or sublimation, which eats away mass from the particle. Snowdrift sublimation is a relative efficient process, since snowdrifting particles are surrounded by air on all sides (in contrast to particles at the surface). Hence, this constitutes another, two-step, mechanism by which the snow surface loses mass: first snow particles are swept up by the winds, after which they are slowly sublimated away. Calculations have shown that, averaged over the entire continent, surface and snowdrift sublimation may be of equal importance in removing mass from Antarctica's surface.

Over most of Antarctica's vast ice sheet, snow is deposited quite infrequently during a few precipitation events per year, indicating that the snow layering is equally irregular. Erosion of snow at one particular location and deposition of the same snow elsewhere adds to the potential confusion when studying snow layers. Even though researchers have been able to recover annual layers from most sites, they must always consider the possible disturbing effects of drifting snow.

Snow Density and Snow Dunes

Generally, freshly fallen snow has a density of about 100–150 kg m^{-3} (the density of solid ice is 920 kg m^{-3}). On Antarctica, however, the density of surface snow is as high as 300–400 kg m^{-3}. The main cause of the high surface density is the action of the surface winds. During snowdrifting conditions, individual particles collide, break, and generally become more round. Starting as snow flakes, they quickly turn into much smaller, rounded particles which can be more densely stacked. This process is referred to as wind packing. Another reason for the densification is the metamorphosis by sublimation after snow is fallen on the surface, a process known as aging.

Readily recognizable features of the Antarctic surface are the snow dunes, or sastrugi. They occur virtually everywhere over the continent, though their size ranges considerably from place to place (sastrugi up to one meter in height have been reported). Their ultimate cause is the wind, sweeping up loose snow particles in a quasi-regular fashion. Extended areas of sastrugi have been found to severely obstruct land-based transport, for instance when using snowmobiles. Elongated mega snow dune systems, not unlike the patterns seen in subtropical sand deserts, have been observed from space. As it turns out, the transport of snow by the wind resembles the sand transport very closely, and the existence of snow dunes is a clear manifestation of that.

Outlook

It is clear that the specific surface climatic conditions of the Antarctic are causing phenomena not seen elsewhere on Earth. Antarctica's meteorological conditions, snow texture, and glaciological features are currently being scrutinized through ground-based fieldwork, by satellites and using numerical modeling. It is anticipated that the combination of these approaches will eventually lead to the solution of the many riddles that Antarctica still holds today.

ICE CHEMISTRY

Most of the ice in the Antarctic Ice Sheet is extremely pure. However, along with the water molecules, there are traces of chemicals, which give the ice many of its physical properties. There are also small bubbles of trapped air containing atmospheric gases. Because concentrations are generally very low, analysis of these chemicals is challenging, but is now very common in ice core laboratories worldwide. The changing concentrations of the chemicals, in both the ice and the air bubbles, give an excellent indication of the past content of the atmosphere. By drilling ice cores from the Antarctic Ice Sheet, scientists have been able to reconstruct the climate of the Antarctic, and the concentrations of atmospheric gases and particles, over time periods up to 800,000 years.

The Chemical Content of Antarctic Ice

The past temperature of the Antarctic is derived from measurements of the isotopic content of the water molecules themselves. However, all the other information derives from the small amounts of added impurities, which come from the atmosphere through long-range transport and mixing.

Various sources contribute to the chemical content of the ice. In coastal regions, material derived from sea salt is often dominant. Recent work suggests that the sea ice surface, as well as open water, is a source for this sea salt component. Another major impurity that comes from the ocean is sulfur-based ions: sulfate and methanesulfonate (MSA). Both these ions are the products of atmospheric oxidation of another compound (dimethylsulfide) which is emitted by marine algae. The concentration of sea salt in particular falls off rapidly from the coast towards inland areas of Antarctica.

Sulfate can also come from volcanic activity. In particular, after major eruptive volcanic activity, sulfur dioxide reaches the stratosphere and falls over the whole Earth (including the ice sheets) over a period of generally 2–3 years. This is detected as a high spike of sulfate in an ice core, and these spikes are very useful for synchronising different ice cores to each other and to known volcanic eruption dates.

Despite the very large distance across the Southern Ocean, small amounts of terrestrial dust reach Antarctica, and can be identified either by measuring the insoluble dust or by measuring ions or metals (such as aluminium) that are primarily associated with terrestrial dust. Geochemical analysis of such dust has indicated that South America is a particularly important source of dust to Antarctic ice.

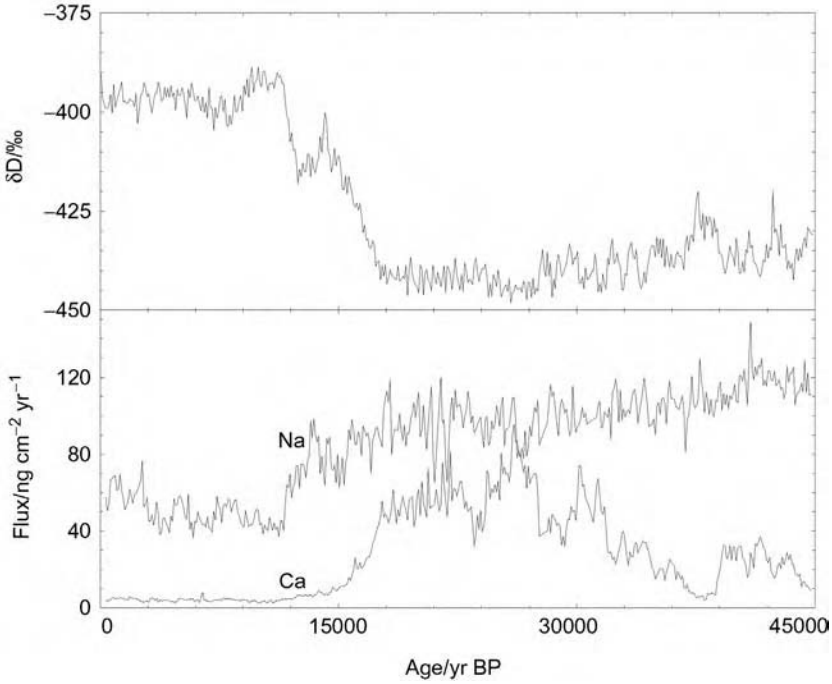
Other chemical material also reaches the ice—for example nitrate, which probably comes from the upper troposphere or lower stratosphere; small amounts of organic material; and even tiny amounts of pollutants such as lead from vehicle exhausts.

In addition to the chemicals trapped in snow, samples of the atmosphere are isolated into the tiny air bubbles that form when the snow turns to solid. Within these bubbles are found all the stable gases from the atmosphere: nitrogen and oxygen, but also greenhouse gases such as carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O). In deeper ice (below several hundred metres depth) the air bubbles form air hydrates—separate crystals of gas molecules caged by water molecules. However, the air from these hydrates can also be extracted and analysed in the same way as that from the bubbles.

There is still some discussion about the way in which the nongaseous impurities are included in the ice. In laboratory experiments, ice is able to exclude most impurities from its lattice, pushing them into the grain boundaries. In nature, this could occur on formation of the ice, or during subsequent movement of grain boundaries through the ice. A few compounds are expected, on both theoretical grounds and experimental evidence, to be included in the lattice: for example hydrochloric acid (HCl) and ammonium hydroxide can sit in the ice lattice and take part in hydrogen bonding within it. There is clear experimental evidence that, in some circumstances, impurities are indeed excluded, both to the grain boundaries (where two grains meet) and to triple junctions (where three grains meet). In the latter case, veins of impurity can be present that have liquidlike properties even at temperatures as low as –70°C. However, there is also evidence that, under some circumstances, impurity is held in inclusions within the crystals themselves. Whatever the microphysical location, ice chemistry is generally conserved through time, and apart from some minor diffusion, immobile.

Impurities play a decisive role in determining the electrical properties of ice, the growth of ice grains, and possibly the mechanical flow properties of the ice. In the case of the electrical properties, while pure ice has a small direct current (dc), and larger high frequency conductivity, this is generally overwhelmed by an additional conductivity due to ionic impurities. This forms the basis of two common techniques of analysis that can be carried out on solid ice, electrical conductivity analysis (ECM) and dielectric profiling (DEP). For example, large increases in conductivity are seen across volcanic eruption horizons, due to the high concentration of sulphuric acid in the ice.

Impurities with a significant vapour pressure are not entirely fixed in the upper snowpack, and some of



Antarctic ice core chemistry over the last 45,000 years from the European Project for Ice Coring in Antarctica (EPICA) Dome C core (Röthlisberger et al. 2002). The top panel shows deuterium, representing temperature, with the transition from the last glacial maximum (LGM), c. 20,000 years ago, to the warm Holocene period. In the lower panel, both sodium (Na, top line, representing sea salt) and especially calcium (Ca, lower line, representing terrestrial material) were at much higher concentrations in the LGM.

them can be reemitted as the temperature and snow surface area changes, or can be photolysed in the upper few cm of snow. At some sites the emission of chemicals from the snowpack can have a significant effect on concentrations of chemicals in the lower atmosphere. For example, photolysis of nitrate from snow seems to control the concentrations of NO_x (NO + NO_2) in the Antarctic ice surface/atmosphere boundary layer at many sites, with significant further effects.

Ice Chemistry Sampling and Analysis

A wide range of chemical analyses is carried out on ice cores. For the impurities in the ice itself, the ice may be cut (using a bandsaw) into individual depth increments, and then analysed. The method of ion chromatography has been very widely used to measure the major ionic impurities such as sodium, calcium, chloride, nitrate, and sulfate. Insoluble dust has frequently been measured by particle counting techniques, such as the Coulter Counter or laser optical methods. Metals and isotopes of them have been measured by various techniques, with inductively coupled plasma-mass spectrometry (ICP-MS) most often favoured in recent years. For all these methods, strong precautions against contamination must be taken, and the use of clean air laboratories and particle-free clothing and gloves is often necessary. As an example, although concentrations of lead have increased in Antarctic ice since preindustrial times, they remain about 1/1000 of the levels found in typical European tap water, so it is very easy to contaminate samples unless precautions are taken. Because the outside of ice cores is often very dirty, due to contact with drills and drilling fluids, it must normally be removed before sampling and analysis is attempted.

New methods of sampling and analysis have come to the fore. These generally involve melting strips of ice core on a hot plate. The outer, contaminated parts of the core are melted into an outer ring and drawn away for less sensitive analyses, while the inner, clean part can be directed through tubes to analysers. This procedure produces a stream of melt that can be sampled regularly or continuously, and it decontaminates the ice as part of the process. In early realisations of this method, known as continuous flow analysis (CFA), the water was directed to various streams where absorption or fluorimetric methods were used to analyse for compounds such as hydrogen peroxide and formaldehyde, as well as metals such as calcium and sodium. In some laboratories, CFA melters are now also used to provide sample streams for fast ion-chromatographic methods and mass spectrometers, and for discrete sampling to clean containers.

Ice Core Chemical Records

A wide range of ice core chemicals has been measured, covering timescales from seasonal up to 800,000 years. Over shorter timescales, records of recent decades have revealed whether pollution reaches Antarctica, even in small quantities. Variations over years to centuries have been linked to modes of atmospheric circulation, and offer the possibility of reconstructing such modes back into the preinstrumental period. Over longer periods, chemicals in the ice vary strongly between warm "interglacial" periods (such as the Holocene, the last 10,000 years of relative warmth), and cold "glacial" periods.

The concentrations of most chemicals vary strongly with the seasons. For example, the marine biogenic component (MSA and part of the sulfate) peaks in the summer period of marine productivity, while sea salt peaks in the winter half-year. Concentrations also vary from year to year, presumably as a result of a combination of changing source strength and atmospheric transport. Several authors have made links between concentrations of chemical components at various ice core sites and meteorological parameters such as the strength and location of atmospheric pressure features, the passage of the Antarctic circumpolar wave, and the amount of sea ice present. The patterns are complex, and more work, at more sites, is needed to establish these methods on a firm enough footing to derive these parameters in the past.

Over recent decades, emissions resulting from human activities have affected most of the Earth's atmosphere. However, no clear increasing trend in concentration can yet be seen in Antarctic snow for chemicals such as nitrate and sulfate that are now predominantly anthropogenic even in Greenland. A clear exception to this is the case of lead. Profiles of lead in snow and ice over the last century show that its concentration increased by at least a factor 5 over the natural level between the nineteenth century and the 1980s. This was first due to metal production activities and then the use of leaded gasoline in countries of the southern hemisphere. It parallels (but in a much weaker form) similar trends seen in Greenland (Northern Hemisphere) records. Concentrations have decreased in the last two decades, as unleaded fuels have been introduced.

The greenhouse gases provide the clearest example of an anthropogenic effect seen from Antarctic ice cores. Antarctic ice cores have shown that the CO_2 concentration has increased from about 280 ppmv (parts per million by volume) in 1800 to its present value above 370 ppmv. Methane concentrations have nearly doubled in the same time. On glacial–interglacial timescales, the greenhouse gases vary naturally with climate.

The spikes of sulphuric acid in the ice have been documented and compiled to give inventories of the past strength and numbers of volcanic eruptions. Whilst it is difficult to compile an accurate inventory from a single core, combining several cores gives the best hope of deriving an objective volcanic index into the past—information which is needed to evaluate the effect of volcanic eruptions on climate. Attempts have also been made to use another chemical in the ice, ^{10}Be, to derive an index of solar activity—another essential forcing factor for climate change.

Most of the major chemical components in the ice also vary in concentration dramatically with climate. Over the last 800,000 years, the Earth's climate has varied with a period close to 100,000 years; in the latter part of the record, the variation has consisted of short (10,000–30,000 year), warm interglacials and long, cold glacial periods. Most chemical concentrations are much lower during warm than cold periods. For example, the flux of insoluble dust to central East Antarctic ice was more than a factor 20 higher during the last glacial maximum (LGM, about 18,000 years ago) than in recent times. Fluxes of sea salt were about a factor 2 higher at the LGM than today. The cause of the increased dust concentration is probably a drier and windier climate in the source, most likely Patagonia, although a more vigorous transport could also have played a role. Dust concentrations in Antarctic ice can therefore give information about South American climate. The cause of the higher sea salt fluxes remains under discussion, but one idea is that the higher concentrations are a result of stronger sea ice production.

In summary, although Antarctic ice is rather pure, its chemical content has important physical effects, and the changing concentrations document changes with time in the Antarctic atmosphere. Ice core chemistry, in combination with ice core isotopic and gas measurements, provides the most powerful possible tool for evaluating past changes in the atmosphere, and their interactions with climate.

ICE CORE ANALYSIS AND DATING TECHNIQUES

Ice cores are an immensely powerful tool for determining past climatic and environmental conditions. However, they are a challenge for analysts, because it is generally necessary to process large numbers of samples, using as little ice as possible, and at low concentrations of many analytes. It is also crucial to date ice cores correctly and to be able to synchronise them with other paleoclimate records.

Processing and Physical Analysis

A huge range of physical and chemical analyses is made on the most important ice cores. The first step is the initial processing of the cores, which often includes some physical analysis, as well as sectioning of ice for different analyses. In some cases, this processing is carried out at the field site, in others at home laboratories.

Because ice cores are drilled in discrete lengths, of at most a few metres each, the first process to occur after drilling has to be logging—marking the cores for length and orientation, and fitting each core to the previous one to establish the continuous sequence.

Dielectric profiling (DEP) measures the capacitance and conductance of ice at a range of frequencies. Curved electrodes on either side of the core are connected to a commercial measuring device. From the measurements, the high-frequency permittivity (related to density), and conductivity (related to chemical content) can be determined. Either a sequence of electrodes or a moving electrode is employed to make measurements at a resolution of mm to cm. The conductivity data show the depths where major changes in chemistry (e.g., volcanic eruption material) occur, allowing alterations in the subsequent sampling strategy. A related technique, the electrical conductivity measurement (ECM), is carried out at direct current frequencies, and measures the current between a pair of electrodes (with typically 1 kV between them) dragged along an ice surface. A fresh ice surface is preferred, and so ECM is normally carried out after a cut has been made along the core length. ECM responds only to acidity in the ice core, and is used particularly to document volcanic acid input.

Other physical measurements have been made by running instruments along the length of cores. A line scanner or camera can record the optical properties of ice. This documents the presence of air bubbles, of visible ash layers (from volcanic tephra) and of so-called cloudy bands: bands of milky ice, normally associated with high impurity content. Cloudy bands apparently occur at annual spacing in ice from the last glacial period in Greenland, and can be used to assist annual layer counting for dating.

Thin sections of ice, prepared with a microtome, are required for measurement of crystal size, shape, and fabric. These point to the deformation and grain growth history of the ice, which in turn is controlled by the large scale flow and temperature history, as well as the intrinsic properties of the ice. Crystal fabrics are measured using crossed polarisers. Crystals with different orientations show up in different colours with this technique. Automatic mapping of the fabrics generates statistics about the ice structure. Deformation tests can also be made, to understand the mechanical properties of ice: if realistic stresses are applied they require months or years for each experiment, although extrapolation from shorter experiments is also carried out.

Stable Isotopes of Water and Cosmogenic Isotopes in Ice

The measurement to which most other ice core data are often keyed is that of the stable isotopes of water. The ratio of both $^{18}O/^{16}O$, and $^{2}H/^{1}H$ (^{2}H is deuterium, D) in water, although the result of complex processes in the hydrological cycle, is generally considered to be mainly a measure of the temperature at the time and place of snowfall. It is therefore a very useful paleoclimate proxy, and can sometimes also be used as a dating tool. Values are expressed as a difference ($\delta^{18}O$ or δD) from the ratio found in standard ocean water, in parts per thousand (‰). A derived property, the deuterium excess ($\delta D - 8*\delta^{18}O$), is related to properties at the ocean source, and obviously good precision in the measurement of the individual isotopes is mandatory if the excess is to be calculated accurately. The ratios are measured on small water samples using mass spectrometry after equilibration with CO_2 (for $\delta^{18}O$) or reduction to H_2 (for δD).

The isotope ^{10}Be is produced by interaction of cosmic rays with major atmospheric constituents. The production rate is determined by factors that shield the Earth from cosmic rays: the Earth's geomagnetic field strength and solar properties linked to solar activity. To measure ^{10}Be concentrations in ice, volumes of melted ice (typically 150 g with instruments available in 2005) are concentrated on an ion exchange resin, and after appropriate treatment, the ^{10}Be concentration is measured using accelerator mass spectrometry. This measurement requires a lot of ice, but is very useful, both in chronology and as an indicator of past solar activity.

Analysis of the Chemical Content of Ice

Although only low concentrations of ionic and other chemicals exist in ice, they can be used as indicators of numerous environmental parameters, such as sea ice conditions, past atmospheric transport, volcanism, and past biogenic activity. The major ionic impurities (Na^+, Mg^{2+}, K^+, Ca^{2+}, Cl^-, NO_3^-, SO_4^{2-}) are present at μg kg^{-1} (ppb) levels, and have traditionally been measured by ion chromatography (IC). Insoluble dust has been measured (both for concentration and size) using the Coulter Counter instrument. Samples must be cleaned before they are melted, to remove external contamination, particularly from drilling fluids.

In recent years, the traditional route of cutting individual samples of a few mL for such analyses has been partially superseded by methods (known generically as continuous flow analysis or CFA) in which a length of ice with square section (typically 3 cm $\times$ 3 cm) is placed vertically on a hot plate with concentric channels. The liquid from the central disc is automatically cleaned by this procedure and can be directed either to clean vials for IC analysis or to channels in which individual components are measured by using chemical reactions that produce a colorimetric response (absorption or fluorescence). This technique has been used very successfully for components such as Na^+ and Ca^{2+}, as well as ammonium and species not measured by IC, such as formaldehyde. Continuous flow methods in which light scattering is used to measure dust concentration have also been developed.

A range of other chemicals is measured less frequently in ice. Ultra-trace elements (including heavy metals such as lead [Pb]) are present only at ng kg^{-1} (ppt) levels, and require extreme precautions against contamination. Inductively coupled plasma-mass spectrometry (ICP-MS) has generally superseded other techniques for these elements, and in one laboratory, CFA has been coupled to ICP-MS. Organic and biological molecules are less commonly measured in ice cores, although they clearly have potential as rather specific markers of particular sources.

Finally, a range of isotopes of the chemical components in ice can be measured, although low concentrations make such measurements difficult. They are used to add information about the origin of material in the ice. For example, ^{34}S in SO_4^{2-} allows volcanic sulfate to be differentiated from that of marine origin, while the isotopes of Pb, Sr, and Nd can be used to fingerprint the geographical provenance of terrestrial dust. Mass spectrometry, using a range of preparation and introduction techniques, is the measurement method.

Analysis of Gases in Ice

When snow is compressed to form solid ice, air bubbles are trapped, and these act as a sample of all the stable components of air. Although the bubbles subsequently convert into air hydrates under pressure at depth, these too can be recovered to allow analysis of the gas content of the ice, and hence of the past atmosphere. For some insoluble gases, such as methane (CH_4), a simple wet extraction can be employed, but for more soluble gases (such as carbon dioxide, CO_2), it is necessary to use a dry method: either crushing or sublimation. In the crushing method, the ice is placed in a container, which is evacuated, and the ice is then crushed or milled into pieces sufficiently small that all the air can be removed. The resulting gas samples can be analysed for a whole range of atmospheric constituents, as well as for their isotopic ratios.

CO_2 is analysed either by infrared laser spectroscopy or gas chromatography. Mass spectrometry is the method of choice for most of the other gas measurements. CH_4 and N_2O (nitrous oxide) are other greenhouse gases that are determined. ^{13}C in CO_2 and CH_4 is now measured as a way of understanding changing sources and sinks. ^{18}O in the oxygen content of the air (as opposed to that in water, discussed previously) is another important analyte, bringing information that is extremely important for linking ice core and marine sediment records, since the ^{18}O content of both is partly controlled by global ice volume. The total air content of the ice is to first order controlled by the atmospheric pressure, and hence the altitude of the ice sheet. Finally, trace gases at even lower concentrations (such as halocarbons) are now routinely measured in columns of firn air (where large volumes of air are available), and are starting to be measured in gas bubbles below the firn.

Dating Techniques

Accurate dating is essential for comparisons between records, and for understanding the controls on regular periodic climate variations. At sites with high snow accumulation rates, annual layer counting may be possible. Many markers in the ice (including $\delta^{18}O$ and often dust and ionic impurities) vary seasonally, providing records that can be counted. Poor core quality or hiatuses in snow accumulation certainly limit the possible accuracy of such layer counting. Not all markers reliably have one peak per year: for this reason, counting using multiple proxies is strongly recommended. Under good conditions, it has been suggested that counting to a precision of around 1% may be possible in the Holocene period (last 10 kyr, 1 kyr = 1000 years), although the precision is certainly reduced in older ice.

Such counting can be checked by the use of fixed markers of known age. For example, peaks of beta-radioactivity are always found in snow from 1964 due to the large amount of atmospheric nuclear bomb tests carried out in the preceding year. Peaks in sulfate (also reflected in the ECM and DEP) are found in years when large volcanic eruptions took place, such as 1815 (Tambora), 1883 (Krakatoa) and a sequence of peaks around 1259 AD (unknown volcano). In earlier periods, profiles of volcanic spikes can be matched between cores to synchronise them, although the exact dates of each eruption are unknown.

A new method to date ice from the last 10 kyr has recently been developed. The production of ^{10}Be (see previous discussion) is controlled by the same factors as that of ^{14}C, which is measured in annually dated tree rings. After appropriate modelling, it is possible to match the small multidecadal wiggles in ^{10}Be in ice with the residuals around the trend of ^{14}C in tree rings, in order to tie ice cores to the dendrochronological scale.

For sites with low snow accumulation rate and for older ice, annual layer counting is not possible. Most commonly these cores are dated using a glaciological flow model. Because ice flow (and thinning of layers) follows simple physical laws, the age can be modelled using a thinning function provided we know how the snow accumulation rate has varied with time. This can also be estimated using a simple model that relates snow accumulation to site temperature through vapour pressure. The free parameters in the model can be estimated if we have a few points at which the age is known. For example, a peak in ^{10}Be flux, found in all ice cores at around 41 kyr before present (BP), is believed to be related to a magnetic change which has been radiometrically dated in other sediments. Such ice flow models have been used to date most of the major deep ice cores. The greatest limit to such age scales is probably that they assume that the ice flow has been steady with time, an assumption that appears to have been violated in some cases.

These methods give an age scale for the ice, but the air bubbles in the ice have a younger age (because at the depth where they close off, typically 80 m, the ice is decades to centuries old, while the air is much younger). Determining the difference between these two ages is critical for determining the phasing between, for example, changes in temperature and changes in CO_2 concentration. Modelling of firn properties and the air enclosure process is used to do this.

The age scales of different cores can be tied together using properties that must change simultaneously at different sites. For the gas age scales, rapid changes in methane concentration are particularly effective for this purpose. Methane has a short mixing time in the atmosphere compared to its lifetime, so even Greenland and Antarctic cores can be tied together when fast (decadal-scale) changes occur, as they did several times during the last glacial period. For ice age scales, volcanic eruption signals are excellent synchronisers, provided one can be sure that the same eruption is sampled in both cores. Synchronisation can be used to transfer a timescale from a well-dated high accumulation rate core to less well-dated cores from low accumulation rate sites. In the long term, it may be possible to link together a whole series of cores, and to provide a common timescale constructed from the best information available from all of them, although such a project has not yet been realised.

ICE CRYSTAL SIZE AND ORIENTATION

A glacier is made up of small crystals that form during the compaction near the ice sheet surface, of snow into ice. The ice crystal size (typically $\sim$1 mm) near the surface is related to the size of the snow flakes at deposition, which in turn is related to air temperature, and the crystals are randomly oriented. In the upper layers (the top few tens to hundreds of metres in the Antarctic Ice Sheet), the ice crystals grow at a temperature-dependent rate.

Deeper, where the ice begins to flow because of the stresses imposed on it by gravity (i.e., by the weight of the ice itself), the size and orientation of the crystals begin to change in response to the flow. The higher the flow rate, the smaller the ice crystals will become. Furthermore the crystals begin to align in particular directions related to the stress configuration. Throughout most of the deeper ice in Antarctica, where the ice is in shear approximately parallel to the bed, the crystals align so that the crystal glide planes are parallel to the flow direction. The optical or c-axis of an ice crystal is perpendicular to the glide plane. Thus in the ice sheet deep layers, the c-axes all tend to be near vertical. By examining ice thin sections mounted between crossed polaroid filters one can measure crystal size and orientation. Each crystal appears as a different colour due to its orientation, and using a universal stage, the orientation of individual crystals can be measured. A map, or fabric diagram, of the crystal orientations is then drawn. In glaciology, a microscope is not required to see the crystals, which are much larger than those of most other minerals, and a larger universal stage is used, usually referred to as a Rigsby stage.

A feedback mechanism operates between the crystal fabric pattern and the ice flow. While the ice flow under different stress patterns generates different crystal orientation patterns, so too does the fabric pattern affect the ice flow rate. For example, ice with a strong vertical crystal orientation fabric pattern in near horizontal (bed-parallel) shear will flow as much as ten times faster than ice with a random crystal orientation pattern. Thus, an understanding of the crystal structure of the ice and an understanding of the physics of how ice flows is essential if accurate models are to be developed of the Antarctic Ice Sheet, and if accurate estimates are to be made of changes in the size and shape of the Antarctic Ice Sheet.

ICE DISTURBANCE AND COLONISATION

Marine life on the Antarctic coast, and also in the Arctic, is vulnerable to ice disturbance from the shore line to as deep as 550 m water depth. Icebergs produced by calving from glaciers, fast ice that forms on the sea surface, and anchor ice that crystallizes on the sea bed are all hazards to benthic (bottom-living) organisms, especially those that are sedentary. Yet this disturbance also provides niches for hiding, new surfaces to graze on, release from competition, and space for colonization.

Fast Ice

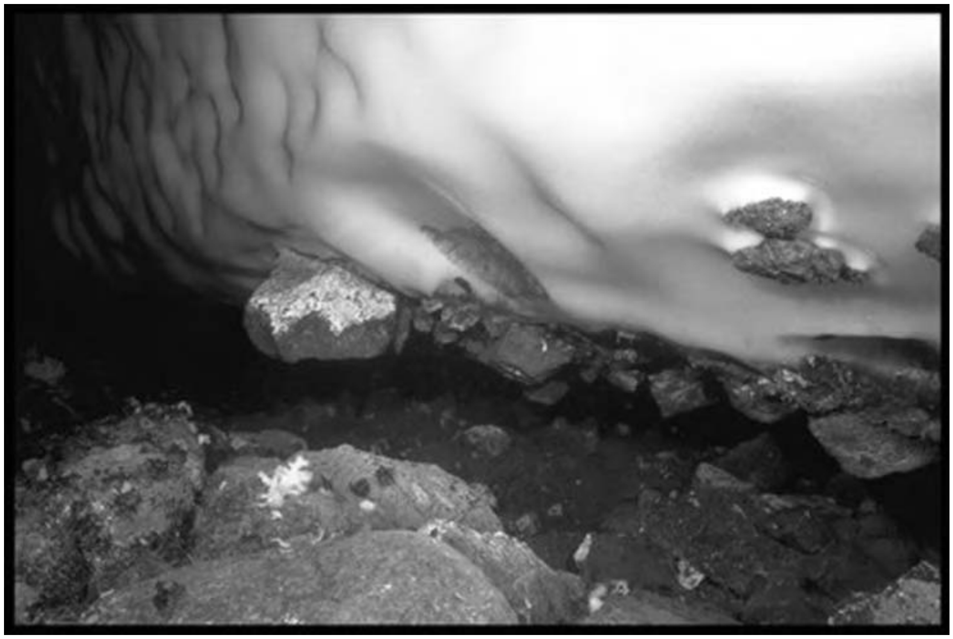
Where ice on the surface of the ocean meets the shore, it attaches to the land as fast ice. When this happens, the shoreline frozen to the fast ice becomes unavailable to marine life. Additionally, more shoreline is scoured by ice moving with the waves and currents when the fast ice breaks up in the summer. Fast ice can also affect seabed at a distance. As the ice forms on the surface of the ocean in the fall, salt from the sea water is captured between the ice crystals. The salt is excreted over the winter as concentrated brine which, being heavier than seawater, sinks to the seafloor. The brine collects in seafloor depressions, such as those created by ice scour, where it kills animals and algae living on the seafloor or burrowing underneath. The dead organisms decompose, in the process using up the oxygen in the brine pools. The lack of oxygen results in the pools becoming high in sulfur and iron, giving them an odour and a black colour. These "black pools of death" then become lethal traps for shrimps and fish that may blunder in. First discovered in the Arctic, black pool formation can occur in coves and inlets in the Antarctic wherever water movement is limited. Fast ice also has positive impacts, however. It provides a winter habitat for a diversity of microbes and ice algae which feed krill and fish. In the spring, small photosynthetic organisms called diatoms grow on the undersurface of the fast ice, attracting more grazers. When the ice breaks up in the summer, the diatoms fall to the seafloor, where they then become food for the bottom fauna.

Ice Foot

Fast ice can extend several meters below shore in the shape of a foot. This ice foot can persist for much of the year and limit accessibility of the shore to the short summer when it is not present. Then, fast growing algae and diatoms colonize the shore, giving it a grassy, green-brown appearance. This attracts motile grazers such as the limpet *(Nacella concinna)* and amphipods (small shrimplike crustaceans). Once the sea surface refreezes, the diatoms disappear, the grazers move deeper, and the ice foot forms again.

Anchor Ice

Where seawater is supercooled (cooled below its freezing point), as occurs in McMurdo Sound close to the Ross Ice Shelf, large plates of ice form, anchoring to the fast ice, ice foot, and seabed, and covering the seabed to as much as 30 m water depth. When this anchor ice accumulates to the point that it becomes too buoyant to remain attached, it can rip off grazing



Undersurface of a grounded iceberg in McMurdo Sound showing the vulnerable marine life. Boulders frozen into the iceberg can be lifted and carried thousands of kilometres, leaving evidence of past ice movements. (Photograph by Kathleen E. Conlan, copyright 1997, Canadian Museum of Nature.)

or ice-trapped organisms. Sea urchins and sea stars are attracted to the anchor ice, grazing on the diatoms that grow on the plates. Once the anchor ice lifts off, small opportunistic animals, which reproduce rapidly and in large numbers, quickly invade the cleared space, burrowing into the sediment to eat detritus and diatoms. Anchor ice spreads along the coast over the winter and recedes as the water slightly warms in summer. The extent of anchor ice formation is influenced by climate and currents, even El Niño–Southern Oscillation (ENSO) events that originate thousands of kilometres to the north. Low anchor-ice years enable the fast growing bush sponge and its sea star predators to invade. Thus, anchor ice, like other disturbances, produces destruction for some but opportunity for others.

Ice Scour

Ice scour in very shallow water can occur many times within a year, but it can be very patchy and rapidly decreases in frequency with depth. Icebergs (ice calved off glaciers and ice shelves) can have deep drafts underwater, some reaching the seabed as deep as 550 m underwater when they turn over. Pressure ridges, formed by drifting pack ice pressing against shore-frozen ice, also send ice keels underwater. Combined, these icebergs and pressure ridges can scour paths up to 350 m wide, 15 m deep, and 15 km long over the surface of the seafloor. About 1.5 million km^2 of Antarctic seabed is vulnerable to being bulldozed, deformed, and resuspended by these ice keels. Physical consequences of ice scour are long-term changes to the seabed and (in the Arctic) damage of seafloor structures such as cables, wellheads, and pipelines. Biological consequences are destruction of communities of algae and animals, loss of biodiversity, and changes in community composition. In the Weddell Sea, where the original community is dominated by giant volcano sponges, the scours may take centuries to fully recolonize. These sponges provide many hiding and attachment places for other animals, which cannot return until the sponges recolonize and grow. However, the newly ploughed seabed can be rich in nutrients and stimulate diatom blooms which then attract grazers. Like in the anchor ice zone, these new scours provide space for poor competitors that could not occur without periodic disturbance. Fishes are then attracted, hunting for the small worms, crustaceans, and other early colonizers. Ice scour may also resuspend food particles. Thus, ice scour has positive influences as well. As long as the recurrence of ice scour is not so frequent that colonization cannot progress, an ice-scoured seabed can form a patchwork of colonists of various types, thus increasing overall biodiversity. Regional warming is resulting in thinner and less extensive sea ice, which would mean fewer pressure ridges scouring the inshore. On the other hand, glacier melt and breakup should produce more deep draft icebergs, such as the huge B-15 iceberg, part of which lodged off Ross Island in 2001 and affected the local penguin rookeries.

ICE–ROCK INTERFACE

The nature of the ice–rock interface is poorly known in most parts of Antarctica. It is likely to be analogous to areas now exposed in North America and Europe that formerly underlay the Ice Age ice sheets, which contain distinctive suites of glacial landforms. The last Glacial Maximum ice sheet reached the continental shelf edge in many parts of Antarctica, and submarine areas exposed by glacial retreats show a subset of the glacial landform features seen elsewhere.

Observation of the ice–rock interface is restricted to field and remote-sensing studies of formerly glaciated areas; the drilling of boreholes (through kilometres or more of ice); and sounding using seismic (sound) or radar (electromagnetic) waves. Boreholes are either mechanically drilled or hot-water-drilled. Two mechanically drilled holes have reached the bed (at Byrd Station and Berkner Island), while numerous hot-water drillings have accessed the subglacial environment, particularly in the Siple Coast area. The latter have been well-instrumented, permitting measurements of water pressure and motion of ice over sediment beds as well as deformation within the sediment. The boreholes show a complex picture, with sediment frozen onto the base of the ice sometimes found, and the ice either slipping over the sediment or causing deformation within the sediment at some depth.

Seismic soundings discern whether the underlying bed is made of bedrock (solid rock created by nonglacial processes); stratified, generally nonglacial sediments; or unstratified or weakly stratified sediments which are presumably of glacial origin. Seismic soundings detect whether subglacial sediments are dilated (opened up), implying that the sediment is deforming or has been very recently deposited. Radar soundings inform about the geometry of the ice-bed contact and whether water is present, implying the occurrence of sliding and geological activity. Radar and seismic soundings suggest that material underlying the ice base is highly variable—sometimes bedrock, sometimes sediment, and sometimes ponded water.

The processes of erosion and deposition which shape the ice–rock interface are fundamentally governed by temperature. Towards their bases, ice sheets and glaciers warm as geothermal heat flow and frictional heating counteract the cooling effect of downward-moving ice. In many parts of Antarctica, the heating is sufficient to warm the ice to its melting point at the bed, and slip of ice over the bed can occur. Once this happens, rock and sediment at the bed can be fragmented and moved (erosion), or, where the transporting power of the glacier is decreasing, deposited. Material can be transported in a basal layer within the ice centimetres or metres thick, or in a layer of deforming sediment tens of millimetres to metres thick. In addition, flowing water at the glacier bed can cause erosion and deposition of sediment. The relative proportion of material transported by each process is poorly known, and probably varies strongly in space and in time.

Where ice is at the melting point it may melt or freeze, compensating warming and cooling trends in the ice. Water drains from melting areas and drains towards areas where there is freezing on of water. If there is insufficient water inflow, ice will freeze on to the bedrock or sediment. Sediment can be frozen to the base of the ice forming ice lenses and layered sediments.

The erosional effects of ice sheets are expressed throughout the world at a variety of scales (Benn and Evans 2003; Bennett and Glasser 1996)—large U-shaped valleys tens to hundreds of kilometres long and kilometres or even tens of kilometres wide; roche-moutonnées and whaleback forms (hillocks), tens to hundreds of metres wide; and small-scale polishing and friction marks. The clearest expression in Antarctica is through the large valleys cut through mountain ranges, which drain much of East Antarctica and parts of West Antarctica and the Antarctica Peninsula. A spectacular example is the valley containing the Byrd Glacier in the Transantarctic Mountains.

The primary depositional effect of ice sheets is the emplacement of subglacial sediments, or till. Till is generally a diamicton, that is, it contains grains of two distinct sizes, one clay-silt, the other stones centimetres in size. Subglacial till often shows that it has been deformed beneath the glacier, both through obvious tectonic features and from microscopic investigations of the fabric, which show characteristic patterns of grains related to deformation (Meer and others 2003). Abundant till is found on the Antarctic continental shelf. Till can be shaped into or draped over other forms, the most important of which in Antarctica are drumlins and megascale glacial lineations (Clark 1993). Drumlins are tens to hundred of metres high, and hundreds of metres to kilometres in plan form, typically in an ovoid form aligned with ice flow; megascale glacial lineations are subdued features, tens or hundreds of kilometres long and hundreds of metres to kilometres wide, aligned with glacial flow. Surface melt features ubiquitous in the Northern Hemisphere (e.g., eskers and, hummocky moraine) are not seen in Antarctica owing to the absence of such melt. Extensive zones of drumlinlike features have been discovered on the seabed in Antarctica, exposed by the retreat of the ice sheets, and also sounded through ice. Some spectacular arrays of megascale lineations have been found aligned along former ice-stream troughs (Canals et al. 2000).

Erosion of bedrock occurs by at least two distinct processes, plucking and abrasion. The latter occurs when tools (i.e., stones) gripped by moving ice or till are dragged over bedrock, resulting in striations (scratches) and polishing. Without abrading tools to perform scratching, erosion of the bedrock by clean ice would be very limited. The supply of tools is believed to be by plucking, which is the removal of blocks and stones of often prefractured rock by the ice. Observations of shattering show that this occurs mainly on the downstream (lee) side of obstacles of various sizes of a few tens of centimetres to tens of metres. The two main processes of erosion are believed to be responsible for the two particle-size families in diamict (till).

The origin of drumlins and related features remain as controversial as they were 2 centuries ago. Three principal mechanisms have been proposed: an instability in deforming till; dunes left by subglacial outburst floods; and interactions between ice flow and thermal regime. These mechanisms reflect different subglacial debris transport pathways. Observations of the rate of drumlin formation by seismic or radar sounding will therefore illuminate how sediment is being transported under glaciers.

ICE SHEET MASS BALANCE

Introduction

The Antarctic Ice Sheet changes shape and size over time as a result of a balancing act between snow being deposited (and subsequently compressed under its own weight to form ice) on the surface of the ice sheet, and the flow of the ice towards the coast where it discharges into the sea (either by melting or by iceberg calving). This ice sheet mass balance is positive if the amount of ice resulting from deposition on the ice sheet exceeds the amount flowing out (i.e., the ice sheet is growing), or negative if the amount of ice is less than that discharging from the area (i.e., the ice sheet is shrinking). Ice sheet mass balance can be examined at different elevation levels from the summit of drainage basins down to the terminus. It can also be considered over large areas (e.g., the entire Antarctic Ice Sheet), or over small areas (e.g., individual glacier accumulation basins). Because of the different bedrock topography and different climate regimes, the Antarctic Ice Sheet is often considered in two major sections, the East Antarctic Ice Sheet and the West Antarctic Ice Sheet, separated by the Transantarctic Mountains. Rignot and Thomas (2002) estimated the East Antarctic Ice Sheet mass balance to be positive; +22 $km^3\ yr^{-1}$ (433 $km^3\ yr^{-1}$ accumulation minus 411 $km^3\ yr^{-1}$ outflow). But they estimated the mass balance for the West Antarctic Ice Sheet to be negative; –48 $km^3\ yr^{-1}$ (381 $km^3\ yr^{-1}$ accumulation minus 429 $km^3\ yr^{-1}$ outflow).

Study of the Antarctic Ice Sheet mass balance is important and urgent because changes in the ice mass are closely linked to global sea level change. Variations in sea level over the past million years are highly correlated with changes in the global ice mass, and the response of the ice sheets to climate change in the future could raise global sea level. For the short term, however, the Intergovernmental Panel on Climate Change (IPCC) estimated that the Antarctic contribution to twentieth-century sea level rise (Church and Gregory 2001) was a lowering of between 0.2 and 0.0 mm yr^{-1}. This estimated lowering results because atmospheric warming may result in an increase in snow accumulation over the cold ice sheet (e.g., Polar Research Board 1985). In this scenario in the longer term (hundreds to thousands of years), however, this increased accumulation would result in an increase in sea levels as the increased mass of ice moved to the coast and dissipated into the ocean. On the other hand Kapsner et al. (1995) and Cuffey and Clow (1997) cite cases in which warming does not lead to higher accumulation. It is expected also that the influence on sea level of higher accumulation may be counterbalanced by increased basal melting from the floating ice shelves. Basal melting is estimated to account for up to one third of the loss from the ice shelves within which much of the Antarctic Ice Sheet terminates (Jacobs et al. 1996). While ice shelf basal melting is important for considerations of the Antarctic Ice Sheet mass balance, it has no direct effect on sea level since the ice is already floating. However the significance of the role of the oceans through melt could be important in a warming climate. If melt rates increase due to ocean warming, this could have an indirect but significant effect on ice discharge, leading to sea-level rise.

Two different but complementary techniques are used to measure ice sheet mass balance. The first is the component (or flux) technique in which the input and output fluxes are individually measured or estimated. This technique is particularly important when applied to individual drainage systems within the ice sheet, and can be used to isolate the causes of mass balance change. The second is by direct measurement of mass changes without separately determining the input and output fluxes.

The Component Technique

The Input Component

The input component to ice sheet mass balance is the net accumulation of snow at the surface. Additional minor effects include atmospheric frost deposition and wind export of drift across the coast. Accumulation rates are most commonly estimated by measuring the thickness of annual layers in ice cores, but because the number and spatial coverage of ice cores across the ice sheet is poor (even though several new ice cores have been drilled over the past decade), current estimates of mass input have large errors. For the future, there is some promise that space-borne techniques (Bolzan and Jezek 1999; Winebrenner et al. 2001) will soon provide an improved picture of the accumulation distribution across the ice sheet, and new techniques such as ground penetrating radar (GPR) profiling of firn stratigraphy, precise global positioning system (GPS) positioning, and direct measurement of ice thickness change (measuring the position of firn anchors) (Hamilton et al. 1998) will improve the coverage and accuracy of accumulation data. The International Trans-Antarctic Scientific Expedition (ITASE) (Mayewski and Goodwin 1997) provides an ideal opportunity for these measurements.

Once the snow has deposited on the ice sheet surface, it is subject to redistribution by the wind, and sublimation, densification, and metamorphism. These processes need to be well understood before the ice sheet mass balance input can be accurately assessed. At the same time, climate models can be used to estimate the precipitation over the ice sheet, but these must be physically based and tested against the measurements.

The Output Components (Ice Dynamics, Fluxes, Melt/Freeze, Calving)

The output term for the component technique is the ice flux across the downstream margin of the area under consideration (e.g., if considering the entire

Antarctic Ice Sheet, the coast). The flux is the product of the distance across the downstream margin, the mean ice thickness across the downstream margin, and the mean ice velocity through the margin. Thus we need detailed measurements of ice thickness and ice velocity. To understand the mass balance of the entire Antarctic Ice Sheet, we require these measurements in detail across the entire ice sheet. Of particular importance is the mass balance of the grounded ice, so we need to know the location of the grounding zone (the zone in which the ice begins to float, becoming separated from the land). This is not easy, given that it is covered by the ice (several hundreds of metres thick). New satellite remote sensing data have led to major advances in our current knowledge of the location of the grounding zone, especially in the important regions of fast glacier outflow (e.g., Rignot 2002), coastal ice flux, and inferred ice shelf bottom melting. From these data, we have learned that major changes are taking place at several specific locations in the Antarctic (e.g., Pine Island and Thwaites Glacier basins) on much shorter timescales than previously thought. If we assume the ice sheet is in balance (i.e., the snow accumulation is balanced by the flux) then, with knowledge of each of the other terms, we can calculate what the ice velocity distribution would be. This velocity is called the "balance velocity" and comparison of its values with actual measured values provides a good estimate of whether the ice sheet is in balance, growing, or shrinking. There have been several major advances in recent years towards more accurate estimation of ice sheet mass output. These have included continental-scale mapping of balance velocity and ice surface and bedrock topography (Bamber et al. 2000; Budd and Warner 1996; Lythe and Vaughan 2001) and observations and estimates of ice velocity on large outlet glaciers and Siple Coast ice streams (Rignot 2002).

The Integrated Technique

For the integrated technique, changes in the volume and mass of the ice sheets can be determined by satellite measurements of changes in ice-sheet surface elevation. Corrections are required, however, for the vertical motion of the underlying bed (due to height changes in the bed rock caused by compression due to the load of the ice above) and for variations in near-surface firn density (due to temperature, the accumulation itself). Changes in the bedrock are estimated from coupled models of the ice and lithosphere dynamics (Le Meur and Huybrechts 1996). In addition, measurements of changes in the Earth's gravity field, from observed perturbations to satellite orbits, can be related to changes in the mass of ice (Bentley and Wahr 1998).

The best currently available data of surface elevation change for the Antarctic Ice Sheet comes from satellite radar altimetry (most notably so far from the Earth Resources Satellites ERS-1 and ERS-2 for the period 1991–2001). New radar (ENVISAT and CryoSat) and laser altimeter (GLAS/ICESat) satellite missions will extend these data for another decade. ICESat and CryoSat will also provide information on surface elevation change with time in regions where the ice surface is changing the most (the fast-flowing outlet glaciers and ice margins). Recent results (Shepherd et al. 2002; Zwally et al. 2002) from analysis of ERS-1 and ERS-2 altimeter heights have provided the most accurate measurements so far of ice sheet mass balance (e.g., showing that the portion of the grounded ice sheet upstream of the Pine Island and Thwaites Glaciers has thinned by up to 30 cm yr^{-1} over the past decade).

Conclusion

One of the longest standing and most important problems in polar science is also the most challenging to understand. Despite several international programs over the past 50 years to examine the mass balance of the Antarctic Ice Sheet, the relationship between the large ice sheets and sea level change is still not completely understood, and we are still not certain whether the ice sheet is growing, shrinking or in balance. A recent assessment of Antarctic Ice Sheet mass balance studies (ISMASS Committee 2004) stated that "the 20th century Antarctic mass imbalance seems near to zero or slightly negative. The newly recognised importance of ice shelf melting now emphasises mechanisms that may offset the 21st century expected growth due to global warming."

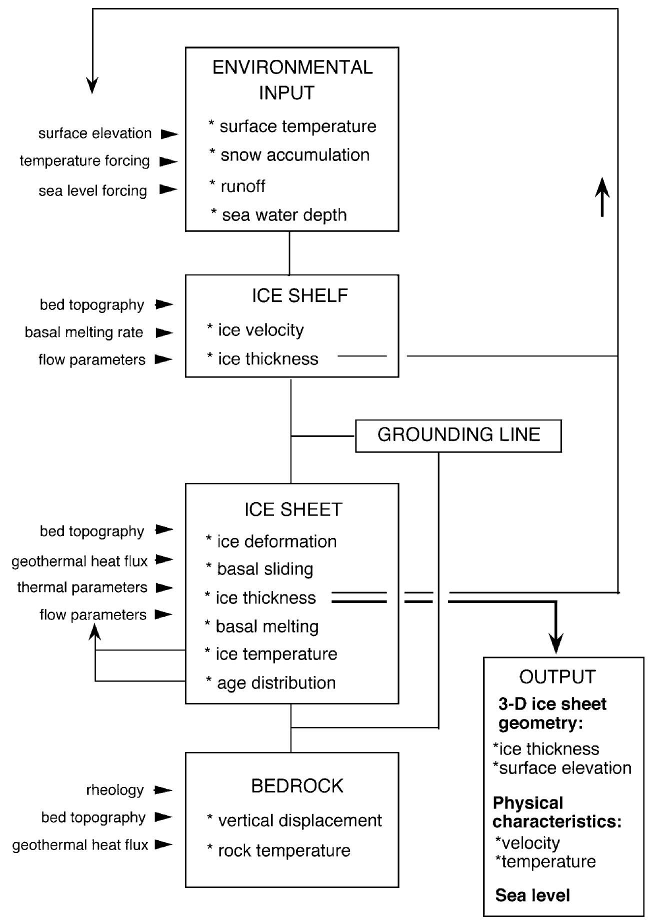
ICE SHEET MODELING

Ice sheet modeling underpins much of our understanding of the Antarctic Ice Sheet. A primary motivation for developing mathematical models of ice flow is to gain better insight of the key processes controlling ice-sheet behaviour and to predict the ice sheet's response to external forcing. Modeling necessarily implies a simplified description of reality, however analytical methods can only be used for the most simple problems. Therefore, ice-dynamic models use numerical methods to solve continuous equations on a numerical grid with the aid of a computer. Ice-flow models are commonly based on fundamental physical laws and assumptions thought to describe glacier flow.

Models can be separated into two categories, namely diagnostic and prognostic models. A diagnostic model describes a certain process while a prognostic model predicts how a quantity or process evolves with time. Diagnostic ice-sheet models often isolate a small part of the ice sheet in great detail or consider the physics of a specific process in a schematic way. They are useful to highlight the importance of certain mechanisms and provide insight in key processes governing ice flow. Prognostic models mostly predict the evolution of ice thickness and thus glacier geometry over time. Such models often attempt to be comprehensive in the number of processes taken into account, however sometimes at the expense of a rigorous consideration of the full details of a particular component.

A further distinction can be made on how models embody horizontal space: either they study the dynamics of selected one-dimensional flowlines within the ice sheet or they study the ice sheet in the full two-dimensional horizontal plane. The former type is often referred to as flowline or flowband model and the latter as planform model. Planform models often average processes over the vertical extent, in which case these models are referred to as two-dimensional planform or vertically integrated models. Otherwise they incorporate vertical processes explicitly. Examples of such vertical processes are ice temperature, stress, and velocity components, as well as ice crystal fabric and water content. Such models are called three-dimensional thermomechanical models and are at the top end of the class of ice-sheet models. They are able to describe the time-dependent flow and shape of real ice sheets, and are akin to general circulation models developed in other branches of climate science. Their development closely follows technical process in such fields as computer power, ice-core and sediment drilling, remote sensing, and geophysical dating techniques, which are both providing the required calculating means and the necessary data to feed and validate such models.



Structure of a comprehensive three-dimensional ice-sheet model applied to the Antarctic ice sheet. The inputs are given at the left-hand side. Prescribed environmental variables drive the model, which has ice shelves, grounded ice, and bed adjustment as major components. The position of the grounding line is not prescribed, but internally generated. Ice thickness feeds back on surface elevation, an important parameter for the calculation of the mass balance. The model essentially outputs the time-dependent ice-sheet geometry and the coupled temperature and velocity fields. (From Huybrechts 2004.)

Historically, planform time-dependent modeling of ice sheets largely stems from early work by Mahaffy (1976) and Jenssen (1977), extending on the pioneering "Derived Physical Characteristics of the Antarctic Ice Sheet" of W. F. Budd and colleagues at the Australian National Antarctic Research Expeditions published in 1971. These landmark studies introduced many concepts and techniques that are still used in glaciology today. The most important concept made use of the fact that the horizontal extent of an ice sheet is large compared with its thickness. In what became known as the shallow-ice approximation (Hutter 1983), longitudinal derivatives of stress, velocity, and temperature are assumed small compared to vertical derivatives. This greatly simplifies the numerical solution. Although the assumption is only fully satisfied over inland portions of continentally based ice, it has shown general applicability in large-scale ice-sheet modeling as long as surface slopes are evaluated over horizontal distances at least an order of magnitude greater than ice thickness.

The core of an ice-sheet model calculates how ice flows downhill in response to stresses set up by gravity. This ice flow results from internal deformation and from ice sliding over its bed where the basal temperature has reached the melting temperature and a lubricating water-saturated layer has formed. Whereas basal sliding depends to a large extent on the properties of the bed under the ice, internal deformation is the inherent manifestation of individual ice crystals subjected to stress. This deformation is reasonably well understood on the macro scale and can be reliably modelled taking into account Glen's flow law. That is an empirical relation derived from laboratory tests, which is most commonly used in ice flow modeling. It considers ice as a nonlinear viscoelastic fluid, relating strain rates to stresses raised mostly to the third power. The rate of deformation for a given stress also depends on the temperature of the ice and the fabric of the ice. The warmer the ice, the easier it deforms. For the temperature range encountered in the Antarctic Ice Sheet, three orders of magnitude are involved. In the flow law, this temperature effect is usually incorporated by adopting a temperature-dependent rate factor. If the ice temperature is calculated simultaneously with the velocity field, the flow is called thermomechanically coupled. In some instances, the ice has developed a strong fabric, with the majority of crystal axes aligned in one preferred direction, making the ice ‘‘soft’’ with respect to some stress and ‘‘hard’’ with respect to other stresses. Such fabric development may influence the strain for a given stress by an additional factor 3 to 10.

Because glacier flow is sufficiently slow that accelerations can be neglected, Newton’s second law of motion reduces to an equilibrium of forces. The action force making ice flow in the direction of decreasing surface elevation is the driving stress. This action is opposed by resistive forces acting at the boundaries of the ice mass. These boundaries include the glacier bed (basal drag), the lateral margins (lateral drag), and the up- and down-glacial ends (gradients in longitudinal stress). In interior portions of ice sheets, the force balance is essentially between the driving stress and basal drag as predicted by the shallow-ice approximation. In floating ice shelves, there is negligible basal friction and the driving stress is balanced by gradients in longitudinal stresses and by lateral drag. This makes the velocity calculation nonlocal as opposed to inland ice flow. In ice shelves, driving stress is balanced more broadly, so that modelling the behaviour at any point requires knowledge of all of the surrounding stresses affecting the ice mass. Lateral drag and longitudinal stress gradients also play an important role in the fast outlet glaciers and ice streams that are responsible for the bulk of the ice discharge towards the margin. As such they represent a transitional region between inland-ice and ice-shelf dynamics. Because of the low driving stresses in the downstream portions of such ice streams, much, if not all, of the differential flow between the ice surface and the bedrock is caused by either basal sliding or by deformation of a subglacial mud (till) layer. Fast-glacier conditions at the base are, however, poorly understood. Processes related to bed roughness, till rheology, and basal water pressure are all thought to be important elements, but a realistic basal boundary condition for use in numerical models has not yet been developed.

Based on these principles, the advent of bigger and faster computers has allowed elaborate numerical models of the Antarctic Ice Sheet to be constructed. At the heart of such a model is the simultaneous solution of two evolutionary equations for ice thickness and temperature, together with diagnostic representations of the ice velocity components. These express fundamental conservation laws for momentum, mass, and heat, supplemented with Glen’s flow law for polycrystalline ice deformation. The model solves the thermomechanically coupled equations for ice flow in three subdomains, namely the grounded ice sheet, the floating ice shelf, and a stress transition zone in between at the grounding line. The flow within the three subdomains is coupled through the continuity equation for ice thickness, from which the temporal evolution of ice sheet elevation and ice sheet extent can be calculated by applying a flotation criterion. The latter treatment allows for migration of the grounding line, separating the land-based ice from the surrounding ice shelf, in response to changes in climatic boundary conditions. The various subdomains reflect the two major traditions of ice-deformation modeling, evident in the very different physical conditions in ice shelves versus inland ice. An important difficulty in whole ice-sheet models lies with the coupling of grounded ice flow with floating ice flow and with modeling flow in complex regions such as ice streams, where the simplifying assumption that one shear stress largely dominates inland flow and one stretching stress largely dominates shelfy flow breaks down. Progress is being made in ice-flow models to combine the two traditions of ice-flow modeling in a more comprehensive fashion (e.g., Pattyn 2003; Payne et al. 2004). However, a full calculation of the complete stress distribution for whole-ice-sheet integrations over longer time periods is numerically not yet feasible.

Whole-ice-sheet modeling of the Antarctic Ice Sheet further involves simulation of surface mass fluxes (snow fall, wind drift, sublimation, melting followed by runoff or refreezing), sinking or rising of the underlying bedrock in response to changing ice load, heat transfer under the ice and into the bedrock affecting melting/frozen regions and the deformation rate of ice, interactions of ice shelves with the ocean, and more. Interaction with the atmosphere and the ocean in large-scale Antarctic Ice Sheet models is carried out by prescribing the climatic input, consisting of the surface mass balance (accumulation minus ablation, if any), the surface temperature, and the basal melting rate below the ice shelves. Changes in these fields are often heavily parametrized in terms of air or ocean temperature but can also be derived from calculations with atmosphere and ocean models. Models of this type are usually forced by time series of regional temperature changes (available from ice-core studies) and by the eustatic component of sea-level change, relative to present values.

Three-dimensional ice sheet models are typically implemented using finite-difference techniques on a regular grid of nodes in the two horizontal dimensions, and using a stretched coordinate system in the vertical. Horizontal grid resolutions are mostly in the range of 10 to 50 km with between 20 and 100 layers in the vertical, concentrated towards the base where the bulk of the deformation takes place. In finite-difference models, gradients of continuous functions are obtained by dividing the values of the parameter at grid points by the distance between the grid points. Finite element implementations also exist but these are often restricted to a smaller domain. An advantage of the finite element method is that the element size can be reduced in areas of high gradients and increased in areas of low gradients. Furthermore, element shapes can be adjusted to conform to boundaries that would otherwise be awkward to model with rectangular elements. However, changing spatial patterns over time and varying ice-sheet domains have proven to be a challenge to the popularity of finite-element methods in glaciological modeling. Recent Antarctic model studies have benefited from much improved compilations of crucial input data such as bed elevation, surface elevation, and ice thickness that became available on high-resolution grids from the BEDMAP project (Lythe et al. 2001).

Three-dimensional models of the Antarctic Ice Sheet have been used to examine mechanisms and thresholds of ice-sheet inception during the Tertiary (DeConto and Pollard 2003), the expansion and contraction of the Antarctic Ice Sheet during the glacial-interglacial cycles (Huybrechts 2002), and the likely effects of greenhouse-induced polar warming (Huybrechts et al. 2004). In this context, the key interactions being investigated are between the effects of a change in climate on the accumulation and ablation fields and the ice sheet's response in terms of changed geometry and flow, including the ice sheet's contribution to the worldwide sea level stand. Related work considers the Antarctic Ice Sheets as a boundary condition for other components of the Earth's geophysical system, providing changes in surface loading for isostasy and gravity models, or providing changes in freshwater fluxes for ocean models. Thermomechanical ice-sheet models are also being used to investigate the potential for internally generated flow instabilites, especially concerning the West Antarctic Ice Sheet, or explain recently detected accelerations of outlet glaciers taking into account higher-order stress calculations (Payne et al. 2004). The general appreciation is that current models available to the community perform best for the largely continental-based East Antarctic Ice Sheet; however, many challenges pertain to the modelling of the marine-based West Antarctic Ice Sheet.

ICE SHELVES

General Characteristics

Ice shelves are the floating parts of an ice sheet. They form at the margins where the ice sheet becomes thin enough to float free of a bed that lies below sea level, allowing seawater to circulate beneath the ice. Ice-shelf-like features also form in the interior of ice sheets where the ice floats on subglacial lakes. Dynamically, ice shelves are distinct from other parts of the ice sheet in that they rest on a frictionless substrate, so that ice motion is controlled only by the degree of lateral confinement.

Antarctica contains most of the ice shelves that currently exist on Earth. They range in thickness from less than 100 m to over 2000 m and individually cover areas of up to 0.5 million km^2. Although their combined area is only 13% of that of the grounded ice sheet, around 80% of the grounded ice drains into the ice shelves before being lost to the oceans. Ice shelves thus play a critical role in the overall ice budget of Antarctica.

Elsewhere, especially in Greenland, glaciers that terminate at the coast often have short tongues of floating ice. Although technically ice shelves, they are normally too small to be attributed a name distinct from that of the parent glacier. The larger ice shelves of Antarctica are different in that they are fed by multiple glaciers, the outflows from which coalesce to form a distinct glaciological feature.

Ice floating on water tends to spread horizontally and thin, in a manner analogous to that of a drop of oil, only much slower owing to the much higher viscosity of ice. This process gives rise to the typical ice shelf profile with thick ice at the inland margin becoming progressively thinner with distance downstream (i.e., with time afloat). The horizontal spread of the ice also means that the velocity of the ice increases with distance downstream with speeds reaching kilometres per year at the ice fronts. The forces that drive the spreading are proportional to ice thickness, so the thicker the ice the more rapidly it tends to thin. Over time this process evens out small-scale thickness variations leading to a progressively smoother upper surface. This lack of surface topography is a characteristic feature of ice shelves.

Most ice shelves are confined within embayments, or contain regions where the ice runs aground on the seabed. Horizontal spreading of the ice is then restricted in one or more directions and the rate of thinning is reduced. Such confinement is thought to be critical to the stability of the larger ice shelves. Reduction in the amount of confinement, caused for example by thinning of the ice reducing the area of contact with the seabed, could lead to breakup of the ice shelves.

Ice shelves are fed by the flow of ice from grounded parts of the ice sheet and by snowfall on the upper surface. In some places accumulation of mass also occurs at the lower surface, through the freezing on of seawater. Mass loss occurs predominantly by the production of icebergs, a process known as calving, and by the melting of ice from the underside. Calving from ice shelves tends to produce massive tabular icebergs, the largest of which can exceed 10,000 km^2 in area. More rarely, some mass loss occurs by surface melting or sublimation.

As ice shelves are already afloat, the direct contribution to global sea level rise that would be associated with their decay or disintegration is small. It is nonzero because the freshening caused by melting of the ice would lead to a small expansion of the ocean, giving a sea level rise of around 3 cm if all the water in the ice shelves were distributed globally within a layer of seawater 300 m thick. However, a confined ice shelf provides a resistive force that is felt by the ice streams that discharge grounded ice into it. Removal of an ice shelf can thus cause accelerated flow across the grounding line, at least temporarily while the ice streams adjust to the new conditions. The likely magnitude and duration of such an adjustment is still the subject of debate. Being in contact with both the atmosphere above and the ocean below, ice shelves are seen as sensitive indicators of climate change in Antarctica.

At the time of the last glacial maximum (LGM), around 18,000 years ago, the Antarctic Ice Sheet expanded to cover most of the continental shelf. The current configuration of ice shelves around Antarctica is the product of thinning and retreat of the ice sheet as the Earth's climate entered the current interglacial stage and temperatures and sea level rose worldwide. It is an open question as to whether the ice sheet and surrounding shelves have completed their adjustment to this change in climate.

Ice Shelf Research

The first sighting of one of Antarctica's vast ice shelves was made in 1841, when James Clark Ross discovered the ice shelf that now bears his name. He made water depth soundings along part of the ice front, and deduced that the ice must be floating. The generally flat and crevasse-free surface of the ice shelves meant that they became the avenues by which many of the exploratory expeditions of the early twentieth century accessed the interior of the ice sheet. The ice shelves were hence the subjects of much of the early glaciological work in Antarctica, which started during the exploratory era and culminated in the International Geophysical Year of 1957–1958. Determining the thickness of the ice and underlying water layer were the major goals. Measurements of ice shelf motion were hampered by the complete lack of fixed reference points away from the ice shelf margins.

The 1950s were a period of major advance in the understanding of ice flow. Because of their relatively simple dynamics, with frictionless upper and lower surfaces, ice shelves became test-beds for the new theories of ice deformation. Studies undertaken in Antarctica during the 1960s and early 1970s demonstrated that the behaviour of large ice masses was consistent with an ice flow law that had been developed from laboratory scale observations.

In the late 1960s the advent of satellite navigation techniques revolutionised the study of Antarctic ice shelves. The motion of points in the interior of even the largest ice shelves could now be measured with high accuracy. A major survey of the Ross Ice Shelf was undertaken during the 1970s, with a variety of measurements being made at 200 sites evenly distributed over the ice shelf. The new data on ice motion and the rapid growth of computer power stimulated the development of numerical models of ice shelf flow that still underpin our understanding of ice shelf behaviour.

Concurrent with the 1970s survey, a hole was drilled through the Ross Ice Shelf to access the ocean beneath at a point 500 km in from the ice front. These were the first observations made deep within the cavity beneath a large ice shelf and indicated that an active circulation must flush seawater in and out. Early theories of the ocean circulation and of the resultant melting and freezing at the ice shelf base were advanced during the late 1970s and early 1980s. Most of the work that has been undertaken on Antarctic ice shelves during the 1990s and into the twenty-first century has been aimed at improving our knowledge of these processes and their role in determining both the mass balance of the ice shelves and the properties of the underlying ocean. The drilling of access holes, particularly through the Filchner-Ronne Ice Shelf and more recently the Amery Ice Shelf, ship-based surveys along the ice fronts and the application of increasingly sophisticated computer models of the ocean beneath the ice shelves have been at the heart of recent advances in understanding.

Developments in satellite remote sensing technology have gradually opened up new techniques for ice shelf research. Early imagery was used to track the motion of ice fronts and large features visible on the ice shelves. The initial slow retreat and eventual rapid disintegration of Wordie and parts of Larsen Ice Shelf were observed in this way. Increasingly accurate radar altimeters, used to measure the surface elevation of the ice, have shown that many ice shelves on the Antarctic Peninsula and in the Amundsen Sea are thinning at rates of the order of 1 m yr^{-1}. Satellites carrying advanced radar can detect ice motion, and accelerations in the flow of ice shelves in the Amundsen Sea have been observed. Understanding the causes and consequences of these changes is one of the major goals of current ice shelf research. Although it is believed that atmospheric warming has been responsible for changes in the Antarctic Peninsula, the causes of the changes in the Amundsen Sea are unknown. They could reflect continuing retreat of the ice sheet following the LGM, or could be driven by changes in the ocean leading to increased basal melting.

Interaction with the Ocean

Their strong interaction with the seawater beneath them is a defining feature of ice shelves. The fundamental cause of this interaction is the pressure dependence of the freezing point of seawater. The deeper one goes in the ocean, the higher the pressure and the lower the freezing point of the water. Seawater that is cooled through contact with the atmosphere cannot be made colder than about –1.9°C. At this temperature ice begins to form. However, the temperature at which the phase change occurs falls by about 0.75°C for every 1000 m of water depth. Seawater that is cooled through contact with the base of an ice shelf can therefore attain a temperature lower than the surface freezing point. Water that has such a property is referred to as ice shelf water (ISW).

When seawater that is warmer than its depth-dependent freezing point comes into contact with the base of an ice shelf, it gives up some of its heat to melt ice. This is true even when the temperature of the salty water is lower than the melting point of the pure ice making up the ice shelf. In this case the process is technically one of dissolution rather than melting. Ice dissolution is the mechanism by which salt sprinkled on roads can clear them of ice even when the air temperature remains well below zero. Melting (or dissolving) the ice shelf freshens the seawater, lowering its density.

Water flowing into the cavity beneath an ice shelf cannot be colder than its surface freezing point, unless it has been in prior contact with another ice shelf. The water is therefore warmer than its freezing point at depth. When it contacts the ice shelf base the ice melts. The fresher, less dense ISW rises towards the surface, constrained by the sloping ice shelf base. As the ISW rises melting continues as long as the water temperature remains above the freezing point. However, as the water ascends, the falling pressure means that its freezing point rises. Eventually the ISW temperature drops below the rising freezing point and melting gives way to freezing at the ice shelf base. The ice that forms is virtually pure and the salt left behind in the ISW increases its density. This process continues until the ISW is no longer lighter than the surrounding water and thus ceases its rise along the ice shelf base. The overall result is an overturning circulation that melts ice from the deepest parts of the ice shelf base and freezes ice onto the shallower parts. The whole system is sometimes referred to as an "ice pump." Where the ice shelves are very thick at their inland margins, melting and freezing rates of metres of ice per year result.

Around most of the Antarctic coastline the winters are sufficiently cold that all the waters close to the ice shelves are cooled to the surface freezing point. Thus, further cooling beneath an ice shelf inevitably produces ISW, as described previously. However, along the coasts of the Amundsen and Bellingshausen seas, subsurface water temperatures can exceed 1°C throughout the year. Melt rates in excess of 10 m yr^{-1} can result, and there is no freezing beneath the ice shelves, because the water is never cooled sufficiently to form ISW. The warm water is a derivative of Circumpolar Deep Water (CDW), and understanding the reasons for its presence on the continental shelf is a critical step in defining the cause of the ice shelf thinning in the Amundsen Sea. If CDW were to gain access to the continental shelves in other regions we would see major thinning of Antarctica's ice shelves. Reduction in the amount of ISW produced would also have consequences for the global ocean circulation, since ISW is one ingredient in the densest form of Antarctic Bottom Water (AABW). AABW is found at the bottom of the ocean throughout most of the world, and its formation around Antarctica is one component of the global overturning circulation that regulates the Earth's climate.

ICEBERGS

An iceberg is a floating mass of freshwater ice that has broken from the seaward end of a glacier or ice shelf. Icebergs are found in the oceans surrounding Antarctica, in the seas of the Arctic and sub-Arctic, and in fjords and lakes fed by glaciers. In the Antarctic, typical newly calved icebergs are tabular, with diameters of order kilometres, thicknesses of 200–300 metres and freeboards of 30–50 metres, giving a mass of order a billion tons.

Origin

Most Antarctic icebergs calve from floating ice shelves, which occupy one-third of the Antarctic coastline. The shelves are fed at their landward ends by the Antarctic Ice Sheet, and their seaward fronts are afloat. Under the pressure of ice squeezing outwards from the centre of the continent, ice shelves move seaward at 0.3–2.6 kilometres per year. Their fronts are exposed to stresses from currents, tides, ocean swell in summer, and the pressure of drifting pack ice in winter. Eventually a fracture occurs, often along an existing line of weakness such as a crevasse, to produce a freely floating iceberg. Some apparently minor ice shelves are prolific generators of icebergs because of their rapid velocity (e.g., the small Amery Ice Shelf drains one-eighth of the Antarctic Ice Sheet and produces 31 cubic kilometres of iceberg volume annually).

Direct observations of iceberg calving are rare. The calving of a large iceberg has been observed immediately after the ice front had been hit by another iceberg, implying that the collision caused the calving. A special mechanism occurs in the case of glacier tongues, long narrow floating ice tongues which are the output of especially fast-flowing glaciers. Here calving can be caused by long ocean waves which cause the tongue to oscillate until it fails in flexure. The recent mass breakout of icebergs from Antarctic Peninsula ice shelves, ascribed to global warming, is thought to occur because surface meltwater in summer fills crevasses at the top surface and produces a tensile stress at the crevasse base.

Some Antarctic icebergs calve from glaciers which originate in coastal mountains, such as those parts of the Transantarctic Mountains which form the Antarctic Peninsula or face the Ross Sea coast. Because such glaciers are narrow, fast-flowing, and riven with crevasses, the icebergs are usually smaller than bergs of ice shelf origin and are more randomly shaped.

Structure

A new Antarctic tabular iceberg has the same structure and physical properties as its parent ice shelf. This implies that the freeboard of the iceberg, the above-water part, is not actually ice at all but rather compressed snow. The ice shelf has the same layered structure as the continental ice sheet from which it was squeezed out, with recently fallen snow on top, and older annual layers beneath. Each layer is compressed by the snow above it, so that density increases with depth. A typical density profile through an ice shelf or iceberg shows that at the top, where the density might be only 400 kg per cubic metre (pure ice has a density of 920), there is free passage for air or water through the spaces between the crystal grains. When the density reaches 800 kg per cubic metre, deeper in the berg, the air channels close off and turn into isolated bubbles. At this point the material becomes truly "ice," as opposed to the material above, which is called firn. Ice begins some 40–60 m below the surface of the iceberg, which corresponds approximately to the waterline and to about 150–200 years of snow deposition. Further increases in density towards the iceberg bottom are associated with the compression of the air bubbles; pressures within bubbles in glacial ice have been measured at 10–15 atmospheres, with the bubbles tending to be spherical or ellipsoidal, of diameter 0.33–0.49 mm, and with mean diameter decreasing with increasing depth.

The upper part of a recently calved berg is significantly warmer than its parent ice shelf. As soon as the berg drifts into more temperate regions, especially when it drifts free of the surrounding pack ice cover, it begins melting at its upper surface. The meltwater percolates through the permeable uppermost 40–60 m, refreezing at depth and giving up its latent heat. By this means the above-water part of a tabular iceberg is brought relatively quickly to temperatures close to the melting point. With its warm temperature and low density, this part of the berg has little strength and is easily eroded away. The main mechanical strength of the iceberg resides in the "cold core" below sea level, where very low temperatures of –15°C to –20°C remain, and where latent heat transfer through percolation and refreezing is impossible.

Sizes and Shapes

Antarctic tabular icebergs can be extremely large. One measuring 180 km square with a freeboard of 30–40 m was seen off Clarence Island by the whalecatcher *Odd I* in 1927; though it was the largest reliably observed at the time, it has been eclipsed by others, including the 2000 calving of B-15, accurately observed via satellite. Recently many giant icebergs have been seen in the Antarctic, and ascribed to climate change. It is true that the Antarctic Peninsula has warmed significantly in recent years (by 2.5°C since the 1950s), and that, apparently as a consequence, three of its ice shelves, the Wordie and Wilkins on the west side and the Larsen on the east, have been disintegrating, emitting large numbers of icebergs. Each retreat of the Larsen Ice Shelf since 2000 involved the release of a vast area of shelf ice in the form of giant icebergs. A 2002 breakout involved 3250 km^2 of shelf lost in 35 days.

However, the remainder of the Antarctic is not warming at present, and emissions of large icebergs are sporadic events that are probably no more frequent than in the past but are now more easily detected by satellite. For example, a giant berg that approached the coast of Argentina in November 1999 was iceberg B-10A (labelling system of Joint Ice Center, Suitland, Maryland), of dimensions 38 × 77 km and a reported freeboard of 90 m. It calved from the Thwaites Glacier in the Amundsen Sea and spent long periods aground; in 1995 it broke into two.

A decade earlier, two giant iceberg events occurred on opposite sides of the Antarctic. Iceberg B-9 calved from the Ross Ice Shelf in 1987 between the Bay of Whales and King Edward VII Peninsula, destroying the Bay of Whales (used by Amundsen as a base in 1910–1912) as a feature of the Ross Ice Shelf front. At calving it was 154 km long (the second longest iceberg ever) and 35 km wide with an area of 4750 km^2. The ice shelf front was advancing at 0.84 km per year. About twenty-four other large icebergs were produced in this event. The average thickness of the area of shelf that calved was 230 m, giving a volume of 1100 km^3 for B-9, equivalent to an average year's calving from the entire Antarctic coast, and equal to about 0.6% of the volume of the Ross Ice Shelf. The berg remained in the eastern Ross Sea region for 2 years, moving mainly with the depth-integrated current. In the Weddell Sea, two independent calving events occurred in 1986. On the Larsen Ice Shelf a 95 $\times$ 95 km section broke away in January–March 1986 followed by a 55 $\times$ 50 km section in July. On the Filchner Ice Shelf a 90 $\times$ 210 km area broke out in June, carrying with it the Russian Druzhnaya research station. The Filchner icebergs remained in place for some time after calving, but the Larsen icebergs quickly emerged into the Southern Ocean east of Clarence Island.

In the ice-free Southern Ocean, surveys of iceberg diameters show that most bergs are of diameter 300–500 m, with few exceeding 1 km. Stability calculations lead to the conclusion that wave-induced flexure breaks down most larger tabular bergs to this range of sizes, leaving a few exceptionally large bergs intact.

Antarctic bergs are usually tabular at the time of calving (although domed or concave, depending on the local shape of the ice shelf), but evolve via further calving to tilted shapes, or by erosion of the above-water part to a variety of more random shapes.

Erosion and Melting

After an Antarctic tabular iceberg emerges into the open ocean, it has little remaining strength above the waterline, which becomes subject to wave action. The high level of turbulence along the waterline increases heat transport into the ice and preferentially melts out a wave cut that can penetrate for several metres into the berg, such that the snow and firn above it collapse. At the same time the turbulence level is enhanced around existing irregularities in the berg, such as cracks and crevasses. Waves eat their way into these, and turn cracks into caves whose unsupported roofs may also collapse. Through these processes a berg in the open sea leaves a trail of broken-off fragments, called growlers if they are small and bergy bits if they are larger (according to World Meteorological Organization definitions, a growler is the size of a grand piano while a bergy bit is the size of a small house). Eventually through these inroads the iceberg may evolve into a drydock or pinnacled berg, composed of apparently independent elements that are in fact joined together below the waterline. Such a berg may look like a prehistoric stone circle, with shallow water in the centre.

Apart from losses due to erosion, pure melt also occurs from the sidewalls and bottom. The melt rate depends on the salinity and temperature profiles of the water column as well as the relative velocity between the berg and the near-surface water. Most estimates of melt rate are based on tank measurements of the melt of vertical ice walls. A variety of effects are seen, because of the cooling and dilution that occur when ice melts into salt water. The molecular diffusivity of salt is much less than that of heat, so diluted water remains near the wall while the cooling diffuses further from the ice. In unstratified water this causes a bidirectional flow, with a horizontal flow inwards towards the wall, changing into an upwelling flow directly against the wall and, at greater depths, a downward flow some distance from the wall. With a salinity gradient, however, a series of discrete steps can be produced, each of constant temperature and salinity, but with temperature decreasing and salinity increasing with depth. The slight inclination of the step boundaries to the horizontal results in a net upwelling as well as a flow of meltwater away from the berg. In the field, this "staircase structure" has been observed in measurements made close to the ice front of the Erebus Glacier Tongue, but in open water turbulence tends to destroy the structure.

An eroded berg may capsize due to reduced stability. For an Antarctic berg this is uncommon, although tiltmeter measurements show that some long narrow bergs roll with a very long period, implying marginal stability. In most cases an eroded Antarctic berg settles into a new orientation, tilted to some extent and thus exposing a new waterline for wave erosion. Large tabular icebergs also flex under the influence of long ocean swell, and in major storms may break up through flexural failure; the subunits have a bigger overall immersed surface area, and so melt more rapidly.

Distribution and Drift Trajectories

Freshly calved icebergs usually move westward initially, in the Antarctic Coastal Current. They may run aground and remain aground for years before moving on. Once the berg breaks away from the coast it comes under the influence of the Antarctic Circumpolar Current or West Wind Drift, the great eastward flowing current system that circles the globe in the Southern Ocean. Driven by wind and current the iceberg's track becomes easterly, but the Coriolis force due to the Earth's rotation also gives it a northward component. It is found that the breakaway from the coast tends to occur at four well-defined longitudes or "retroflection zones," situated in the Weddell Sea, east of the Kerguelen Plateau at 90° E, west of the Balleny Islands at 150° E, and in the northeastern Ross Sea. These are related to the partial division of the water south of the Antarctic Circumpolar Current into gyres (circulating current systems) such as the Weddell and Ross Sea gyres.

The berg's long northeasterly voyage can take it completely around the world, moving it far to the north of the Antarctic sea ice limit and even to the north of the Antarctic Polar Front. It is preserved by its high heat capacity, but it eventually reaches a low enough latitude to break up and melt. Under extreme conditions (e.g., if caught in a cold eddy), an iceberg may reach an unusually low latitude; the lowest recorded was 26°30′ S, 25°40′ W, off Brazil, while another low-latitude Atlantic sighting was in 1828, at 35°50′ S, 18°05′ E, where clusters of bergs of 30 m freeboard were observed.

Much work has gone into the modelling of iceberg drift, to derive drift velocity under known wind and current. An iceberg is acted upon by the frictional drag of the wind on its smooth surfaces (skin friction drag) and protuberances (form drag). The current acts upon its immersed surfaces, with the force changing direction with increasing depth (the so-called Ekman spiral). A large factor is the Coriolis force, which diverts icebergs to the left of their track in the Southern Hemisphere. This force is relatively stronger on icebergs than on sea ice (because icebergs have a larger mass per unit of sea surface area), so icebergs usually move more to the left of the wind than sea ice, typically some 40°–50° to the left, at about 3% of the wind speed. Short-term motions can seem quite bizarre. For instance, if a wind suddenly arises, a berg will initially describe loops (called inertial loops) before settling to a steady velocity.

Iceberg Scour and Sediment Transport

Just as sea ice can scour the seabed in shallow water, so an iceberg can plough a furrow several metres deep when it runs aground. Such scour marks have been known in the Labrador Sea and Grand Banks since the early 1970s, and in 1976 the first Antarctic marks were discovered in 16° W off the Dronning Maud Land coast of the eastern Weddell Sea. Later observations were made off Wilkes Land and Cape Hallett at the eastern entrance to the Ross Sea. Evidence indicates that long furrows are made when an iceberg is driven by sea ice, while freely floating bergs make only a short scour mark or a single depression. Apart from simple furrows, "washboard" patterns occur, created when a tabular berg runs aground on a wide front and is then carried forward by tilting and ploughing on successive tides. Circular depressions have also been seen, thought to be made when an irregular iceberg touches the bottom with a small "foot" and then swings to and fro in the current like a leaf in the wind. Such movement of a berg was actually observed off Cape Hallett. Grounding bergs have a deleterious effect on the seabed ecosystem, often wiping the seabed clear of all life.

Both icebergs and pack ice transport sediment in the form of pebbles, cobbles, boulders, and finer material, and even plant and animal life, thousands of miles from their source area. Antarctic bergs may carry stones and dirt on their underside, lifted from the glacier bed and later deposited out at sea as the berg melts; it is possible that most basal debris is melted off under the ice shelves. The presence of ice-rafted debris (IRD) in seabed sediment cores is an indicator that icebergs or sea ice occurred in the ocean at that location in a known era (given by the depth in the sediment at which the debris is found), and so is valuable as a way of mapping the distribution of icebergs, and thus of cold surface water, in past epochs such as glacial periods. The type of rock in the debris can also be used to identify the source region of the iceberg that dropped it.

It is ice-rafted plant life that gives the occasional exotic colour to an iceberg. Bergs are usually white (the colour of snow or bubbly ice) or blue (the colour of glacial ice, which is relatively bubble-free). A few deep green icebergs are seen in the Antarctic; it is believed that these are formed by the freezing of seawater rich in organic matter onto the bottoms of the ice shelves from which the icebergs later calved.

Climatic Role

Apart from local effects such as the production of fog, icebergs have two potential climatic roles. One is the effect of iceberg production on the mass balance of the parent ice sheets, and the other is the effect of their melt on the ocean.

The volume of the Antarctic Ice Sheet is 28 million km^3, which represents 70% of the global stock of fresh water, including groundwater. The mass balance is maintained by gain from snowfall balanced by loss from melting under ice shelves and calving of icebergs; contributions from summer runoff and from surface sublimation are negligible. Estimates of annual snowfall over the Antarctic continent are about 2000 km^3, so if the Antarctic Ice Sheet is in neutral mass balance the iceberg flux must be no greater than this value. Estimates of iceberg flux do start at this value, but some run much higher. Such fluxes, while huge, are less than the flow rate of the Amazon River (5700 km^3 per year). It is significant that the annual loss of ice from the ice sheet amounts to only one ten-thousandth of its mass, so that it constitutes an enormous passive reservoir. Global warming could lead to a greater rate of loss from this reservoir by iceberg calving and ice shelf melting, which would make an increased contribution to global sea level rise. At present the retreat of small subpolar and mountain glaciers is believed to contribute about 50% to the rate of rise, the rest being due to thermal expansion as the ocean warms.

Another effect of iceberg melt upon the ocean is freshening. The total Antarctic melt adds 0.1 m of fresh water per year to the surface water south of the Convergence. This dilution, if averaged over a mixed layer 100–200 m deep, amounts to 0.015–0.03 parts per thousand of salt. Melting icebergs thus make a small but not negligible contribution to maintaining the Southern Ocean pycnocline (the density boundary separating low-salinity surface water from higher-salinity deeper water), and to keeping surface salinity in the Southern Ocean to its observed low value of 34 parts per thousand or below in summer. If iceberg flux were to increase significantly due to global warming, this contribution would itself increase, and the Southern Ocean would become more strongly stratified.

An annual production of 1000 km^3 of Antarctic iceberg ice is about one-tenth of the annual production of Antarctic sea ice. Icebergs therefore make up a not insignificant fraction of the total volume of floating ice in the Antarctic. Sea ice has a neutral overall effect on ocean salinity, but an important differential effect, in that it increases ocean salinity where it forms (often near the coast), encouraging convection and bottom water formation, and decreases ocean salinity where it melts (often much further north in the Southern Ocean). Icebergs, on the other hand, always exert a stabilising effect on the water column, but only when they melt, which tends to be at lower latitudes rather than near the Antarctic coast where deep-water formation takes place.

Iceberg Detection and Destruction

Icebergs in the open sea produce squealing, popping, and creaking sounds due to mechanical stresses and cracking, which can be heard underwater up to 2 km away. In summer, bergs produce a high-pitched hissing sound called "bergy seltzer," due to the release of high-pressure air bubbles from the ice as it melts in the warmer water. In principle, therefore, icebergs can be detected by sonar. However, commercial ships rely on visual observation or radar. A decaying iceberg poses an additional danger to shipping because of its trail of growlers and bergy bits. Although small in size, they have masses (up to 120 tonnes for growlers; up to 5400 tonnes for bergy bits) which are capable of damaging or sinking ships. Furthermore, as they drop into the sea they often roll over, losing their snow layers to leave a smooth surface of wetted ice that offers a low radar cross-section in a heavy sea and that is visually hard to discriminate against foam and whitecaps. It is often the undetected growler or bergy bit that sinks a ship while the larger parent berg is detected and avoided.

Icebergs were responsible for the disappearance of many ships off Cape Horn during the windjammer era, and a new threat exists today. Large container ships, unable or unwilling to use the Panama Canal, can reach high southern latitudes on great circle transits from Australasia to Cape Horn. No special measures exist to protect such vessels, unlike in the North Atlantic where the International Ice Patrol was established in 1913 following the loss of the *Titanic* in April 1912. It keeps a continuous plot of the known or estimated location of every berg in the danger area, transmitted twice a day to shipping. Ships and aircraft are used for detection, aided today by satellite image interpretation, especially synthetic aperture radar (SAR), which combines high resolution (of order 20 m, capable of resolving most bergs) with day-and-night weather-independent capability. The latest generation of SAR, such as the Canadian Radarsat and the European Envisat, survey wide swaths (up to 450 km) in every orbit and so are capable of surveying the entire danger zone once per day.

During the 1950s–1960s, the US Coast Guard attempted to fragment dangerous icebergs. All methods were unsuccessful, especially explosives, since ice and snow are so effective at absorbing mechanical shock that the yield of fragmented ice was often no greater than the mass of explosive used. Recently it was found that very cold ice, such as in the lower part of an iceberg, can be fragmented successfully by the use of slow-burning explosives such as thermit, which can be implanted by drilling, itself a dangerous process because of the possibility of capsize.

Iceberg Utilisation

The immense amount of fresh water in an iceberg has inspired consideration of its use as a water source. Captain James Cook and other Southern Ocean explorers recovered iceberg ice directly for their ships; Cook stated that "this is the most expeditious way of Watering I ever met with." However, the earliest use of natural ice was as a refrigerant, before the days of industrial refrigeration. The Romans cut ice from Alpine lakes and transported it in straw to Rome, but ice use became more important in the nineteenth century in Europe and North America with their growing city populations and the need to transport and preserve perishable food like fish. Ice was cut from lakes, or exported from glaciers in Norway and Alaska by ship. In Alaska this continued until the 1950s. The first recorded instance of iceberg towing was the export of small icebergs from Laguna San Rafael in southern Chile to Valparaiso and Callao as part of a refrigerating ice supply business.

The idea of using iceberg ice for drinking or irrigation began with a suggestion by John D. Isaacs of Scripps Institution of Oceanography in 1949. He sought to relieve California's water shortage by towing icebergs from Alaska or Antarctica. No suitable technology existed, but during the 1960s iceberg towing evolved in the Labrador Sea, for protecting oil rigs. It was found that a floating bridle around the berg, attached to several tugs, was feasible and safe. This inspired a revival of Isaacs' idea in the form of further studies and two major conferences, at Ames, Iowa, in 1977 and in Cambridge, UK, in 1980. A stimulant was governmental interest by Saudi Arabia, which sought an alternative to expensive desalination.

The conclusions were that unprotected icebergs melt when towed through equatorial waters, and no viable insulation method existed. Therefore the destination must be in the same hemisphere as the source. The ideal site should have cold surface water and favourable currents along the towing route; deep water close inshore to permit nearshore mooring; and a serious local need for irrigation or drinking water. For Antarctic bergs this suggests three regions:

1. The Atacama Desert coast of northern Chile and southern Peru, with the cold northward-flowing Humboldt Current and a narrow shelf (less than 20 km in places). Irrigation could enormously increase agricultural productivity, as achieved in the past by the Mochicas.
2. The Namib Desert region of southern Angola, Namibia, and South Africa. Here there is cold upwelling near shore, a narrow shelf, and a coastal desert, the so-called Skeleton Coast. Suitable icebergs would come from the Weddell sector.
3. Western Australia and the Great Australian Bight. This is close to the Antarctic Circumpolar Current; there are places such as Rottnest Island off Perth where deep water reaches close inshore, and there is a need for drinking water for the expanding cities of Perth and Fremantle, which depend on groundwater. Suitable icebergs might be found near the Amery Ice Shelf.

The technology of finding, harnessing, and towing an iceberg involves many serious problems. For each destination there is an optimum source zone that involves minimal towing times. Icebergs that are already far north are usually in an advanced stage of melt, so younger bergs might be preferred. Even the most powerful tugs only modify the iceberg's drift by adding 1–2 knots of towing speed, so understanding of iceberg dynamics is essential in determining source area and towing strategy. Icebergs can be located by SAR imagery, so it will be possible to inspect several bergs until a suitable one is found. Towing will be by a number of powerful tugs attached to a floating bridle, with some danger of berg fracture under swell action. Assuming that the iceberg can be delivered to a coastal site, it must be anchored offshore and then reduced rapidly to pieces small enough to be towed ashore, melted, and processed.

The final stage is to make use of the iceberg fragments. Here an attractive idea is to make use of the latent heat of fusion of ice (330 kilojoules per kilogramme) to derive energy from the iceberg as well as water. The concept is called Icetec or ITEC, and a plan was developed for Saldanha Bay in South Africa. The iceberg fragments are towed into a storage basin created in the inner bay and separated from the main bay by a lock. Here the fragments melt, and the melt water is fed into an ammonia heat exchanger as used in ocean thermal energy conversion (OTEC) schemes. The warm Saldanha Bay water (20°C) fed into the seaward side evaporates the ammonia, which drives a turbine and is then condensed by iceberg meltwater. The warmed meltwater is fed back to the iceberg pool to enhance the melt rate of the bergs and to be cooled back to near freezing point. Some of the meltwater is drawn off for drinking or irrigation, sufficient to keep a constant level of water in the basin. It was estimated that the value of the electrical power is twice that of the water. Such a scheme could feed an agricultural complex with settlement and industry attached, or the electricity could be used to pump water to a more distant spot for use as drinking water. The idea is risky and requires huge initial investment, so no implementation has yet occurred. There are also international legal questions surrounding the free use of Antarctic icebergs.

ICESAT

ICESat (Ice, Cloud, and Land Elevation Satellite) is a NASA Earth observation satellite launched in January 2003. The primary purpose of ICESat is to determine the mass balance of the Greenland and Antarctic Ice Sheets and floating ice shelves by measuring small changes in surface elevation with an accuracy better than 1 cm/year averaged over 100 km by 100 km areas. Changes in the ice mass, which are caused by differences between the mass input from snow accumulation and the mass output from iceberg discharge and melting, are calculated from the measured elevation changes. ICESat data is being used to determine the present-day mass balance of the Antarctic Ice Sheet and its contribution to global sea-level rise, and to study the relationships between ice changes and changes in polar precipitation, temperature, cloudiness, and other factors. Comprehensive satellite measurements are needed because the ice balance and the processes that influence mass changes undergo interannual and decadal variations, as well as longer-term changes.

Other scientific objectives of ICESat include measurement of sea-ice freeboard height for estimation of sea ice thickness, global measurement of cloud heights, and the vertical structure of clouds and aerosols; precise measurement of land topography and vegetation canopy height, and measurement of surface reflectivity.

The only instrument on ICESat is the Geoscience Laser Altimeter System (GLAS), which is the first laser altimeter on an unmanned Earth-orbiting spacecraft. GLAS emits a laser beam at 1064 nm to measure the elevation of Earth's surface and the heights of dense clouds and a second beam at 532 nm to measure the vertical distribution of thin clouds and aerosols. The distance from the satellite to the surface is measured to an accuracy of 3 cm, and the position of the satellite above the Earth ($\sim$600 km) is determined to 3 cm using global positioning system (GPS) receivers. Star-trackers on ICESat enable footprint locations on the surface to be calculated to 6 m horizontally. The resulting accuracy of the ice surface-elevation measurements is 20 cm averaged over 70 m diameter laser footprints spaced at 172 m along the track. The coverage of ICESat extends from 86° N to 86° S and the repeating ground tracks of the measurements lie within about 200 m of each other.

ICESat was designed to operate continuously for 3 to 5 years, but laser problems have limited the measurements to three observation periods a year for about 5 weeks each. By the end of 2005, ICESat acquired enough data to produce the most accurate surface elevation map ever made of Antarctica, to detect changes in surface elevations, and to map detailed ice features including: surface undulations, ice-shelf rifts, ice rises, ice fronts, and ice flowlines. The first ICESat is expected to be followed by an advanced ICESat mission to measure ice changes over at least 15 years. Additional information on ICESat can be obtained at http://icesat.gsfc.nasa.gov and data can be obtained from http://nsidc.org/daac/icesat/.

IMPERIAL TRANS-ANTARCTIC EXPEDITION (1914–1917)

After Roald Amundsen and Robert Falcon Scott had reached the South Pole, Sir Ernest Shackleton, who had so nearly attained it on the British Antarctic Expedition (1907–1909), still saw the Antarctic as the place in which to win fame and fortune. He needed an ambitious project to capture the imagination of the public and potential sponsors. Crossing the continent of Antarctica fitted the bill. Such an expedition had been proposed in 1908 by the Scottish Antarctic scientist William Speirs Bruce, but he had been unable to raise sufficient funds. The German Wilhelm Filchner had also planned a crossing but only got funds for an expedition into the Weddell Sea.

Shackleton took over Bruce's scheme with the latter's approval. The exact details of the expedition were always hazy and subject to change, as was usual with Shackleton's plans. They were viewed with scepticism by several influential people, such as Shackleton's friend and later biographer Hugh Robert Mill. The official programme was extremely ambitious. Twelve men would be landed at Vahsel Bay (discovered by Filchner) at the bottom of the Weddell Sea, six of whom would make the 1800-mile (2900 km) crossing. They would sledge to the South Pole where the party would follow Shackleton's route from his previous expedition and emerge at McMurdo Sound in the Ross Sea region. A second team would set up base at McMurdo Sound and lay depots for Shackleton to pick up on his way northwards from the Pole. The crossing party would record geomagnetism, meteorology, glaciology, and geology. The remaining members of the Weddell Sea party would make additional journeys towards Graham Land (Antarctic Peninsula) and to Enderby Land. The ships would have programs of surveying coastlines and oceanographic work.

The expedition's two ships were *Endurance* and *Aurora*. The former was a wooden barquentine of 350 tons originally called *Polaris;* Shackleton chose the name *Endurance* from his family motto, "per ardua vincimus"—"By endurance we conquer." The name proved to be apt. *Aurora,* which would be used for the Ross Sea party, was purchased from Douglas Mawson who had used it on his Australasian Antarctic Expedition (1911–1914).

Unlike previous British expeditions, Shackleton planned to rely on dogs for transport and went to considerable trouble to obtain them. He arranged for the Hudson's Bay Company to send agents to buy 100 of the best dogs they could find in fishing villages on the shore of Lake Winnipeg. Equipment included dome tents designed for ease of erection and felt-lined canvas boots, which would become known as "Shackleton boots" although they were based on Amundsen's design. Shackleton also prepared innovative sledging rations that would be compact through the use of dehydrated foods and would prevent scurvy.

Finding funds for the expedition was a problem that required all of Shackleton's optimism and charm. The main backers were the Scottish cotton millionaire Sir James Caird, who contributed £24,000; Dudley Docker of BSA (British Small Arms), who contributed £10,000; and the British government, £10,000. Other significant donors included Dame Janet Stancomb Wills and Miss Elizabeth Dawson Lambton. Nevertheless, finances were always straitened, especially for *Aurora* and the Ross Sea party.

By contrast, staffing the expedition was simple. A report in a newspaper (not an advertisement as is popularly supposed) was followed by applications from more than 5000 men (and three girls). Fifty-six, including several Antarctic veterans, were chosen. Declaration of war on August 5, 1914, robbed the expedition of some personnel, and Shackleton offered the expedition and its ships to the British government, but Winston Churchill, First Lord of the Admiralty, replied with the telegram "Proceed." Shackleton joined *Endurance* at Buenos Aires and, because of reports of German naval activity off Chile, decided to head for South Georgia instead of the Falkland Islands. On reaching there on October 26, he learned from the Norwegian whalers that it was a bad year for pack ice; their recommendation was that he should delay departure. A month was spent modifying the structure of *Endurance,* acquiring stores from the whaling stations, training the dogs, and carrying out scientific work.

Eventually, *Endurance* set out for the Weddell Sea on December 5, and Coates Land was sighted on January 10. Then, with land in sight and only a short distance from their destination at Vahsel Bay, the ice floes closed in and the sea froze. *Endurance* was trapped and never escaped. At their farthest south, 77°00′ S, *Endurance* was formally declared a winter station and the ship's daily routine was abandoned. The ship began to drift northwards as scientific work and the training of men and dogs continued through the winter. However, from July onwards the ship began to experience bouts of pressure from the ice. On October 24, it began to leak, and two days later Shackleton gave the order to abandon ship. The complement set up Dump Camp on a large ice floe nearby.

Shackleton impressed upon his men that he would get them to safety if they would follow his orders. He also realised that he had to show clear, firm leadership, maintain a flexible approach, and preserve morale. However, given the uncertainties of their position, the best course of action was not easy to discern. The nearest settlements were the whaling stations at South Georgia and Deception, although there was a small Argentine station on the South Orkney Islands. Another option was to cross the Antarctic Peninsula to waters where whaling vessels operated in the summer. Paulet Island was a good staging post to the whaling stations because there was a stone hut built by the survivors of the Swedish South Polar Expedition's ship *Antarctic,* as well as stores left by their relief ship. (Shackleton was aware of this because he had been responsible for purchasing them and suggesting that they be left in the Antarctic for future use.)

To improve the chances of making a landfall, as well as to maintain morale, Shackleton ordered a march westwards across the ice floes. Progress was so slow that it was soon abandoned and Ocean Camp was established. It was near enough the wreck of *Endurance* for more stores and material to be recovered and a comfortable camp was established. *Endurance* eventually sank on November 21. A second attempt to move camp was made, but dragging sledges with three boats and their stores still proved backbreaking work. Six days and only 10 miles farther forward, another halt was called. Patience Camp was established without many of the amenities of Ocean Camp. The party now settled to wait until their northward drift brought them to open sea. Without the clockwise current, the Weddell Sea gyre, they would never have escaped. The dogs and Mrs. Chippy the cat were killed to save the meager food supplies. Seals and penguins were collected for food, but hunting became difficult as the floes broke up and floated loosely with open water between.

On April 9, 1916, the ice had dispersed sufficiently for the men to take to the three boats, named after the sponsors: *James Caird, Dudley Docker,* and *Stancomb Wills*. Paulet Island was no longer in reach, and Elephant Island and Clarence Island were the only options. The 7-day voyage that took them to a precarious landfall at Cape Valentine on Elephant Island was the most horrific part of the entire expedition. Sailing between ice floes that threatened to crush them and battered by stormy seas, the men suffered the miseries of seasickness, hunger, thirst, and soaking with freezing water. By the time they landed, some were at the end of their tether, but they could not stay at Cape Valentine to recuperate because the narrow beach backed by high cliffs would clearly be covered by storm surges. Frank Wild was despatched by boat to search for a better camping place and discovered a spit of land that became known as Point Wild. It was only just inhabitable but the expedition managed to survive there for 4 months.

Shackleton now determined to go for help, and the 22-foot (6.7 m) *James Caird* was prepared with a canvas and packing case decking, a stiffened keel, and an extra mast. On April 24, Shackleton set sail for South Georgia, 800 miles away. With him were Frank Worsley, captain of *Endurance* and skilled in both navigation and handling small boats; the carpenter "Chippy" McNish, whose skill had enabled the three boats to survive stormy seas to reach Elephant Island; Antarctic veteran Tom Crean; and two seamen, Timothy McCarthy and John Vincent. Taking advantage of a southerly wind, they headed northwards to clear the pack ice and then turned eastwards towards South Georgia. South America was nearer but they would have had to sail against the prevailing wind and current. The voyage to South Georgia took 16 days in indescribable conditions. The seas were stormy, on one occasion a giant wave nearly sank them; ice had to be chipped from the deck by men clinging tightly to the rigging; their clothes were not waterproof and, when off-watch, they lay in sodden sleeping bags on the rocks and bags of shingle used as ballast.

Salvation depended on Worsley's navigation, but there were very few occasions when he could take a sun-shot with his sextant. They made landfall at the western end of South Georgia but a storm blew up that nearly wrecked them on the cliffs of Annenkov Island before they made a landing on May 10 in Cave Cove on Cape Rosa, at the entrance of King Haakon Bay. Men and boat were unfit to sail around to the whaling stations on the north side of the island, so they had to cross the island. After a few days' rest, they moved to the head of the bay and turned *James Caird* upside-down for shelter at Peggotty Bluff.

Shackleton, Worsley, and Crean now set out on the final stage of their mission: the crossing of the unmapped interior of South Georgia. Although Stromness whaling station was only 22 miles (35 km) away, they had to cross glaciers and a mountain range equipped only with screws in their boots for crampons, an adze for an ice axe, and a length of rope. They were extremely fortunate with the weather and, with hardly a stop for food or rest, they reached Stromness in 36 hours.

The outside world was now aware of the plight of the 22 men stranded on Elephant Island, but rescue proved difficult. Four attempts were made to rescue them before the Chilean tug *Yelcho* found a way through the ice and reached Elephant Island on August 30. All the men were safe, having survived four months living in squalid, cramped conditions under the remaining two boats. Perce Blackborrow had his frostbitten toes amputated, and the health of some other men was deteriorating. The party was also running short of food.

Shackleton now turned his attention to the rescue of the Ross Sea party, which became known as "Shackleton's forgotten heroes." They had sailed from Hobart, Tasmania, on *Aurora,* and Aeneas Mackintosh had led a sledging party that established a depot at 80° S on February 20. *Aurora* was blown out to sea on May 6, taking most of the land party's supplies. It became trapped in heavy pack ice, the rudder was broken, and the ship drifted in the Ross Sea through the winter. When eventually released from the ice in February 1916, *Aurora* could only limp back to Port Chalmers, New Zealand.

Ten men had been left ashore and they wintered uncomfortably at Cape Evans, the base of Scott's last expedition. Conditions were improved by using food and equipment left by Scott's and Shackleton's earlier expeditions. On September 1, nine men and four dogs made an early start to lay more depots, the last being at Mount Hope (84° S). The Rev. Arnold Spencer-Smith died of scurvy and the remainder barely reached the safety of Hut Point. Impatient to get back to Cape Evans, Mackintosh and V. G. Hayward set off across newly formed sea ice. A gale blew up, the ice was swept out, and the men were never seen again. On January 10, 1917, *Aurora* returned with Shackleton on board, and the survivors were brought out to Wellington, New Zealand.

The Imperial Trans-Antarctic Expedition was a complete failure. None of its objectives had been achieved. Three men and one ship had been lost, as had such scientific specimens as had been collected. Nevertheless, the expedition was a "glorious failure," and the rescue of the complement of *Endurance* from the Weddell Sea has become one of the greatest epic stories of polar exploration, while Shackleton has become a paradigm for teaching leadership skills.

INDIA: ANTARCTIC PROGRAM

India got involved in scientific research in Antarctica under a joint Indo-Soviet agreement between the Indian Space Research Organisations (ISRO) and the Hydro Meteorological Services (HMS) of the USSR. Dr. Paramjit Singh Sehra became the first Indian ever to winter over the South Pole in the 17th Soviet Antarctic Expedition during 1971–1973 and carried out research related to upper atmosphere.

In 1981, the first Indian Scientific Expedition to Antarctica (ISEA) was launched under the leadership of Dr. S. Z. Qasim, whose team reached Antarctica on 9 January 1982. The decision to launch the expedition to Antarctica was taken by the government of India keeping the scientific, environment, geopolitical, and national interests in mind. Since then, annual Indian Antarctic expeditions (IAEs) have been launched without interruption; to date India has launched twenty-three expeditions. In addition, four special expeditions have also been launched: Weddell Sea Expedition; krill biology; Pilot Experiment for Southern Ocean (PESO), for integrated oceanography research of the Southern Ocean; and for observing the total solar eclipse in November 2003. Since the nineteenth IAE, the launching point has been shifted from Goa, India, to Cape Town, South Africa.

In 1983, India established its first permanent station, Dakshin Gangotri (70°45′ S, 11°37′ E), and the team wintered there to carry out scientific and logistic tasks. On 12 September 1983, India achieved the status of Consultative Party, on 1 October became a member of Scientific Committee on Antarctic Research (SCAR), and in 1986 became a member of the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR). In 1997 India also ratified the Protocol on Environmental Protection to the Antarctic Treaty thus reaffirming India's commitment to protecting the Antarctic environment. India hosted the eleventh COMNAP/SCALOP (Standing Committee on Antarctic Logistics and Operations) meeting at Goa in 1999, and the working group meeting on ecosystem monitoring and management of CCAMLR in August 1998 at Cochin. India occupied the CCAMLR chair beginning in November1998 for a period of 2 years.

In 1988–1989, India established its second permanent station, Maitri (70°46′ S, 11°44′ E), which is being used for scientific research. It is equipped with modern facilities to carry out research in various domains of polar science and can accommodate twenty-five wintering members. The summer huts around Maitri accommodate around forty-five summer team members. The research is focused towards understanding the role of Antarctica in the global climate system and its connections with monsoon and other large scale systems utilizing the data from ice core analysis, remote sensing, and other *in situ* observations. The disciplines range from microbial study to the evolutionary history of Antarctica, including human physiology and cold region adaptation, and cold region engineering and communication. The station is equipped with modern communication facilities, INMARSAT and HF Communications.

On 25 May 1998, India's Department of Ocean Development (DOD) established the premier polar research institute, the National Centre for Antarctic and Ocean Research (NCAOR), at Goa, to manage the entire gamut of polar activities by converting the erstwhile Antarctic Study Centre, an attached office of DOD. NCAOR has become a full-fledged research centre with world-class laboratory support, ice core repository, and analysis facility for palaeoclimate research. NCAOR also maintains the Sagar Kanya Ocean research vessel for oceanographic research in the country.

Expedition members are selected by NCAOR from throughout India by open advertisement and following a peer review process, after which they are finally approved by the Department of Ocean Development of the Government of India. The selected team members are medically screened by physicians from the prestigious All India Institute of Medical Sciences in New Delhi and given acclimatization training at Auli in the foothills of the Himalayas. Before departure to Antarctica, they are also briefed at NCAOR by experts in firefighting, survival, first aid, medical, team management, and environmental protection. The average expenditure per expedition is around Indian Rs. 200 million.

Currently there are more than seventy institutions in India that are involved in the Indian Antarctic Programme and the logistics are managed by Army personnel from the Ministry of Defense. Around 300 publications have resulted from Antarctic research by India. The web address for further information is http://www.nic.in.

INSECTS

Insects are a monophyletic group of arthropods distinguished by three main body regions, the head, thorax, and abdomen, with the thorax bearing three pairs of legs and two pairs of wings, though the latter may often be reduced or absent. With 4–8 million extant species, they are thought to be the most diverse group of organisms on the planet, constituting as much as 70% of animal species richness. Although springtails are also characterized by three pairs of legs, and were once sometimes thought to be closely related to insects, they are regarded as sufficiently distinct to place them in a different group. In consequence, springtails are not discussed here. However, springtails are often included in discussions of the ecological roles of insects because they dominate the soil fauna, along with mites, especially in Antarctic systems. These two groups of arthropods are amongst the most significant soil animals in Maritime Antarctic and sub-Antarctic systems, and in some continental Antarctic sites such as Cape Hallett in northern Victoria Land. In other parts of continental Antarctica they are typically less speciose with lower abundances.

There are no free-living insects found in the continental Antarctic. Only ectoparasitic species, such as fleas and lice, which feed and typically remain on their seabird hosts, can be found here. These are also the most diverse group of insects found in the whole of the Antarctic region, and include seals among their hosts, too. However, there are three free-living species found in the Antarctic region, and they are all flies. *Belgica antarctica* is an indigenous, nearly wingless midge. Its larvae are found in a variety of habitats such as nutrient-enriched sites close to seal wallows and bird nesting areas, in detritus, in mosses and algae, and in cyanobacterial mats in seasonal melt streams, and it has a life cycle that extends over 2 years. Adult males and females are active only in the summer, and tend to be short-lived. This species is most closely related to *Eretmoptera murphyi,* which is endemic to South Georgia but was accidentally introduced to Signy Island (South Orkney Islands). Molecular clock data suggest that the two species are separated by tens of millions of years. In turn, they are separated from their closest ancestors by some 70 million years, suggesting that the biogeography of these species has been dominated by vicariance associated with the breakup of Gondwana. The third midge species found in the region is the winged *Parochlus steinenii*. This species is found on the maritime Antarctic South Shetland Islands and as far north as sub-Antarctic South Georgia, Tierra del Fuego, and the Andes in southern South America. Although thought to be a possible introduction by humans to the region, sequence data indicate a divergence time of 7.6 million years between populations on South Georgia and the South Shetland Islands, indicating natural colonization. The only other insects found in Antarctica are introduced species that typically do not live for long or reproduce outside of the occupied stations on the continent. Most noteworthy amongst these is a small population of *Lycoriella* sp. (Sciaridae) established in the sewage processing system of Casey Station (East Antarctica), and another in the bond store of Rothera Station (Antarctic Peninsula).

On the sub-Antarctic islands there is a greater diversity of indigenous species, typically increasing with incoming levels of solar radiation and to some extent with greater plant species richness, which in turn is associated with increasing island area. Islands to the north usually have greater species richness than those to the south. The importance of energy in determining species richness is becoming increasingly well appreciated globally, and the Antarctic region is not an exception in this regard. Nonetheless, the insect faunas have long been thought of as disharmonic. That is, there are many orders that are missing from the island faunas by comparison with similar continental sites. Thus, the flies (Diptera) and beetles (Coleoptera) predominate in terms of species richness, although some islands are also home to one or two moth (Lepidoptera), bug (Hemiptera), and parasitic wasp (Hymenoptera) species. By contrast, orders such as the bristletails (Archaeognatha), dragonflies (Odonata), mayflies (Ephemeroptera), cockroaches (Blattodea), mantids (Mantodea), stoneflies (Plecoptera), and antlions (Neuroptera) are missing, and groups typical of most systems, such as butterflies, bees, and ants, are also conspicuous by their absence. This disharmony is attributed to the isolation and cold climates of the islands, which might explain the fact that the idiosyncratic nature of the faunas is less pronounced for many of the more temperate Southern Ocean islands and those that lie closer to continents (e.g., Auckland, Campbell, Falkland islands). On the sub-Antarctic islands, the most widely distributed species are the beetles *Palirhoeus eatoni* (Curculionidae), *Meropathus chuni* (Hydraenidae), and *Halmaeusa atriceps* (Staphylinidae), the moth *Embryonopsis halticella* (Yponomeutidae), and the flies *Anatalanta aptera* (Sphaeroceridae) and *Apetaenus litoralis* (Tethinidae). The distribution patterns of the insects do not form highly nested subsets, suggesting that the origins of most of the species are from the continents closest to the island or archipelago in question. However, the biogeographic origins of many of the groups, such as the *Ectemnorhinus* group of weevils, remain a mystery.

Herbivory and detritivory are common amongst insects of the Antarctic region, with predation and parasitism being rarer. Amongst the herbivores, several are noteworthy because they consume algae, lichens, mosses, and liverworts. Lichen and bryophyte feeding is uncommon amongst insects in general, which usually prefer angiosperms. However, weevils in the sub-Antarctic region predominantly feed on cryptogams, with angiosperm herbivory being rarer. It is thought that these strategies evolved in response to the paucity of angiosperms, but abundance of cryptogams, during the Quaternary glaciations. One of the most unusual of these weevils is *Palirhoeus eatoni,* which is an intertidal to supra-littoral species specializing on algae and their lichenized forms. Both larvae and adults are tolerant of a wide variety of osmolalities associated with life on rocks that are inundated both by seawater and by rain. Detritivores are thought to be especially important for nutrient cycling in vegetated terrestrial areas on the sub-Antarctic islands, and larvae of the tineid moth, *Pringleophaga marioni,* are considered keystones that form the bottleneck to nutrient cycling at the Prince Edward Islands. The larvae of this moth species benefit from high temperatures of occupied wandering albatross nests and are more abundant here than elsewhere on the islands. Albatrosses thus serve as thermal ecosystem engineers for these caterpillars. Predation is restricted to a small number of carabid and staphylinid beetle species, which prey on springtails, weevil larvae, and occasionally spiders. In turn, spiders, lesser sheathbills *(Chionis minor),* and kelp gulls *(Larus dominicanis)* are the chief predators of insects. Sheathbills are especially reliant on insects for winter survival, while in summer they forage amongst seabird colonies and seal haul out areas. Amongst the insects, parasitism is perhaps the rarest lifestyle, with only a single recorded parasitoid species, the wasp *Kleidotoma icarus,* which parasitizes the fly *Apetaenus litoralis* on the Prince Edward Islands and Îles Crozet. Unlike the Arctic regions, pollination by sub-Antarctic insects appears to be absent and indeed there are very few obviously entomophilic flowers in the sub-Antarctic. Whether insect-pollinated flowers are absent because of an absence of pollinators or vice versa is not clear, and it is a topic that has enjoyed comparatively little attention in the region.

The majority of Antarctic and sub-Antarctic insects are freezing tolerant although several species are freeze intolerant. That is, they are able to survive the formation of ice in their tissues (although ice formation within the cells has not been documented in these species). However, they tend to be moderately so, such that the temperature at which they die is only a few degrees lower than the temperature at which they freeze. The preponderance of moderate freezing tolerance appears to be a feature of the Southern Hemisphere because it is true also of insects from New Zealand, South America, and the alpine regions of southern Africa. In the Northern Hemisphere, most species tend to be freeze intolerant, though in the highest Arctic regions the majority of species are strongly freezing tolerant such that they can survive many degrees of freezing. It is thought that the mild subzero temperatures of much of the southern temperate zone, which mean that temperatures fluctuate around the freezing point, and the likelihood of summer cold snaps and winter thaws are all factors that have promoted moderate freeze tolerance. This strategy effectively means that insects do not have to engage in the protracted biochemical preparation that typically precedes freeze avoidance, but can resist moderate freezing at any time. Indeed, it has been shown that moderately freeze-tolerant caterpillars of the tineid moth, *Pringleophaga marioni,* can survive repeated freeze-thaw events with little ill effect, although long-term cold inhibits their growth.

Low growth rates over multiple seasons are common to many Antarctic and sub-Antarctic insects. Indeed, the overall life history strategy of these species can be considered flexible, with little seasonality and few records of true cue-mediated diapause. Life cycles typically last for a year or longer, with the longest being that of the moth *Pringleophaga marioni* (>5 years). Nonetheless, there are peaks in activity in some species, such as the summer activity of the Maritime Antarctic species *Belgica antarctica,* the spring emergence of adult *Ectemnorhinus similis* weevils, and the distinct mid-summer emergence of the fly *Calycopteryx moseleyi* (Micropezidae), a species closely associated with the Kerguelen cabbage *(Pringlea antiscorbutica)*. Seasonality also appears to be more typical of species occupying southerly sites. For example, there is distinct seasonality and synchronization of emergence in the same species on the colder Heard Island by comparison with those from warmer Marion Island. These differences in seasonality between the islands are also responsible for opposite altitudinal size clines among weevil species on the islands. On Heard Island, body size within a species typically declines with altitude owing to the declining in growing season with increasing elevation. On Marion Island, the opposite is found. Increases in size with declining temperature in relatively aseasonal environments are common in many insect species. In general, Antarctic insects respond most strongly to the abiotic environment that, along with plant community type, appears to have a substantial influence on assemblage composition. By contrast, horizontal (i.e., competitive) interactions are rare, and restricted to *Amblystogenium* ground beetles on Possession Island, and perhaps to rock face-dwelling weevils on the other South Indian Ocean Province Islands.

Many insect species have been unintentionally introduced to the Antarctic region and have survived there. On the continent such species are restricted to scientific stations, but further north they have established and invaded many islands. The most widespread alien invasive species are the fly *Psychoda parthenogenetica* (Psychodidae), the aphid *Rhopalosiphum padi,* and the thrip *Apterothrips apteris* (Thripidae). Most of the introduced species are of European origin, though some southern continental species have also invaded the islands. In addition, there have been several interisland transfers, such as of the carabid beetles *Trechisibus antarcticus* and *Oopterus soledadinus* from the Falklands to South Georgia and in the latter species also to the Kerguelen archipelago. Some purportedly indigenous species, such as the diving beetle *Lancetes angusticollis* (Dytiscidae) on South Georgia, may have been introduced by sealers and whalers before scientific documentation of the biotas began. The accidental nature of the introductions is reflected by the strong relationship between annual numbers of visitors to an island and the numbers of introduced insect species that have successfully established on an island, although islands with greater numbers of indigenous plant species, and those that have greater incoming energy also support larger numbers of invasive alien insects. In some cases, ameliorating climates have only recently made certain islands susceptible to colonization by alien species. For instance in the case of the fly *Calliphora vicina* (Calliphoridae), climate warming at Kerguelen has meant that the islands only became habitable for the species in the mid-1980s.

The effects of invasive alien species have been investigated at only a few sites. On South Georgia, the invasive ground beetle, *Trechisibus antarcticus,* increased its range substantially during the 1990s. In those sites where it is present it has substantial direct and indirect effects on the indigenous perimylopid beetle *Hydromedion sparsutum* (Perimylopidae) At Kerguelen, the introduced carabid *Oopterus soledadinus* is having similar effects on indigenous species, whilst the introduced fly *Calliphora vicina* is thought to be responsible for a decline in the abundance of an indigenous competitor, *Anatalanta aptera*. On Marion Island, larvae of the introduced midge *Limnophyes minimus* (Chironomidae) reach considerable densities in a variety of waterlogged communities. It has been suggested that they increase nutrient turnover substantially in these habitats as a consequence of their activity. A further effect of introductions is to increase trophic complexity on the islands. For example, on Marion Island, introduced *Rhopalosiphum padi* aphids are now being parasitized by an introduced *Aphytis* wasp, so effectively adding another trophic level that was previously absent in lowland vegetation communities. Several recent studies have also raised concerns about negative interactions between indigenous and alien species that will be precipitated by climate change. The invasive alien species typically have rapid life cycles and many of them are parthenogenetic. They show strong physiological (e.g., growth and development) response to increasing temperature. By contrast, indigenous species usually have long life cycles, and are not particularly fecund. Moreover, they respond more weakly to elevated temperature (i.e., they have shallow rate-temperature curves). In consequence, it seems likely that with the increases in temperature that are being documented in many parts of the Antarctic region, invasive alien species will be at an advantage, at least from a life history perspective. What this means for ecosystem dynamics and functioning is presently not clear.

Introduced rodents also pose a threat to the insects indigenous (and in many cases restricted) to the Antarctic region. On several islands, insects constitute the dominant food source for house mice, *Mus musculus (sensu lato),* and insects are also consumed by rats on other islands. House mice are thought to be responsible for the marked differences in insect abundances between Marion Island and the nearby, mouse-free Prince Edward Island, as well as substantial declines in body size of weevils on the former but not the latter island. The mice are also responsible for more than an order of magnitude decline in the biomass of larvae of the indigenous tineid moth *Pringleophaga marioni* between the late 1970s and late 1990s. By consuming these larvae, mice are also thought to be substantially altering nutrient cycling at the island, and this is expected to intensify as mouse numbers increase in response to warming, precipitated by global climate change. Moreover, mice have also indirectly affected lesser sheathbill numbers by consuming invertebrates, which form the major winter food source of this bird. Indirect effects of other introduced species have also been documented. For example, reindeer on South Georgia are thought to be affecting the body size of the indigenous beetle *Hydromedion sparsutum,* by altering the availability of high quality food sources such as the tussock grass, *Parodiochloa flabellata*.

Antarctic and sub-Antarctic entomology has had a venerable history. Among the early taxonomists and collectors who have worked on the region's fauna are H. N. Moseley (of the *Challenger* Expedition), G. R. and C. O. Waterhouse (a father and son), and C. Eaton, G. Enderlein, R. Jeannel, J. L. Gressitt, L. Brundin, P. J. Darlington Jr., Ph. Dreux, and G. Kuschel. The midges of the Crozet Islands and southern continents formed the subject of a long and heated debate between Brundin and Darlington concerning the importance of dispersal versus vicariance in the region. Today it is clear that both processes are important, though phylogeographic and molecular systematic work has demonstrated that dispersal is perhaps more common than previously thought. Although systematic work, and especially molecular approaches to the subject, continue on the insects of the Antarctic, much work is now focussed on ecology, physiological responses, and increasingly the genomic underpinnings of these functional responses. Antarctic ecosystems and their insect inhabitants are thought to be model systems for understanding the likely outcome of interactions between indigenous and invasive species under a climate of environmental change.

INTERNATIONAL CONVENTION FOR THE PREVENTION OF POLLUTION FROM SHIPS (MARPOL)

The International Convention for the Prevention of Pollution from Ships, 1973, as modified by the Protocol of 1978 relating thereto (MARPOL 73/78) regulates the prevention of deliberate, negligent, or accidental pollution of the marine environment from ships. It emerged largely in response to the increasing number of oil tanker pollution incidents during the 1960s and 1970s (in particular the *Torrey Canyon* grounding in the English Channel in 1967) and the recognition that pollution from the routine operation of vessels was a greater threat to the marine environment than catastrophic accidental releases.

The convention combines two international treaties adopted in 1973 and 1978 and a number of amendments adopted piecemeal since then. It has six technical annexes:

Annex I	Regulations for the Prevention of Pollution by Oil
Annex II	Regulations for the Control of Pollution by Noxious Liquid Substances in Bulk
Annex III	Prevention of Pollution by Harmful Substances Carried by Sea in Packaged Form
Annex IV	Prevention of Pollution by Sewage from Ships
Annex V	Prevention of Pollution by Garbage from Ships
Annex VI	Prevention of Air Pollution from Ships

Annex I of MARPOL 73/78 entered into force on October 2, 1983. Today, 128 countries are signatory to Annexes I and II of the Convention. States signing up to the convention must accept Annexes I and II, which include strict regulations for ship design. However, they may choose whether to accept the optional Annexes III, IV and V. Annex VI was adopted in September 1997, but has yet to come into force.

The Secretariat of MARPOL 73/78 is based within the International Maritime Organization (IMO), London.

In 1990, the Marine Environment Protection Committee (MEPC) of the IMO recommended that the Antarctic (defined as the sea area south of latitude 60° S) be given the highest level of protection as a Special Area relating to Annex I (Oil) and Annex V (Garbage). This amendment formally entered into force on March 16, 1992.

Under Annex I of MARPOL 73/78, the discharge of oil or oily mixture from any ship in the Antarctic Area is prohibited, except in accordance with stringent conditions on processed bilge water, or in cases of emergency. Oil or oily wastes must be stored on board vessels and discharged at Port Reception facilities outside the Antarctic Area.

Similarly, under Annex V of MARPOL 73/78, the disposal into the sea of all garbage (including plastic) other than food waste, is prohibited. Port states which are party to the convention are required to provide adequate facilities to receive garbage. Disposal of food wastes into the sea is prohibited less than 12 nautical miles from the nearest land.

Annex IV of the Environmental Protocol largely mirrors Annexes I, IV, and V of MARPOL 73/78, although there are a number of minor differences. Where the specific provisions of Annex IV are weaker than MARPOL 73/78, Article 14 states that "With respect to those Parties which are also Parties to MARPOL 73/78, nothing in this Annex shall derogate from the specific rights and obligations thereunder."

INTERNATIONAL GEOPHYSICAL YEAR

The International Polar Years 1882–1883 and 1932–1933 contributed a little to knowledge of the Antarctic region but nothing about the continent itself. By 1950 it was felt that scientific and technical advances justified a third polar year, with particular attention to the south. The idea took shape at a dinner given by James van Allen, an American expert on the use of rockets for high-altitude research, in honour of the British geophysicist Sydney Chapman, FRS. The suggestion was passed to the Commission on the Ionosphere and forwarded enthusiastically to the International Council of Scientific Unions (ICSU), which formally accepted it in 1951.

In response to protests from meteorologists and geomagnetists, the programme was widened and named the International Geophysical Year (IGY). The subjects were to include the aurora, cosmic radiation, geomagnetism, glaciology, gravity, ionospheric physics, meteorology, and seismology. Cartography, geology, oceanography, and biology were not included. The scope was worldwide, but Antarctica was to receive special attention because of previous neglect and its unique features, such as the wide separation of its geographic, magnetic dip, and magnetic invariate poles. Work was also to be done in the Arctic, with establishment of links by three pole-to-pole meridians along which to record phenomena such as air circulation, electric activity in the stratosphere, and magnetic fields in space. A Comité Special de l'Année Geophysique Internationale (CSAGI) was set up to plan programmes and invite participation. The IGY was planned to run for 18 months to ensure adequate sampling of data and to span an expected peak of sunspot activity. From CSAGI's general programme, detailed plans were passed on to national IGY committees and organisations selected to carry out the work.

By May 1954, twenty nations had agreed to cooperate. The United States, through its National Academy of Sciences and National Research Council, with the Department of Defense supporting the placing of scientists and their equipment in remote locations, made the greatest contribution, but could not dictate to others. At this stage, the Cold War was still on; the Soviet Union was not a member of ICSU and had not suggested participation. However, Stalin had died the previous year, and Soviet scientists began to fraternise with colleagues in other countries. A CSAGI meeting in Rome in 1954 proved crucial when it was notified by the Soviet Embassy that the Soviet Academy of Sciences would send representatives. It joined ICSU but political disputes threatened. Since the USSR had hitherto shown no interest in the Antarctic land-mass, there was surprise when establishment of three stations was announced, one at the South Pole, where, as they presumably knew, the US had decided to place one. Fortunately, their representatives, led by Vladamir Beloussov, a distinguished, serious, but reasonable expert on tectonics, accepted that there was an enormous gap in central East Antarctica and agreed to put the station there, at the Pole of Inaccessibility, instead.

Argentina and Chile had sent ambassadors, not scientists, and both Chinas wanted to participate but neither would tolerate the other's presence. Amicable settlements were largely due to Colonel Georges Laclavere, chairman of CSAGI, whose forceful resolve to put science before politics set the tone for the meetings. Agreement that there should be exchange of personnel between national stations helped greatly.

When things began, on 1 July 1957, the IGY included scientists of sixty-four nationalities involving 4000 stations, those in Antarctica numbering fifty-five from twelve countries (Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, South Africa, the United Kingdom, the United States, and the USSR). The Sun began proceedings precisely on time with a major flare accompanied by a spectacular auroral display and disruption of communications worldwide. Shortly after that, the USSR launched Sputnik I to the consternation of the US, which then put increased effort into rocket and satellite development, much to IGY's benefit. Explosions were fired at different heights and ionospheric measurements were recorded in experiments described as some of the greatest ever conducted in pure science. Although having no intended relation with Antarctica, the results were later welded in with magnetic observations, mainly from the Antarctic, to produce a magnificent concept of the entire magnetosphere. Apart from this, a programme of three World Days per month for intensive observations in related disciplines was agreed, and there were also periodic 10-day Meteorological Intervals. Data were to be freely exchanged and World Data Centres, each having a complete set, were established in the US, the USSR, and a third jointly between western Europe, Australia, and Japan.

The Commonwealth Trans-Antarctic Expedition led by Vivian Fuchs and Edmund Hillary was contemporary with the IGY but not part of it, although interacting, carrying out gravity determination and seismic soundings, and being a means of involving the reluctant New Zealand with the IGY.

The cost of the IGY, around US$280 million, was carried mostly by the US and the USSR. Reports, filling forty-eight volumes of the *Annals of the International Geophysical Year,* appeared between 1957 and 1967. At the end of the IGY, the USSR decided to maintain its status in the Antarctic, and the US was certainly going to stay if this were so. Other countries wanted to get footholds as well. An unexpected outcome was improvement in international relations. Politicians had the acumen to realize that IGY scientists had worked together harmoniously regardless of hostilities between their respective governments. In 1961 the Antarctic Treaty came into force, shelving territorial claims for an indefinite period and setting the Antarctic aside for scientific purposes. It was becoming accepted that heavy cargo planes as well as ships could link Antarctica with the rest of the world, and research stations could be established more easily. Without immediate prospect of commercial exploitation and with the Treaty's ruling that all research results should be common property among the nations, there was no incentive for governments to dictate the course of research, and scientists were largely free to follow their own interests. Biologists, envious of IGY success, entered into similar international cooperation, and under the auspices of ICSU devised the International Biological Programme, which ran worldwide for 10 years from 1964. Besides providing a model for other international arrangements, the Treaty has worked through the Scientific Committee on Antarctic Research (SCAR) to promote science and conserve the Antarctic wilderness

INTERNATIONAL GEOSPHERE-BIOSPHERE PROGRAMME (IGBP)

The International Geosphere-Biosphere Programme (IGBP) is an international research programme that studies the interactions between biological, chemical, and physical processes, and human systems. Its vision is to provide scientific knowledge to improve the sustainability of the living Earth.

IGBP is built on interdisciplinarity, networking, and integration. It addresses scientific questions where an international approach is the best or the only way to provide an answer, and adds value to a large number of individual, national, and regional research projects through integrating activities to achieve enhanced scientific understanding of the Earth system.

The Programme dates back to 1986 when the International Council for Science (ICSU) decided that an international collaborative research endeavour on the phenomenon of global change was required. The planning phase (1987–1990) involved about 500 scientists from around the world.

Implementation began with the official launch of five projects in 1990, and an additional five projects were launched during the 1990s. The projects have focused on different aspects of the Earth system: the hydrological cycle, terrestrial ecosystems, ocean fluxes, ocean ecosystem dynamics, atmospheric chemistry, land-ocean interactions in the coastal zone, land-use and land-cover change, past global changes, and global analysis, integration, and modeling. Infrastructural support is provided by the IGBP Secretariat in Stockholm, Sweden, established in 1989, and by project offices around the world.

In 1999 the Scientific Committee of IGBP, which guides IGBP research, launched a synthesis phase to assemble the key findings of the first decade of IGBP research, and to provide the foundation for the second decade of research. Several realisations emerged from the synthesis to guide the scientific planning for the second decade of IGBP research: the Earth is a complex system that life itself helps to control; the dynamics of the Earth system are characterised by thresholds and abrupt changes; the human enterprise drives multiple, interacting effects that cascade through the system in complex ways; global environmental change is much more than climate change and is happening now; and our planet is, in many respects, in a state far different from anything seen in the last half million years.

IGBP's Antarctica-related research has, to a large extent, focussed on synthesising available ice core data. Ice cores provide a record of the deposition of atmospheric chemicals to the snow through time, with the most recent deposits being at the top of the ice core, and the oldest at its base. One example of research on ice core data focuses on mineral aerosols, which are soil particles suspended in the atmosphere in arid regions with strong winds (for example North Africa). Some of these particles are transported very long distances and are deposited in the ice sheets. Ice core records go back over 400,000 years and show large variations with time. Colder periods, such as ice ages, tend to have much greater (2–100×) concentrations of mineral aerosol particles than warm periods such as today. These higher deposition rates have been hypothesized to be caused by the decreased precipitation and carbon dioxide or strong surface winds in the source region. IGBP's projects GAIM (Global Analysis, Integration, and Modelling) and PAGES (Past Global Changes) have helped synthesize this and other information on the Earth's environment in the past to better understand the processes that control atmospheric carbon dioxide concentration between glacial and interglacial periods. Higher concentrations of mineral aerosols during the cold periods may have helped cool the Earth's surface, and may be partly responsible for the lower carbon dioxide levels during the colder periods.

By 2003 this synthesis phase was largely complete and phase II of the IGBP programme was launched, based on a new set of overarching scientific questions, and organised around a new structure with a focus on biogeochemical sciences with relevance to issues of societal concern, interdisciplinarity and integration, and Earth system context. The IGBP network now involves more than 2000 scientists from around the world, and has National Committees in seventy-eight countries. IGBP collaborates with various organizations and programmes, and is one of four partners in the Earth System Science Partnership (ESSP), which involves DIVERSITAS (An international programme of biodiversity science), IHDP (International Human Dimensions Programme on Global Environmental Change), and WCRP (World Climate Research Programme).

INTERNATIONAL POLAR YEARS

The First International Polar Year was the brainchild of Lieutenant Karl Weyprecht of the Austro-Hungarian Navy. As coleader of the Austro-Hungarian Exploring Expedition of 1872–1874, Weyprecht had wintered in the ice, on board *Tegetthoff,* off the southeast coast of Franz Josef Land (Zemlya Frantsa-Iosifa). On the basis of that experience, and of his thorough knowledge of earlier polar expeditions, Weyprecht proposed a drastic change in direction in polar investigations. He felt that the era of uncoordinated, independent expeditions aimed primarily at geographical exploration, but with negligible scientific results, was over. Useful scientific results could be attained only through a series of synchronous expeditions distributed over the polar regions to obtain one year's observations made according to a standard method. He envisaged the major effort being directed to meteorology, terrestrial magnetism, and auroral studies.

The outcome was the formation of an International Polar Commission, which first met in Hamburg on October 1, 1879. After several meetings of this commission, Weyprecht's dream became a reality as the First International Polar Year of 1882–1883. A total of eleven nations participated (United States, British Empire, France, Germany, Austrian Empire, Netherlands, Norway, Sweden, Denmark, Finland, and Russia). They established fourteen primary scientific stations, twelve of them in a circumpolar ring in the Arctic, and two in the Southern Hemisphere. The latter were the German station at Royal Bay, South Georgia, and the French station at Bahia Orange, not far from Cape Horn.

The meteorological observations to be taken at all stations included measurements of atmospheric pressure and temperature, relative humidity, wind speed and direction, cloud amount and type, precipitation, and hours of sunshine. The magnetic program was very demanding in terms of frequency of observations. Thus on so-called term days (the first and fifteenth of every month), the magnetic variation instruments were read every 5 minutes for 23 hours, and every 20 seconds for the final hour of the day.

The personnel of the German station at Royal Bay totaled ten men: six scientists led by Dr. K. Schrader, and four workmen. They traveled from Hamburg to Montevideo on board the steamer *Rio,* and from there on board the corvette SMS *Moltke* of the German Navy. They reached Royal Bay on August 20, 1882. The station buildings included a living hut, a magnetic and meteorological observatory, a barn, a zoological laboratory, and an observatory for watching the transit of Venus. Even quite recently the iron framework of the revolving dome from the last building was one of the most conspicuous relics on the site.

The observations started on schedule on September 1. In their off-duty hours, the scientists pursued their own specialties. Dr. Karl von den Steinen, a medical officer and ornithologist, made a detailed study of the avifauna. Dr. H. Will concentrated on botany and geology. E. Mosthaff surveyed the area and produced some elegant maps.

Particularly during the autumn and spring, the off-duty scientists made numerous trips by boat or on foot around the surrounding area. The Brocken, Krokisius, and Pirnerberg were climbed several times, and both the Ross and Weddell glaciers were visited. Measurements were made of the surface velocity of the Ross Glacier by taking repeated bearings on identifiable target boulders.

The Transit of Venus was observed on December 6, 1882. The sky was clear at the time and a perfect series of readings was obtained, despite violent winds that threatened to blow the revolving dome from the observatory. Late in August 1883, both the barograph and tide gauge traces showed unusual fluctuations. It was later deduced that these were caused by the eruption of Krakatoa in Sunda Strait on August 27. The German Navy's corvette *Marie,* Captain Krokisius, evacuated the party on September 6, reaching Montevideo on the 22nd.

Organization of the French contribution was entrusted to the French Navy, and the Cape Horn area was selected as its field of operations. The station personnel consisted of six scientists (five of whom were naval officers) and a support staff of fifteen. Leader of the shore party was Lieutenant-de-vaisseau Edmond-Jena-Léopold Courcelle-Seneuil. The ship's captain (and overall head of the expedition) was Capitaine-de-frégate Louis-Ferdinand Martial. His vessel was the bark-rigged steamer *Romanche.* She was to remain in the Cape Horn area for the entire year, engaged in oceanographic and survey work. *Romanche* sailed from Cherbourg on July 17, 1882. Having called at Teneriffe and Montevideo, it reached its destination, Bahia Orange, on the east side of Isla Hoste, just north of False Cape Horn on September 6.

Despite days of continuous rain, and some vicious williwaws (localized squalls), the observatories were completed and the observations began on September 26. All the buildings, including the living huts, had been completed by October 22.

On October 28 Marial took *Romanche* to sea on the first of a series of survey voyages that extended from Isla de las Estados on the east to Canal Cockburn and Punta Arenas on the west. Martial focussed especially on the area south of the Canal Beagle, and produced a superb chart of the area from there south to Cape Horn. *Romanche* called several times at the Anglican mission station at Ushuaia run by the Reverend Thomas Bridges. *Romanche* also spent 10 days at Port Stanley in the Falkland Islands in March.

Despite violent storms that tipped over one of the buildings and tore parts of the roofs off others, the scientific programs at Bahia Orange proceeded smoothly. Just as with the German station on South Georgia, the French scientists took advantage of a clear "window" on December 6, 1882, to get excellent observations of the transit of Venus.

All observations were discontinued on September 1, 1883, and the scientists with all their baggage had been reembarked by the evening of the 2nd. Having called at Ushuaia, *Romanche* headed for Punta Arenas and Cherbourg. Apart from the central studies of meteorology and terrestrial magnetism, the nine volumes of the official reports of the French expedition include detailed studies of the zoology, botany, and anthropology of the Cape Horn area.

As forerunners of the long list of complex multidisciplinary expeditions that would follow, both expeditions can rightly claim a very significant role in the scientific study of the Antarctic and adjacent areas. While no stations were established in the Southern Hemisphere as part of the Second International Polar Year (1932–1933), the major Antarctic effort involving numerous countries during the International Geophysical Year (1957–1958) represented a direct continuation of the work of the First International Polar Year. Plans are currently proceeding for celebrations and scientific efforts for another Polar Year in 2007–2008.

INTERNATIONAL WHALING COMMISSION (IWC)

The International Whaling Commission (IWC) is the intergovernmental body established to conserve whale stocks and regulate whaling. There were sixty-six member nations in 2005.

Historical Background

The invention of the explosive harpoon combined with the development of steam-powered catcher boats in the 1860s heralded modern commercial whaling. The Antarctic quickly became the dominant whaling area. The first whaling station was established on South Georgia in 1904 when it took 195 whales. By 1930–1931, over 37,000 whales had been killed. The catastrophic decline in the price of whale oil led to the first effective limitation of catches (negotiated by whaling companies) in the early 1930s.

In the light of a world shortage of fats after World War II and earlier attempts to develop international agreements, discussions were held in London in 1945 and in Washington in 1946 on the international regulation of whaling.

Establishment of the International Whaling Commission

The International Convention for the Regulation of Whaling was signed in 1946 and established the IWC. Its objective is "to provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry," thereby placing conservation as well as exploitation at its forefront. Finding the difficult balance between "conservation" and the "interests of...the whaling industry" has dominated the history of the IWC.

The IWC comprises one commissioner from each government who has "one vote and may be accompanied by one or more experts and advisers." Regulatory measures (catch limits, seasons, size limits, etc.) can be amended by a three-quarters majority of members voting (excluding abstentions).

The convention states that amendments to the regulations "shall be based on scientific findings." The IWC has a Scientific Committee comprising scientists nominated by governments and latterly, a large number of invited experts.

Two aspects of the convention have attracted particular criticism: (1) governments can "object" to any decision with which they do not agree within a certain time frame; and (2) governments can issue permits to catch whales for scientific purposes. However, without these, the convention would probably not have been signed. Perhaps more significant in terms of good management is that operations cannot be restricted by numbers or nationality—this would have reduced economic and conservation problems associated with increasing numbers of vessels chasing limited quotas.

Up to the Moratorium

A serious problem of early management was the use of the Blue Whale Unit (BWU) to set catch limits (one blue whale equalled 2 fin, 2.5 humpback, or 6 sei whales). Unfortunately, this allowed whalers to reach their quota with a take consisting of multiple species of whales, allowing them to continue the industry at a time when being forced to take a single species would have proved economically unviable. This is apparent from the catch data up to the 1970s, which reveal that as blue whale catches declined, so fin whale catches (the next largest species) increased until they too were overexploited and sei whale catching began.

Although as early as 1952 it was recognised that the Antarctic catch quota was too high, it was difficult to get all whaling nations to agree to a reduction. This was the start of an unhappy period for the IWC. After considerable argument and controversy, by 1971–1972, the international catch limit had been reduced to 2300 BWUs and certain species, including the blue and humpback whales, had been completely protected from commercial whaling.

In the mid-1970s, largely as a result of the 1972 UN Conference on the Human Environment, the IWC established a permanent Secretariat, a decade of research, an international observer scheme, and a new scientific management procedure aimed at bringing all stocks to an optimum sustainable level and protecting stocks <54% of their estimated preexploitation size. Even so, doubts were expressed by some over (1) the theoretical and practical application of the management procedure and (2) the morality of whaling, irrespective of the status of the stocks.

There was also an increase in IWC membership—from eighteen (four nonwhaling) in 1963 to thirty-nine (twenty-six nonwhaling) in 1982 when, by a single vote, a moratorium on commercial whaling was adopted (effective 1986). Four nations (Japan, Norway, Peru and USSR) lodged objections, although Peru, and Japan subsequently withdrew theirs. In 2005, only Norway carries out commercial whaling.

It could be argued that the IWC's record up to 1982 was disastrous (e.g., in the Antarctic):

1. Blue whales had been reduced to at best 5% of their original numbers—hardly a good example of "conservation of whale resources"; and
2. The 1983–1984 catch (comprising only Antarctic minke whales which had not been considered worth catching in 1947–1948) had decreased to only 1/25th of the catch from when the IWC was founded—hardly "the orderly development of the whaling industry."

However, while it is easy with hindsight to condemn, no species became extinct due to modern whaling—IWC actions, while insufficient, were much better than nothing. Since the 1970s, the trend has been towards conservative management to a degree unparalleled in any fisheries commission. It is indicative of the inherent problems within the IWC that the moratorium decision is hailed by some as its greatest success and others as its most abject failure.

The Commission Today

Commercial Whaling

The Scientific Committee has developed a groundbreaking, extremely conservative procedure for determining safe catch limits (the "Revised Management Procedure"), which was adopted by the IWC in 1994. However, the IWC will not set catch limits for commercial whaling until it has agreed and adopted the "Revised Management Scheme" (RMS) that will include nonscientific issues (e.g., inspection and enforcement).

Aboriginal Subsistence Whaling

Limited aboriginal subsistence whaling is permitted for Denmark (Greenland, fin and minke whales), the Russian Federation (Siberia, gray and bowhead whales), St. Vincent and the Grenadines (Bequia, humpback whales) and the United States (Alaska, bowhead and gray whales).

Scientific Permit Whaling

Scientific permits have become a major controversial issue within the IWC with some claiming they are merely a way around the moratorium and others claiming that they are essential for rational ecosystem management. Proposed permits have to be submitted for review by the Scientific Committee but the ultimate decision lies with the proposing nation. In recent years the commission has voted to urge governments not to issue permits. The largest permits are issued by Japan. In the Antarctic, Japan has just completed a 16-year programme during which around 440 Antarctic minke whales were caught annually. Japan has decided to begin a new expanded Antarctic programme from 2005–2006 with annual catches of 850 Antarctic minke, fifty humpback (not to begin for 2 years) and fifty fin (ten in the first 2 years) whales.

Sanctuaries

IWC Sanctuaries can include no other measures than banning commercial whaling. The first sanctuary was south of 40° S between longitudes 70° W and 160° W

and lasted until 1955 when it was opened up to release pressure on other areas. At present there are two sanctuaries, the Indian Ocean Sanctuary (established in 1979) and the Southern Ocean Sanctuary (established in 1994).

Research

The IWC funds and acts as a catalyst for cetacean research (in 2004–2005 over $450,000 was allocated to scientific research in addition to work undertaken by individual governments). One major program is a series of Antarctic cruises to estimate abundance that has been carried out since 1978. The work carried out by the IWC Scientific Committee is recognized worldwide. The commission has increasingly published scientific reports and papers and this culminated in the launch of the *Journal of Cetacean Research and Management* in 1999.

The Future

The objective of the convention assumed that whales are a natural resource to be harvested but that this must be done sustainably. No population of whales is under threat of extinction from whaling and any acceptable management procedure will ensure that this cannot happen. However, there is clearly a divergence of opinion within the IWC on the acceptability of whaling, to an extent unparalleled in any similar organization. It is, for example, difficult to think of any fisheries organization where some of the members believe it is immoral to catch fish under any circumstances. This must be addressed if the IWC is not going to fragment, with potentially serious consequences for the world's cetaceans.

INTRODUCED SPECIES

The Antarctic continent and some of the most southerly islands of the Southern Ocean have escaped the ravages of invasive species. The lower latitude islands have had their share of many of the invasive species that have ruined the ecology of oceanic islands throughout the world. The effects of these have in many cases all but eliminated the seabirds or changed the vegetation. A few species—mice, rats, cats, and rabbits—are the most prominent but there is a range of other species. Fortunately some failed to establish viable populations so their impact was either short lived or nonexistent. In recent years, considerable efforts have been taken to remove or control invasive species so that the impact can be reversed and the islands allowed to recover.

The southern islands fall into three geographical groupings; the Atlantic, the Indian, and the South Pacific Oceans. There are however some general aspects that affect all the islands. Where humans have had a permanent or long-term presence, the problem of invasive species is usually greater. The most widespread species, mice and rats, came in accidentally with early sealers and whalers, or as a result of shipwrecks. Rabbits and some others were deliberately liberated to provide a source of meat for shipwrecked mariners or semipermanent residents. Cats were introduced to reduce the rats and mice, as an ill-conceived early attempt at biological control, or have established from domestic pets turned loose.

Many of the islands share many of the southern seabird species, but several have their own endemic subspecies or even species. A good number have endemic terrestrial birds. Fortunately, few species have become extinct, as most islands are island groups, rather than a single land mass. Because some, often very small, islets have remained free of invasive species, the endemic species have been able to survive.

It is very obvious to the observer when visiting the islands as to whether an island does or does not host invasive species. In those that do, obvious endemics

are missing and seabird numbers are minimal. There has been little work to quantify the decrease in seabird populations due to invasive mammals, but the decrease in seabird numbers or the absence of one or more species, can be attributed to the invasive species. On Marion Island, feral cats were estimated to have killed 250,000–500,000 small petrels annually. On some other islands there have been major reductions (e.g., Amsterdam albatross *(Diomedea amsterdamensis)* on Île Amsterdam and MacGillivray's prion *(Pachyptila macgillivrayi)* on Île St. Paul).

The terrestrial species have been affected more, and there have been some extinctions: the merganser *(Mergus australis)* in the Auckland Islands (although collecting also contributed to the extinction); the parakeet *(Cyanoramphus novaezelandiae erythrotis)* and rail *(Rallus philipensis macquariensis)* on Macquarie Island—again, some species have managed to survive on offshore islets; tussock bird *(Cinclodes antarcticus)* and Cobb's wren *(Troglodytes aedon cobbi)* on the Falkland Islands; the teal *(Anas aucklandica nesiotis)*, pipit *(Anthus novaeseelandiae aucklandus)* and snipe (*Coenocorypha aucklandica* subsp. nov.) on Campbell islands; the snipe *(C. a. aucklandica)* and teal *(A. a. aucklandica)* in the Auckland islands.

While introduced mammals command most attention, a few bird and freshwater fish have also been introduced. There have been introductions of plants, mostly accidental, with seeds being carried ashore in clothing or stock food. The grass *Poa annua* is the most widely distributed example. Some of the more permanently occupied islands have a greater range of alien plant species recorded. Information on invertebrates is harder to access but it parallels the introduced plant species.

The Falkland Islands were the only sub-Antarctic islands with an endemic mammal, the Falkland fox *(Dusicyon australis)*, which was exterminated by the early settlers. This was later replaced by the introduction of the Patagonian fox *(D. griseus)*, and efforts are now underway to control or eliminate this introduced species.

It is easy to look back and criticize our forebears, but what are we doing to overcome the problem and to prevent reoccurrences? Prevention is always cheaper than cure, and to prevent further species reaching the sub-Antarctic islands, the sovereign countries need to develop biosecurity policies and insist on strict quarantine procedures. Transport to southern islands has become easier and many are now on the annual tourist itinerary. To reduce the chances of new invasive species reaching the islands, landings should be permitted only at designated places. This would enable the most valuable biological islands to be excluded from visits by tourists. Even scientific research parties should be strictly regulated and the Republic of South Africa's rigid policy in relation to Prince Edward Island may serve as an example.

Even at designated landing sites, the tourist operators should be forced to insist on very strict procedures to prevent the introduction of animals and plants. Washing and sterilizing boots and checking clothing for seeds should be the minimum requirements. Hopefully, those visiting such places will appreciate their irreplaceable values and will have no problem with such enforced requirements.

Most countries with territory in the Southern Ocean have begun some projects to clear some of the invasive species from these islands. Notable ones have been Marion Island where feral cats have been removed, which stopped the high mortality of small petrels; St. Paul Island where the rats and rabbits were removed, and even before the last animals had been destroyed, MacGillivray's prion and great winged petrel *(Pterodroma macroptera)* had recolonized from a nearby rock stack, La Quille. At Macquarie Island, the Stewart Island weka *(Gallirallus australis scotti)* and cats were removed, and rabbits substantially reduced. Grey petrels *(Procellaria cinerea)* have since recolonized and populations of some of the smaller petrels have increased.

At Campbell Island, feral cats had died out some years after the removal of feral sheep (which were remnants of the farming era). Recently rats were removed in a major programme. Already the pipit has recolonized, and it is hoped to reintroduce teal from captive-reared stock. It is expected that petrels will begin to recolonize. On nearby Auckland Island, feral cattle, goats, and rabbits have been removed, and mice from one of the islands. Plans are being made to remove feral pigs from the main island.

Elsewhere, the French have controlled cattle numbers and their range on Île Amsterdam. On Îles Kerguelen some rat and rabbit eradication is underway on islands within the Golfe du Morbihan. This will give the seabirds that nest on some of the "clean" islands within the gulf the chance to expand onto these islands. In the Falkland Islands, some work has begun to remove rats and rabbits from some small islands, both there and on South Georgia. On the latter, it is important that rats are removed before the glaciers, which constrict their present range, recede, and allow them access to the remainder of the island. It is essential that efforts to correct the mistakes of the past are maintained or, even better, increased so that the sub-Antarctic islands can return to their full ecological potential.

IONOSPHERE

The global ionosphere is a result of the balance between the production and loss of ionization in the upper atmosphere; the exact form of these processes being complex and changing with season, solar cycle, altitude, and geographic position. Ionospheric constituents are constrained by the geomagnetic field, and altered by the neutral atmospheric composition and motions. The polar ionosphere is more complex because the Earth's magnetosphere is linked directly to it along near vertical geomagnetic field lines. The magnetosphere, energised by changes in the solar wind, imposes electric fields on the polar ionospheric plasma and ionizes deep into the Earth's atmosphere with high-energy particles. Finally, the Arctic and Antarctic ionospheres respond differently to these processes because of the greater separation of the geographic and geomagnetic poles in the Southern Hemisphere. But none of this was known when the Antarctic ionosphere was first exploited.

Almost two decades before the ionosphere was explored scientifically, Douglas Mawson's 1911–1914 Australasian Antarctic Expedition used Macquarie Island (54°30′ S, 158°57′ E) as a relay station for wireless communications (on 500 kHz) between Cape Denison (67°00′ S, 142°40′ E) on the Antarctic mainland and more northern locations. Considerable difficulty was initially experienced but after improving the equipment location, successful communications were achieved in February 1913. Mawson recognised the potential scientific value of propagation experiments for exploring the polar upper atmosphere, but his technicians could not mount any definitive experiments and the analysis of the communication records was delayed in publication so that Arctic propagation work overtook the results.

During the Byrd Antarctic Expedition (1929–1930) Malcolm Hanson made the first ionospheric observations for either polar region using a Breit and Tuve pulse system—a forerunner of the modern ionosonde. Working in heroic conditions, at Little America (78°34′ S, 163°56′ W), Hansen built up a seasonal picture of the ionosphere. His most outstanding finding was the discovery that the upper ionospheric layers persisted through the polar night, while the lower layers disappeared. No successful explanation for this observation was found for over 40 years. He also showed the layers had a diurnal variation in height and that returns could be complex and apparently come from large ranges. Although his results received coverage at conferences and in print, they were then neglected.

After these notable firsts, little additional progress was made monitoring and understanding the Antarctic ionosphere until the International Geophysical Year (IGY), which proved to be a watershed in many fields of geophysical science.

The vertical-incidence ionosonde is a major tool for studying the Antarctic ionosphere. An ionosonde is a cosited swept-frequency pulsed transmitter and receiver forming a vertically directed high-frequency (HF) radar system. A frequency pulse is transmitted upwards and may be reflected from the ionosphere, the reflected signal being observed with the receiver. This process is repeated at a sequence of frequencies usually starting at 1.0 MHz and finishing around 20 MHz. A picture of the ionization observed above the ionosonde is then built up into an ionogram, which is constructed by displaying the returned signal as a function of frequency (typically, the horizontal axis) and time delay, usually called virtual height (the vertical axis).

Ionosonde stations were established on some sub-Antarctic islands by 1946 and the first mainland observations were made in 1950 at Terre Adelie (60°40′ S, 140°1′ E). At this time, it was felt that there was little difference between the two polar ionospheres. However, the IGY gave a major impetus to the geophysical sciences and many countries opened ionosonde stations in Antarctica in 1957–1958. Among other results, the IGY observations showed that in the Weddell Sea sector, during summer, the peak electron density was high during local night with lower values during the daytime. In winter, this was reversed and typical midlatitude behaviour was seen. Also, across the polar cap the peak height and electron density in the polar cap of the ionosphere was found to be a function of Universal Time (UT), rather than local time, having a maximum near 06 UT. This is unique to the Antarctic ionosphere and no similar feature has been unambiguously identified in the Arctic. These and similar results helped define the unexpected differences between the Antarctic and Arctic ionospheres and initiated a search for their explanation.

The Earth's atmospheric density decreases exponentially with height by several orders of magnitude between the ground and the ionosphere. The lowest atmospheric layer is the troposphere; home of the "weather" and all life on Earth, where chemical composition is largely constant with height and temperature decreases gradually upwards. This region is bounded by the tropopause (10–12 km), and above this is the stratosphere, a region of increasing temperature that maximises near the stratopause (50 km), where ozone absorbs the Sun's ultraviolet radiation. The temperature falls in the mesosphere, reaching a minimum of 180 K at the mesopause (80–85 km); the coldest region of the Earth's atmosphere. Above this, solar radiation is absorbed, heating the thermosphere to over 1000 K. Below the turbopause ($\sim$120 km) the atmosphere is mixed uniformly and above it mixing is inhibited and the various atmospheric species separate under molecular diffusion. The bulk of the ionosphere is embedded in the thermosphere. Modelling suggests changes in the tropospheric climate, possibly due to anthropogenic sources, may be more easily detected in the upper atmosphere, and especially in the Antarctic ionosphere. Preliminary studies support this conjecture, making this an important, current research topic.

Monochromatic radiation absorbed in an atmosphere where the density decreases exponentially upwards will, at some height depending on the absorption process, have a maximum ion-electron production rate. Provided the loss rates are fast enough, the number density of free electrons will follow the shape of the production function, having a maximum where production is greatest. This is called a Chapman layer. While misleading in some respects, the concept of an ionospheric layer has proved valuable for organising thinking about the nature of the global ionosphere. Conventionally, the ionosphere is divided into three layers, the D layer (below 90 km), E layer (peaking near 110 km), and F layer (200–500 km), the latter being further divided into the F1 layer (200–250 km) and F2 layer. All the layer properties depend on time of day, season, solar cycle, and geographic location.

The normal E region is formed by the absorption of extreme-ultraviolet (EUV) radiation and has a peak near 110 km, the free electrons being lost rapidly in fast chemical reactions. Because of the fast loss rate, the amount of ionization present in the E region can be described by the solar zenith angle (which depends on the Sun's position in the sky and the geographic location). The normal E region forms rapidly at dawn as the Sun appears, reaches a maximum at local noon as the Sun reaches its zenith position in the sky, and disappears at dusk when the Sun disappears. Similarly, during a solar eclipse, the extent of ionization in the E region closely follows the epoch of the eclipse. No other ionospheric layer is as well behaved.

Above the E region, charged particle motion is affected by the geomagnetic field. Charged particles in free space gyrate in circles about the magnetic-field lines. The time for one circuit of a field line, and the radius of gyration, both depend on the particle mass; consequently, electrons travel more rapidly in smaller gyrations than the heavier ions. As the altitude increases and the distance between collisions increases, the geomagnetic field influence also increases. Low in the E region the geomagnetic field has little effect on either ions or electrons, but by 100 km the smaller gyrations of the electrons allow them to follow the geomagnetic field between collisions and by 140 km both ions and electrons are constrained by the geomagnetic field.

The F region is the most important and most complex ionospheric layer. Fast chemical reactions in the E region (mainly ion-ion recombination) lead to charge neutrality. However, the decrease in atmospheric density means fewer suitable ions are available and different, slower chemical reactions (including attachment reactions between electrons and neutral species) predominate in the lower F region, leading to the formation of the F1 layer during day time. In fact, the chemical loss rate falls off more rapidly than the production rate as transport effects become important. In the upper F region, downward diffusion of particles under the action of gravity and constrained by the geomagnetic field (called ambipolar diffusion) is the primary loss mechanism and, to a first approximation, the F-region ionization peak is in diffusive equilibrium. But this alone does not explain its climatology and persistence throughout the night.

Thermal heating of the neutral atmosphere during daytime and cooling at night leads to a pressure gradient forming across the geographic poles from the late afternoon to the early morning. The thermospheric wind results from the balance between the pressure gradient, viscosity, Coriolis force, and collisions with the ions, which are constrained by the geomagnetic field. Viscosity and collisions are dominant in the F region resulting in the wind blowing across the pole in the direction of the pressure gradient. The separation between the geographic and geomagnetic poles is sufficient for winds to explain the Weddell Sea anomaly. During daytime summer the prevailing thermospheric wind blows across the South Geographic Pole, carrying the ionosphere down the field lines into a region of faster loss rate, resulting in reduced ionization. Twelve hours later the region is still illuminated by the Sun and the same wind pushes ionization up field lines into a region of lowered loss rate leading to increased ionization. In winter, with no solar illumination present the wind cannot increase nighttime ionization above the daytime level.

The Antarctic ionosphere UT variation mentioned earlier also depends on wind action and the separation of the geographic and geomagnetic poles. At 06 UT, the geographic pole is on the midnight side of the magnetic pole, so the neutral wind blows over the polar cap, away from the Sun moving ions up the field lines, into a region of lower loss rate, increasing both the peak electron density and peak height. In the Northern Hemisphere the smaller separation between the poles results in little or no UT effect. These uniquely Southern Hemisphere relationships are complex, the balance between the different effects depending on season and solar cycle.

A distinguishing feature of the polar ionosphere is the presence of high-energy charged particles (usually electrons) that precipitate (travel) down geomagnetic field lines and ionize the neutral atmosphere. The higher the energy of the incoming particles, the deeper they penetrate into the atmosphere; the height of maximum production depending on the incoming particle energy and the production rate depending on the particle flux. These charged particles either come directly from the Sun, or gain their energy from processes in the magnetosphere that are driven by the Sun.

The Sun's atmosphere, called the solar wind, is a turbulent, supersonic plasma (containing electrons, ions and a magnetic field) flowing outwards from the Sun, past the Earth, and out beyond the orbit of Pluto. Threaded throughout the solar wind is a magnetic field, called the interplanetary magnetic field (IMF), which is frozen into the plasma; that is, the structure of the IMF is dominated by plasma motions. Periodically, the solar wind is disrupted by massive disturbances called coronal mass ejections (CME), which start at the solar surface as eruptions of solar material and form complex plasma disturbances by the time they sweep past the Earth's orbit. When the turbulent outflow of the CME strikes the Earth, the impact on the magnetosphere can be experienced at ground level due to a series of processes whose study forms part of the growing field of space weather.

The Earth's geomagnetic field carves out a comet-like cavity in the turbulent solar plasma, and the outer boundary is the limit of the Earth's influence. The cavity is compressed in the sunward direction, the dayside of the Earth, and stretches away from the Sun in a long tail on the Earth's night side. The outer boundary contains the magnetosheath and magnetopause, and the magnetosphere fills the interior of the cavity above the ionosphere. The geomagnetic field lines that make up the bulk of the magnetosphere pass through the polar ionosphere as they connect to the Earth, so the polar ionosphere is directly linked to the magnetosphere. The outer magnetosphere faces towards the Sun and changes in Universal Time in response to solar-wind disturbances, while the Earth, the plasmasphere and the neutral atmosphere rotate inside this cavity dragging the embedded polar ionosphere through a changing magnetospheric environment. The larger offset of the poles in the Southern Hemisphere leads to differences between the two polar ionospheres.

As the turbulent solar wind flows past the Earth, charged particles within the magnetosphere are accelerated by varying amounts depending on their location in the magnetosphere. Dynamic events, such as magnetic storms (initiated by solar wind disturbances), and substorms (events that appear to be contained entirely within the magnetosphere, although probably triggered by changes in the IMF) modify the magnetospheric acceleration processes. The precipitating particles accelerated in different magnetospheric regions precipitate down the geomagnetic field lines imposing gross order on the polar ionosphere. While one-to-one identification between magnetospheric regions and ionospheric features is a little subjective, the prospect offers tantalizing research possibilities.

During a magnetic storm all high-latitude processes increase in complexity as the magnetosphere deposits energy and momentum into the polar thermosphere. Precipitating electrons and protons collide with the atmosphere and deposit five to ten times more heat directly into the neutral atmosphere. The polar ionosphere will be modified in highly complex ways by the precipitating particles associated with the storm, possibly solar protons that have ionized deep into the polar ionosphere, and by increased magnetospheric convection and enhanced thermospheric winds. The particle ionization increases the thermospheric conductivity and combined with the magnetospheric convection electric field produces the main atmospheric energy source during the storm. The resulting Joule heating effect can be two or three times greater than precipitation effects alone. Furthermore, the regions responsible for magnetospheric energy sources, as well as increasing the amount of energy deposited into the neutral atmosphere, expand equatorward by as much as 10° to 15°, extending the domain of the polar ionosphere to midlatitudes. The energy increase disrupts the neutral atmosphere and ionosphere globally and is the source of an ionospheric storm; a global event that produces massive changes in the mid- and low-latitude ionosphere. The culmination of these processes is a rich domain for space weather research.

When precipitating particles ionize the D region, HF absorption increases. A riometer is a vertically directed, single-frequency (often 30 MHz) receiver that records the signal strength of incoming galactic emissions, changes being interpreted as absorption due to particle precipitation. Absorption events that prevent ionosondes from recording ionograms can be monitored by a riometer. There are two important types of absorption event. Some major solar flares produce energetic protons that are guided to high latitudes first by the IMF and then by the geomagnetic field. There they can ionize nearly the entire continental Antarctica D region leading to a sustained absorption event, called polar-cap absorption (PCA), which can last for several days. When a PCA is seen on a cosmic-ray detector at the ground it is called a ground-level event (GLE). Auroral absorption is almost entirely restricted to the auroral zone and is caused by particles accelerated in the magnetosphere. It shows much greater temporal structure (briefer, more intense events with diurnal variation in occurrence) and smaller spatial structure than a PCA. New multibeam riometers show these events can intensely ionize only a small patch of the sky.

Energetic electrons ionize the E region forming transient E-region layers, called sporadic E (Es) after their midlatitude counterparts that are produced by wind shears. However, like the normal E layer, and unlike the thin midlatitude Es layers, the particle layers are thick enough to prevent radio waves from passing through them. On ionograms, the particle-Es layer appearance alters depending on whether the layer is overhead (called particle E) or oblique (often called retardation Es) and whether it is accompanied by irregularities (called auroral Es). In principle, as an ionizing region moves towards and above an ionosonde station, the ionograms will first show retardation Es and auroral Es, which then change to particle E when overhead. By recognizing the overhead particle-E layer, it is possible to estimate the likely incoming particle energies by measuring the layer height. However, this is often difficult because any change in the ionizing particles will produce immediate changes in the E-region ionization due to the fast chemical loss processes. Less energetic electrons can ionize the F region leading to increased ionization irregularities that appear on ionograms as spread F.

In the polar ionosphere, the magnetospheric convection electric field maps down geomagnetic field lines into the ionosphere causing it to move in a direction perpendicular to both the convection electric field and the geomagnetic field. The neutral atmosphere collides with ions drifting in response to this field and gains momentum, adding the magnetospheric convection electric-field pattern to the polar neutral wind field. Modern ionosondes making Doppler measurements can detect the convection effects in the ionosphere, as can the more powerful coherent HF radars that are organised in a cooperative network (called SuperDARN, for Super Dual Auroral Radar Network) covering both polar regions; SuperDARN offers especially rich research prospects.

The auroral region forms a defining boundary for the polar ionosphere and it is tempting to organise all polar phenomena with respect to it. Auroral phenomena are associated with the precipitation of energetic electrons into the atmosphere. Optical aurora, a by-product of the ionization and subsequent chemical-loss processes, are linked to Es on ionograms. Auroral precipitation can be divided into two regions, an inner region corresponding to the oval and associated with soft electron fluxes forming Es layers and spread F on ionograms, and a second zone 5° to 10° equatorward of the oval associated with more energetic electrons, diffuse aurora and greater HF absorption. Like all polar phenomena, these vary constantly.

Equatorward of the auroral oval, the F-region ionization reduces, forming a trough where ionization levels are lower than those seen in either the auroral or midlatitude ionosphere. The trough is thought to be formed by a combination of electron-loss processes and convection circulation, some convection paths lying in regions of low production for several hours. At the equatorward edge of the auroral oval the trough ionization increases sharply due to increased particle precipitation, although other processes may be present and even dominant at times. A further complication is that more than one trough is seen, both in space and in plasma constituents. There are fewer synoptic studies of the Southern Hemisphere trough, but what evidence there is indicates differences from the Northern Hemisphere. The southern trough is seen in all seasons and not just winter and equinox, and all times of the day rather than only at night.

The cusp region centred on local noon and poleward of the auroral oval is open to magnetosheath particles that can precipitate into the polar daytime ionosphere between the cusp and the auroral oval, heating the ionosphere and increasing irregularities. Patches of ionization can be detected as entities using airglow, incoherent-scatter radars (only available in the northern hemisphere), and ionosondes. When the IMF is southward, 200 to 1000 km diameter patches of roughly circular ionization enhancements, sometimes a factor of ten above the background ionization, move across the polar cap with the general plasma drift. Patches are likely to be caused by convection entrainment passing through the polar cusp and are associated with a tongue of F-region auroral-oval ionization that was first identified in IGY ionosonde data. When the IMF is northward, weaker more elongated features aligned with the noon-midnight line drift across the polar region from dawn to dusk.

The polar ionosphere is permeated by ionization irregularities of widely varying spatial and temporal form. Smaller-scale irregularities, from metres to tens of kilometres in size, cause scintillations on global transionospheric radio-propagation paths, and after the equatorial-anomaly region scintillations are most severe near the auroral zone. Scintillations show considerable fine structure and while particle precipitation is clearly involved, other processes including plasma instabilities contribute to the drifting, and temporally evolving irregularity composition. All aspects of polar irregularities are the subject of ongoing research efforts.

The polar ionosphere forms a highly complex interface between the neutral atmosphere and the magnetosphere, with energetic particles accelerated in the magnetosphere increasing its ionization and convection drifts modifying the polar thermospheric winds. In addition, because the Antarctic ionosphere is accessible from the ground, it offers a valuable ground-based observation platform for studying the magnetosphere, complementing the rich space-based data sources now available and anticipated in the future. Dynamic processes in the ionosphere (ionization, chemistry, diffusion, winds) depend on geographic location and geomagnetic dip whereas magnetospheric processes (particle precipitation, convection) depend on the position of the geomagnetic pole. The greater polar separation in the Southern Hemisphere offers possibilities for discriminating between competing magnetospheric and geographic processes in the ionosphere, further increasing the research value of the Antarctic ionosphere.

ISLANDS OF THE SCOTIA RIDGE, GEOLOGY OF

The Scotia Ridge is the name given to the eastward-closing cusp of submarine ridges and rugged islands that connect the Andean Cordillera of South America with the Antarctic Peninsula, partially enclosing the Scotia Sea. It includes the island of South Georgia, the South Sandwich Islands, and the South Orkney Islands and is composed partly of fragments of an original continental connection between South America and the Antarctic Peninsula and new crust generated by the subduction of oceanic crust belonging to the South American plate beneath the Scotia Sea. It forms a complex boundary of the Antarctic plate with the Pacific and South American plates and contains the small tectonic Scotia, Sandwich, and Drake plates. Only the East Scotia Sea is actively spreading. On the eastern side of the Scotia Sea, oceanic crust belonging to the South American plate is being subducted beneath the Scotia Sea to form the volcanic South Sandwich Islands as an intraoceanic island arc. The northern and southern parts of the Scotia Ridge are slow-moving sinistral transform faults accommodating relative movement between the larger plates. Both South Georgia and the South Orkney Islands were part of the Mesozoic margin of Antarctica and South America. Major magmatic arcs were established along the length of the southernmost Andes and Antarctic Peninsula during the late Mesozoic and Cenozoic initially during a period of widespread extension that lead to the development of the South Atlantic Ocean and Weddell Sea basins.

The Scotia Sea and Scotia Ridge developed their present form over the past 40 million years as a complication of the South American–Antarctic plate boundary representing the final stage in the breakup of the Gondwana supercontinent and the isolation of Antarctica in a South Pole position. Fragmentation of the land connection dispersed continental blocks eastwards to form the north and south Scotia Ridges.

South Georgia

It is generally accepted that South Georgia was first sighted by Antonio de la Roche in 1675 with the first geological survey carried out during the South Georgia Survey 1951–1957. The island is the emergent part of an isolated microcontinental block the geology of which can be matched closely to that of western Patagonia and Tierra del Fuego, the South Georgia block having formed part of the Pacific margin of

Gondwana. For much of the Mesozoic, the southwestern edge of Gondwana was an active plate margin above the easterly subducting, proto-Pacific ocean floor. The rocks of South Georgia represent various stages in the evolution of the active margin, in particular the development of an island-arc–back-arc-basin system of middle Jurassic to mid-Cretaceous age.

The oldest rocks are polyphase-deformed metasediments that were intruded by an extensive tholeiitic suite of gabbroic plutons which migmatized the country rock. This magmatic episode thinned the continental crust; further rifting and emplacement of tholeiitic magma led to the creation of mafic crust (composed of lavas, dykes, and plutons) with oceanic crustal characteristics. The middle–late Jurassic magmatic episode is represented by an igneous and metamorphic complex (Drygalski Fjord Complex) and an ophiolite suite, now exposed in the southern part of South Georgia (Larsen Harbour Complex). It is likely that a similar mixture of thinned continental crust and oceanic crust forms much of the hidden floor of the marginal basin

During the early Cretaceous an island-arc–back-arc-basin system was active in the area. The island-arc suite, a series of mudstones with interbedded tuffs and overlying volcaniclastic breccia, crops out on isolated islands off the southwest coast. All of the pyroclastic rocks are andesitic and have the calc-alkaline chemistry typical of island arcs. Deposition of the clastic rocks began in the latest Jurassic and continued into the late Aptian or Albian; intrusions of dioritic stocks, sills, and dykes of late Cretaceous age represent a late phase of igneous activity.

The age of deposition in the marginal basin is poorly constrained but probably contemporaneous with deposition of the arc sediments. Most of South Georgia is formed of a c. 6 km thick unit of Lower Cretaceous andesitic greywackes (Cumberland Bay Formation), derived from the volcanic arc and deposited by turbidity currents. These flowed both across and along the basin, forming a laterally variable complex which was penetratively deformed early in the late Cretaceous. Deformation was associated with closure of the basin and westerly underthrusting of the basin floor. The volcaniclastic turbidites were thrust over a series of siliciclastic turbidites (Sandebugten Formation) of unknown age that may have been derived from the opposite (continental) side of the basin.

The arc and the basin were separated by a major fault during deposition. The line of this is now marked by a mylonite zone that records both dip-slip and strike-slip movement. This is the only unit in the island younger than mid-Cretaceous.

South Sandwich Islands

The South Sandwich Islands were first sighted on January 31, 1775, by Able Seaman Freezland from Captain Cook's ship HMS *Resolution*. They form a 350 km long, north–south orientated, cresent-shaped volcanic arc that is regarded as one of the classic global examples of an intraoceanic arc. The eleven islands are small, typically 3–8 km across, and entirely volcanic in origin (Baker 1968, 1978). They typically rise 500–1000m above sea level and are subaerial summits of edifices that rise some 3 km above the surrounding seafloor. The arc is currently volcanically active with intense fumarolic activity on several of the islands, and there have been at least six historic eruptions. The only radiometric dates for the arc are four K-Ar ages on volcanic rocks, the oldest being 3.1 ± 0.3 Ma (Baker et al. 1977). The arc is tectonically simple, being located on the small Sandwich Plate, which is overriding the southernmost part of the South American Plate at the South Sandwich Trench. The arc lies on crust that formed at a back arc spreading centre that has been active for at least 15 million years. Extension may have been initiated as a result of a change of direction of South American–Antarctic relative motion about 20 Ma.

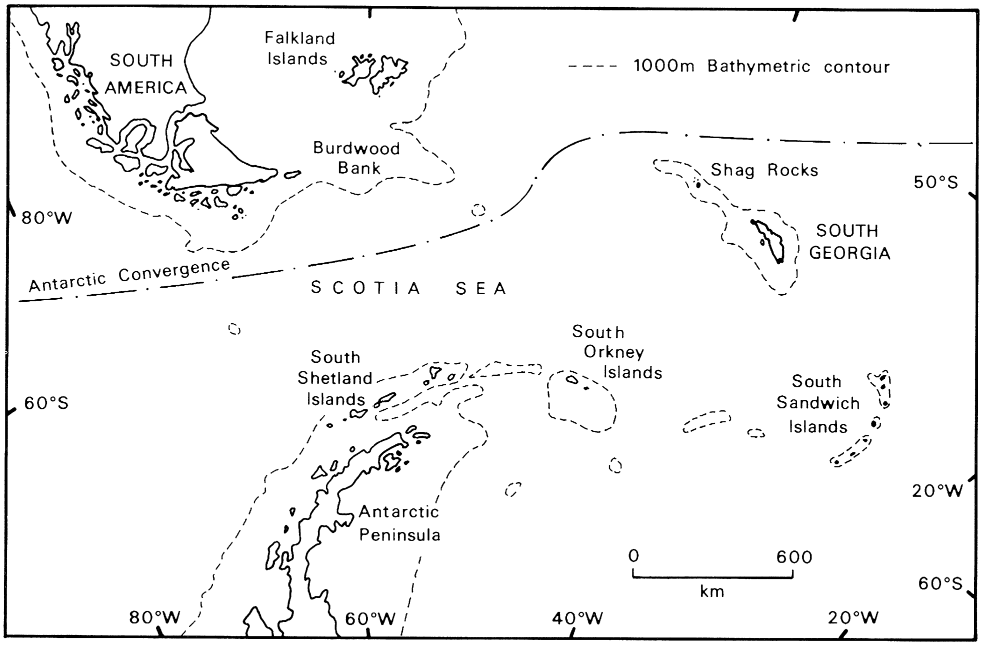
Compositionally the volcanic rocks range from basalt to rhyolite with mafic rocks (basalt and basaltic andesite) being volumetrically dominant. They show three geochemical trends, low K tholeiitic, tholeiitic, and calc-alkaline with high-Al basalts being common. The mafic magmas were derived from mantle that had been depleted by a previous melt extraction probably related to the back arc spreading.

South Orkney Islands

The South Orkney Islands are a group of mountainous islands lying northeast of the Antarctic Peninsula and on the southern part of the Scotia Ridge. They were discovered during a joint cruise by Capt. George Powell, a British sealer in the sloop *Dove,* and Capt. Nathaniel Palmer, an American sealer in the sloop *James Monroe* in 1821.

The islands consist of metamorphic (Scotia Metamorphic Complex) and sedimentary rocks (Greywacke Shale Formation) that represent the products of subduction-related accretion and of sedimentation, respectively, in a forearc environment along the Pacific margin of Antarctica before and subsequent to the fragmentation of Gondwana. The rocks lie on the Pacific side of any relics of the contemporaneous magmatic arc.

BAS GEOMAP :1 SOUTH GEORGIA

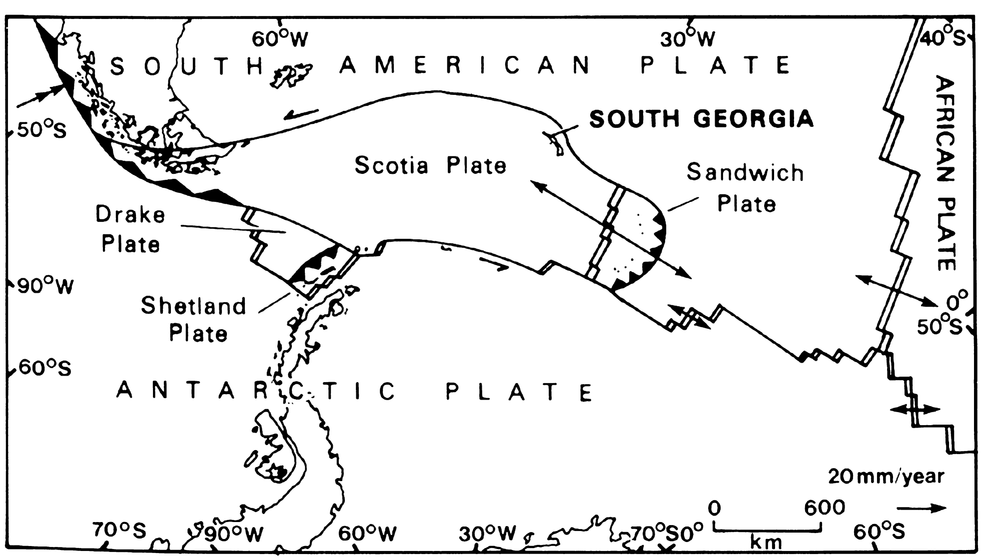


Location map showing the islands of the Scotia Ridge between South America and the Antarctic Peninsula.

The islands were rotated and translated from an original position within the Powell Basin during the formation of the Scotia Ridge.

Scotia Metamorphic Complex (SMC)

The SMC consists of interlayered graphitic phyllite, mica schist, metachert, marble, calc-silicate, and amphibolite. The metamorphic grade is commonly epidote amphibolite or amphibolite (Tanner et al. 1982). It has yielded K-Ar cooling ages of 190 Ma on hornblende and micas. The mica schists comprise mapable units of pelitic or semipelitic schist, psammite, and rare quartzite layers. The amphibolites include fine grained greenschist, coarse hornblende gneiss, epidote amphibolite, and calc amphibolite. Massive white marble bands up to 3 m thick are the most distinctive rocks. Whole rock chemical analysis suggests that the amphibolites are metamorphosed basaltic rocks and



Present-day plate tectonic map of the Scotia Ridge (after British Antarctic Survey, 1985).

have affinities with MORB-type and alkali basalt of an intraoceanic island tectonic setting. Finely laminated Mn rich garnetiferous quartzite layers are interpreted as meta cherts. The protoliths on Signy Island are typical of a subduction zone environment (ocean basalt, limestone, chert, clastic sediments). The intense and pervasive ductile shearing, tectonic interleaving of lithologies and coaxial folding has lead to suggestions that the deformation and accompanying metamorphism represented the subcretion of material from a downgoing oceanic plate beneath the forearc wedge at depths in excess of 20 km in the subduction zone (Dalziel 1984). A structural analysis has shown that the subduction complex rocks on have suffered intense shearing throughout their deformation history in a consistent north-northwest–south-southeast direction during ductile thrusting towards the NNW. Vertical or steeply dipping dolerite dykes intrude the metamorphic rocks.

Greywacke-Shale Formation (GSF)

The sedimentary strata consist of poorly fossiliferous greywacke and shale of turbiditic facies associated with rare mafic pillow lavas containing prehnite and pumpellyite. Bedding and primary structures are ubiquitously recognizable although the rocks are everywhere deformed by one major set of subisoclinal to tight asymmetric folds with associated axial planar slaty cleavage. The folds vary in attitude from upright through overturned and reclined to recumbent. The regional setting, structural style, and an observed transition structurally downward into the metamorphic rocks of the SMC suggest that the strata were deposited partly in trench-slope basins that are within the zone of active deformation in the wedge. Upper Triassic fossils were uncovered from a chert layer conformable within greywacke and shale layers off Laurie Island (Dalziel et al. 1981).

Spence Harbour Conglomerate/Powell Island Conglomerate

At the eastern end of Coronation Island, the metamorphic rocks are unconformably overlain by a sequence of conglomerates and sandstones referred to as the Spence Harbour Conglomerate and elsewhere within the island group as the Powell Island Conglomerate. The conglomerates consist almost entirely of metamorphic debris derived from the underlying metamorphic complex. A thick black shale bed contains a fauna of poorly preserved brachiopods, bivalves, and gastropods, belemnoidia together with some fragments of fossil wood and one or two echinoid spines and plant debris. The typical conglomerate is a well indurated light grey or buff coloured rock composed of closely packed pebble-sized lithic fragments embedded in a matrix of grit or coarse sand.

ISOTOPES IN ICE

Like other elements, the constituents of water—oxygen and hydrogen—occur in different isotopes. Different isotopes of one element have different atomic masses due to a different number of neutrons in the nucleus. Stable oxygen atoms (which always have eight protons) have eight, nine, or ten neutrons, resulting in three isotopes with the atomic mass numbers 16, 17, and 18 respectively (^{16}O, ^{17}O and ^{18}O).

Hydrogen has two stable isotopes, ^1H and ^2H (deuterium, represented by symbols ^2H or D). The mixing ratios R of the isotopes in different natural substances on Earth are rather stable:

oxygen:	^{16}O	^{17}O	^{18}O
mixing ratio:	997,570 ppm	380 ppm	2,050 ppm
hydrogen:	^1H	^2H (Deuterium)	
mixing ratio:	999,885 ppm	115 ppm	

Isotopes of one element have the same chemical characteristics. Small fractionations in their composition occur in processes, depending on the atomic mass, like evaporation, condensation, and diffusion. Relative deviations of isotope ratios can be measured very precisely in special isotope ratio mass spectrometers and recently also by laser spectroscopy.

Because variations of isotopic ratios are small, they are expressed as so called δ-values defined as:

$$\delta = \left(\frac{R_{sample}}{R_{standard}} - 1\right) \cdot 1000(‰)$$

Mean ocean water is taken as standard for ^{18}O and ^2H (The absolute mixing ratios for the Vienna Standard Mean Ocean Water provided by the International Atomic Energy Agency (IAEA) are 155.76 ppm for ^2H and 2005.2 ppm for ^{18}O). Water with a ^{17}O molecule is seldom used for ice core analyses.

Water evaporating from the ocean is depleted in heavy isotopes because water molecules with a heavy isotope have a slightly lower vapor pressure than normal molecules. If clouds loose water by precipitation, heavier isotopes are preferred. Heavy isotopes in the clouds are, therefore, more and more depleted as more water is lost by precipitation. The remaining relative water content, compared to the one at the source region, depends on temperature. Therefore, the isotopic composition of precipitation depends on condensation temperature as well. This is the main principle on which the isotopic "paleothermometry" is based.

The main goals of the water isotope analyses of ice cores are

- To reconstruct continuous and detailed profiles of past local temperature changes by combined water isotope analyses.
- To obtain information about the origin of the water deposited on site as snow and about the associated hydrological cycle.
- To contribute in establishing accurate time-scales for ice cores by counting annual layers, if seasonal variations can be detected in the isotope profiles or by estimating past accumulation rates based on the local temperature.

The δ-values for oxygen and hydrogen in precipitation depend not only on condensation temperature but also on the temperature of the source regions and the cooling process of the air. In fact, δ-values of single precipitation samples are not well correlated with the local temperature during precipitation. On the other hand, it has been observed that the δ-values of precipitation samples collected during one year are well correlated with the mean annual surface temperature at the sampling sites, especially in polar regions. General circulation models allow us to calculate the pattern of mean δ-values as function of different climatic conditions (Jouzel et al. 2000).

Ice cores drilled in polar ice sheets provide precipitation samples from the past. δ-values of ^{18}O or ^2H measured on such samples allow us to estimate the local temperature in the past. The δ^2H-record of the Vostok ice core allows us to reconstruct the temperature evolution during the past 420,000 years (Petit et al. 1999). The data are available from Petit et al. (2001). The record shows that the temperatures were most of the time lower than today. The cold epochs, called ice ages, have been interrupted about every 100,000 years by warm epochs, so called interglacials. Our present epoch, the Holocene, lasting about 12,000 years until now, is the most recent of these interglacials. The difference in the δ^2H values between the last glacial maximum (lowest temperatures) and the Holocene is about 60‰; this corresponds, according to present knowledge, to a local temperature difference of about 9°C.

A more recent ice core drilling at Dome C in Antarctica allows us to extend the isotopic record to 740,000 years before present (BP) (EPICA community members 2004). One interesting result is that the interglacials before 450,000 years BP were less warm but lasted longer.

Either δ^2H or $\delta^{18}O$ can be indifferently used to reconstruct temperature records. The two values are correlated by the relation: $\delta^2H = 8 - \delta^{18}O + d$. The parameter d is called the deuterium excess. It would be constant if equilibrium processes alone took place during evaporation and condensation of water. However, ocean water often evaporates into air with humidity below the saturation pressure and nonequilibrium processes also occur during the formation of snow. The deuterium excess in polar precipitation is mainly influenced by the conditions in the oceanic moisture source region (temperature, relative humidity and to a lesser degree, wind speed). The deuterium excess, d, varies between 5.5‰ (last glacial maximum) and 9.5 ‰ (at present) in samples from the Dome C ice core. Based on this change in the deuterium excess, it is estimated that the change in the temperature at the source region, assumed to be mainly the Indian Ocean at about 40° S, is roughly 4.5°C between the last glacial maximum and the present warm epoch (Stenni et al. 2001).

The δ-values of ^{18}O and ^{2}H not only vary with long-term temperature variations, but also with seasonal temperature changes. δ-values are lower in winter than in summer precipitation. This can be used to identify annual layers in ice cores. However, for ice cores from the interior of the Antarctic Ice Sheet, the accumulation rates are so small, that these seasonal variations are not preserved. Another way to determine ice core chronologies is to use ice flow models. For such models an accumulation history is needed. A first approximation to establish such an accumulation history is to assume that accumulation rates are proportional to the derivative of the water vapor saturation pressure at the precipitation site and, therefore, a function of the local temperature, which can be estimated based on the isotope records (Jouzel et al. 1987). Accumulation rates during ice ages were only about 50% of those at the present time.

ITALY: ANTARCTIC PROGRAM

Italy signed the Antarctic Treaty in 1981. Four years later, the Italian Parliament approved a law that established the National Programme of Antarctic Research (PNRA). The PNRA planned research activities from 1985 to 1991. The purpose of this activity was to make Italy a Consultative Party to the treaty, considering the enormous potential for the research work that could be performed in the continent. Already some Italian explorers and scientists had been to Antarctica in the second half of the nineteenth century.

In 1991 a new law was approved that extended the duration of the Antarctic activities with programs of 5 (now 3) years. The PNRA is being continued under the authority of the Ministry for Education, Universities and Research (MIUR). The PNRA includes research activities in many fields, including Earth sciences, atmospheric physics, cosmology, biology, oceanography, environmental sciences, and technology. In the course of its development, the PNRA has moved more and more towards multidisciplinary studies of global phenomena.

ENEA, the Italian Government Agency for New Technologies, Energy and Environment, has implemented the Antarctic programme for its first 17 years. In 2002 the organisation of the PNRA was modified: a consortium of four national agencies for the implementation of the PNRA was established. The agencies and their shares are ENEA (28%), National Research Council (24%), National Institute for Geophysics and Volcanology (24%), and Institute of Oceanography and Experimental Geophysics (24%).

A number of ministries are involved in the PNRA, as well as universities and research institutes. The Ministry of Defence gives a contribution in the training of candidates, the Navy performs hydrographic surveys, the Italian Air Force gives meteorological support and, when available, provides a C-130 for air transport from New Zealand to Antarctica. The Italian Foreign Office coordinates the Italian presence in the Antarctic Treaty Meetings.

Many Italian scientific activities are performed in cooperation with other countries, and by Italian law 20% of the research must be carried out with international cooperation. The same law initiated research in the Arctic in order to compare similar situations in the two hemispheres, and eventually a small research station was established in Svalbard.

From 1985 to 2004, PNRA oversaw nineteen expeditions, one each year. In 1985, a number of Italian scientists were sent to Argentine and Australian stations to gain experience in Antarctic work. The construction of the first research station, the site of which had been selected during the 1985–1986 expedition to the Ross Sea region, was begun in the second expedition. It was named Terra Nova Bay (TNB) Station and located at 74°42′ S, 164°06′ E. In 2004 its name was changed to Mario Zucchelli Station (MZS) for the man who was manager of the PNRA for 17 years. The station covers approximately 7000 m^2, and in addition to standard equipment has a sea-water desalination facility and wastewater treatment. The tank farm holds 1.8 million litres of fuel. To date, the station has been inhabited only in summer (November to March).

In the second expedition, besides the construction of TNB, the first research activities, mostly in Earth sciences, were begun. That made possible the admission of Italy as a Consultative Party to the Antarctic Treaty (1987). In 1988 Italy became a full member of the Scientific Committee on Antarctic Research. The second station, Concordia, was built more recently in cooperation with the French. It started operation in 2004–2005, with its first wintering personnel in 2006.

The following years saw the progressive enlargement of TNB and the broadening of the spectrum of scientific activities. In the third expedition (1987–1988) there was the first oceanographic and marine biology survey of the Ross Sea, while the ship OGS *Explora* performed the first of ten geophysical campaigns. From the fifth expedition, a fast connection between New Zealand and TNB was established, using a Hercules C-130.

During the sixth expedition (1990–1991), an automatic system was installed at TNB, capable of running a number of scientific experiments and transmitting the results to Italy. The system allows the data collection when the station is not manned during the Antarctic winter. The seventh and eighth expeditions were reduced in both size and duration, because of a delay in funding. However, the observatory activities at TNB continued normally and a large refueling of the station was possible. In the eighth year there was also a mission on the Antarctic Plateau in the direction of Dome C, for a distance of 350 km, using tracked vehicles. This was the first mission for a project that continued later with the establishment of a camp for fifty people at Dome C, where the European Project for Ice Coring in Antarctica (EPICA) was implemented. This project was nearly concluded in 2002–2003, having recovered ice cores about one million years old. This will allow the reconstruction of climate going back to that age. At Dome C, during the activity for EPICA, Station Concordia was constructed. This exceptional site has an elevation of about 3230 m above sea level and is located approximately 1200 km from the coast. The year-round base, made of two interconnected steel cylinders, will be an ideal site for studies in Sun–Earth relationships, astronomy and astrophysics, seismology and atmospheric physics, available to scientists of all interested countries,

The 1996–1997 expedition involved the largest number of people (340), thus becoming a test of Italian science and logistics after 10 years of Antarctic experience. Oceanography was the main subject of this expedition, with a programme on the ecology of the Ross Sea and the launch of long-term monitoring on the penguin colony at Edmonson Point. Another important international programme in this expedition was the Cape Roberts Project on paleoclimate, from recent to Oligocene (about 35 Ma). It consisted in the drilling of the sea bottom from a sea-ice platform.

The regular utilisation of Twin Otter light transport plane, for the flights connecting TNB and Dome C started during the eleventh expedition.

From 1998 to 2000 there was important international cooperation. While the ice drilling at Dome C reached a depth of 786 m, at the US McMurdo Station there was the successful implementation of the international project Boomerang (Balloon Observation of Millimetric Extragalactic Radiation and Geophysics) that collected data on the origin of galaxies. The International Trans-Antarctic Scientific Expedition collected ice samples and data along a 1152 km line between TNB and Dome C. The Cape Roberts Project was successfully concluded with the collection of a rock core 939 m long. The Airborne Polar Experiment performed a series of flights inside the polar vortex measuring in situ the seasonal decrease of the ozone layer.

Meteorites have been collected from the ice cap not far from TNB in several summer campaigns. In the nineteenth expedition, they amounted to about 5 kg.

An ice-strengthened vessel (M/V *Italica,* 5600 tons) resupplies the coastal station with heavy cargo and fuel, in addition to supporting research at sea and hydrography. About ten flights of the Hercules link MZS to New Zealand just before the beginning of the summer season. One or two Twin Otters are used to link MZS to Concordia, heavy loads usually reaching Concordia from the French station Dumont d'Urville on tracked vehicle convoys. Two to four helicopters carry scientists to local surveys and sampling. Most of the transportation is made on a charter basis. The OGS *Explora,* which is owned by an institute based in Trieste, makes marine geophysics surveys in the Ross Sea, around the Antarctic Peninsula and in the South Atlantic.

The scientific production of the Italian programme amounts (at this writing) to some 2040 papers. The PNRA's annual budget from 1999 to 2003 was typically around €25 million, ranging from a minimum of €21.4 million in 1999 to a maximum of €29.7 million in 2001. It includes core science, operation and logistics, investments, overheads such as costs for the headquarters and part of personnel, the normal salaries of the scientific personnel being paid by the home institutions.

J

JAPAN: ANTARCTIC PROGRAM

Start and Preparation for Organization

Japan resumed its activities in Antarctica on the occasion of the International Geophysical Year (IGY), after its first expedition by Nobu Shirase in 1911–1912. Present Antarctic programs of Japan have been continuing nearly 50 years and developing in accordance with changes of international schemes, administration systems, logistic facilities, etc.

The Science Council of Japan (JSC) established the National Committee for the Third International Polar Year in June 1952 in response to the call for participation in research programs in the International Polar Year (IPY). The government of Japan decided formally to join in international Antarctic research in the IGY and established Headquarters for Japanese Antarctic Research Expedition, consisting of executive officers of governmental agencies concerned and scientific advisors, chaired by the minister of the Ministry of Education (now the Ministry of Education, Culture, Sports, Science and Technology, MECSST) in November 1955. It has been responsible for the administration of the expedition and for approval of all programs, both scientific and logistical, since its establishment. The Antarctic Special Committee of JSC, which became independent from the IGY Committee in October 1955, worked on planning the research programs consisting of upper-atmosphere physics, meteorology, solid earth geophysics, geology, physical geography, glaciology, oceanography, and cartography for the first year of the 3-year program. The biological program was added in the second year. Researchers were dispatched from national universities and governmental agencies such as Radio Research Laboratories, Meteorological Agency, Hydrographic Office, and Geographical Survey Institute. The logistics plan, including construction of station buildings, telecommunication facilities, electricity system, etc., was also made by the committee. Logistics support people were selected mainly from private companies. However, all expedition members were employed by the government.

IGY and Expedition Ship *Soya*

Ice-strengthened R/S *Soya* of the Maritime Safety Agency sailed for Prins Harald Kyst (Prince Harald Coast), East Antarctica, from the Port of Tokyo 8 November 1956 for the first time. The Japanese Antarctic Research Expedition I (JARE-I) landed on the east coast of Lützow-Holmbukta (Lützow-Holm Bay) and constructed and opened Syowa Station. The IGY research program of Antarctica was extended for some years and finally semipermanently through the International Geophysical Cooperation by international agreement via the Antarctic Treaty in 1959. However, the operation of Japan was interrupted because the institution for conducting activities in

Antarctica was of provisional nature at that time and the expedition ship became decrepit. Syowa Station was closed 8 February 1962. The main scientific results in this first stage (JARE-I to JARE-VI) were the acquisition of basic data on the following: climate, aurora, cosmic ray, ionosphere, geomagnetism, and seismic activity at Syowa Station; bedrock and glacial geology of newly discovered Yamato Mountains and of coastal areas; glaciology, including explosion seismology; and mapping.

Establishment of Base and Operation with a New Icebreaker

The government of Japan decided to resume Antarctic research in August 1963 and began necessary preparations. Syowa Station was reopened formally 1 February 1965, with an agreement for the construction of the icebreaker *Fuji* and the establishment of a permanent national organization as a core of polar research, which has been conducted by researchers from universities and national institutes since IGY.

Science programs were divided into two categories for their appropriate operation and management: "research projects" and "routine observations." The former includes aurora observation, atmospheric sciences, glaciology, geology, and biology. These programs are to be conducted by scientists mainly from universities. The latter consists of routine meteorological observations, ionosphere observation, seismic monitoring, geodesy and cartography, and oceanographic observations on board the expedition ship. Several governmental agencies carry out routine observations: Meteorological Agency for meteorological observations, Radio Research Laboratories for ionosphere observation, Geographical Survey Institute for geodesy and cartography, Hydrographic Office for physical and chemical oceanography and for tidal observation at Syowa Station, and Polar Research Division of National Science Museum (Polar Research Center afterwards) for seismic monitoring and biological oceanography.

Main research projects of the early stage (JARE-VII to JARE-XIV) after resumption of expedition were an inland over-snow traverse to and from the South Pole in 1968–1969, rocket observation of aurora in 1970–1973, and glaciological fieldwork including wintering at a small inland station, Mizuho, in 1969–1973.

The National Institute of Polar Research (NIPR) was established by MECSST as one of national institutes for joint use by universities in September 1973. It grew out of the Polar Research Center of the National Science Museum. It has been the national center both for polar research and for organization and operation of Antarctic expedition since its start.

Research programs were made in advisory planning committees set out in NIPR. Committees were settled to cover four fields: upper-atmosphere physics, meteorology and glaciology, earth sciences, and biology. Each committee was chaired by a scientist from an organization (mainly from a university) other than NIPR. Routine observation programs were planned by organizations concerned respectively. Programs for logistics support such as renewal of living quarters and telecommunication facilities were made by the logistics advisory planning committee. The Headquarters for JARE approves all research programs and operations in the Antarctic region at its general assembly every year, though programs have been mostly multiyear ones.

Main programs and results from 1972–1974 to 1982–1984 (JARE-XV to JARE-XXIV) were rocket observation of aurora as a part of International Magnetosphere Study, marine biology as a part of BIOMASS programme (some research ships from universities and a governmental agency participated in this program), micrometeorology and glacial climatology in POLEX SOUTH programs, explosion seismology for crust and upper mantle study, and meteorite searches. The discovery of the "ozone hole" in 1982 and collection of many "Yamato Meteorites" are noteworthy among various results.

Age of New Development

The new icebreaker *Shirase* was placed in commission in November 1983, relieving the duty of *Fuji*. The capability of *Shirase* for ice navigation and cargo transportation made it possible to introduce programs that need large-scale operation. Construction of Asuka Station began near the foot of the Sür-Rondane Mountains in 1984–1985 in order to carry out earth science and biology field programs. Year-round meteorological and geophysical observations were also carried out until 1991. The first deep ice coring was carried out in winter 1995–1996 at Dome Fuji station, which was constructed at the summit of the dome 3810 m above sea level. A 2500 m long ice core was obtained. The second deep ice coring started in the 2003–2004 season in order to study global environmental changes in the last 800,000 years, using international intercontinental air transportation system. Long-term earth science investigations of Enderby Land, 400 km east of Syowa Station, were carried out for study of the crustal evolution of one of the oldest complexes of the world. Various investigations in upper atmosphere physics such as receiving of signals from satellites by a large parabola antenna and polar patrol balloon observations are being conducted at Syowa Station. Continuous gravity measurement using a superconductivity gravimeter, GPS observation, and tidal observation are being carried out for the purpose of global monitoring of change of the Earth. The Intelsat system was introduced into Syowa Station and started service February 2004. The system serves scientists for real-time research as well as for private telecommunication. The main research projects in 2005–2007 are as follows: (1) continuation of deep ice coring at Dome Fuji Station, (2) Late-Cenozoic Antarctic ice sheet history and global change, (3) geophysical mapping around Syowa Station (Japan-Germany collaboration study on airborne geophysics), and (4) time-serial studies on biological processes and greenhouse gases in the seasonal sea ice zone.

In addition to the above, NIPR carried out small-scale joint programs as part of national programs: US–Japan Search for Meteorites in Victoria Land from 1976–1977 to 1979–1980 and US–New Zealand–Japan Mount Erebus Eruption Mechanism Studies from 1980–1981 to 1985–1986.

Nongovernmental Programs

Besides governmental programs, Japanese researchers from several universities and institutes conducted geochemical field investigations in the Dry Valleys region in Victoria Land from 1963–1964 to 1986–1987. Transportation and other logistical support were provided by Division (now Office) of Polar Programs, NSF of the US, and by Antarctic Division, DSIR of New Zealand (now NZ Antarctic Programme). Japan Polar Research Association, a nongovernmental foundation, continued to provide grants for fieldwork. The Dry Valley Drilling Project (DVDP), which became an important part of the said programs, was performed jointly by the US, New Zealand, and Japan. The government of Japan shared the expense.

Reform of NIPR

NIPR reformed its administration system in April 2004, in accordance with the reformation of national universities and institutes by the legislation. The system for planning and administration of research programs is expected to be improved in the near future.

Governmental Budget

Budget for governmental programs is variable every year due to change of programs, degree of ship repair, etc. The budget for 2004 fiscal year in round numbers was: for research projects, 600 million Japanese yen (US$5.6 million); for routine observation, 170 million yen (US$1.6 million); for logistics except ship operation, 750 million yen (US$7.0 million); for ship operation, 2.3 billion yen (US$21.5 million); and for other expenses including exchange of scientists under the Antarctic Treaty, 100 million yen (US$0.9 million). 30 billion yen (US$28 million) was appropriated for renewal of a large helicopter and an icebreaker as part of multiyear funding.

JAPANESE ANTARCTIC EXPEDITION (1910–1912)

The Japanese Antarctic Expedition, which sailed aboard *Kainan-maru* from Japan on December 1, 1910, had been sent on its way by a crowd of 50,000 well-wishers. Lieutenant Nobu Shirase's ambition to be a polar explorer had caught the popular imagination of a country eager to be regarded as an equal by the West and frustrated by the economic and territorial outcomes of military victory in two wars. Shirase's backers included former prime minister Count Shigenobu Okuma, many prominent figures of the Japanese establishment, and large sections of the popular press. However, the government refused to release substantial funds voted to the expedition, and the explorers were dependent on donations from wealthy individuals and public subscription.

The aim of the expedition was to land on the eastern side of the Ross Sea, and set out the following spring hoping to reach the South Pole before Robert Falcon Scott—like the British, Shirase and his backers were still unaware of Roald Amundsen's expedition. The departure of the expedition was delayed by problems obtaining a suitable ship, and lack of space meant using dog sledges for transport instead of horses. Thirty dogs and two Ainu drivers, Yasunosuke Yamabe and Shinkichi Hanamori, joined the expedition from the Japanese territory of Karafuto on sub-Arctic Sakhalin Island, but when Captain Naokichi Nomura brought *Kainan-maru* into Wellington Harbour in New Zealand only six dogs were left alive. After taking on fresh supplies, they sailed on February 11, 1911, setting course for the Ross Sea at a date when most other vessels would have been leaving Antarctic waters.

The first ice was seen on February 28, and on March 6 they sighted the mountains of Victoria Land. Off the Possession Islands the sea started to freeze around them, with floes up to 2 feet (61 cm) thick. Near Coulman Island on March 12 they reached 74°16′ S, 172°07′ W before turning the ship around in the ice to escape from the pack. At a meeting on March 15, they decided to set course for Australia, and, after a stormy voyage in a damaged ship, they dropped anchor in Sydney Harbour on May 1, 1911.

The Australian government granted them official status, and they erected their prefabricated hut at Parsley Bay Reserve on Sydney Harbour. With the support of Professor T.W. Edgeworth David, the famous Australian explorer and academic, an initially mixed reception from the Sydney press was soon overcome. While *Kainan-maru* was undergoing repairs, Nomura returned to Tokyo, Shirase remaining with his men in Sydney.

Nomura brought fresh supplies and twenty-nine dogs from Japan, and *Kainan-maru* sailed from Sydney on November 19, 1911. They now planned to land on the Ross Ice Shelf between 160° and 170° W and explore the area to the southeast, land a party in King Edward VII Land, and use *Kainan-maru* to explore the seas to the east. They saw the first iceberg on December 11, and struggled through the pack until sighting the mountains of Victoria Land on December 3. They were held up by ice again before their first landing on January 16, 1912, at 78°17′ S and 162°50′ W in Kainan Bay, although the surface was too crevassed to allow access to the interior.

Kainan-maru proceeded west, and moored to the ice in the Bay of Whales late on January 16. While supplies and equipment were being unloaded, visits were exchanged with the crew of *Fram,* waiting in the bay for Amundsen's return from the South Pole. By a tremendous effort they transported everything to the top of the 200-foot (60 m) ice cliff of the Barrier in less than 28 hours, and established a base camp at 78°33′ S, 164°22′ W.

The sledging party that set off southeast across the Ross Ice Shelf the following day was aptly named the Dash Patrol. Shirase led his four companions on a short but probably record-breaking journey. On January 28 they reached 80°05′ S after travelling approximately 147 miles (237 km) in nine days through very mixed weather, having covered just over 56.5 miles (91 km) the day before, much of it uphill. They raised the Japanese flag and buried a copper casket containing the names of everyone who had contributed to the expedition's funds, before starting back to the base. Their return journey was even more remarkable. In just over nine hours on January 28 they sledged 70 miles (112 km), covering the remaining 78 miles (125 km) in two main stages to arrive at the base camp early on January 31. Their success was largely due to the skill and efforts of the Ainu dog drivers, Yamabe and Hanamori.

In the meantime *Kainan-maru* had sailed east for King Edward VII Land on January 19. Four days later it was moored to the ice at 76°56′ S, 155°55′ W, and Genzo Nishikawa and Chikasaburo Watanabe climbed to the foot of Scott Nunataks, walking more than 37 miles (60 km) in 30 hours with nothing but their coats, a tin of condensed milk, and some biscuits. Next day *Kainan-maru* sailed east again, reaching 76°06′ S, 151°20′ W on January 26, besting Scott's 1902 record in that direction by nearly 11 miles (17.3 km). Returning west it paused from January 29 to 30 at 77°50′ S, 158°40′ W in Okuma Bay to collect rocks embedded in icebergs, before picking up the main party from the Bay of Whales on February 4.

After another stormy voyage across the Southern Ocean, the expedition arrived in Wellington on March 23. Shirase returned to Japan by steamer to organise payment for the men and develop the motion picture that they hoped would defray the expedition's debts. *Kainan-maru* arrived in Tokyo Bay on June 20, 1912, to a hero's welcome with a lantern parade through the city, and Shirase and Nomura were granted an audience with the Imperial Family.

The geological and biological samples collected in Antarctica were analysed by researchers at Tokyo Imperial University and exhibited throughout the country, and at least five separate accounts of the expedition's achievements were published. Sadly, Emperor Meiji's death shortly after their return eclipsed all other news from Japan, and the achievements of the Japanese Antarctic Expedition did not receive the international recognition they undoubtedly deserved.

K

KELP GULL

Kelp gulls *Larus dominicanus* are a large slate-black-and-white gull with a 1.2- to 1.4-m wingspan and a body mass of approximately 1.0–1.4 kg; males are typically 10%–15% larger and heavier than females. Individuals take 3 years to reach maturity. Their plumage is characteristic and diagnostic for first-year and second-year birds; third-year and adult birds are indistinguishable. First-year birds have a streaked or speckled dark-brown-and-grey plumage, with dark legs and a dark bill. Second-year birds have a "salt and pepper" plumage, with pale bill, streaked or patchy white and bleached brown feathers, and dark legs. Adult birds are slate-black above on the wings and body, and white below, with pale lemon-straw-coloured legs, a pale-yellow bill with prominent red spot on the lower mandible, and a yellow eye with an obvious red orbital ring.

Breeding populations of kelp gulls are present on all Southern Hemisphere continents, and on most islands and island groups south of the Subtropical Front. The southernmost breeding record is 68° S on the Antarctic Peninsula. They are absent from the highest-latitude islands in the Southern Ocean (Balleny Islands and Scott I and Peter I Øy) and from the warm-water Île Amsterdam, and Tristan da Cunha and Gough Islands. The current global population is estimated at more than 1.2 million breeding pairs, of which more than 1 million are believed to breed in New Zealand. Breeding populations have increased in South America, South Africa, and New Zealand in the recent past and are believed to have established in Australia in the late 1950s. Breeding populations are year-round residents with high fidelity to nest sites—there is some evidence of intraseasonal migration by individuals. There is some postbreeding dispersal, with sightings of birds of all ages away from natal sites. Studies have speculated that the Australian population originated in New Zealand. Extent of dispersion appears to be colony specific, with individuals at some breeding colonies present year round. There is no evidence of movements away from sub-Antarctic islands. Antarctic Peninsula colonies are occupied if food is available.

Breeding season varies with locality and latitude, with southerly localities later in breeding-season events than northerly sites, with eggs laid as early as August in Australia and as late as December on the Antarctic Peninsula. Most sub-Antarctic islands' populations lay eggs in November and December. The clutch is typically three eggs, and nests are characteristically close to the coast on sub-Antarctic islands and on the Antarctic Peninsula. Nests are constructed from vegetation and may be almost a metre in diameter and approach half a metre in height. Both adults incubate the eggs, brood, and feed the chicks. Few banding studies have been conducted to establish longevity but kelp gulls are likely to reach 20 years. Age at first breeding is 3 or 4 years, and most birds breed annually.

Nesting can be solitary to colonial. Breeding colonies on sub-Antarctic islands and on the Antarctic Peninsula are typically small to medium in number. Breeding pairs are monogamous and most are maintained from one breeding season to the next. Courtship feeding initiates pair-bond reestablishment during winter months. Breeding territories may be maintained interseasonally and there is a high fidelity to nest site. Postbreeding flocks comprising all age classes form once chicks have fledged. Nesting behaviour is easily disturbed by humans.

Kelp gulls are omnivorous, and feed primarily in the intertidal region, although individuals will scavenge at carcasses and beach-washed material. Kelp gulls will occasionally follow fishing vessels for discards. Individuals will attend breeding sites of seals to scavenge placentae and have been observed feeding on discharged sewage. Their primary food comprises molluscs, crustaceans, and fish, but this is dependent on location and seasonal food availability. Birds are able to dive briefly to obtain food from below the water surface. Kelp gulls will drop molluscs onto rocks to break the shells. Birds may occasionally kleptoparasitise, stealing food from conspecifics or from individuals of other species such as terns and penguins.

KERGUELEN ISLANDS (ÎLES KERGUELEN)

Îles Kerguelen (48°27′ to 50°00′ S, 68°27′ to 70°35′ E) are located in the in the Southern Indian Ocean, 1500 km southeast of Africa and 1800 km southwest of Australia. The archipelago comprises a main island (Grande-Terre) and about 300 offlying islands, islets, and rocks. The total area is about 7200 km^2. The coastline (about 2800 km) is deeply distorted by inlets into numerous peninsulas and fjords.

High mountains occur in the west part of the archipelago. The maximum height is Mont Ross (1850 m asl). By contrast, extensive plateaus with many ponds constitute the eastern side. Between these two sides, deep glacial valleys and numerous rivers and lakes are present, a heritage of past glacial events and strong tectonic activity. The islands are of volcanic origin and the rocks are mainly of basaltic composition, the oldest being more than 25 million years old. An exception is visible on the southwestern part of the archipelago, Péninsule Rallier du Baty, where different metamorphic rocks are dominant (granites, gabbros). The Cook ice cap, 50 by 20 km, is the remains of an ice sheet that formerly covered the major part of the archipelago. Numerous other small glaciers occur in the west.

Climate, as recorded by Météo-France at Port-aux-Français since 1951, is characterized by cool temperatures (3.1°C in winter, 6.5°C in summer), moderate precipitation (770 mm per year), and strong westerly winds. However, the relief on the west creates a foehn effect that is responsible for a strong gradient of precipitation, varying from more than 3500 mm per year on the west coast to less than 700 mm per year in several places in the Golfe du Morbihan. In addition, there is evidence of drastic changes in the recent climate conditions: temperatures have increased by 1.3°C since the mid-1970s, and precipitation has been halved during the same period. As a consequence, all the glaciers are currently retreating and, at least at low altitude, summer droughts threaten the native biota, which has never experienced such environmental conditions.

The native flora comprises twenty-nine vascular plant species: twenty-two phanerogams and seven pterydophytes. The only endemic species is *Lyallia kerguelensis* Hooker f. (Hectorelliaceae). Most of the other species are sub-Antarctic species and grow in the other islands of the southern Indian biogeographic province, namely Marion, Prince Edward, Crozet, and Heard islands. The cosmopolite blue grass *Poa annua* is the only species with an uncertain status: it occurs in most of these islands but was likely early introduced by man, as suggested by the high rate of its current extension in the most visited areas. Beside these vascular plants, numerous bryophyte and lichen species, probably several hundred, are present but very few studies have been carried out on these groups.

Vegetation varies considerably along the altitude. Up to 250 m asl, the Kerguelen cabbage (*Pringlea antiscorbutica,* Brassicaceae), *Acaena magellanica* (Rosaceae), and the grass *Festuca contracta* usually dominate in moist habitat with deep organic soils. Cushions of *Azorella selago* (Apiaceae) occur on moraine slopes and exposed plateaus. *Dechampsia antarctica* and *Agrostis magellanica* occur along stream banks and in bog areas. Above the plateaus, open feldmark vegetation of grasses, ferns, mosses, and lichens can occur, but many high areas are devoid of vegetation.

In addition to these native species, sixty-nine alien species were recently recorded. Only seven are invasive and widely distributed within the archipelago

(Cerastium fontanum, C. glomeratum, Sagina procumbens, Stellaria media, Taraxacum erythrospermum, T. officinale, and *Poa annua),* while the remaining persistent species are linked with sites that are or have been intensively used by humans. Most of these introduced plants are European and are favoured by the current trends in the climatic conditions.

About 150 invertebrate species are known from Îles Kerguelen, some of them endemic to the Southern Indian Ocean sub-Antarctic province. The insect fauna show spectacular morphological and physiological adaptations, such as wing reduction or starvation capacities. The wingless fly *Anatalanta aptera,* for instance, living in bird colonies, is able to survive without food during several months in winter, waiting for the return of birds. The invertebrate fauna are dominated by decomposers (numerous earthworms, collembola, diptera), with few herbivores (weevils) and rare predators (two spider species and one staphylinidae). This disharmony in the trophic structure of the invertebrate community is responsible for its high sensibility to introduction of alien species: the carabid beetle *Oopterus soledadinus,* accidentally introduced in the early twentieth century, is currently spreading in several littoral sites of the archipelago, where it constitutes a serious threat for the native invertebrate fauna. A total of thirty introduced invertebrate species have been recorded, only a few of them being widely distributed: earthworms *(Dendrodrilus rubidus tenuis),* diptera *(Calliphora vicina, Fucellia maritima),* and aphids *(Myzus ascalonicus, Rhopalosiphum padi).*

The islands host thirty breeding species of bird, the most common species including king penguin, macaroni penguin, rockhopper penguin, wandering albatross, Kerguelen shag *(Phalacrocorax verrucosus),* sub-Antarctic skua, kelp gull, Kerguelen tern, Antarctic tern, a pintail *(Anas eatoni)* endemic to Îles Crozet and Îles Kerguelen, and a black-faced sheathbill *(Chionis minor minor)*. There are also numerous petrels, including the Cape petrel, white-headed petrel, Kerguelen petrel, blue petrel *(Halobaena caerulea),* white-chinned petrel *(Procellaria aequinoctialis),* Wilson's storm petrel, black-bellied storm petrel, Antarctic prion, South Georgian diving petrel *(Pelecanoides georgicus),* and Common diving petrel *(P. urinatrix)*. Two species of marine mammal breed on the islands: southern elephant seal and Antarctic fur seal.

Twelve alien vertebrate species have been introduced, five salmonid fishes, and seven mammals (mouse, rat, rabbit, sheep, mouflon, reindeer, and cat). These mammals have considerable impacts on the indigenous ecosystems naturally devoid of mammalian herbivores or carnivores: for example, only the rosaceae *Aceana magellanica* survives on islands where rabbits are present, rats and mice have a strong impact on invertebrate communities, and cats eat several thousands birds each year. Rabbits and rats have been recently removed from experimental islands in conservation actions.

Îles Kerguelen were discovered by Captain Yves-Joseph de Kerguélen-Trémarec, who made two claims: on February 12, 1772, and again during his second expedition in December 1773. They were explored by Captain James Cook in 1776, who named them after Kerguélen (with the alternative name Islands of Desolation). Sealers, whalers, and several scientific expeditions visited the islands in the nineteenth century. In 1908 a sheep farm and a whaling station were established at Port Jeanne d'Arc, continuing until 1930. A scientific station was established at Port-aux-Français in 1950. It hosts about one hundred people in summer and fifty in winter. Today, the fishing activity (the two main fish species concerned are *Notothenia squamifrons and Champsocephalus gunnari*) is strictly controlled in terms of authorized ships and amount of catches.

KERGUELEN TERN

Kerguelen terns *(Sterna virgata)* only breed on the southern Indian Ocean islands of the Prince Edward Islands, Îles Crozet, and Îles Kerguelen. Nonbreeders have been seen on islands in these island groups that are not used by breeding birds (e.g., Île aux Cochons). About 50 pairs breed on the Prince Edward Islands, more than 150 pairs on Îles Crozet, and 1500 to 2000 pairs on the Îles Kerguelen archipelago. The populations on the Kerguelen archipelago are growing because of the introduction of salmonid fish, but on Îles Crozet, the Kerguelen tern is threatened by introduced black rats *Rattus rattus* and cats *Felis catus*.

Kerguelen terns are usually only seen near their breeding islands. Most birds feed within 2 km of the shore and few go farther offshore. The birds are most frequently seen in open waters in the surf zone or along sheltered parts of the coastline, but are sometimes also seen in the littoral zone. Kerguelen terns are one of the few species that can be seen inland, some kilometres from the coast, where they nest in terrestrial habitats, such as rocky or sparsely vegetated swards. Kerguelen terns are sedentary and do not disperse far. Juveniles have been observed with adults, not only after fledging but also during the winter in the seas around breeding grounds. Sometimes they form mixed-species flocks with Antarctic terns *S. vittata*.

Individuals nest in small colonies, generally on flat and gently sloping ground on exposed clifftops, rocky islands, hills, or plateaux. Other places used are gravel plains, valleys, river flats, and occasionally shell or pebble beaches. Sandy beaches are avoided. The breeding places are characterized by scree and other stony debris, and the vegetation is sparse or closely cropped. Nests have been found up to 100 m above mean sea level and, at the furthest, 2.4 km from the coast.

The clutch size for Kerguelen terns differs among islands. On Îles Crozet, they usually lay one egg, on Marion I one or two, and on Îles Kerguelen two. Incubation lasts 24 days; the chicks fledge after 31 to 39 days but remain dependent on their parents for a further 20 days. The timing and duration of breeding varies between years and among breeding sites. After their first visits to the colonies, Kerguelen terns lay their first eggs in August or September, on Îles Crozet from early October to early January, and hatchings occur from early November to late January. For courtship feeding, the male brings a fish or sometimes crustaceans or insects to the female.

Kerguelen terns feed on fish, crustaceans (amphipods, isopods, and crabs), and other terrestrial or marine invertebrates (annelids, spiders, insects). The food changes seasonally: in September they feed mainly on crustaceans, during incubation in November on fish, and during chick rearing in December mainly on terrestrial arthropods. They mainly forage in inshore marine waters, only occasionally venturing up to 2 km from the islands. The food is taken by plunging into the sea from 3 to 4 m above the surface. The terns prefer the surf zone along the coast and sometimes forage in the inshore beds of seaweed, in which they feed just below the surface of the water. At low tide some terns feed in shallow intertidal pools on stony as well as sandy beaches. In some cases during spring and summer, feeding also occurs in freshwater terrestrial wetlands near breeding colonies. These sites include fell meadows, damp meadows, bogs, and marsh terraces. Fishing in rivers has also been recorded. Sometimes the birds feed among closely cropped terrestrial vegetation. In terrestrial habitats, they forage both aerially and on the ground.

KERGUÉLEN-TRÉMAREC, YVES-JOSEPH DE

Yves-Joseph de Kerguélen-Trémarec (1734–1797) was a Breton naval officer who had for years hoped to conduct a voyage of discovery to the southern oceans. He followed in the wake of well over two centuries of French explorers (Paulmier de Gonneville, Jules Marie Crozet, Marie-Joseph Marion-Dufresne, and Jean-Baptiste Bouvet de Lozier) who explored the southern seas. With the French government eager to follow up on the earlier discoveries of its explorers and extend its sphere of global influence, Kerguélen-Trémarec succeeded in obtaining approval for a voyage of exploration. He sailed from Lorient on the Breton coast of France on May 1, 1771 with instructions to sail south from Île de France (now Mauritius, 20°17′ S, 57°33′ E) to discover a continent south of Île St. Paul (38°55′ S, 77°41′ E) and Île Amsterdam (37°57′ S, 77°40′ E). Based on de Gonneville's reported landfall in 1503–1504 when he was blown south of the Cape of Good Hope, such a landmass was expected to be temperate and inhabited, and Kerguélen-Trémarec was to establish good relations and trade agreements with the inhabitants.

He departed from Île de France on January 16, 1772 with two vessels, *La Fortune* under his direct command, and *Le Gros Ventre* under François Alesno Comte de St-Allouarne. On February 12, Kerguélen-Trémarec sighted a small island and the following day a larger landscape at 49°40′ S, and 61°10′ east of Paris (longitude 2°20′ E). (Longitude determinations in Kerguélen-Trémarec's day were still imprecise, and the general position of 'les Kerguelen, now named after their discoverer, is 49°20′ S, 69°30′ E). Stormy weather separated the ships and prevented Kerguélen-Trémarec from landing, but St-Allouarne launched a boat under the command of a Breton named Boisguehenneue who was able to land at Sea-Lion Bay (now Anse du Gros Ventre) and took possession for King Louis XV. The land was named "La France Australe." Approximately 75 miles of coastline were examined, but due to poor conditions the men had to quit the area.

Upon his return to civilization, Kerguélen-Trémarec greatly exaggerated the significance of his land discovery. He delightedly described having found the central mass of the long-sought Antarctic continent and that it was favorably positioned as a convenient link to India, the Moluccas, China, and the South Seas. He predicted that the economic vitality of 'le de France would be tripled and that La France Australe would be so arable as to provide all the crops needed for 'le de France's inhabitants, thus obviating the need to resupply the island all the way from France. He claimed that La France Australe had abundant natural resources—wood, diamonds, rubies, marble, and more. Not only this, but if there were human inhabitants, they would be primitive and incapable of being offended, implying that they could be put to productive use without resistance.

His report engendered well-deserved skepticism, even ridicule, but he was persuasive enough, the latitudes were low enough, and France's interest in extending its dominion great enough that influential Frenchmen listened: the head administrator of 'le de France wrote enthusiastically that Kerguélen-Trémarec had discovered for France a whole new world. St-Allouarne had sailed directly to Australia after the landing at La France Australe, and thus no timely first-hand report of the bleak conditions ashore had reached France to counter Kerguélen-Trémarec's fantastic account. Kerguélen-Trémarec was awarded the esteemed Cross of St. Louis and outfitted for another voyage to the area, this time in three ships, *Le Roland, L'Oiseau,* and *La Dauphine*. The vessels sailed March 26, 1773 and were to proceed eastward between 40° and 60° S.

On this second voyage, the officers were inept; the ships arrived at the Cape of Good Hope in poor condition with many of the crew seriously ill. By now, St-Allouarne's account had reached France, and authorities were newly skeptical of Kerguélen-Trémarec's tales of the islands' temperate climate and natural riches. Kerguélen-Trémarec's sick men were replaced with poor substitutes, and the ships arrived at La France Australe on December 14, 1773 in unfavorable weather amid terrible conditions aboard. A landing was effected on January 6, 1774, not by Kerguélen-Trémarec, whose leadership seemed to be foundering, but by Charles de Rosnevet of *L'Oiseau*. Wildlife was abundant, but no humans were found inhabiting these inhospitable islands that were incessantly enshrouded in fog, whipped by gales, and pelted by rain. The men examined the islands more carefully, prepared crude charts, and returned to France.

Meanwhile, James Cook had completed a high-latitude circumnavigation; in February 1773 he passed well south of Kerguélen-Trémarec's position, thus proving that no land discoveries north of his latitudes constituted part of an Antarctic continent. Kerguélen-Trémarec had to admit the folly of all his earlier assertions, except the land discoveries per se. He fittingly named the island group the Land of Desolation. It is telling that Joseph Dalton Hooker, the young botanist on James Clark Ross' Antarctic voyage of 1839–1843, referred to Îles Kerguelen after a lengthy visit as one of the "most wretched spots on the globe."

Kerguélen-Trémarec arrived at Brest, France on September 7, 1773. A variety of charges were laid against him, including smuggling a woman aboard *Roland* for his personal pleasure, carrying goods to trade for his own benefit, failing in his responsibilities as leader, and professional misconduct. He was arrested, court-martialed, and imprisoned for 4 years. In some measure, however, he was eventually forgiven the transgressions of his ludicrous assertions and misdeeds, for the islands, about 300 in all, are collectively Îles Kerguelen in his honor, and have belonged to France since 1893.

KILLER WHALE

The killer whale *(Orcinus orca)* is a toothed whale (suborder Odontoceti) in the order Cetacea (whales, dolphins, and porpoises); it is, in fact, the largest member of the dolphin family (Delphinidae). Also commonly referred to as "orca," it is the most widespread animal in the world, after humans. Although more common in high latitudes than in the tropics, it is found throughout the world's oceans.

The highly contrasting black-and-white pattern is easily the most familiar of any of the cetaceans, making the killer whale perhaps the most universally recognizable marine animal. The pattern is essentially black above and white below, with a prominent white eyepatch just above and behind the eye, and a large white flank patch that extends dorsally from the area of the vent, and then posteriorly along the flanks. The "saddle patch" is a pale gray area posterior to the dorsal fin that extends ventrally, and then anteriorly as a thin taper. Young calves have an orange tinge to all of the white-pigmented areas, which usually disappears within 1 year. Killer whales that live in close association with pack ice are often coated with a yellowish diatom film, giving them a brown-and-yellow appearance.

Killer whales are strongly sexually dimorphic and, among cetaceans, are second only to the sperm whale *(Physeter macrocephalus)* in the degree of physical differentiation between males and females. Adult males reach a total length of 9.0 m and females up to 7.7 m. Few have been accurately weighed, but a 6.75-m male weighed 5568 kg, and a 6.7-m female weighed 3810 kg. Neonate calves are 2–2.5 m long and weigh approximately 200 kg. Compared to females, adult males also have proportionately large extremities, including flukes, flippers, and dorsal fin. The impressive dorsal fin of an adult male can reach almost 2 m in height, nearly twice that of the female. Adults have ten to twelve (up to fourteen) teeth in the upper and the lower jaw; they are pointed and conical, and all have the same general shape (homodont).

Worldwide, there is only one species of killer whale recognized, and no named subspecies. It has become clear, however, that some killer whale communities (perhaps mainly in higher latitudes) include subpopulations that specialize on different prey and appear to be reproductively isolated. The formation of these "ecotypes" is correlated with a divergence in morphology, behavior, and vocalizations within sympatric killer whale populations, and may ultimately be responsible for initiating speciation events. For example, based on ecological and genetic differences, it has been suggested that the fish-eating and mammal-eating killer whale ecotypes in the northeast Pacific probably qualify as separate species (or at least subspecies), although no formal recognition has been suggested.

Based on catches from whaling vessels operating in Antarctica in the early 1980s, two groups of Soviet scientists independently described two new species of killer whales. They were named *Orcinus nanus* and *O. glacialis,* but their existence has been discredited and largely ignored by cetologists because the descriptions were inadequate and there are no extant holotypes (voucher specimens).

More recently, three distinct ecotypes of killer whales were described from field observations in Antarctica, and designated Types A, B, and C. Each of these ecotypes is readily identifiable at sea, and each appears to have distinct prey and habitat preferences. Type A appears to be the "typical" globally distributed killer whale. It is black and white, has a circumpolar distribution in Antarctica, lives in open water, and occurs in small groups (averaging around fourteen individuals). It apparently migrates south to Antarctica each summer to feed on Antarctic minke whales *(Balaenoptera bonaerensis)*. The minkes also migrate to Antarctica each summer, to feed on seasonal krill blooms, and Type A killer whales intercept them north of the ice edge.

The Type B killer whale also has a circumpolar distribution, but is especially common in waters around the Antarctic Peninsula. This form has a tripartite color pattern with a black dorsal cape, gray sides, and white underparts. It also has a noticeably large white eyepatch compared to the other forms. It forages in small groups (averaging approximately twelve animals), and hunts among loose pack ice where it has been seen to feed only on ice seals and elephant seals *(Mirounga leonina)*.

The Type C killer whale occurs mainly in East Antarctica. It also has a gray, black, and white color pattern, but the eyepatch is small and slanted. It forages in large groups (averaging 46 individuals, although groups of 300–400 have been reported), occurs in dense pack ice and among leads in fast ice, and has been observed feeding only on Antarctic toothfish *(Dissostichus mawsoni)*. During the winter, Types B and C have been observed both in Antarctic waters and in lower latitudes, leaving their migratory status unclear.

Although these three forms occupy adjacent and, at times, overlapping ranges, they do not occur in mixed schools and there have been no reports of intergrades (i.e., possible hybrids). This has led to the conclusion that they may represent two, or possibly three, separate species. Currently, it is not clear how these three forms relate to the two new species that were proposed by the Soviet scientists. The latter descriptions were so vague that it is impossible to determine whether the same or different species were being described, although in both cases "dwarf" forms were indicated. Recent measurements of Type C killer whales in the southern Ross Sea from aerial photographs indicate that they are on the order of 1.5–2 m shorter than the "regular" killer whales measured by Soviet whalers. Although this provides further evidence that there might be multiple species in Antarctica, additional data on genetics and morphology will be necessary to provide confirmation.

Nearly all that is known about the life history, behavior, social structure, and ecology of killer whales has come from ongoing studies in the northeast Pacific during the past three decades. Males there live an average of about 30 years (estimated maximum: 50–60 years); they attain sexual maturity at about 15 years, and continue to grow until they reach physical maturity at 21 years. Females live an average of 50 years (maximum: 80–90 years); they give birth to their first calf between 11 and 16 years of age (mean 15), and average about one calf every 5 years during a reproductive life span of about 25 years. After that, they enter a postreproductive period lasting from 10–30 years. The gestation period is 15–18 months, and calves can be born during any month of the year. Calves nurse for at least one year and are weaned probably between 1 and 2 years of age.

Killer whales generally live in stable groups of related individuals for their entire lives. Among fish-eating populations studied to date, the basic social organization is matrilineal: an older female lives with her sons and daughters, and the offspring of her daughters. Among mammal-eating forms, the matriline is also the basic social unit, but the offspring tend to disperse more readily, which results in the smaller average group sizes. It has been suggested that different optimum group sizes have evolved among the different ecotypes to meet the demands of prey specialization (for example, smaller groups are apparently more efficient for hunting small marine mammals), and this has been mediated through varying degrees of dispersal within the matrilineal social structure.

Four basic behavioral modes have been described for killer whales: traveling, feeding, resting, and socializing. Traveling (including foraging) takes up 60%–95% of the activity budget, with fish-eaters spending considerably more time resting and socializing than mammal-eaters.

In Antarctica, the different ecotypes exhibit different foraging behaviors that are also related to prey specialization, although all ecotypes forage cooperatively and any large prey items are usually shared among the group. Small prey is usually swallowed whole underwater; large prey is often brought to the surface and dismembered.

Type A killer whales prey on minke whales up to 9 m in length, and they probably also take calves of larger whales, as well as any sick or injured adults. To kill prey this large requires a coordinated effort by all members in the group, and observations to date suggest that individuals within a particular killer whale group may fill specific roles during these attacks. For example, some individuals stay beneath the prey to prevent it from diving; others may position themselves on the prey's head to prevent it from surfacing and breathing; still others bite down on appendages to slow the animal down and tire it out. To reduce the possibility of injury to the attackers, these attacks often last 2–3 hours, and have been recorded to last more than 7 hours. When killer whales feed on large whales, they prefer the lips and tongues, and when prey is abundant these are often the only parts that they take.

Type B killer whales typically fan out and move through areas of loose pack ice to search for seals hauled out on ice floes. While foraging, members of the group regularly stop and lift their heads vertically out of the water (spyhopping) to visually locate potential prey. Once a seal is detected, the whales have several behaviors for taking it off the ice. If the ice is thin, a whale can crash through from below; if it is thick but small, a single whale can lift up the edge of the floe and spill the seal into the water; for heavier, larger floes, groups have been seen to rush the floe and turn at the last instant, producing a wave that washes the seal into the water.

Little is known about the foraging behavior of Type C killer whales because most of the prey is apparently small enough that it is swallowed whole, underwater. Fish-eating killer whales in Norway are known to herd smaller fish and keep them in a tight ball by swimming around them, releasing bubbles, and slapping their flukes; they then strike the ball with their flukes and feed on the stunned prey.

Young Type C killer whales have been observed herding Adélie penguins *(Pygoscelis adeliae)* in this manner and then letting them go unharmed. It has been suggested that the whales are just "practicing" for feeding on fish schools.

Killer whales, like most delphinids, produce a wide variety of clicks, whistles, and pulsed calls used for echolocation and social signaling. Group-specific dialects are common among the populations studied to date; these appear to reflect relatedness among individuals and groups, and probably assist in maintaining group identity and avoiding inbreeding. Among North Pacific ecotypes, fish-eating forms are much more vocal when traveling and foraging than mammal-eating forms, presumably because all marine mammals have acute underwater hearing and mammal-eating killer whales must therefore hunt silently. These vocalization patterns will likely apply to Antarctic ecotypes also.

Historically, whalers in Antarctica were less interested in taking killer whales (because of their small size), and the catches were generally always small. For example, although the former USSR took 110 killer whales in 1958–1959, they only averaged 24 per season from 1969 to 1978. During the 1979–1980 season, when the International Whaling Commission reduced the allowable Southern Ocean sperm whale catch to zero, the USSR harvested 916 killer whales, which have a somewhat similar oil to that of sperm whales. The following year, the prohibition on whaling in Antarctica was extended to include killer whales and none has been taken (legally) since then.

Antarctica may have the highest density and largest overall population of killer whales of anywhere in the world. Two recent (1990 and 1995) population estimates were 70,000 and 80,400 individuals. These figures, however, do not include a breakdown by ecotype, and they may be underestimates because the ships that did the surveys generally did not venture into the pack ice, where Types B and C killer whales are typically found, often in abundance.

Although whaling is not a current threat to Antarctic killer whale populations, commercial fishing for Antarctic toothfish has recently begun in Antarctica, and this represents an unknown, but potentially important, impact because the fishery targets the only known prey of Type C killer whales.

KING GEORGE ISLAND

Location, General Shape, Topography, and Area

King George Island, South Shetland Islands, is located at 62°05′ S, 58°15′ W and lies 144 km to the southwest of Elephant Island. It is separated from Nelson Island to the southwest by Fildes Strait, a narrow passage about 500 m wide. The island is the largest in the South Shetland group, extending 80 km from east to west and almost 30 km from north to south at its widest point. King George Island has an area of 1260 km^2, of which 98 km^2 are ice free (areas calculated using SCAR 2004); 92.2% of the island is covered by a permanent icecap rising to an elevation of 700 m.

The northern coastline is dominated by ice cliffs, punctuated by several prominent headlands, the easternmost of which is known as North Foreland. This rugged and exposed coastline is peppered with offshore rocks and reefs, and is rarely visited. In contrast, the southern coast is comparatively sheltered, and is indented by four large embayments—Sherratt Bay, King George Bay, Admiralty Bay, and Maxwell

Bay, the last of which is enclosed in part by Nelson Island. Apart from a few nunataks protruding through the icecap, the island's ice-free ground is concentrated in the coastal areas. The geology of the island is covered under this encyclopedia's entry for the South Shetland Islands.

At the southwestern extremity of King George Island lies Fildes Peninsula, one of the most extensive ice-free areas found in the South Shetland Islands. Extending approximately 10 km from north to south and up to 4 km in width, Fildes Peninsula has an area of around 33 km^2. The peninsula consists of a series of low hills and small plateaux rising to elevations of around 100 m, with approximately 40 lakes and more than 20 streams. These are the largest freshwater bodies found on King George Island, and some of the most extensive in the region. The combination of relatively gentle ice-free topography together with a safe harbour in Maxwell Bay with good ship-to-shore access has led to the establishment of four scientific stations on the peninsula. Two further stations are located on Potter Peninsula and Barton Peninsula, which are smaller ice-free areas bordering Maxwell Bay to the west.

Admiralty Bay is the largest natural harbour on the southern coast of the island, with a maximum depth of 520 m and a total area of 122 km^2. The first scientific station on the island was established at Admiralty Bay on Keller Peninsula in 1947 (Base G, UK), and there are currently two year-round and three summer-only stations in this region.

The climate at King George Island is typical of the maritime Antarctic, with high precipitation and cloud cover. Precipitation falls mostly as snow, and is around 400 mm annually (Lindsay 1971). The mean daily air temperature is above 0°C for at least one month during the summer, and the mean for the period from December to March exceeds this figure in some years. In winter, temperatures may drop to a mean daily minimum of around –11°C (Lindsay 1971).

Flora and Fauna

The island's ice-free areas support a vegetation cover consisting of algae, lichens, and bryophytes, together with grass and cushion plant formations. Vegetation communities generally resemble those found on the South Orkney Islands and the Antarctic Peninsula, although bryophytes do not form the deep peat accumulations typically found in the South Orkney Islands. While growth is localised and patchy according to conditions, vegetation stands are comparatively extensive for Antarctica. Rich bryophyte development may be found at sites with moist soils, with the most widespread moss turf communities formed by *Polytrichastrum alpinum* and *Polytrichum piliferum*. Large stands of the moss *Sanionia uncinata* are also commonly found on moist flat ground in coastal areas (Lindsay 1971). There is a much greater development of bryophyte communities on the southern coasts than in the north of the island. Drier slopes often support a dense cover of lichen growth, with fruticose lichens such as *Usnea* species commonly forming associations with moss cushion formations. Crustose lichens such as *Caloplaca* and *Xanthoria* species typically occur on more exposed rock surfaces. The two native vascular plants (*Deschampsia antarctica* and *Colobanthus quitensis*) occur at many of the ice-free sites on the southern coast of the island; however, they are largely absent from the northern coast. The most extensive communities of bryophytes and vascular plants are found in sheltered parts of Admiralty Bay, particularly at Point Thomas (close to Arctowski station) (Lindsay 1971).

The ice-free areas also host large colonies of breeding birds in the summer, with thirteen permanent resident species. Of the three species of penguin represented, the most numerous are the chinstraps, with approximately 300,000 breeding pairs, followed by Adélies with around 55,000 pairs, and lastly the gentoos with approximately 10,000 pairs (Woehler 1993). The largest colonies are located along the exposed and rugged northern coast of the island, where 90% of the local chinstraps breed in 15–20 main colonies. The two largest chinstrap colonies are found at

Breeding Bird Species on King George Island

Common Name	Scientific Name
Adélie penguin	*Pygoscelis adeliae*
Chinstrap penguin	*Pygoscelis papua*
Gentoo penguin	*Pygoscelis antarctica*
Sub-Antarctic skua	*Catharacta [skua] antarctica loennbergi*
South polar skua	*Catharacta [skua] maccormicki*
Southern giant petrel	*Macronectes giganteus*
Cape (pintado) petrel	*Daption capense*
Wilson's storm petrel	*Oceanites oceanicus*
Black-bellied storm petrel	*Fregetta tropica*
Kelp gull	*Larus dominicanus*
Antarctic (blue-eyed) shag	*Phalacrocorax [atriceps] bransfieldensis*
Antarctic tern	*Sterna vittata*
Sheathbill	*Chionis alba*

Pottinger Point (~55,000 pairs) and at False Round Point (~50,000 pairs). The other two resident penguin species breed at ice-free locations on the southern side of the island. This pattern of distribution has been explained by the perennial persistence of early-summer sea ice on the northwestern coast, which impedes access by Adélies to ice-free sites at the time when they commence breeding. They therefore seek out the more accessible sites on the more sheltered and relatively ice-free southern coast, while the later-breeding chinstrap takes up residence in the north once the sea ice has started to recede (Trivelpiece and Fraser 1996).

The largest Adélie colony of ~14,500 pairs is at Stranger Point, while the largest gentoo colony is at Ardley Island with approximately 4500 pairs, both situated in Maxwell Bay. There is evidence that numbers of both chinstrap and Adélie penguins on King George Island have been in decline over the last several decades, while gentoo numbers may have exhibited some increase (Woehler and Croxall 1997). The numbers of all species fluctuate widely interannually.

Approximately 3000 pairs of southern giant petrels *(Macronectes giganteus)* breed around the coast of King George Island (Naveen et al. 2000), with the largest single group of around 630 pairs breeding on Penguin Island on the southern coast. This species is known to be particularly sensitive to human disturbance and local declines in numbers have been reported in several locations close to stations and in areas of high activity (Harris 1991a, 1991b; Pfeiffer and Peter 2004). Approximately 100 pairs of Antarctic shags *(Phalacrocorax [atriceps] bransfieldensis)* breed at Turrett Point near Penguin Island (Naveen 2003), while two small colonies, each of ~10 pairs, breed on the northern coast (Poncet, personal communication, 2004).

Several species of seal are common in the region: elephant seals and Weddell seals are regular breeders, while nonbreeding species include Antarctic fur seals, leopard seals, and crabeater seals, the latter often seen on local ice floes.

Mammal Species Observed on King George Island

Common Name	Scientific Name	Breeding
Antarctic fur seal	*Arctocephalus gazella*	Not significant
Crabeater seal	*Lobodon carcinophaga*	Not significant
Elephant seal	*Mirounga leonina*	Yes
Leopard seal	*Hydrurga leptonyx*	Not significant
Weddell seal	*Leptonychotes weddellii*	Yes

Marine Flora and Fauna

The near-shore marine environment around King George Island is characterised by habitats similar to those found in other parts of the South Shetland Islands. The coastal marine flora and fauna are representative of communities found in the transitional area between the sub-Antarctic and continental zones of the Southern Ocean (ASPA No. 151 management plan). Macroalgae colonise near-shore areas to depths of up to 100 m and are found in diverse assemblages, with common species including *Rhodophyta* and *Phaeophyta*. There is a high abundance and biomass of benthic fauna, with bivalve molluscs such as *Laternula elliptica* and *Mysella charcoti* dominating in numbers in many areas up to around 30 m depth. Amphipods and polychaetes are also major components of benthic faunal abundance (ASPA No. 151 management plan), with polychaetes the most abundant group at increasing depths up to around 250 m. Other vagile and scavenger invertebrates include *Sterechinus neumayeri* (sea urchin) and *Glyptonotus antarcticus* (giant isopod). In deeper waters, sessile organisms such as sponges, anemones, and tunicates are present on stable, muddy substrata (Admiralty Bay ASMA management plan). A total of almost 400 benthic invertebrate species have been recorded in Admiralty Bay. Disturbance from icebergs and anchor ice is a major regulating factor of benthic communities in shallower waters (Sahade et al. 1998).

Thirty-five species of fish have been recorded in Admiralty Bay, the majority of which are *Notothenia* or *Trematomus* species (Skora and Neyelov 1992). Offshore, King George Island is surrounded by productive waters that are important foraging grounds for birds and seals breeding on the island and at other nearby locations. Commercial fishing for Antarctic krill is also conducted in the Drake Passage to the northwest of King George Island (CCAMLR 2005).

Protected Areas

Fildes Peninsula and Ardley Island were originally designated Specially Protected Area (SPA) No. 12 in 1966 on the grounds that they were considered a "biologically diverse region with numerous small lakes which are ice-free in summer, that...provides a representative sample of the South Shetland Islands and is an area of outstanding ecological interest" (ATCM Recommendation IV-12). However, immediately after designation, Bellingshausen Station (Soviet

Union) was established in the central part of the site, which resulted in a decision by the Treaty Parties in 1968 to reduce the area to comprise only a small area surrounding a lake in the northeastern part of the peninsula. This remains the most striking example of disregard for the values of a protected area in Antarctica, and it is perhaps indicative of the politics of the day that the SPA was revoked rather than the station removed. The down-sized SPA was revoked completely in 1975, and today Artigas Station (Uruguay) draws its water supply from the lake. Despite being one of the most populated and heavily impacted parts of Antarctica (Harris 1991a, 1991b; Grant 2006), there remains much of biological and scientific interest. However, to date there is no coordinated framework for environmental management of activities in Maxwell Bay, which is one of the most intensively used locations in Antarctica.

Five terrestrial Antarctic Specially Protected Areas (ASPAs) exist on King George Island, four of which were designated on the grounds that they contain significant colonies of breeding birds and seals, as well as locally rich vegetation: ASPA No. 128, Western Shore of Admiralty Bay (17.5 km^2); ASPA No. 132, Potter Peninsula (1.9 km^2); ASPA No. 150, Ardley Island (1.5 km^2), and ASPA No. 151, Lion's Rump (1.3 km^2). ASPA No. 151 also includes a small marine component (<0.5 km^2). The fifth area (ASPA No. 125, Fildes Peninsula) protects two small sites (total area 1.8 km^2) containing fossil outcrops.

An Antarctic Specially Managed Area (ASMA) for Admiralty Bay was adopted in 1996 for voluntary observance to assist with the coordination of activities and to help protect environmental, scientific, scenic, and historical values in the region. The ASMA covers 370 km^2, and comprises the area within the glacial drainage basin of the bay, together with its entire marine area. The responsibility for coordinating implementation of the ASMA management plan rotates between Poland and Brazil, which operate year-round stations in Admiralty Bay.

Discovery, Exploration, History

King George Island was first recorded on 16 October 1819 by William Smith, who claimed possession for the United Kingdom when he landed near North Foreland and named the island after King George III (Headland and Keage 1985). Smith repeated the possession ceremony at King George Bay on 22 January 1820 on a subsequent voyage accompanied by the British naval captain Edward Bransfield. The first charts of the island were prepared on Smith's early voyages. The following years saw an immediate start to the fur sealing industry in the South Shetland Islands, with up to fifty vessels of mainly British and American operators working at King George Island in the summer of 1820–1821. Smith alone reported taking around 30,000 skins that season (Headland and Keage 1985). The over-exploitation of fur seals led to the collapse of the industry in 1824, by which time local populations were virtually wiped out, and although there were brief resurgences from 1843–1854 and 1871–1880, these only further served to eliminate the species almost completely from the island. The local population at King George Island has never recovered, and numbers today are only a small fraction of what they once must have been. Archaeological evidence of sealing activity such as wrecks, shelter ruins, seal bones, and tools still remains.

The early exploration and charting of the island was thus principally by sealers who kept much of their knowledge secret to protect their commercial interests. However, the island was also charted and named (as Waterloo Island) by the Russian Bellingshausen in January 1821, although he did not land. In the same year, eleven men from the *Lord Melville* (a sealing vessel from London commanded by Clark) became the first party to winter over in Antarctica, doing so at Esther Harbour (Roberts 1958). A range of exploratory expeditions visited and charted King George Island in the following decades. Eduard Dallmann left a copper plaque affixed to a post to commemorate the visit of his German expedition on 1 March 1874 onboard *Grönland,* the first steamship to reach Antarctica. The site is protected as Historic Monument No. 36 under the Antarctic Treaty, although unfortunately this failed to prevent the original plaque from being taken, and it is was replaced by a replica in 1987 (Heap 1990).

The modern whaling industry at King George Island began in 1906, with Admiralty Bay being used as a harbour for whale-catchers and factory ships until 1931. Evidence of the industry remains in the form of whale bones still present on many of the bay's beaches.

The Historic Sites and Monuments on King George Island and their reasons for designation are listed in the following table.

Current Human Activities

The major human activities on King George Island today are science, logistics, and tourism. The island is a popular destination for ship-borne tourism, with

Historic Sites and Monuments on King George Island

Site	Location	Reason for Designation
HSM No. 36	Potter Cove	Metal plaque erected by Eduard Dallmann to commemorate his German expedition of March 1, 1874. Original disappeared; was replaced with replica by Germany in 1987–1988.
HSM No. 50	Fildes Peninsula	Plaque commemorating the first Polish Antarctic Expedition in 1976.
HSM No. 51	Point Thomas	Grave of Wlodzimierz Puchalski, who died January 19, 1979, whilst working at Arctowski Station.
HSM No. 52	Great Wall Station	Monolith to commemorate the establishment of Great Wall Station, February 20, 1985.
HSM No. 53	Presidente Frei Station	Plaque and bust commemorating the rescue of survivors from Shackleton's ship by the Chilean cutter *Yelcho*. A replica of the same monument was erected on Elephant Island.

Scientific Stations on King George Island

					Personnel	
Station	Location	Operator	Established	Status	Capacity	Winter
Artigas	Fildes Peninsula	Uruguay	1985	Year-round	60	9
Bellingshausen	Fildes Peninsula	Russia	1968	Year-round	38	25
Great Wall	Fildes Peninsula	China	1985	Year-round	40	14
Presidente Eduardo Frei Montalva/Teniente Rodolfo Marsh Aerodrome	Fildes Peninsula	Chile	1969/1980	Year-round	150	80
Professor Julio Escudero	Fildes Peninsula	Chile	1994	Summer only	20	-

Vicente	Admiralty Bay	Ecuador	1988	Summer only	~6	-
Totals					**598**	**187**

large numbers of vessels visiting stations in Admiralty Bay in particular. Fildes Peninsula is also one of the few destinations for tourist flights to Antarctica, with regular short visits originating mainly from Punta Arenas (Chile) during the summer.

There are currently eight year-round scientific stations and five summer-only stations on King George Island, as well as several temporary or permanent field camps and refuges. Twelve countries operate stations on the island (Argentina, Brazil, Chile, China, Ecuador, Germany, Peru, Poland, Republic of Korea, Russia, United States, and Uruguay). Scientific and logistic personnel are present on King George Island year-round, with a winter population of almost 200 and a significant increase in numbers up to a maximum of around 600 in summer.

The first station to be established on King George Island was established in 1947 by the Falkland Islands Dependencies Survey (FIDS, United Kingdom) on Keller Peninsula, Admiralty Bay, and named Base G. Continuous occupation of Base G ceased in 1961. Small huts in Admiralty Bay were also established by Argentina around the same time (and also at Potter Cove), and later by Italy (1976–1977), before the construction by Poland of a year-round station (Henryk Arctowski) at Point Thomas in 1977.

The largest station complex on the island is operated by Chile, and is situated on Fildes Peninsula. Eduardo Frei Montalva station was established in 1969, and is operated year-round by the Fuerza Aréa de Chile (Chilean Air Force). It also contains a small civilian community (Las Estrellas) with its own school, church, hospital, and bank. A gravel airstrip (Teniente Marsh Aerodrome) was built close to Frei station in 1980, and was extended to its current length of 1300 m in 1984. This airstrip is suitable for large, fixed-wing aircraft and is a major hub for transport to and from other stations and field camps in the Antarctic Peninsula region. Professor Julio Escudero station was established beside the Frei complex in 1994 to house scientific personnel, and is operated independently by the Chilean Antarctic Institute. The entire complex is occupied by up to 170 people during the summer.

Located immediately adjacent to the Frei complex, Bellingshausen station was constructed by the Soviet Union in 1968. It was used primarily as a resupply station for the large Soviet fishing fleet operating in the Antarctic Peninsula region until the late 1980s, and remains operational year-round as a scientific station. In 1984, Uruguay established Artigas station on the eastern shore of northern Fildes Peninsula, and in 1985 the Great Wall station was constructed by China, around 0.5 km to the southwest of Frei.

Scientific stations are also located on two further ice-free areas on the southern coast of King George Island, within the Maxwell Bay area. Jubany Station was established by Argentina at Potter Cove (Potter Peninsula) in 1982, built around the huts that had been established at the site by Argentina in 1947–1948, and has since been occupied continuously. In 1994, Germany constructed the neighbouring Dallmann Laboratory, which is occupied by both Argentinean and German scientists and supported by the facilities of Jubany Station. The Republic of Korea established the year-round King Sejong station at Marion Cove (Barton Peninsula) in 1988.

Brazil established its year-round Comandante Ferraz station close to the abandoned Base G in 1984. A summer-only field camp (Peter J. Lenie, also known as "Copacabana") was constructed close to Llano Point within ASPA No. 128 (Western Shore of Admiralty Bay) in 1985, and has since been occupied every summer by scientists studying the surrounding bird colonies. Ecuador also has a small field camp (Vicente) at Hennequin Point, which has been irregularly occupied during summers since 1988, and a summer-only station was constructed by Peru at Crépin Point in 1989.

KING PENGUIN

Second largest among the penguins, king penguins *(Aptenodytes patagonicus)* are important in sub-Antarctic latitudes. At 85–95 cm they are only slightly shorter than emperor penguins *(A. forsteri),* but at just 9–17 kg they are half their mass. Their close relationship with emperor penguins is clear from their general body shape, size, and pattern of coloration. Adult king penguins are easily distinguished, however, by their thinner body, relatively long bill, and deep orange auricular patches in a characteristic inverted-teardrop shape on either side of the head. The corresponding patches on emperor penguins are more oval in shape and yellow in color. Immature members of both species have paler colors, but the longer bill and teardrop-shaped auricular patches are still characteristic of king penguins. The genders are alike in coloration, but males are slightly larger than females.

There is continuing argument over the number and taxonomy of several penguin species, but the king penguin is clearly distinct. The latest taxonomy places the king and emperor penguins with the brush-tailed *(Pygoscelis),* crested *(Eudyptes),* and yellow-eyed *(Magadyptes)* penguins. Together, these four genera appear to have split off from the striped *(Spheniscus)* and little *(Eudyptula)* penguins early in their evolution.

King penguins currently breed at nine islands in the sub-Antarctic that are scattered around the south Atlantic and Indian oceans: Macquarie, Heard, Kerguelen, Crozet, Prince Edward, Marion, South Sandwich (few), South Georgia, and the Falklands (small population). Formerly, they also bred on Staten Island and parts of Tierra del Fuego. They are absent from the south Pacific between Tierra del Fuego and New Zealand, but forage throughout the rest of the sub-Antarctic waters of the southern ocean. Two subspecies are currently recognized, *A. p. patagonicus* at South Georgia and the Falklands and *A.p. halli* everywhere else. The situation may be more complex, however, because there is considerable body-size variation at different islands and there is good evidence that the populations on Kerguelen and Crozet are genetically isolated from each other.

King penguins are unique among the penguins in that they do not breed annually. In fact, at c. 400 days, king penguins have the longest nesting cycle of any seabird. There is also more variation in the schedule of breeding than other penguin species. Some populations try to breed every other year (e.g., Crozet and Possession Islands) and other populations are able to succeed twice in 3 years (e.g., South Georgia). This variation results in birds' being present and breeding at king penguin colonies year round. A single colony may have different adults incubating eggs, performing courtship, feeding large chicks, and moulting all present simultaneously.

Typically the breeding cycle begins (i.e., year 1) with courtship in the spring. Unattached birds use upright postures and calls to advertise for mates. A bird will stand erect with the head horizontal and flippers held close to the body, then raise the head to point at the sky, extend the neck, and call. The calls use two frequency bands simultaneously so they have internal harmonics. They sound somewhat like a trumpeting elephant. Calls are important during courtship to advertise for mates, but they are also used to locate and identify mates and chicks.

Once the pair is established and mated, the female lays a single egg in late November. She holds the egg on her feet and covers it with a loose flap of skin on the lower abdomen. There are no nests constructed. She will incubate the egg for a few hours then pass it to the male. After that, they will alternate incubating the egg and foraging in 4 further shifts of 12–18 days. The males and females split the duties of incubation. When the egg hatches after 54 days, the pair alternates brooding/feeding the chick and foraging with 1 adult guarding the chick at all times.

After 31 days, the adults leave their chick behind at the colony and bring food every 5–7 days for another 5–7 weeks. It is at this point that king penguins vary from other penguin species. The combined efforts of courtship, incubation, and brooding take so long that the chick is not ready to fledge by the time the weather and sea conditions begin to deteriorate in March and April. The parents have fed their chicks to c. 12 kg (nearly adult size) but it is too late for the chicks to moult and learn how to forage on their own. The adults then abandon the chicks for a variable period that ranges from a couple of weeks to a few months depending on conditions and colony. The chicks may lose a third of their body mass before the adults return and resume feeding them for another two months.

When the chick fledges in October or November, the adults moult, then begin the breeding process anew. This time the egg will be laid in February and the entire process gets shifted in the year. By the time this chick fledges, it will be the end of summer in year 3. Now the adults will be back on track to start over at the beginning of year 4. The adults are flexible to the point that if they lose an egg or chick early in the spring then they will start again in late summer. Or if they lose a chick in late summer, fall, or winter, they will reset their schedule at year 1 and begin again in October. Consequently, the best they can do is two chicks every 3 or 4 years, depending on their colony. This complex and variable breeding schedule and the lack of a physical nest site are why king penguins have very low pair fidelity with a 71% divorce rate between years.

Newly hatched chicks are brown and nearly naked of feathers. They quickly develop their first light brown down coat. By the time they go to the crèche, their downy coat is long and rich brown, unlike any other penguin. By the time they fledge, they moult into immature plumage with little or no orange and yellow pigments so they look like faded adults. Immature king penguins moult into their full adult colors at the beginning of their third year. A few of those 3-year-olds will attempt to breed, but normally they will be 4 or older before they start to breed.

King penguins primarily eat fish during the breeding season, but squid are much more important in the winter. While they are feeding a chick at the colony, king penguins rarely travel more than 300 km from their colony, but travel much farther during the winter months. They are capable of diving to over 300 m. Their foraging trips are regularly longer than 4 or 5 days and king penguins have developed a remarkable physiological adaptation. Using antibiotic enzymes in their intestinal tract, they are able to preserve partially digested food so bacteria do not spoil the partially digested fish and squid that they are taking back to their chicks.

Eggs and small chicks are preyed on by skuas (*Catharacta* spp.), giant petrels (*Macronectes* spp.), and sheathbills (*Chionis* spp.), though most of their opportunities come from scavenging abandoned eggs and chicks. As the king penguin chicks grow, they quickly become too large for all predators except giant petrels. Adults are essentially free from predators on shore, but are killed by leopard seals *(Hydrurga leptonyx)* and orcas *(Orcinus orca)* at sea.

King penguins were commercially hunted as a source of oil in the nineteenth and twentieth centuries. They were exterminated from Tierra del Fuego and the Falkland Islands (c. 1870), and some colonies were destroyed on Macquarie Island and at South Georgia. Since that persecution stopped, they have recolonized Heard Island and the Falkland Islands and the populations worldwide have been growing. Estimates of the worldwide population range from 1.6–2.2 million breeding pairs—their unusual breeding schedule make them notoriously difficult to estimate. King penguin populations are currently not threatened directly, but there is some concern for indirect competition with commercial fisheries in some of their range.

LAKE ELLSWORTH

From the various subglacial lakes identified thus far in Antarctica, subglacial Lake Ellsworth stands out as a suitable candidate for *in situ* measurement and sampling. Located at 79.0° S, 90.5° W in West Antarctica, only ~20 km from the ice divide, the lake has been measured by the radio-echo sounding technique to be about 10 km in length. Ice thickness over the lake is around 3.4 km and, like that of Lake Vostok, the lake's ceiling has a noticeable slope (by around 200 m over its entire length), which may drive water flows within the lake. Modeling of the ice-sheet thermal regime shows that, with a background level of geothermal heating, the ice sheet above Lake Ellsworth is expected to be warm-based both now and during full glacial periods. As the lake occupies a distinct deep topographic hollow, it is likely that it will have remained in place even if the ice sheet topography has changed (water in lakes not bounded by significant relief may, however, "outburst" as a consequence of such change). The age of Lake Ellsworth is, therefore, likely to be as old as the ice sheet itself. The age of the West Antarctic ice sheet is, however, not known. It is probably much less old than the 15 million years of East Antarctica, and could be as young as a few hundred thousand years. The age of the lake's water is dictated by the age of ice that melts into the lake, which in West Antarctica should be around 150,000 years or so.

Despite its being younger than many subglacial lakes, the boundary conditions of Lake Ellsworth will be much of the same as any other lake, making it appropriate for exploration as an analogue to others. Given that the base of the West Antarctic ice sheet has been accessed on several occasions, there is precedent for *in situ* exploration of Lake Ellsworth. This may make environmental issues concerning lake access easier to overcome in Lake Ellsworth than in East Antarctic subglacial lakes, where the ice sheet base has never been reached.

Subglacial Antarctic Lake Exploration (SALE) group of specialists. http://salegos-scar.montana.edu/

LAKE VOSTOK

Subglacial Lake Vostok, being over 250 km in length and 80 km wide, is by far the largest subglacial lake in Antarctica. It was discovered in the 1970s using a technique called radio-echo sounding (RES). Scientists did not appreciate either the full extent of the lake or that the Russian base Vostok Station was located over its southern end until satellite altimetry of the ice-sheet surface, during the early 1990s, revealed an unusually flat region above the lake (caused by the change in flow dynamics as ice moves from being grounded on rock to floating in the lake water). As a consequence, seismic data acquired at Vostok Station in the 1960s were reinspected to reveal the depth of the lake's water column to be 510 m. Since about 1996, additional RES data have been obtained over Lake Vostok. These data show that the ice thickness over the lake increases steadily from 3750 m in the south to 4200 m in the north of the lake. As the ice-sheet surface varies by only 50 m or so, this thickness change manifests itself as a sloping lake ceiling. The rate of subglacial melting and freezing will vary in relation to this slope; melting will occur where the ice is thickest, and freezing will take place at the southern end where the ice is thinner. This pattern of melting and freezing has been confirmed by both RES studies of the lake-water interface and the Vostok Ice Core, which has sampled around 60 m of refrozen lake ice from its base. Subglacial melting and freezing above Lake Vostok will lead to heat exchange between the ice and lake, and flow of lake water. Although the mean speed of water flow has been modeled numerically to be on the order of 1/10th of a millimeter per second, the Coriolis force (due to the spinning of the Earth) may result in ascending/descending plumes of water with a greater flow speed. Airborne gravity measurements over Lake Vostok reveal the lake cavity to consist of two basins. Direct measurements of lake's bathymetry are only possible, however, using seismic surveying, which has yet to be applied fully to this environment.

Lake Vostok has received world-wide scientific and media coverage as an extreme habitat in which unique microorganisms may exist. Over the past 10 years, there have been several conferences dedicated to understanding how this lake may one day be explored. Many glaciologists believe, however, that alternative subglacial lakes, such as Lake Ellsworth in West Antarctica, may be better suited for exploration, at least in the first instance.

Critical to the nature of the inhabitants of Lake Vostok will be its age and origin. The lake is likely to be as old as the ice sheet itself, which some scientists believe is around 15 million years in East Antarctica. The age of the lake's water, however, will simply be as old as the ice that melts into it, which for Lake Vostok is around 1 million years. The origin of Lake Vostok has received considerable debate in the recent literature. Airborne geophysics reveals a preglacial geological fault along the lake's long axis. Lake Vostok may, therefore, be located within a trough that predates the ice sheet. However, the extent to which glacial erosion may have subsequently contributed to the excavation of the lake's cavity remains unknown.

LAMBERT GLACIER/AMERY ICE SHELF

A drainage basin is defined as the topographic land area that contributes material flow to a common outlet region or point. In Antarctica the catchment input is snow, and the output glacial ice. The ice flows slowly at first from the high inland divides and summit domes, before gradually gaining pace as it funnels into individual glaciers and ice streams. Glaciers exhibit channel flow in well-defined bedrock valleys or depressions, whilst ice streams are currents of ice in the ice sheet that flow faster than the surrounding ice (often on a deformable bed).

The Lambert Glacier drainage basin occupies an area of 1.5 million km^2, comprising some 16% of the total area of East Antarctica. Its southernmost point is Dome Argus (81° S, 77° E), high on the Polar Plateau at an elevation of approximately 4040 m. The basin annually drains some 35–40 billion tonnes of ice per year via a number of outlet glaciers through the Prince Charles Mountains into the Amery Ice Shelf, which itself contains 71,000 km^2 of floating ice. This system, the largest in East Antarctica, has a highly convergent flow pattern, with mass discharge focussed through the front of the Amery Ice Shelf, which accounts for less than 3% of the East Antarctic coastline.

The Lambert Glacier is one of the largest in the world, measuring 800 km in length by 32 km wide in places. Ice thickness reaches 3500 m deep in a bedrock trough along the eastern edge of the graben (geological subsidence fault) in which the glacier flows. Surface speeds there are as little as 60 m/yr, and even lower deep inland, but approach 900 m/yr near where the glacier crosses the grounding zone (where it starts to float and become an ice shelf), at the confluence of several major outlet glaciers (Lambert, Mellor, Collins, and Fisher) west of the Mawson Escarpment at 73.3° S.

Ice thickness on the Amery Ice Shelf reaches 2800 m near the grounding zone, reducing to less than 300 m some 650 km to the north, along the 200-km-wide iceberg calving front in Prydz Bay. Over the northern half of the Amery, much of the thickness reduction is a consequence of thinning and spreading, without change to total ice volume, as the embayment containing it widens out into the open ocean. In the south, however, almost half the initial ice volume is lost due to extensive basal melting that dramatically thins the shelf in the first 120 km after becoming afloat, through contact with the relatively warm ocean waters circulating in the cavity beneath it. Although the ocean water has a mean temperature of only –2°C, it is still several degrees above the local freezing point at the great depths of the ice shelf keel, due to the pressure dependence of the freezing point.

The resulting cool fresher meltwater flows northward along the upward sloping base of the shelf. As it does, frazil (fine spicules or plates of ice) crystals form within the rising plume, because the freezing point increases with the reduction in pressure at shallower depths. These frazil crystals accumulate in pockets or indentations in the base of the shelf, where they compact and consolidate into what is called marine ice (dark green or jade icebergs are a result of this ice). The total amount of accreted marine ice is thought to comprise roughly half that lost through basal melting near the grounding zone, the remainder modifying properties of water masses later emerging from beneath the shelf with reduced salinity chiefly on the western side. Under the Amery, marine ice forms essentially in two longitudinal bands (where different ice streams merge) along the northwestern and north-central sections of the shelf. The layer can be more than 200 m thick, making up more than 40% of the total ice thickness in places. Production of marine ice effectively transfers mass from the thickest parts of the shelf near the grounding zone, to thinner sections toward the front, possibly increasing overall stability of the system.

The southern portion of the Amery has a bare ice surface ablation zone, with sinuous melt streams and shallow lakes often dominating the surface in summer. The northern shelf is subject to incursion of synoptic weather systems, bringing precipitation across the coast producing an overall snow accumulation zone. Parts of the northern Amery thus exhibit a three-layer vertical structure: local snowfall, continental ice from the interior basin, and marine ice accreted to the base at depth.

Iceberg calving is the other principal source of mass loss from the ice shelf. Flow speed at the central calving front is close to 1200 m/yr, but overall ice shelf advance is perhaps only 85%–90% of this, as small chunks of ice shed intermittently throughout the year. Major calving events, producing large icebergs with linear dimensions greater than 25–30 km, tend to be episodic in nature, as is the case for most large ice shelves. The last such breakout for the Amery occurred in the early 1960s, whilst the development of several long rifts currently projecting back from the front suggest that a major calving is imminent, and that periodicity for the Amery is on the order of 40–50 years. These events are natural cycles resulting from weakening of the ice shelf as it slowly spreads and thins further into Prydz Bay through time.

LARSEN, CARL ANTON

Carl Anton (C. A.) Larsen (August 7, 1860–December 8, 1924) was a sea captain, whaler, and leader of several expeditions to Antarctica that resulted in geographical and scientific discoveries. He started so-called modern whaling in Antarctic waters, and thus led the way for the foundation of that industry.

Larsen was the son of a sea captain from outside Larvik, a port town in southern Norway. He went to sea as a young boy, and sailed on vessels chasing small bottlenose whales in the North Sea. This was an expanding industry at the time. Larsen was given the command of a bottlenose whaling vessel owned by Christen Christensen from nearby Sandefjord. Their association would become important for the future development of the whaling industry.

In the 1880s modern whaling was developing along the shores of northern Norway. The whalers had become able to chase the large, fast-swimming rorquals (blue whales, fin whales, humpback whales) with new powerful technology. It was also discussed in Norway and several other countries at the time to search for new whaling grounds in Antarctica. In the southern summer of 1892–1893, three expeditions went south. One Norwegian expedition was organized by Christen Christensen, who had the idea, the capital, and a vessel, *Jason,* a former sealer. Larsen was hired as the captain and expedition leader.

The expedition in *Jason* caught no whales, but observed them in abundance. The expedition was also of some significance in terms of scientific discoveries. It sailed south in the western parts of the Weddell Sea, and discovered petrified wood (fossils) at Seymour Island, which attracted scholarly attention. After returning to Norway, Larsen and *Jason* immediately returned south for a second season (1893–1894), this time accompanied by two more vessels, *Castor* and *Hertha*. *Jason* sailed back into the Weddell Sea, where it made new geographical discoveries and worked its way through the ice farther south than any vessel had been before in this area of Antarctica (68°10′). The ships also visited South Georgia. After returning home, Larsen put forward the idea of starting a whaling operation there.

Larsen did not immediately proceed with his southern whaling plans. Instead he worked as a manager at a Finnmark (northern Norway) shore whaling station in the late 1890s, and gained valuable experience regarding how modern whaling was organized according to the way Svend Foyn had built up his business.

In 1901 Larsen again travelled to Antarctica, this time as the captain of *Antarctic,* the vessel of the first Swedish South Polar Expedition. This expedition carried out an extensive scientific program along the Antarctic Peninsula, the Falkland Islands, and Tierra del Fuego in South America. *Antarctic* also stayed in South Georgia waters in 1902, and Larsen's plans to start whaling there gradually materialized. The expedition ended dramatically in February 1903 when the *Antarctic* was crushed by the ice and sank in the Weddell Sea, east of Paulet Island, on its way to pick up a shore party at Snow Hill Island farther south. Before the ship entered the ice, another shore party had been left at Hope Bay on the northern tip of the Peninsula, so the expedition members—without a vessel—were spread across three different locations where they had to winter. After an epic tale of survival, the scientists and sailors were rescued by an Argentine vessel in November of 1903 and brought to Buenos Aires.

The short stay in the Argentine capital was of great significance for Larsen. He presented his idea about South Georgia whaling to the local business community, and suggested the founding of a company and setup of a shore whaling station at the island in the sheltered harbour of Grytviken. He quickly received backing, and the name of the new company became Compañia Argentina de Pesca. Larsen returned to Norway, but went to South Georgia again in the autumn of 1904 with three vessels (a steam catcher boat and two transport vessels), crew, and equipment to erect a shore plant. This marks the beginning of modern whaling in Antarctica.

At South Georgia, five more stations were built in the years before World War I. The companies were of different nationalities, but the majority of the whalers came from Norway.

Larsen organized his South Georgia enterprise the way it had been done in Finnmark: setting up a shore station. His former associate, Christen Christensen, started whaling in 1905 with a floating factory ship operating together with steam catcher boats farther south in the South Shetlands. Together with South Georgia, this became the major whaling ground for years to come.

Larsen managed the Grytviken station until 1914. He extended the plant and even built a church for the whalers (1913). In his last years at South Georgia, he considered plans for whaling in other areas, but instead returned to Norway and his home outside Oslo. He bought two large inland farms and planned to develop them into model breeding farms. The project was of limited success, and once more he turned his attention to Antarctica and whaling.

It was well known that there were large numbers of whales in the Ross Sea, and in 1922 Larsen cofounded a company to pursue whaling there. In 1923 the factory ship *Sir James Clark Ross* steamed south together with catcher boats and Larsen as the expedition leader. They worked their way through the ice into the open waters of the Ross Sea. The whaling was a success, and the expedition proved that modern whaling could be undertaken independently from shore bases. It led the way for the next big expansion of the Antarctic whaling industry, the pelagic whaling.

Larsen was back in the Ross Sea the next season. For some time, his health had been failing, and he died on the whaling ground in December 1924.

Larsen was a pioneer whaler, both by transferring whaling from shore stations from north to south, and by venturing into the Ross Sea. He was also one of the most remarkable expedition leaders of the Heroic Age of Antarctic exploration around the turn of the century. His skills as a captain in the rough Antarctic waters were well known and highly respected. Throughout his career, Larsen also took much more of an interest in the scientific part of his expeditions than what would normally have been expected of a sailor.

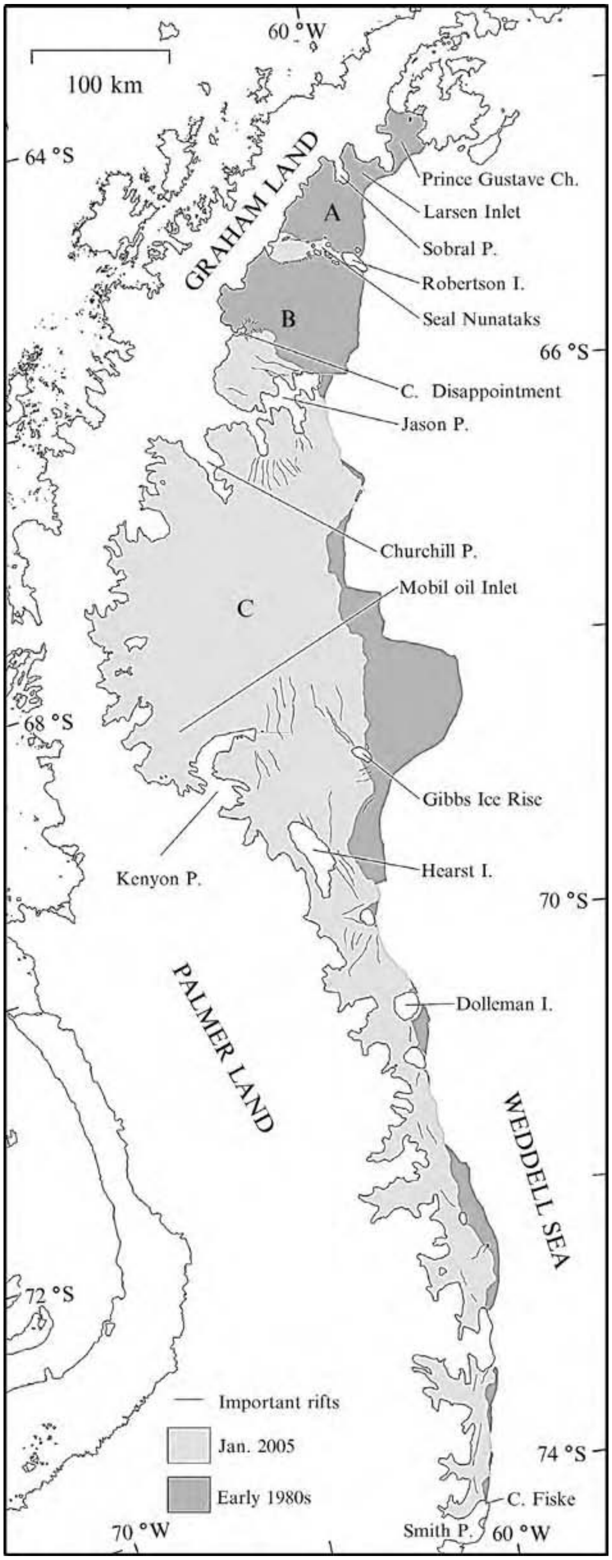
LARSEN ICE SHELF

The Larsen Ice Shelf (68° S, 63° W) fringes the eastern coast of the Antarctic Peninsula. It was discovered in December 1893 by Carl A. Larsen, leader of the Norwegian (Sandefjord) Whaling Expedition (1892–1894), and first traversed in October 1902 by Otto Nordenskjöld, Lieutenant José María Sobral, and seaman Ole Jonasen, members of the Swedish South Polar Expedition (1901–1904).

Until the late 1980s the Larsen Ice Shelf extended from Prince Gustav Channel (64° S) to Cape Fiske (74°15′ S), at Smith Peninsula, covering approximately 103,400 km^2. Five major sectors were distinguished: the portion at Prince Gustav Channel; that between Sobral Peninsula and Robertson Island; the portion between Robertson Island and Jason Peninsula; that between Jason Peninsula and Gibbs Ice Rise; and the one between Gibbs Ice Rise and Cape Fiske. The last four are usually referred to as Larsen A, B, C, and D, respectively. In addition, the portions at Larsen Inlet and between Seal Nunataks are usually treated separately. Documented frontal variations of the northernmost sectors date back to the mid-1940s. In general, the sector at Prince Gustav Channel retreated, whereas Larsen A and B advanced until 1975 and 1995, respectively. Dramatic changes have occurred since the late 1980s. Larsen Inlet disintegrated between 1989 and 1992. Larsen A and the sector at Prince Gustav Channel disintegrated in a few weeks in January–February 1995. In February–March 2002, the portion of Larsen B north of Cape Disappointment disintegrated following an almost identical pattern. In January 2005, as a consequence of these losses and iceberg calving, the area of Larsen Ice Shelf was approximately 78,515 km^2, implying a reduction of 24% since the early 1980s.

On average the ice shelf surface rises 34 m above sea level (asl). It is highest (about 70 m asl) at the grounding line, where the ice sheet starts to float and becomes an ice shelf, and lowest (30 m) at the frontal ice cliffs in the Weddell Sea. The average ice thickness is 240 m, with a maximum of 750 m at Mobil Oil Inlet, and a minimum of about 160 m (and locally less) at Seal Nunataks.

A variety of surface features are observed, especially on Larsen C, but most of them are best appreciated in satellite images because of their low amplitude and large extension. Flow stripes forming at the mouth of tributary glaciers are ubiquitous. These can be traced from the grounding line to the front, delineating ice pathways. Pressure waves appear down ice from lateral topographic obstructions, being especially conspicuous south of Churchill Peninsula and north of Kenyon Peninsula. Rifts, crevasses cutting the entire thickness of the ice shelf, are well developed south of Jason Peninsula and east of Kenyon Peninsula, in Larsen C, and between Hearst and Dolleman islands, in Larsen D. Another rift was located at the limit between Larsen B and the portion between Seal Nunataks. Under normal conditions rifts are present near the ice front and margins, due to extensional opening of fractures. In Larsen A and B, however, ubiquitous rifting developed just prior to the collapses and marked the initiation of these events. Meltwater ponds, sometimes connected by meltwater streams, form in the northernmost sections during warm summers due to large ablation rates. Ice dolines, rounded depressions 0.1–1 km in diameter and 10–20 m in



Larsen Ice Shelf.

depth, are uncommon features that appeared on Larsen A and B in the years prior to their collapses. It is hypothesized that they form due to intense melting and percolation, being considered a sign of ice shelf instability. Minor debris bands are observed on the portion at Seal Nunataks and southeast of Jason Peninsula.

The mass balance of the upper surfaces (ice-air) of Larsen A and B and the portion at Seal Nunataks is known through measurements performed between the early 1980s and 2001. These measurements indicate that the mass balances of Larsen A and the section at Seal Nunataks decreased steadily beginning in the late 1980s and became negative in the beginning of the 1990s. The northernmost part of Larsen B followed a similar pattern, but the balance became negative in the mid-1990s. The southern part of Larsen B, including the surviving portion, also had a decreased balance but it remained positive during the observation period. The mass balance of the lower surface (ice-ocean) has not been measured, but calculations suggest that net melting dominated during the last decade. Recent estimates, supported by field and satellite measurements, indicate that the resulting effect of the negative mass balances on both surfaces during the last decades was a net thinning of the ice shelf.

Ice velocities in Larsen Ice Shelf are in the range of 10–30 m per year in the section at Seal Nunataks to almost 600 m per year at the centre of Larsen C, largely reflecting the rates of ice input from the tributary glaciers. Significant (up to 26%) increases in ice velocity were measured on both Larsen A and B in the years prior to their collapses.

The partial loss of Larsen and other ice shelves in the Antarctic Peninsula region, observed since the late 1980s, is an important environmental issue for the Antarctic. A regional atmospheric warming of 2.5°C measured since the 1940s, in synergy with a 0.32°C warming of the Weddell Sea since the 1970s, appears to be the most likely cause. It is thought that the Larsen Ice Shelf became progressively weakened by the percolation and in-depth refreezing of meltwater produced during warmer summers. Additionally, increased basal melting, resulting from a warmer sea, might have simultaneously thinned the ice shelf, further increasing its exposure to crevasse fracture. The disintegration of ice shelves has no direct effect on sea level. However, the collapse of Larsen Ice Shelf triggered the acceleration of some of its former tributary glaciers. The increased ice discharge, which is not counterbalanced by an increased snow accumulation, is actually contributing to sea level rise.

LARVAE

The life history of most marine invertebrates includes the spawning of gametes followed by the development of a free-living larval stage, which can survive by feeding on phytoplankton or on their yolk supply. In some species the embryos are carried by their parents and released later as either larvae or juveniles. Larvae are in general very different from the adult form and must undergo a metamorphosis to resemble the juvenile or adult body plan. Benthic marine invertebrates in shallow warm water usually generate free-swimming planktonic larvae throughout the year. On the other hand, it has been suggested that polar and deep-sea benthic species generally brood their larvae to protect them from the harsh conditions (Thorson's rule). In polar areas, reproduction and release of juveniles or larvae are also closely related to food availability and to the seasonality of primary production. However, since the 1990s, studies in coastal areas, in bays, and under sea ice have revealed planktonic larvae of an increasing number of Antarctic taxa.

Planktonic development seasonally supplies the Antarctic pelagic food chains with a mass of additional organisms, in some locations mainly due to just one larva morphotype. Many of the individually most successful species in shallow water, such as the sea urchin *Sterechinus neumayeri,* the gastropod *Nacella concinna,* and the nemertean *Parbolasia corrugatus* have planktonic larvae. The ecological dominance of these species with planktotrophic development could be related to the capacity of their larvae to recolonise highly disturbed shallow habitats.

Current estimates of larval abundance in the maritime Antarctic range from 100 to 1600 ind·100 m^{-3}. The major variability in larvae numbers in Antarctic coastal waters has been attributed to seasonality rather than to site or depth. In the shallow waters of Admiralty Bay (King George Island), the succession of invertebrate larvae according to seasonality seems to have been similar for many years, indicating the maintenance of adult reproductive strategies over time. In terms of larval numbers, gastropod veligers can be locally dominant, particularly in mild environmental conditions and higher phytoplankton concentrations. The occurrence of nemerteans and echinoderms has been associated with the onset of summer and high solar radiation levels, whilst different polychaete larvae morphotypes seem to be present throughout summer and during early winter. Bivalve and nudibranch veligers, trochophores, sipunculan pelagosphera, holothurian pentaculae, echinoplutei, ophioplutei, Ascidian tadpoles, cirripedes, bryozoan coronate, and cnidarian planulae have all been recorded in Antarctica.

The coastal Antarctic areas are a source of undiscovered larval biodiversity and the latest studies are trying to identify larvae at low taxonomic levels (i.e., to species), using modern molecular techniques.

The seasonal occurrence of invertebrate larvae may reflect and indicate changes in the ecosystem, including global warming, since reproductive cycles and larval survival are likely to change as a consequence of (seasonally and regionally) rising sea temperature. Planktonic development favours wider dispersal of larvae and establishes connections between the marine populations that are linked by the exchange of larvae. Furthermore, the structure of benthic communities is determined by the supply of recruits, including larval transport mechanisms, settlement success, and post-larval processes. Particular oceanographic conditions, promoted by strong Antarctic katabatic winds, can also control pelagic–benthic coupling and the spatial distribution of larvae. The dynamics of larval movements are critical to the design of conservation units and managements strategies in Antarctica.

LAW, PHILLIP

Phillip Law has had a varied career: teacher, scientist, Antarctic explorer, and educational administrator. He is famous mainly for his 19 years of Antarctic work, as the leader of the expeditions that established Australia's permanent presence in Antarctica and explored the major portion of the coast of Australian Antarctic Territory.

Phillip Garth Law was born on April 21, 1912 at Tallangatta, Victoria, the son of a school teacher. He was educated at a country high school at Hamilton, Victoria, and proceeded to Ballarat Teachers College. From this he gained a 1-year scholarship to commence a science degree at Melbourne University. Following that year he taught at secondary schools in the country and in Melbourne, continuing his university studies on a part-time basis. In 1939 he graduated BSc with first-class honours in physics.

Throughout his life, Law participated vigorously in a wide variety of sports, including winning the Australia Universities' Lightweight Boxing Championship at Brisbane in 1936. His mountaineering and skiing activities formed a useful basis for his Antarctic work.

In 1939 he took 2 years' leave from the Education Department to undertake an MSc in physics at Melbourne University. When war broke out later that year, he became a research physicist working on optical instruments for the Scientific Instruments and Optical Panel of the Ministry of Munitions. For this, he was despatched to battle fronts in New Guinea to report on the conditions of gun sights, range-finders, and other optical instruments. At the end of the war, he resigned from the Education Department to become a lecturer in physics at Melbourne University.

In 1947 the Australian Commonwealth government planned an exploratory voyage to Antarctica during the southern summer of 1947–1948. Law heard about it from his professor, applied, and was appointed as senior scientific officer for what became known as the Australian National Antarctic Research Expeditions (ANARE). The project was to locate possible sites for permanent stations that the government could operate. However, the only ice-strengthened ship available was *Wyatt Earp,* a converted fishing ship, used by Lincoln Ellsworth as base ship for his pioneer flights across Antarctica in the 1930s. In 1948, sea ice was very heavy, and the expedition was unable to land on the continent.

Law installed on the ship a set of equipment to record the intensity of cosmic radiation in the atmosphere. This was a program being run by the Melbourne University Physics Department. Law succeeded in operating (and repairing) the equipment, investigating the variations in cosmic-ray intensity with latitude. Later during 1948 he was able to continue these measures on an Australian troop ship on a voyage from Australia to Japan.

During the southern summer of 1947–1948, teams were also recruited and sent to install stations on Heard and Macquarie islands, two sub-Antarctic islands in the Southern Ocean. A former army ship, HMALST 3501, was used to transport them there. The teams stayed at these stations for 1948 and ran weather and upper-atmosphere observations and did some mapping.

In January 1949, the Commonwealth created an administrative office—the Antarctic Division, later titled Australian Antarctic Division (AAD)—and appointed Law its first director. The government's objectives were to operate stations in Antarctica to support Australia's claims there and to run scientific research. This was not possible initially, as no ice-strengthened ship was available. So for the first 4 years in his position, Law built up his headquarters staff, developed administrative procedures, and set up science research programs on Heard and Macquarie islands. He brought in other government departments and universities with science and technology specialisations to collaborate in setting up research programs and to provide some personnel.

Law sailed to the island stations each summer on the HMALST 3501 (later renamed HMAS *Labuan*). The new teams took over the stations, new buildings and equipment were installed, and new scientific research programs started. Law also sailed on the Norwegian-British-Swedish Antarctic Expedition vessel MV *Norsel* to Dronning Maud Land in summer 1949–1950, to observe at first hand their operations.

In 1953 a Danish polar ship, *Kista Dan* of the J. Lauritzen Company, was launched and Law chartered it for summer 1953–1954. He chose a location at the western end of Australian Antarctica, in Mac. Robertson Land, for the development of the first Australian base. Despite very heavy sea ice, the ship reached its objective and the first station was built. Law named it Mawson after the famous Australian scientist and explorer Sir Douglas Mawson. Leaving a ten-man wintering team, Law directed the ship on an easterly exploration cruise along the coast, and into a violent storm in sea ice from which they were very lucky to emerge safely.

During the following southern summers Law chartered polar ships from the Lauritzen Company. They sailed south from Melbourne to the stations, which were resupplied and had their wintering teams changed over before cruises were made along the coast of Antarctica. Using the ship held in the pack ice as a base, Law led teams of specialists exploring the islands and rock outcrops, landing by motorboat or sledging over the ice (helicopter transport came later). Surveyors mapped the locations' positions, magnetic measurements were made by geophysicists, and geologists and biologists made their recordings. These activities were often hazardous due to the weather and sea ice conditions. Nevertheless, during Law's directorship, the whole of Australian Antarctica was mapped.

At Mawson each year, scientific researches and data recordings of geoscience effects were developed, and glaciologists and geologists sledged southwards over the Plateau. In 1957 a second station, Davis, was built in the Vestfold Hills. When the international science associations declared 1957–1958 the International Geophysical Year (IGY), the three Australian polar stations (Mawson, Davis, and Macquarie Island) were very well prepared. The US installed a station, Wilkes, in the central part of Australian Territory, which they operated during the IGY. Law visited the US in 1958 and arranged for Australian teams to take it over; Australia still operates a Casey station at that site, although the station has been rebuilt several times.

In 1966 Law resigned from direct activity in Antarctic explorations to become executive vice-president of the Victoria Institute of Colleges. He retired in 1977. In recent years he has accompanied tourist ships to Antarctica as a lecturer.

LEOPARD SEAL

The leopard seal *(Hydrurga leptonyx)* population is estimated to be 222,000–440,000. These seals were not hunted by sealers, who had little interest because their blubber is not thick enough to produce much oil and their skins have never been of significant commercial value. Today they are considered to be common but are difficult to see in large numbers because of their solitary nature.

The main leopard-seal population remains within the circumpolar Antarctic pack ice, but seals are regular, although not abundant, visitors to the sub-Antarctic islands of the Southern Ocean and to the southern continents. The most northerly leopard-seal sightings are from the Cook Islands.

Leopard seals use the ice floes of the pack ice to haul out on each day to sleep. They prefer smaller ice floes, from 2 to 20 m in diameter. The amount of pack ice varies with the seasons. It is at a maximum extent between August and October and a minimum between February and March. The number of seals within an area is inversely related to the amount of pack ice that is available to them.

Adult leopard seals do not seem to migrate. Tagged seals have remained within the Antarctic pack ice within the same region over many years. Surprisingly, for seals that drift as they sleep hauled out on moving ice floes, they are relatively sedentary. Satellite-tracked seals move at speeds and distances comparable to the movement of the ice floes they haul out on. However, young seals appear to be more mobile. Subadult seals move north during the winter and small numbers are seen on the sub-Antarctic islands. Perhaps, as the younger seals do not need to remain within the pack ice to breed, they can escape food shortages during winter by dispersing northwards.

The number of leopard seals on the sub-Antarctic islands varies on a 4- to 5-year cycle. This is correlated with oscillating current patterns of the Antarctic Circumpolar Wave. Perhaps this is causing resource shortages in those years. Individuals can exceed 20 years of age.

Leopard seals are relatively large seals with reverse sexual dimorphism where the females are larger than the males. Females grow up to 3.8 m and weigh up to 500 kg, males up to 3.3 m and 300 kg. The head of the leopard seal is disproportionately large and the female's skull attains a greater length and is more massive than the male's. Both the hind- and the foreflippers are long and powerful, with the first and fifth digits of the hind flippers broadly palmate at the tips beyond the nails.

Male leopard seals are sexually mature by 4.5 years and females by 4 years of age. Females give birth to a single pup and wean it on the ice floes of the Antarctic pack ice. Length at birth is about 120 cm. Births are believed to occur from October to mid-November and mating from December to early January, after the pups have weaned. The mothers nurse their pups for up to 4 weeks. Males do not remain with the females through lactation as with crabeater seals, and only mother–pup pairs are observed on the ice floes. Mating in the wild has been observed rarely, but captive seals mate only in the water. There is a period of delayed implantation from early January to mid-February. Implanted fetuses have been found after mid-February when the corpus luteum has begun to increase in size and the corpus albicans from the previous pregnancy is regressing.

Leopard seals are highly solitary. Individual seals are widely distributed at densities ranging from 0.003 to 0.151 seals/km^2. However, there appears to be an age-related difference in their spatial behavior, because juveniles may be seen close together, even on the same ice floe.

Leopard seals are spectacular hunters and are at the top of the Antarctic food chain, taking a range of prey types—penguins, seals, fish, and krill—although this varies at different times of the year. During spring and summer, penguins and seals become important in the diet. Penguins that are captured from under the water are flicked violently as the seal surfaces to dislodge chunks of flesh. Young crabeater seals hunted soon after weaning learn to roll to avoid the leopard seals' canines. This leaves two parallel rake marks on the surviving seal and most crabeater seals (78%) bear the scars of an encounter with a leopard seal. During winter, fish and krill become important. Krill are captured by straining mouthfuls of water through their unusual three-cusped, interlocking molar teeth. Although there have been many reports of leopard seals chasing or stalking people in Antarctica, there has only been one incident where a human has been killed by a leopard seal.

Acoustic behavior is important in the mating system of the leopard seal. Leopard seals become highly vocal before and during the breeding season. Male seals sing underwater for long periods each day from early November through to January. Individual males sing distinctively different patterned songs. Female leopard seals also use long-distance acoustic displays during the breeding season. However, the females sing for only a brief period from the beginning of oestrus until they have been mated. This is presumably to advertise that they are receptive to mating. The calls of the leopard seal are low-to-medium frequencies and so powerful that they can be heard through the air–water interface and felt vibrating the ice.

LICHENS

Lichens are a Phylum (Ascomycota) of cryptogams (spore-bearing organisms). However, they are unique as each lichen is a composite of an alga (photobiont) and a fungus (mycobiont) living symbiotically and creating a specific structural form usually unlike either of the symbionts. The alga is the photosynthetic component providing carbohydrates and energy for growth, while the fungus provides the organism's structure and is responsible for the uptake of water and nutrients from its substrate and the atmosphere. The fungal component is the major structural part of the lichen (thallus) and is responsible for the production of spores (i.e., sexual reproduction), although most species can also reproduce asexually by various types of vegetative structures. In some species the photobiont is a cyanobacterium (blue-green alga). Since the dominant component of lichens is a fungus (which is a microorganism deriving its energy saprophytically from decaying organic matter), lichens should strictly be referred to as lichenized fungi and not as plants (which contain chlorophyll and obtain their energy through photosynthesis). Lichens have a remarkable capacity to survive in extremely severe environments; they are capable of withstanding long periods of drought as well as enduring fluctuations in thallus temperature (e.g., from –20°C to 40°C within a few hours in polar and alpine habitats).

The lichen thallus develops a characteristic structure with a distinct growth form, largely dependent on which species of fungus and alga combine. How this selection is made is largely unknown, but a germinating lichen (fungus) spore develops thread-like strands (hyphae), which grow over the substrate "foraging" for a specific algal partner. Once this happens, the hyphae envelop the alga, both multiplying and developing a structure, predominantly fungal in nature but with layers of photosynthetically active algal cells just below the surface. However, most lichens are capable of dissemination and colonization by means of specialized vegetative structures that contain both fungal and algal components, and are therefore instantly ready for developing a new thallus when substrate conditions are favourable. Lichens have a wide range of structural shapes (growth forms), usually only a few centimetres in diameter or height, but some achieve much greater dimensions. They are typically slow-growing and long-lived, and exceptionally large thalli are of great antiquity; estimated ages of from 500 to over 5000 years have been reported for individual thalli.

Antarctic lichens are well adapted for survival in low temperatures and can achieve substantial rates of photosynthesis (production of carbohydrates required for growth from carbon dioxide in the presence of sunlight and water) well below 0°C. Very low rates of carbon assimilation have been recorded at temperatures of –10°C to –17°C in a few continental species (e.g., *Umbilicaria aprina*). Even at subzero air temperatures, the microclimate in which the lichen is growing can be 20°C to 30°C above ambient. The optimum temperature for net photosynthesis in most maritime Antarctic species is <5°C, and for continental species <3°C. However, photosynthesis ceases when the thallus is exposed to very strong sunlight (photoinhibition) when it becomes very warm and quickly desiccates. Thus photosynthesis is very intermittent, and this greatly restricts growth.

Diversity and Biogeography

Because of their unique physiological tolerances, lichens are the predominant terrestrial life form throughout much of Antarctica, particularly the drier and more windswept habitats. In suitable areas, especially at coastal sites, they may cover several hectares of rocky terrain. About 420 species are known, with the greatest diversity (about 75%) occurring in the maritime Antarctic (western Antarctic Peninsula, South Shetland Islands, South Orkney Islands, and South Sandwich Islands). About 90–100 species are known from continental Antarctica (excluding the western Antarctic Peninsula). Unfortunately, no Antarctic lichens have common names. The majority have a close affinity with southern South American flora, from where they have originated. However, many also occur in New Zealand, which reflects the Gondwanan origins of much of the flora before the tectonic breakup of that ancient landmass. About 25% of the lichens have a bipolar distribution, occurring, and probably evolving, in the Arctic and northern temperate regions and reaching the opposite end of the planet by "mountain-hopping" along ranges connecting the Northern and Southern Hemispheres, such as the Rockies–Andes chain. About 10% of the Antarctic lichen flora have a worldwide distribution. The early isolation of the continent from other landmasses has led to a large number of lichens' evolving as endemics (about one-third of the maritime Antarctic species and c. 50% of continental Antarctic species).

Growth Forms

The majority of species have a crustose (encrusting) or microfoliose (minutely leaf-like) growth form in which the thallus closely adheres to the substratum, which is usually rock, although some colonize soil and moss. These are sometimes referred to as microlichens. Each thallus can reach several centimetres across, and where many of these coalesce multicoloured patches of several species can cover several square metres of rock. Many of these lichens are brightly coloured, due mainly to anthraquinone pigments, and are nitrophilous (i.e., having a requirement for nitrogen). They often grow extensively on coastal rocks close to penguin and other seabird colonies. The typical orange-colored lichens include numerous species of *Caloplaca, Candelaria, Candelariella,* and *Xanthoria,* while other colourful nitrophilous genera including *Acarospora, Amandinea, Buellia, Haematomma, Lecidea, Lecanora, Verrucaria,* and several others add a splash of white, grey, yellow, brown, and black to the rock. Away from the influence of birds, rock surfaces are often covered with a mosaic of nitrophobous (nitrogen-avoiding) crustose lichens, such as *Acarospora* (yellow), *Lecanora* and *Lecidea* (various colours), *Placopsis* (pink), *Pleopsidium* (yellow), *Rhizocarpon* (green), *Tephromela* (white), etc., while soil may be colonized by large patches of powdery white or greenish encrustations of *Lepraria* and *Leproloma*.

The larger, more prominent but less diverse macrolichens include the foliose (leaf-like), squamulose (thallus comprising a mass of scale-like lobes), and umbilicate (attached centrally by a stalk to rock) growth forms, mainly growing on rock, and the bushy, much-branched fruticose growth form, again mainly on rock, but some of these also colonize mosses. Foliose species are mostly lithophytes (growing on rock), attaching to their substrate by root-like rhizines, but a few grow on mosses or coarse soil. Most foliose species occur in coastal habitats and seldom reach altitudes above a few hundred meters. Several are nitrophilous, occurring near bird colonies, notably species of *Dermtocarpon* (grey), *Flavoparmelia* (yellow), *Parmelia* (brown), *Physcia* and *Physconia* (grey), *Turgidosculum* (black), and *Xanthoria* (orange). Moss- and soil-inhabiting genera include *Leptogium* (black), *Peltigera* (grey-brown), and *Psoroma* (greenish-brown, squamulose growth-form). *Turgidosculum complicatulum* is the lichenized form of the green foliose nitrophilous alga *Prasiola crispa,* which is very abundant in wet areas around bird colonies. *Leptogium puberulum* is one of the very few lichens that prefer wet habitats such as seepage areas on rock faces and below melting snow patches. This is because its photobiont is the cyanobacterium *Nostoc,* which, in its free-living state, grows in similar wet sites. Only a few species of umbilicate lichens occur in Antarctica, all belonging to the genus *Umbilicaria*. Of these, *U. antarctica* are particularly abundant on sheltered coastal cliffs in the maritime Antarctic and can reach exceptional size, although their plate-like thalli are reduced to a ragged leathery structure by wind and ice action. The largest recorded thallus, on a rock face on Signy Island, South Orkney Islands, measured c. 45 x 25 cm. *U. decussata* has much smaller thalli, attaining only 1–2 cm diameter in exposed habitats. However, this remarkably cold- and drought-tolerant lichen is one of a small group that grow as a community throughout continental Antarctica in one of the most severe environments on Earth. They also occupy similar habitats in the high Arctic.

The fruticose lichens are amongst the most prominent Antarctic lichens, again found mainly in the maritime Antarctic. The often large bushy genus *Usnea* is very abundant, notably *U. antarctica* (grey-green) and *U. aurantiaco-atra* (grey-yellow), festooning cliffs and covering rocky hillsides. The latter usually have many large black disc-shaped apothecia, the spore-producing structures of lichens. Coastal cliffs near seabird colonies may also have large strap-shaped yellow thalli of *Ramalina terebrata,* while exposed ridges and plateaux in the northern maritime Antarctic are often colonized by a similar black species, the endemic *Himantormia lugubris*. Sometimes associated with the *Usnea*s and *Umbilicaria antarctica* on sheltered cliffs are long straggling thalli of the black lichen *Bryoria austromontana,* which can attain exceptional lengths of over 40 cm. Several fruticose lichens grow directly on mosses and soil. In some communities, various mosses and often brightly pigmented lichens create a surprising patchwork of colour. These may include *Alectoria nigricans* (grey-buff), *Bryoria implexa* (black), *Cetraria aculeata* (purple-brown), *Coelopogon epiphorella* (brown), *Sphaerophorus globosus* (orange-brown), *Stereocalon* spp. (white and pinkish-grey), and the ubiquitous *Usnea antarctica*. The black *Usnea sphacelata* and *Pseudephebe minuscula* are two of the most stress-tolerant lichens, occurring almost exclusively in the harshest environments of continental Antarctica. Together with their usual associates, *Buella frigida* and *Umbilicaria decussata,* these species contain dark pigments that protect the thallus from potentially damaging ultraviolet radiation, which is much greater at high latitudes and altitudes. Another genus of fruticose lichens, *Cladonia,* has many species in the maritime Antarctic, all growing on moss or soil. They commence as a primary thallus of scale-like structures (squamules), which usually disappears once the secondary thallus develops. This is an erect hollow tubular structure (podetium), occasionally branched, and often terminating in a cup-like scyphus.

Ecology of Lichen-Dominated Communities

Throughout the Antarctic biome, lichens are the dominant plants in all but the wettest habitats, with a very few exceptions. However, their occurrence and the development of communities are restricted by local environmental conditions, notably instability of the substratum (e.g., cryoturbation of soil and stones, exfoliation of rock surfaces), rock type and surface texture, permanent shading from direct solar radiation, excessive exposure to strong wind, the abrasive action of wind-blown mineral particles and ice crystals, and, in the close proximity of birds and colonies, the impact of disturbance and toxic levels of certain chemical elements. Some species exist in profusion and form distinct communities in habitats receiving nutrient enrichment (especially from nitrogenous compounds in meltwater runoff and in aerosol form) from seabird colonies, although even in some nutrient-deficient habitats lichens may develop dense stands.

In the northern maritime Antarctic, diverse communities of nitrophilous lichens (e.g., *Acarospora, Buellia, Caloplaca, Haematomma, Huea, Physcia, Ramalina, Xanthoria*) cover large expanses of sea cliffs and coastal boulderfields influenced by a nutrient aerosol derived from nearby seabird colonies. On a much smaller scale, species of *Candelaria, Candelariella, Physcia,* and *Xanthoria* form a colorful community on moribund moss cushions in continental Antarctic sites. Breeding colonies of snow petrels *(Pagodroma nivea),* on inland nunataks, sometimes several hundred kilometres from the sea (notably in Dronning Maud Land) and at quite high altitude, are relatively lichen-rich oases. Here, nitrophilous lichens (especially *Caloplaca* and *Xanthoria* spp.) form a distinctive community in an otherwise barren landscape. These bird-influenced communities of brightly colored lichens can be seen from a long distance away. Indeed, J. D. Hooker, the naturalist on Sir James Clark Ross' 1839–1843 expedition, remarked of an orange species of lichen: "This plant forms the most curious feature in the botany of Cockburn Island [off the northeast Antarctic Peninsula], a desolate spot of land on the extreme limit of southern vegetation; for there it abounds so as to stain the rocks, and render the colour thus produced visible for many miles. It is partial to the effluvium from decaying animal matter [Adélie penguins and blue-eyed cormorants]..."

Although few lichens occupy wet habitats, several salt-tolerant species frequent rocks inundated by sea spray and occasional temporarily inundated by high tides. However, *Verrucaria serpuloides* is the only true marine lichen known, occurring as very thin black thalli on permanently submerged rocks at depths of 1–10 m in the mid-Antarctic Peninsula region.

The most extensive stands of lichen vegetation, sometimes covering several hectares, occur in the maritime Antarctic region, where favourable habitats, notably raised beach terraces and rocky hillsides near the shore, support spectacular communities dominated particularly by *Usnea antarctica, U. aurantiaco-atra, Himantormia lugubris,* and *Umbilicaria antarctica* in the South Orkney and South Shetland Islands. *Pseudephebe minuscula, Umbilicaria decussata,* and *Usnea sphacelata* occupy similar habitats in the southwestern Antarctic Peninsula region, and also throughout coastal continental Antarctica, locally extending to inland sites often at high altitude. In fact, the latter community (invariably with *Buellia frigida,* and usually *Lecidea cancriformis* and several other crustose species) is remarkable for its consistency of species composition and tolerance of exceptionally cold, dry, and windy conditions. The black thalli of *U. sphacelata,* in particular, often develop stands covering from a few square metres to several hectares on windswept ridges that probably receive almost no winter snow cover, thereby exposing the plants to temperatures below –50°C and relative humidity often below 20%. Its remarkable survival capacity may be because such stands usually occur in areas where clouds commonly form, thus providing a source of atmospheric moisture that lichens are capable of absorbing.

Another prominent coastal lichen community in the maritime Antarctic is dominated by *Umbilicaria* *antarctica* and *Usnea antarctica,* which festoon coastal rock faces, often with exceptionally large thalli in sheltered habitats. Coastal rocks often exhibit a distinct vertical zonation of communities along a hygrohaline (salt water) gradient from below the high water mark to several metres above it, dominated by species of *Acarospora, Buellia, Caloplaca, Lecidea, Verrucaria,* and several other genera. Nonbiotically influenced habitats from near sea level to about 2500 m altitude are often dominated, either abundantly or, in the latter instance, very sparsely, by nitrophobous saxicolous species of yellow *Acarospora, Carbonea, Lecidea, Lecanora, Rhizocarpon, Rhizoplaca, Buellia frigida, Pleopsidium chlorophanum, Pseudephebe minuscula, Umbilicaria decussata,* and *Usnea sphacelata*.

A distinct lichen community occurs on stands of bryophytes. The thick moss turf banks formed by *Chorisodontium aciphyllum* and *Polytrichum strictum* throughout the northern maritime Antarctic support an association of loosely attached fruticose lichens and several crustose species. These include the fruticose *Alectoria nigricans, Bryoria implexa, Cetraria aculeata, Cladina rangiferina* and several *Cladonia* spp., *Coelocaulon epiphorellum, Sphaerophorus globosus, Stereocaulon* spp., *Usnea antarctica, U. aurantiaco-atra,* and crustose *Ochrolechia frigida, Rinodina olivaceobrunnea, Lepraria/Leproloma* spp., and occasional other species. Extensive stands of the mosses *Andreaea* spp., and locally *Bucklandiella suedica* and some other bryophytes, usually have many of these lichens associated with them, usually with a few foliose species (e.g., *Massalongia carnosa, Pannaria austro-orcadensis, Psoroma cinnamomeum,* and *P. hypnorum*).

Throughout the northern maritime Antarctic the current trend of regional climate warming has caused substantial recession of ice field and glacier margins and considerable thinning since the mid-twentieth century. This has revealed many subfossil (a few hundred to several thousand years old) moss turf banks that have retained their original structure and species composition intact. Within the permafrost of such banks many of the present-day macrolichen associates can be clearly identified, as can others on recently exposed rock ledges. However, there is no evidence that any species existed earlier in the Holocene that do not occur at present.

Some introduced substrates in the northern maritime Antarctic are colonized by lichens. Several crustose and foliose species as well as *Usnea antarctica* may be found on weathered and decaying timber associated with human habitation. Timber originating from the 1920s whaling station on Deception Island, South Shetland Islands is heavily colonized by many lichens, as is wood dating from whaling activities at Signy Island about the same period. Concrete foundations and walls of old buildings at many Antarctic stations have been colonized by mainly crustose lichens, especially *Caloplaca* spp., and other anthropogenic materials (e.g., leather, iron, glass) also serve as a substrate for lichens. Whalebone on raised beaches throughout the maritime Antarctic often has a variety of lichen colonists.

Lichens in Extreme Habitats

Most habitats in interior continental Antarctica can be regarded as extreme, in terms of low temperature, prolonged drought, rapidly fluctuating thermal and hydric regimes, high solar irradiance and ultraviolet-B radiation levels, and prolonged winter darkness. Despite these physiologically stressful conditions, lichens have been found in almost all areas where there is ice-free rock, including those closest to the South Pole (at least 15 species beyond 85° S, with three species, *Carbonea vorticosa, Lecidea cancriformis,* and *Sarcogyne privigna,* at 86°29′ S in the La Gorce Mountains). About 25 species have been recorded above 2000 m altitude, with a few collected at around 2500 m (e.g., *Acarospora gwynnii, Buellia frigida, Pseudephebe minuscula, Rhizocarpon geographicum, Rhizoplaca melanophthalma, Umbilicaria decussata*). This appears to be the altitudinal limit at which lichens can survive in Antarctica. At these elevations and at far more southerly latitudes, epilithic (growing on rock) lichens must be exposed for long periods to temperatures as low as –60°C to –70°C in winter (no sunlight to warm the substratum, and usually no insulating snow cover on windblown rock faces) and a summer diurnal range of from 15°C to 20°C (thallus and substratum microclimate) to –40°C. As a probable protective response to extreme conditions, especially high UV-B levels, several lichen species have much darker or even black thalli, rather than the more typical coloration at low coastal sites (e.g., *Lecanora physciella, Rhizoplaca melanophthalma, Umbilicaria decussata, Usnea sphacelata*).

Numerous crustose lichens in extreme continental Antarctic habitats are barely visible, occurring in microfissures in rock or around the edge of large crystals. Often they exist only as apothecia (spore-producing structures), although there may be a substantial weft of fungal hyphae (rhizomorphs) within the fissure penetrating 1–2 cm into the rock (e.g., *Acarospora gwynnii, Caloplaca saxicola, Lecidea cancriformis, Rhizoplaca melanophthalma*). These morphotypes (which in less extreme habitats usually have a distinct thallus) are components of a chasmoendolithic (within rock fissures) community that is both widespread and common, although very obscure, in continental Antarctica. This reaches an extreme development in the cryptoendolithic communities that occur within the coarse crystalline structure of the Beacon Sandstone in the Transantarctic Mountains (at about 74°–78° S) in what is probably the most severe environment for life on the planet. Here, depending on the availability of moisture, various communities occur from just below the iron-stained rock surface to about 10 mm within the rock. These include, in the upper zone, a "protolichen," below which are other distinct biotic zones. In areas where there is no free water, but only atmospheric water vapour, the upper black zone, a few millimetres below the rock surface, is formed by dark brownish, greyish, or greenish masses of dark-pigmented (with melanin) fungal hyphae. These may be covered with precipitated iron compounds and often enclose groups of algal cells to form small globular bodies resembling the early stages of a lichen thallus. Beneath this is a white zone of colorless fungal filaments forming a hyphal mesh around the rock crystals, below which is a green zone formed by abundant algal or cyanobacterial cells. Below the algal zone there are sometimes transparent fungal hyphae. These communities of organisms are of particular relevance in the search for evidence of former life on the planet Mars.

LIGHT-MANTLED SOOTY ALBATROSS

The light-mantled sooty albatross *(Phoebetria palpebrata)* is a small and slender albatross species with a grey body, sooty brown head and wings, and conspicuous white eye crescents. Light-mantled sooty albatrosses weigh about 2.5 to 3.5 kg and have a wingspan of 1.8 to 2.2 m. The bill is slender with a blue-purple stripe on the lower mandible. The juveniles and immatures appear broadly similar to the adults.

Light-mantled sooty albatrosses are evaluated by Birdlife International as "near threatened," as it is considered that the species is close to qualifying, or is likely to qualify, for the "threatened" category in the near future. The total annual breeding population is estimated to be 19,000 to 24,000 breeding pairs, equivalent to 58,000 mature individuals in this biennially breeding species. Light-mantled sooty albatrosses breed at South Georgia (jurisdiction of United Kingdom); Prince Edward and Marion Islands (South Africa), Île Amsterdam, Île St. Paul, Îles Crozet, and Îles Kerguelen (France); Heard Island and Macquarie Island (Australia); and the Auckland, Campbell, and Antipodes islands (New Zealand). The largest populations are at South Georgia, Îles Kerguelen, and the Auckland Islands, but the population trends for this species are largely unknown.

One Îles Crozet population has decreased by 13% since the 1980s and the population on Marion Island is reported to have decreased since the late 1990s. The population on Macquarie Island, which constitutes about 5% of the global population, appears to have remained relatively stable since the 1990s.

Light-mantled albatrosses commonly nest on vegetated ledges or cliffs, which may be situated in either coastal or inland locations. The nests are usually a low cone, constructed of mud and vegetation, and are either solitary or in small groups. Adults return to the colonies during September or October, depending on breeding site. Egg laying is well synchronised and occurs from late October to early November. Both adults alternate in incubating the single egg for 10 weeks until the egg hatches in late December to early January. Chicks fledge in late May to early June at 5 months of age. Light-mantled sooty albatrosses are generally considered biennial breeders, although many adults may defer breeding for more than one season after a successful breeding attempt. Birds return to their natal islands from 6 years of age, and begin to breed at between 7 and 12 years old. The critical demographic parameters of adult and juvenile survival are largely unknown for this species.

Light-mantled sooty albatrosses are dispersive and solitary at sea and have a widespread and circumpolar distribution, ranging from the Antarctic pack ice northwards to 35° S. Limited satellite tracking has shown extensive movements achieved through rapid flight to foraging areas that are visited repeatedly. Birds from Macquarie Island travelled over 1500 km to their foraging grounds south of the Antarctic Polar Front. During the nonbreeding season their range extends northwards and includes subtropical waters in the Australian, New Zealand, and South Pacific Ocean.

The diet of light-mantled sooty albatrosses varies with location; fish, squid, and crustaceans are all important prey items. Feeding behaviours include surface seizing and plunging, and dives to depths of 12 m have been recorded for this species.

Light-mantled sooty albatrosses are known to be killed in longline fisheries, although the level of bycatch for this species on the high seas is uncertain. Their capture during longline operations targeting tuna has been confirmed in Australian and New Zealand waters, and there is also concern over longline interactions in operations targeting Patagonian toothfish *Dissostichus eleginoides*. Introduced predators on some of their breeding islands are also thought to impact this species.

LIVERWORTS

Liverworts belong to the Plant kingdom division Marchantiophyta (formerly, with the mosses, Bryophyta), which comprises two classes (Marchantiopsida and Jungermanniopsida). Mosses and liverworts are still referred to collectively as bryophytes. Genera and species of both, in several orders and families, are represented in the Antarctic.

Growth Forms

Liverworts have two principal morphological forms. The predominant growth form comprises many individual leafy, often unbranched, shoots (Jungermanniopsida), the whole structure being referred to as a colony of shoots. Many of these grow as erect colonies, but others form an interwoven mat of prostrate shoots, sometimes of very small dimensions. The thalloid growth form (Marchantiopsida) is rare in the Antarctic. These are flat strap-shaped plants adhering closely to their soil or rock substrate.

Physiology

The physiology, growth, and reproduction of liverworts are very similar to those of mosses. Their simple anatomical structure, without specialized water-conducting tissues, restricts liverworts to moist habitats, from which they derive their water and nutrients passively and uncontrollably through their leaves and stems. Like mosses, they have no control over water loss during dry or sunny weather, which is a major factor restricting their occurrence to moist habitats. Very few Antarctic species reproduce sexually (i.e., produce sporophytes and viable spores), and even then they do so only very rarely. Most rely on dispersal and establishment by vegetative means, for example, detached shoot fragments or specialized structures such as tiny tubers and gemmae (small multicelled propagules capable of developing into new plants in favourable habitats).

Species Diversity and Biogeography

Most liverworts are generally very inconspicuous components of Antarctic vegetation, almost invariably associated with mosses and often hidden among the moss shoots. All grow in coastal areas, with very few occurring more than 2 km inland. A recent revision of the liverwort flora of the Antarctic, including the South Sandwich Islands and Bouvetøya (climatically and biologically an extension of the maritime Antarctic) listed a total of twenty-seven species in nineteen genera. This is less than a quarter of the moss flora for the biome; a similar number could be found on a single tree trunk in a tropical rain forest. Only one species *(Cephaloziella varians)* occurs in continental Antarctica. Several are restricted to geothermal habitats on the South Sandwich Islands. As with mosses and lichens, no Antarctic liverwort species have common names. Nine species have a sub-Antarctic distribution, eleven are southern temperate, six are bipolar, and one *(Marchantia polymorpha)* has a global distribution, although it was recorded only once as a new colonist on recently created heated ground following an eruption on Deception Island, South Shetland Islands, and has not been seen since. The greatest diversity of species is in the milder, wetter South Orkney and South Shetland islands, although several extend southwards along the west side of the Antarctic Peninsula, with only two species reaching 68° S (*C. varians* and *Barbilophozia hatcheri*). Seventy-five percent of the Antarctic liverwort flora occur on the tiny Signy Island, in the South Orkneys. Many species are rare or are known at very few sites in the Antarctic, and several are restricted to the unique geothermal habitat associated with volcanic activity.

Ecology

Liverworts rarely develop distinctive communities in the Antarctic, although several species occur frequently, if sparsely and inconspicuously, in moss-dominated communities in moist habitats. Loosely aggregated shoots of liverworts often occur intertwined amongst moss colonies, especially species of *Andreaea, Bucklandiella,* and *Schistidium* in fellfield communities, *Sanionia* and *Warnstorfia* in seepage areas and bogs, and the thick turf-forming *Chorisodontium aciphyllum* and *Polytrichum strictum*.

Occasionally liverworts dominate over mosses in some communities, and very occasionally a few species form pure stands of more than 1 m^2. *Cephaloziella varians* is by far the most common and widespread species, occurring almost invisibly in many plant communities throughout the maritime Antarctic. It is also the only liverwort that extends to continental Antarctica, where it reaches 77°00′ S at Cape Geology, Botany Bay, southern Victoria Land. Several species occurring on heated ground around fumaroles on several of the volcanic South Sandwich Islands archipelago in the northern maritime Antarctic form mixed communities dominated by liverworts unknown elsewhere in the Antarctic (e.g., *Clasmatocolea rigens, Riccardia georgiensis, Triantrophyllum subtrifidum*); *Cryptochila grandiflora* also occurs here, and around a single fumarole on Deception Island, South Shetland Islands. The large thalloid species *Marchantia berteroana* is locally common on some northern maritime Antarctic islands (notably Signy Island, South Orkney Islands), forming conspicuous mats of overlapping strap-shaped stems.

Because of their physiological intolerance of dry and cold conditions, liverworts are restricted to low-altitude habitats, mainly in coastal areas. A few (e.g., *Cephaloziella varians, Barbilophozia hatcheri*) are found at up to 350 m altitude. However, there is a unique occurrence of *C. varians* on geothermal ground on Cryptogam Ridge, near the summit of the volcano Mt. Melbourne, Victoria Land, at c. 2700 m. Here, soil surface and vegetation temperatures reach over 30°C, maintaining a warm humid environment throughout the year for this liverwort and the moss *Campylopus pyriformis*. While several mosses exist in a permanently submerged environment in Antarctic lakes, so far there are no known exclusively aquatic liverworts.

LIVING IN A COLD CLIMATE

With no indigenous human population in the Antarctic and the first documented explorers reaching there in the last 4 centuries, the development of a transient population is a most interesting one. The success of humans in Antarctica has depended more on behavior and technology than on biology. The Antarctic population, which spends from a few days to no more than 2 years at a time in Antarctica, survives because of the clothing, food, and shelter available. All survival needs, with the exception of water, must be taken with them. As all water is frozen as ice, considerable energy to melt the ice must also be available. Despite the dramatic changes in technology since the Heroic Era, personnel are still physically isolated, especially during winter, and are subject to the same hostile and unforgiving environment. Some groups during winter are arguably the most isolated on Earth, and cannot be evacuated in the event of a health problem, injury, or mishap, unlike similar remote groups in other extreme environments, including nuclear submarines, theaters of war, mountains, caves, or the International Space Station in orbit.

Humans in Polar Regions

Humans are *tropical* animals in that evidence suggests they evolved in Africa in a hot, moist environment. Their ability to cope with cold is limited. Naked humans at rest and in still air can maintain constant body temperature at an air temperature of 27°C–29°C without raising heat production above the resting value. Mild cooling is tolerated by a rise in metabolic rate. Greater cooling initiates further heat production by increased muscle activity such as shivering, and the body conserves heat by constricting the blood vessels of the skin and shunting blood away from the surface to the body core; the skin is protected by alternating periods of vasodilatation with the vasoconstriction. Additional behavioral action such as folding the arms over the body and bending the legs, or huddling, reduces the surface area of the body and hence heat loss due to radiation and convection. Further heat production may occur by nonshivering thermogenesis, which involves complex metabolic processes.

Coastal Antarctica may not have temperatures as low as the Arctic, but high winds and frequent blizzards increase the wind chill factor and thus cooling. Although there is scientific evidence of both general and local acclimatization to cold by some of the transient Antarctic population, human survival in the colder, higher latitudes such as the Arctic, where the Inuit have lived for millennia, is not due to physiological changes, but to technical knowledge and its application.

Humans have had to overcome the isolation of Antarctica, travel great distances over rough oceans to get there, and be totally self sustaining by complex operations. In addition to cold, depending on the latitude, diurnal sunlight and darkness vary from the maximum of 6 months of summer sun and winter darkness at the South Pole.

Antarctic Populations

Today the total wintering population in the Antarctic is around 1000, almost all at national stations and bases. This number increases more than tenfold during summer, as research programs and tourist visits are at their busiest. The scientists and support personnel at the various bases are a microcosm of the society of their country. They are selected for their ability to perform specific tasks and live in a closed community. Most staff undergo training to facilitate safe living and working in Antarctica. Each country of origin organizes training according to the culture, practices, accepted norms, logistics capabilities (depending on whether travel to Antarctica is by ship or air transport), and legislative requirements (such as occupational health and safety) of the parent country. Preparation may include the development of a remote community, how they will live and interact, and how they might resolve conflict. Personnel traveling into field areas are trained in field survival techniques.

There is much variability in life in Antarctica, especially as numbers of people at bases can vary from more than 200 to less than 10 in winter, and the level of support provided can range from McMurdo Station, with a population of more than 1000 in summer, to several persons in a tent in a remote field location. Further, some groups are military, others civilian, still others a mixture of military and civilian. Most groups consist of males and females, few all-male groups remaining, and some nations have families and children in their communities. People go to Antarctica for a variety of reasons in addition to the specific objectives of research programmes, including the challenge of the environment on the job, the lifestyle, to save money, the fact that it is the last of the world's wilderness areas still relatively pristine, or to simply escape from the "real" world.

Antarctic Stations/Bases

Station facilities in Antarctica are generally modern, insulated, and comfortable. Living quarters have mess and general living areas, kitchens ranging from basic to commercial, bedrooms ranging from individual to bunk rooms, bathrooms, and recreation areas that may include a library and film theatre. Power generation, communications, research laboratories, offices, stores, and workshops may be in the same complex or in separate buildings; some are two or three stories. Other additions at the larger stations include gymnasiums, bowling alleys, or other sporting facilities for volleyball, basketball, squash, racquetball, badminton, or half tennis. Some have chapels or small churches. Few buildings are reminiscent of the Heroic Era, when members of expeditions lived in small, crowded, uninsulated huts and were often cold and suffered privation. The old huts still standing show evidence of attempts to stop the entry of interminable fine drift snow with a variety of materials such as tar paper and horsehair. Buildings have evolved from the wooden huts to wood and aluminum insulated panels. Many of these are of considerable size and complexity. Modern building design allows for both communal areas and places where people can get away if they wish. Stations that previously were buried under snow and had to be abandoned are now replaced by buildings that can be raised above the accumulating snow. Initially, buildings were prefabricated and needed to be constructed in between blizzards in a relatively short time by all staff. They are now constructed by professional teams using heavy equipment over months or years.

How Antarctic Life Has Changed

Technological advances and the experience of living in Antarctica have dramatically altered life there. Long sea voyages by wooden sailing ships, some with steam power, through the stormiest seas on Earth and penetration of the short austral summer sea ice are now replaced by the much faster ice breakers and air transport. Intense physical labor to unload ships at the ice edge and transport buildings, stores, and equipment across the sea ice by dogs, ponies, and man-hauling is now accomplished at wharves by cranes and industrial plants, often with assistance from helicopters. Coal and coke were once the primary source of heating and cooking energy; they were later replaced by electricity and gas appliances, with heating also coming from the cooling systems of the power house. Fossil fuel use is being substituted for by wind and solar power. Paraffin lamps and candles were initially replaced by acetylene generators before being replaced by electricity.

Early groups communicated by leaving messages on snow and rock cairns for summer ships and field parties. Wireless was introduced by Douglas Mawson's Australasia Antarctic Expedition in 1911–1914. Polar cap absorption (PCA) caused lengthy radio blackouts of days to weeks on end. Communications progressed from use of Morse key to radiotelephone, teleprinters, and finally "blackout-free" satellite communications. Satellite phones are used in the field along with other light-weight, reliable hand-held radios, thus eliminating the need for hand cranking generators to power unreliable and heavy radios. Communications is one area that has altered Antarctic isolation, although people may still be totally physically isolated. Use of satellites for phone, fax, scientific data transmission, email, and internet access is common. Navigation is another totally altered system. The Global Positioning System (GPS) and radar now provide accurate and safe navigation to those traveling in Antarctica.

The great physical effort to collect snow and ice and melt them for water has been changed by modern technology of desalination plants in coastal areas and heat probes into the ice, or heavy equipment to gather snow. Old rituals such as the bath in front of the stove while the individual was on night watch every week or two are long since gone. Snow baths in the field may still be the norm when camping in remote areas, but showers are found on tractor trains and at inland camps. Water is still at a premium in Antarctica, and some stations with large populations must restrict each person to several short-duration showers per week. Pit toilets have transitioned through putting waste untreated into the sea, to gasoline and natural gas fired systems and flush toilets and sewage systems, with the sludge from the treatment facilities being removed from Antarctica. Similarly, field toilets have progressed to all waste being retrograded to the coastal stations.

Routine man-hauling, dog sledging, and use of ponies have been replaced by mechanical transport, helicopters, and fixed-wing aircraft. Improvements in clothing and field equipment have altered life in Antarctica. Technological changes in scientific equipment have also resulted in a marked change in the range of research work that can be carried out in Antarctica. Computers, satellites, and sophisticated scientific laboratories are in sharp contrast to some of the primitive scientific equipment used only decades ago. Technology has been important from the first days of humans in Antarctica, but with the rapid changes of the last 50 years, living and working in Antarctica has been and will continue to be improved.

Station/Base Life

Living in Antarctica is little different to living in any other remote, extreme environment, despite Antarctica's being the coldest, highest, driest, windiest, and most isolated continent on Earth. However, those going to Antarctica travel great distances over the most inhospitable oceans and, if air transport is not available, are not able to get out for long periods of the year. High winds and blizzard conditions occur regularly, making movement outside difficult without the use of ''blizzard lines'' or supporting ropes between buildings to prevent people from becoming lost.

Antarctic stations or bases are like small remote towns, as all services must be provided. All have a designated leader or commander, but most work as classless societies with everyone supporting the scientific and other (e.g., art, education) programs. People are very dependent on each other. Most staff have multiple skills, as not all disciplines or occupations normally found in society are represented in the remote communities. Libraries are found universally, but there are no trained librarians, and for the most part the sole doctor, who provides all health-care needs, is aided by ''amateur'' assistants. Scientists may not have the full range of technical support, as they do at a university or research establishment, and therefore must depend on the skills of those present. There are generally no prospects of getting the services of an expert on call. An amazing breadth of skills, and the ability of the staff to improvise, are found on an Antarctic base.

Life is less complex than in society at large. People do not have to conform to many conventions, such as dress, or travel distances to work. This may cause problems as, freed of the routine of normal society, some individuals have difficulty adapting to the less conventional working and social arrangements. Most staff, however, have competed to work in Antarctica, and are self-motivated and committed to accomplishing the tasks they have been selected to perform. There is a basic work output necessary for the safety and well being of each group. Some individuals on a base may have little in common culturally and may not be socially compatible. It is life in a test tube, as all live in close contact. Groups from the same country of origin, living at different geographical locations in Antarctica at the same time, may react to common problems or edicts in very different ways. It depends on the group, the individuals, and leadership, and defies prediction from group to group and year to year. Groups develop customs, rituals, and language to such a degree that dictionaries of specific Antarctic words, terminologies, and usage have been written.

Recreation is an important aspect of base life, and centers around social, musical, sporting, and intellectual activities; the country of origin influences those significantly. National holidays and events are celebrated, many having additional ''Antarctic'' customs and rituals added to the event. Small groups celebrate individual birthdays and anniversaries with highly organized parties and dinners, international cuisine being prepared on most stations. The isolated communities form bands, theatrical, sporting, musical, and dining groups and societies, depending on the size of the base. Mid-winter—celebrated around the shortest day in June—is a strong Antarctic tradition, being observed since the Heroic Era. It may last several days with banquets, plays, rituals, and sporting events. The international aspect of Antarctic life is reflected in events staged between bases in the same locality or competitive events such as chess or darts competitions, conducted at a distance across the continent by radio. Most take advantage of the unique Antarctic landscape to enjoy the outdoors in snow and ice pursuits, observing the seasonal wildlife, photographing the rugged landscape, or just getting away for a few days on a field trip.

Field Life

Despite the disadvantages of layers of polar clothing and the lack of the comforts of a heated base with regular meals and recreation, field life is most rewarding and eagerly looked forward to. Those on either logistic or scientific tractor trains have vans to live in that are more comfortable than tents when the train is stationary, but most uncomfortable as they ride roughly over the wave-like sastrugi at very low speeds of around 5 km/hour for most of the day. Motorized toboggans, four-wheeled motorcycles, and larger all-terrain tracked vehicles have enabled faster speeds and greater mobility when compared to manhauling, skiing, or dog travel, even though the latter, to those who have used it, remains the ultimate in polar field life. In the field, fixed camps may have prefabricated huts of various sizes and description, or large, heated tents. Mobile parties carry a tent—ranging from the classical tetrahedral, polar pyramid with its four poles, square base, sewn-in floor, and double walls to the more modern compact mountaineering and expedition tents. The tents provide safe shelter in the most trying of blizzard conditions.

A polar pyramid tent can be pitched in minutes by one person in calm weather, but in high winds it is a more difficult task that needs rehearsing to allow the wind to assist in the erection. The tubular entrance to the tent is faced across the wind to decrease snow accumulation. The flap surrounding the tent is secured by placing blocks of snow on it, cut by snow shovel or saw; some tents have additional tie-down ropes and pegs to anchor the flap to the snow. Two people usually occupy the tent along with their insulated mats or air mattresses, on which sleeping bags are placed, food and utensil boxes, radio, stove, lamp if summer light is not enough, and scientific equipment, including computers, maps, and navigational and meteorological gear. Cooking is usually done while in the sleeping bag. Food today, even if ration packs are used, is much more appetizing and varied and less monotonous than in the past. The tent is warmed when food is prepared, and from solar heat on clear days. Water vapor is readily generated from breathing and cooking, as well as from clothing and footwear—damp from the perspiration of exercise—which are hung in the peak of the tent to dry. The moisture passes through a vent in the peak or condenses on the inner lining of the tent. Tent dwellers soon learn not to touch this lining to prevent showers of frost from descending on them. They also learn to store snow blocks for melting for water in between the two layers of the tent near the entrance to save going outside. Similarly, one learns to wear adequate clothing when one must go outside to attend to "calls of nature," as a tent can quickly "warm" relative to the outside temperature.

Household tasks such as dressing; removing frozen moisture from clothing, innersoles, and sleeping mats; melting snow for water (at least ten times the volume of snow is required to produce the volume of water needed); cooking meals and preparing drinks or soup to take in vacuum flasks while engaged away from campsite; maintaining radio schedules with main base; and recording scientific data are very time consuming, as it takes much longer to do things under the field situation. Attention must be paid to time, and a routine worked out, as it is very easy to become undisciplined.

Emergency equipment—depending on destination and pursuits—is carried by each party. Everyone depends on each other, and living so close for lengthy periods means each person gets to know the other well, both the positive and negative aspects. There tends to be great camaraderie. Behavioral effects of field living are important, and in little time people tend to become very efficient. This includes simple tasks such as filling vacuum flasks with boiling water each night so there is water to commence breakfast preparation the next morning. Ablutions in the field range from snow baths, teeth cleaning, and simple washing of face and hands to showers at fixed locations.

Food/Diet

As well as discomfort from cold, the nutrition of many of the early expeditions was inadequate in both calories and content such as vitamins. Supplementation from seal, penguin, and bird eggs was frequently the norm. In many instances eating fresh meat kept nutritional diseases such as scurvy at bay. As the food increased in variety, the vitamin and essential mineral content increased, and nutritional diseases became less common. By today's standards the food in the huts a century ago was limited, with few luxury items. Sledging rations in the field were even more spartan and monotonous, and prepared only on a Nansen-type cooker over a small stove. Pemmican—the composition of which varied, but tended to be dried meat with fat or lard, sometimes with added yeast extract—gave high caloric content and was the staple with biscuits, chocolate, and drinks such as cocoa.

Diets today match those of the country of origin, assisted by the facts that modern processing, packaging, and storage give much greater variety and that preparation is in the main by professional chefs who often have a rotation of rostered lay assistants to help. Dietary discretions of all types are accommodated at many bases. Fresh fruits and vegetables are limited in summer unless air supply is possible and absent in winter unless small quantities of salads are grown under hydroponic conditions. During winter, meat is usually frozen or tinned and vegetables are tinned, frozen, or freeze dried. Ration packs are still used today in the field by a number of nations and are high energy, but the variety is great and preparation made easier by use of microwaves at field bases. Many groups in the field eat food that differs little from that on stations, as supplies are regularly flown in. The diaries of early Antarctic explorers, especially those who had to survive against incredible odds, described vivid dreams of dining on fine food at fashionable restaurants as well as rescue fantasies. These men wrote of constant hunger, thirst, lack of sleep, and a monotony of occupation, companionship, and color.

Summer Season

Summer in Antarctica is the season of great activity. The return of the sun brings the wildlife to breed, aircraft break the silence of winter in September/October, and in the following months as the sea ice breaks up ships penetrate to coastal stations. Both bring large numbers of people subsuming the small, remote winter groups. Scientists engage in major programs, many of which are international; support personnel work at rebuilding, maintenance, and repair of stations; and thousands of tourists and adventurers visit. Below the Antarctic Circle, the midnight sun becomes a stimulus for frantic work and play. Twenty-four hours of sunlight can also cause insomnia, referred to as "big-eye." Aircraft and shipping bring a constant turnover of people in austral summer, as personnel strive to complete their programs before transport departs the continent in late February to April. Fresh fruit, vegetables, and supplies are as welcome as new faces. In this age of e-mail and satellite phones, mailed letters and parcels are still welcomed in summer as a connection with the outside world; mail and supplies cannot be delivered during winter.

Winter Season

With summer over, some bases close, while those remaining open during winter have their populations reduced by as much as 80%. As aircraft and shipping activity ceases, fieldwork decreases and the scientific program, apart from observatory functions, is much reduced. Human studies are best investigated during winter. Isolation is more intense and the social environment is very different from that in summer. Although life is less hectic, along with work, it can be boring and repetitive. Altered immune status has been found in those wintering in Antarctica, just as in other populations under stress.

Reports from Antarctic winterers suggest the occurrence of a "winter over syndrome." Symptoms include irritability, hostility, inability to concentrate, difficulty in memory, fugue states that are referred to as the "Antarctic stare" or "long eye," and insomnia. Considerable research has taken place during the past 50 years, but the etiology has not been identified; some psychiatrists and psychologists suggest that the "winter over syndrome" is not a pathological state but an adaptation to small numbers, confinement with the same associates and tasks, isolation from family and work colleagues, inability to leave the hostile environment, and the environment itself, whether cold or photoperiodicity. Not all personnel have the same experience during winter. Many investigations in Antarctica have assumed that the environmental stressors adversely affect physical and mental health. This is possibly due to the abundance of anecdotal reports. Blizzards, changes of temperature and light, and cosmic radiation have all been suggested as having a relationship with psychosomatic manifestations, but there is no scientific consensus. The majority of people adapt well, with the occurrence of psychological/psychiatric problems during the Antarctic winter low. To most, wintering in Antarctica is a very positive experience.

Community life is important in winter to cope with the reduced numbers of people and the added complexities of work. Subgroups are often formed, as staff members are drawn together because of similar work (scientists or nonscientists), social pursuits (drinkers or nondrinkers), and those in relationships (having a partner or not). Folklore, customs, ceremonies, and cultures have developed, with some behavior classed as bizarre by those outside Antarctica. To those in Antarctica it can be "normal." Morale is variable, ranging from "midwinter blues" to fluctuations due to work load, daylight hours, or specific events rather than season. There is no common pattern. Methods of facilitating adjustment to wintering are many and varied. Tolerance and humor are important individual characteristics, while social events, physical endeavors, and activities, such as station newspapers, all play a part. Groups who had husky teams were known to enlarge their human groups by the individual dogs' assuming human status. Food is most important, and those who eat well are generally happier than those who do not. Mutual dependence is universal in Antarctica and there is a unique spirit of camaraderie that extends beyond the national group, to be found between those from different nations who have wintered in Antarctica.

Returning Home

Returning home from Antarctica is a most provocative experience. There is a readjustment to sounds such as traffic noise, smells (especially of vegetation), rain, in some cases use of money, and to society, including family, friends, and work colleagues. Some would say it represents a retribalization from the microcosm of life in Antarctica to society at large.

Summary

Extreme cold, isolation, and long periods of daylight and darkness create challenges for those living in the Antarctic regions. Most people who spend time in Antarctica return home having had an enjoyable and positive experience, seeing their time on the harsh and icy but beautiful continent as stimulating and rewarding. Testimony to this is the large number of people who return for subsequent summer or winter sojourns as members of national research or tourist groups.

M

MACARONI PENGUIN

The macaroni penguin, *Eudyptes chrysolophus,* is one of the largest of the six species of crested penguins. Adult macaroni penguins weigh 5–6 kg, there being variation among individuals from breeding localities. They are blue-black on their backs and white ventrally. Long golden-yellow feather plumes extend from the forehead along the sides of the head above the eyes, forming a broad, loose crest. The large bill is red-brown, eyes dull red, legs and feet pink.

Distribution

Macaroni penguins have a more southerly distribution than most other species of crested penguins, breeding between about latitudes 45° and 65° S in the western Indian (Heard Island and McDonald Islands, Îles Kerguelen, Îles Crozet, and Prince Edward Islands) and South Atlantic Ocean (Bouvetøya, South Sandwich, South Georgia, South Orkney, South Shetland, and Falkland groups of islands and in low numbers at islands off the Antarctic Peninsula). It also extends into the southeast Pacific Ocean along the coastline of southern Chile. The largest colonies are north of about 55° S. In the southwest Pacific Ocean, the macaroni penguin is replaced by the closely related and similar in appearance royal penguin, *E. schlegeli,* at Macquarie Island.

Macaroni penguins leave their breeding localities after moulting, but for many colonies, their at-sea distribution in the nonbreeding season is poorly known. It is thought that they remain in sub-Antarctic waters. Vagrants, mostly moulting immature birds, have been recorded in South Africa and Australia.

Annual Cycle

Macaroni penguins moult once each year, in autumn, when they replace all their feathers. At this time they are ashore for 3–4 weeks and do not feed, as they can not enter the water. Before moulting, they spend about 2 weeks at sea fattening up. Once the moult is complete, they go back to sea during winter to regain condition. In spring they return to their colonies to breed, males arriving at colonies about a week before the females. There is considerable synchrony in the timing of breeding and moult, and colonies are devoid of birds during winter.

After their arrival at colonies for breeding, both parents fast again for periods of 30–40 days. They remain at the nest site until about 8 days after the eggs are laid. The male then departs to sea for about 13 days, leaving the female to incubate the eggs. Soon after his return she departs, for about 10 days. She returns just before the eggs hatch. Both parents are at the nest for the first 2–3 weeks after hatching. The male guards the chick, while the female undertakes short feeding trips to provision it. Later the chick joins a crèche, at which stage both parents feed it, at first the female more frequently than the male, which has fasted a third time for several weeks. The incubation period lasts about 36 days, the fledging period about 60 days. Breeding birds depart on their premoult feeding trip soon after their chicks have left the colony.

Breeding and Survival

Macaroni penguins are colonial breeders, usually breeding in large colonies. They are monogamous, with often long-lasting pair bonds. Nests are on level or steep ground that frequently is devoid of vegetation because of trampling. The female forms the nest scrape, which is then lined by pebbles collected by both sexes.

Macaroni penguins lay clutches of two eggs. The interval between laying of the two eggs is 4–5 days. The first egg is on average 38% smaller than the second egg. It seldom survives, often being dislodged during nest scraping. Only one chick is typically reared to fledging.

Macaroni penguins are able to breed when 3 years old but may defer breeding until they are 8 years old. When food is scarce, substantial numbers of birds do not breed. Annual survival of adults is about 75%.

Food and Feeding

Macaroni penguins feed on euphausiids, amphipods, small fish, and cephalopods. Crustaceans dominate the diet fed to small chicks; larger prey may predominate in the diet of older chicks. Food is caught by pursuit diving. Birds dive to depths of less than 20 m at night, but to greater depths in the day, following the daily migrations of their prey towards the surface at night and away from it in daylight.

During incubation, both sexes undertake extensive foraging trips (at South Georgia on average about 375 km for females and 575 km for males) whereas, during chick rearing, trips are often shorter (at South Georgia about 60 km).

Population Size

Macaroni penguins are more numerous than any other crested penguin, numbering about 9 million pairs. The largest populations are at South Georgia (2.5 million pairs), Crozet (about 2 million pairs), Kerguelen (1.8 million pairs), Heard (about 1 million pairs), Prince Edward (300,000 pairs), and Bouvetøya (100,000 pairs) groups of islands.

Conservation Status

The macaroni penguin is classified as Vulnerable on the Red List of IUCN (The World Conservation Union), because the overall population appears to have decreased by at least 20% over a period of 36 years, equivalent to three generations. It is believed that the population at South Georgia probably halved after 1980. Competition between fur seals and macaroni penguins for food resources may increase as fur seal populations increase. The availability of food around colonies may be influenced by climate change and environmental perturbations.

MACQUARIE ISLAND

Macquarie Island, a tiny piece of ocean floor tectonically uplifted above the surface of the Southern Ocean, is of importance to marine mammals, marine birds, and humans. To thousands of seals, penguins, albatrosses, petrels, and other sea birds, Macquarie Island is of crucial importance as the land on which they breed. To humans, when the island was first discovered in 1810, it was important as a source of wildlife to be exploited: for fur seal skins, elephant seal oil, and, later, penguin oil. Now the island has been recognised by humans as important in its own right, and is reserved as a World Heritage Area, a World Biosphere Reserve, and as the Macquarie Island Reserve, bounded to the east by the Macquarie Island Marine Park.

Macquarie Island, with Bishop and Clerk islets nearby to the north and Judge and Clerk islets to the south, lies in the vicinity of 158°55′ E, 54°30′ S, approximately 1500 km southeast of Tasmania and 1100 km southwest of New Zealand. Just north of the Antarctic Polar Front Zone, and exposed to the winds of the "furious fifties," the island has a cool, moist, windy, but equable climate. Mean surface 9 am air temperature is 5.0°C with seasonal variation of 3.4°C–7.2°C at sea level. Mean annual precipitation is 953 mm, falling as rain, mist, sleet, hail, or snow on approximately 313 days per year. Windspeed at 9 am averages 9.3 m s^{-1}. Extensive cloud cover means that sunshine hours average 2 hours per day. Evidence for climate change is seen in the slightly warmer temperatures and lower precipitation during recent decades.

The elongate island, 34 km long and varying between 2 and 5 km wide, comprises an undulating plateau at 200–300 m above sea level (asl), bounded by steep coastal slopes. The highest point is Mount Hamilton, 433 m asl. At the northwest corner of the island, a marine-cut terrace supports an extensive mire locally known as "the featherbed."

Macquarie Island is the above-ocean part of the Macquarie Ridge Complex, uplifted by plate-boundary processes between the Pacific and Australian tectonic plates. The southern two-thirds of the island is pillow basalts, with an exposed ophiolite complex in the north. The island has been above the ocean surface for approximately 700,000 years, and is still rising at an average rate of approximately 0.8 mm per annum. The present size and shape of the island is a result of interplay between tectonic uplift, sea-level changes, and coastal erosion as uplift proceeds. Cobble-strewn raised beaches up to 280 m asl provide evidence that all parts of the island have, at some past time, been at sea level during the uplift process. These same well-preserved cobbled raised beaches are consistent with glaciation never having been part of the island's geomorphic processes. Instead, landforms have been shaped by faulting processes, by erosion, by wind and water, and by interaction of physical processes with vegetation in terracing hillsides, damming lakes, and forming mires.

The island's vegetation is treeless, with closed herb vegetation on the coastal slopes dominated by tussocks of the grass *Poa foliosa* (up to 1.5 m tall) and the megaherb *Stilbocarpa polaris* (known since sealing days as Macquarie Island cabbage and used then as an antiscorbutic addition to diet). The megaherb *Pleurophyllum hookeri* (a rosette-leafed maroon-flowered daisy) and short tussocks of the grasses *Agrostis magellanica* and *Festuca contracta* and the sedge *Luzula crinita* form closed vegetation cover on many parts of the plateau. The endemic cushion plant, *Azorella macquariensis,* dominates the open vegetation, feldmark, on much of the plateau, important in the vegetation banking the gravel-surfaced terraces that form a striking component of the landscape. Bryophytes (mosses and liverworts) are important components of the vegetation, particularly in the feldmark and in the extensive mires on the plateau and the featherbed.

The vascular flora includes five species of ferns and fern allies, and some thirty-nine species of flowering plants, of which three are endemic (*Azorella macquariensis, Corybas dinemus,* and *Puccinellia macquariensis*) and three considered alien (*Cerastium fontanum, Poa annua,* and *Stellaria media*). The bryoflora includes eighty-eight species of mosses and fifty-one species of liverworts, of which one moss species is considered alien *(Funaria hygrometrica)*. From the island's rocky shores, 103 species of marine macroalgae, including the large bull kelp, *Durvillaea antarctica,* have been recorded.

Populations of previously exploited marine mammals have recovered well. Elephant seals and three species of fur seals (New Zealand, Antarctic, and sub-Antarctic) now breed on the island, with interbreeding between the fur seal species. Populations of king penguins and the endemic royal penguins *(Eudyptes schlegeli)* have also recovered well from exploitation, and continue to expand on the island. Rockhopper penguins and gentoo penguins breed on the island in significant numbers. Four species of albatrosses (wandering, grey-headed, black-browed, and light-mantled sooty), two species of giant petrels (northern and southern) and seven species of smaller petrels breed ashore.

Two species of endemic terrestrial vertebrates have become extinct since humans started visiting Macquarie Island: a flightless parakeet, *Cyanorhamphus novaezalandiae erythrotis,* and a flightless rail, *Rallus* *philippensis macquariensis*. During the same period a larger number of alien terrestrial vertebrate species has arrived and become established: rabbits, cats, ship rats, house mice, and wekas. Each has had significant impacts on aspects of the island's ecosystem: rabbits on terrestrial vegetation, the others on burrow-nesting birds. Management programs have successfully eradicated cats and wekas, and reduced the population of rabbits. Ongoing control or eradication of rabbits, rats, and mice is a significant challenge facing the management of this sub-Antarctic island reserve.

The numerous freshwater lakes and streams on the island support a range of aquatic biota including flowering plants, bryophytes, green algae, diatoms, cyanobacteria, and lower invertebrates (protozoa, rotifers, tardigrades, nematodes, flatworms, segmented worms, freshwater crustaceans). Like the flowering plants, both freshwater and terrestrial invertebrates include a number of endemic species. Nine species of terrestrial invertebrates are considered to be resident alien.

The first time Macquarie Island was used for serious scientific purposes was during the Australasian Antarctic Expedition (AAE, 1911–1914), when a party of five under the command of George F. Ainsworth established a base to serve as a meteorological station and wireless-relay point between the expedition's main base at Commonwealth Bay and Australia. Significant biological, geological, and survey work was also carried out. When the AAE members departed, the station was maintained briefly by the Commonwealth Meteorological Service. As during the AAE, since 1947 a scientific research station has been maintained at the northern end of the island, at which biological, geological, climatological, and upper-atmospheric research are conducted. For its scientific interest and for its wild beauty, Macquarie Island has become of considerable interest to ecotourists. As at all visited sub-Antarctic and Antarctic sites, the ecosystem on Macquarie Island is at risk from human visitation, and management includes careful quarantine, in order that the characters for which the island is valued are maintained.

MAGNETIC STORM

A magnetic storm is an interval of large nonsecular variation of the geomagnetic field, usually on a global scale. The term *magnetic storm* is attributed to Alexander von Humboldt in 1808. Subsequently, many definitions of magnetic storm have been proposed and used. Commonly, a magnetic storm is defined as an interval of extreme perturbation of a local or global measure of the geomagnetic field, usually sustained over a few hours to days. Typically, *extreme* may mean less than about 1% likelihood of occurrence and corresponds to a peak perturbation of the total geomagnetic field of up to 10%. More recently, the magnetic storm has also been defined as a particular pattern of variation of the Disturbance storm time (Dst) index, which is a spatial and temporal average of the northward geomagnetic field variation at low latitude. The characteristic pattern of Dst variation usually shows three phases: (1) Initial phase—an interval of variable duration of Dst above its baseline, often commencing with a sharp rise known as storm sudden commencement. (2) Main phase—a rapid fall of Dst to a minimum after about 10 hours. (3) Recovery phase—slow recovery of Dst towards the baseline over about 2 days. In this definition, magnetic storms are classified according to their strength, measured by the minimum Dst value attained. A typical classification scheme is weak ($-30 \geq$ Dst > -50 nT), moderate ($-50 \geq$ Dst > -100 nT), strong ($-100 \geq$ Dst > -200 nT), severe ($-200 \geq$ Dst > -350 nT), and great (Dst ≤ -350 nT) storms. Under this definition, a magnetic storm is not a particularly extreme event since over 20% of Dst values are less than -30 nT.

Magnetic storms are the result of a stronger than usual interaction between the solar wind (the outflow of charged particles from the sun into interplanetary space) and the Earth's magnetosphere (the comet-shaped region of near-Earth space dominated by the geomagnetic field). This is typically associated with fast-moving magnetic plasma structures from the sun's corona known as coronal mass ejections. The frequency of magnetic storms varies with the 11-year solar cycle—a periodic variation of the number of sunspots on the sun. The frequency ranges from about twenty moderate and stronger storms per year at solar minimum to about forty-five storms per year at solar maximum.

Magnetic storms are also associated with intense aurora, extending to abnormally low latitudes. In Antarctica, storm-time aurorae are likely to be most prominent at locations farthest from the South Magnetic Pole such as the Antarctic coast between Halley and Syowa stations and the Antarctic Peninsula. There can actually be a paradoxical reduction in magnetic and auroral activity in regions closer to the Pole.

Magnetic storms have been identified as a natural environmental hazard that can adversely affect radio communications, electrical power grids, satellite operations, and astronauts. Thus it is desirable to forecast the occurrence of a magnetic storm from its birth on the sun to its impact at Earth, but such forecasts are not yet reliable.

MAGNETOSPHERE OF EARTH

The Earth's magnetosphere is that region of space in which the large-scale motion of electrically charged matter is dominated by the Earth's magnetic field. It is formed by the interaction of the solar wind with the magnetic field of Earth. (The solar wind is the stream of charged particles emitted from the Sun and streaming towards the Earth. It is the ultimate source of energy driving polar phenomena such as the aurora and magnetic storms.) The matter within the magnetosphere is in the plasma state, consisting of positively charged ions and negatively charged electrons. The plasma may be regarded as an electrically conducting gas of very low density.

In a magnetic field, charged particles move easily along the direction of the field; their motion perpendicular to the field is limited. The long period waves known as Alfvén waves are also constrained to move parallel to the magnetic field. (Alfvén waves are waves that exist in a magnetised plasma at very low frequencies. They transport energy precisely parallel to the magnetic field. They are an important mechanism for transmitting information about changes in the magnetospheric configuration from one point to another.) At low latitudes the Earth's magnetic field lines do not extend far into space; at high latitudes they extend deep into space. The properties of the particles and waves travelling along these field lines are determined by the properties of those parts of the magnetosphere that are threaded by the field lines. When they arrive in the upper atmosphere the particles cause phenomena such as the aurora. The waves are associated with disturbances of the magnetic field and the electric field in the ionosphere. The polar regions are therefore the only regions where ground-based study leads to an understanding of the properties of the outer magnetosphere. The Antarctic continent is thus a window into geospace (which is the region of space surrounding the Earth).

The Earth's Main Field

As a first approximation, in the immediate neighbourhood of the Earth itself, the Earth's magnetic field

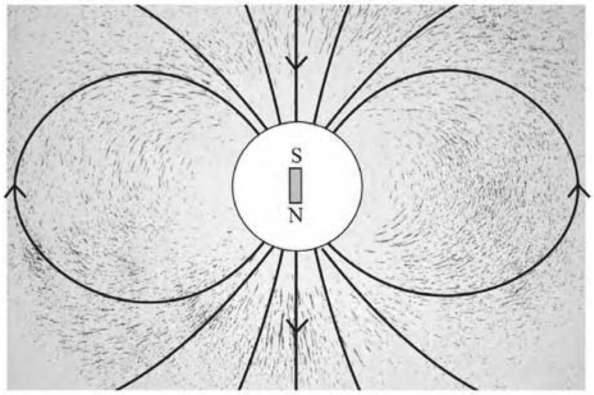

Figure 1 Geometry of a dipole field. This shows a photograph of iron filings under the influence of a magnetic field. Superimposed on it a set of field lines have been drawn. These are lines representing the direction of the magnetic field at each point. Conventionally, in a careful representation, they are drawn as closer together when the field is strong and further apart when it is weak. In the diagrams here the geometry makes this difficult and we have drawn the field lines to represent direction only and do not intend their separation to suggest a magnitude.

resembles that of a bar magnet (a magnetic dipole) at its centre. The actual sources of the field are currents flowing in the molten core of the Earth and driven by the Earth's rotation. The axis of the equivalent dipole is tilted with respect to the axis of rotation of the Earth. The field of such a bar magnet can be visualised by sprinkling iron filings on a sheet of paper covering the magnet. If the paper is tapped gently, the iron filings tend to align themselves along the field.

A magnetised compass needle placed in the Earth's magnetic field tends to align itself with the direction of the field. The end that points towards the north is conventionally labelled the north or north-seeking pole of the magnet. Like poles of two magnets repel each other and unlike poles attract. Thus the equivalent bar magnet producing the Earth's field actually has its south-seeking pole at the northern end as illustrated.

The magnitude of the Earth's field decreases strongly as the inverse cube of the radius so that its value at a distance of 5 Earth radii is less than one percent of its value at the surface. The predominant sources of the field at less than about 4 Earth radii are the internal currents. Before the era of space exploration it was frequently assumed that this was the case out to all distances. As this field decreases the fields of distant current sources external to the Earth become important. These currents arise from the interaction of the charged particles of the solar wind and the magnetic field.

Formation of the Magnetosphere

Impact of the Solar Wind on the Earth

The Sun continuously ejects matter in the plasma state. This plasma is called the solar wind. It consists predominantly of positively charged protons and electrons with a smaller component of heavier ions, mainly helium. The solar wind speed is typically 300 to 500 kilometres per second and its density is a few particles per cubic centimetre, far more tenuous than the best vacuum that can be obtained in the laboratory. It is possible to show that, if a magnetic field exists in the plasma, the magnetic field lines follow its motion as if they were frozen into it. Magnetic fields originating in the Sun have an energy density that is small compared with the kinetic energy density of the solar wind plasma. This magnetic field is, therefore, carried along with the solar wind. It is known as the interplanetary magnetic field (IMF). As the solar wind approaches the Earth it encounters a region where the magnetic field is large so that the field energy density is comparable with, or much larger than, the density of energy associated with plasma motion. Here the plasma motion is strongly affected by the magnetic field. The consequence is that we can divide geospace into two regions. In one the behaviour is dominated by the solar wind flow; in the other it is dominated by the Earth's magnetic field. There are various physical models, described next, that help in understanding how this occurs.

Closed Magnetosphere

As a first approximation we can neglect the magnetic field in the solar wind and regard it as a conducting gas. As the solar wind approaches the Earth the magnetic field increases rapidly. Near the Earth the magnetic field energy density is much larger than the energy density associated with plasma motion, which is therefore controlled by the geometry of the magnetic field. The consequence is that the motion of the solar wind is affected by the Earth's magnetic field. A boundary is formed between the region dominated by the Earth's magnetic field and the solar wind. The geomagnetic field is confined to a cavity, known as the magnetosphere. The boundary of this cavity is called the magnetopause. At the magnetopause there is equilibrium between the pressure of the flowing plasma of the solar wind on the outside, and the effective pressure, arising from magnetic forces, on the inside. The situation is complicated by the fact that the speed of the solar wind relative to the Earth exceeds the speed of sound in the

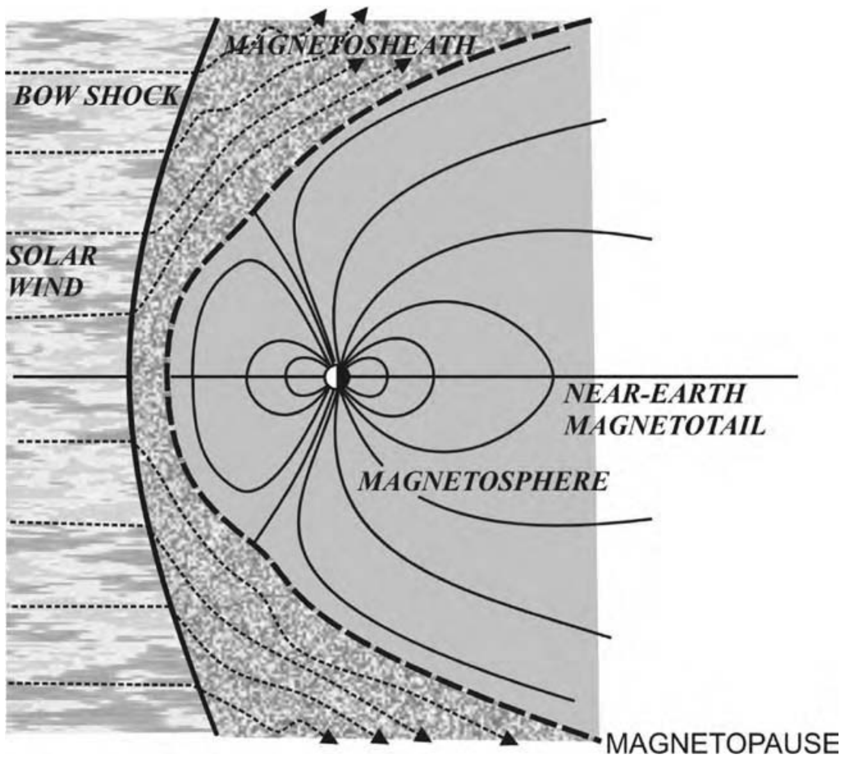

Figure 2 Closed magnetosphere. This figure shows a cross section of geospace in a plane (the noon-midnight meridian plane) containing the Earth-Sun line and the Earth's dipole axis. The bow shock is represented by a heavy line and the magnetopause by a heavy dashed line.

solar wind plasma. This leads to the formation of a shock wave like the bow wave of a ship, or the shock in front of a supersonic aircraft. This is called the bow shock. On the sunward side of the shock the solar wind flows undisturbed: between the shock and the magnetopause its flow is disturbed by the presence of the magnetosphere; it is diverted to flow round the magnetopause. On the Sun-Earth line the distance from the shock to the magnetopause is about 2 Earth radii (12,800 km) and the distance of the magnetopause from the centre of the Earth is about 10 Earth radii (64,000 km).

In this closed magnetosphere model, neither the bow shock nor the magnetopause would be observable from ground-based instruments in Antarctica. Nevertheless, physical processes in the region strongly affect the particles entering the magnetosphere and the magnetic fields within the magnetosphere, leading to many phenomena, such as the aurora and various magnetic disturbances that are observed in the polar regions.

Magnetic Reconnection

The situation becomes more complicated if we take into account the interplanetary magnetic field carried by the solar wind. Suppose, for example, that it is directed in a southerly direction. Then, when the solar wind encounters the magnetopause, the magnetic field is in the opposite direction to the magnetic field just inside the magnetopause. This is represented in Figure 3A, in which PQ represents the surface dividing the two oppositely directed fields. On this surface the magnetic field is zero and it is therefore called a neutral sheet. The inward flow from the Sun means that such a situation is unstable and tends to relax to the situation shown in Figure 3B. Here there is a line perpendicular to the page on which the field is zero—the neutral line, represented by the point O in the middle of the shaded region. Here two magnetic field lines cross, suggesting that the field points in two directions at once! This is not the absurdity it seems, because it is here that the magnitude of the field is zero and the direction in which it points is meaningless. In the shaded region surrounding O the picture of frozen-in field lines does not hold: outside this region it does. Plasma is flowing into this region from the solar wind. If it is not to accumulate it must flow outwards along some other path. Calculation shows that it flows inwards from the solar wind and from the magnetosphere, and outwards along the magnetopause, as indicated by the white arrows. It flows inwards over a large area and

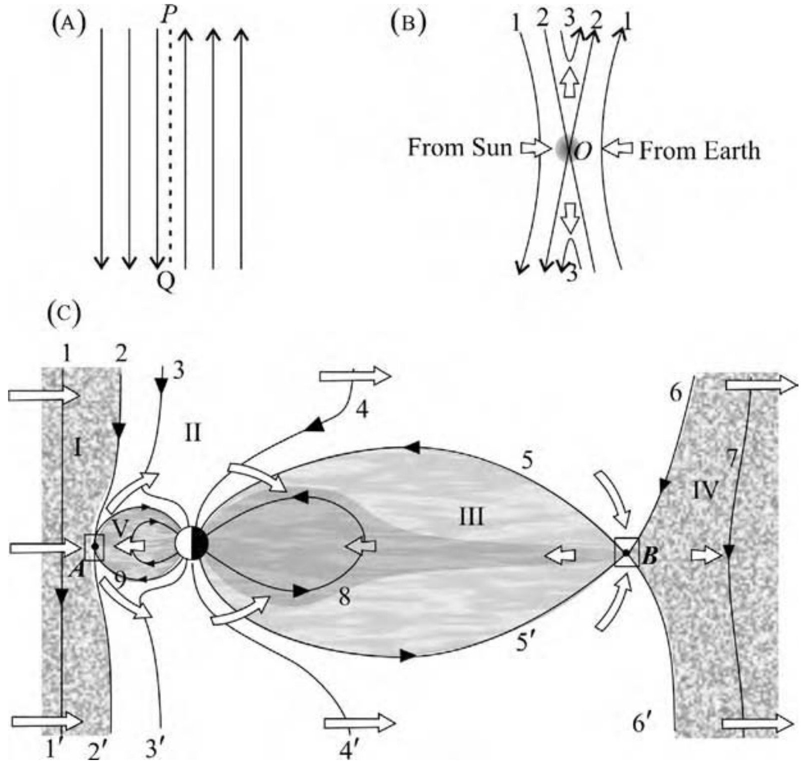

Figure 3 Field line merging: magnetic reconnection (A, B) and open magnetosphere (C).

outwards over a small one, so it is accelerated by this process.

Outside the shaded region the magnetic field lines are frozen into the plasma as described previously. If one follows the motion of the plasma from the solar wind, as it passes through the shaded region, the associated field lines are reconfigured. It is as if, at *O,* they are cut and rejoined in a different configuration. This process is known as magnetic reconnection or magnetic merging.

Open Magnetosphere

Figure 3C illustrates the noon-midnight cross section of the magnetosphere. The Sun is far to the left of the diagram and the solar wind flows from the left. The IMF is southward. Conditions in the small rectangle *A* then favour reconnection. Let us follow a field line in the solar wind region (the shaded region labelled I) at position 1 as the solar wind proceeds towards the Earth. The ends of this field line are either connected to the Sun, or meet each other in the distant solar wind to form a closed loop: they are not connected to the Earth. At a later time this field line has reached position 2 and passes through the reconnection region *A*. The reconnection process requires that, at the same time, plasma is flowing into *A* from the front of the magnetosphere (the shaded region labelled V). At the same time as the solar wind field line reaches the reconnection region *A* a field line from within the magnetosphere reaches it as well and is reconnected as described above. At a later time the two parts of the reconnected field line have reached position 3 and 3′. The field lines in the unshaded region II are carried back as the solar wind flows past the magnetosphere. These field lines are connected at one end to the Earth and at the other to the solar wind; they can be said to have "one foot on the ground." As the plasma flows further the field lines become more and more stretched out, being dragged into a long tail. In the process the magnetic field becomes more and more distorted. Magnetic forces affect the plasma flow. At great distances the pressure is large enough to bring the field lines together at *B* where there is further reconnection as illustrated. The field line at 4 is carried to position 5 and 6, and is reconnected to the field lines in position 5′ and 6′. After reconnection part of the plasma flows on into region IV to rejoin the solar wind, while the remainder flows back towards the Earth through region III, past the Earth on either side, and into region V to take part in the reconnection process at *A*. This process of circulation is driven by the solar wind and is known as magnetospheric convection.

The process described here is greatly idealized. The IMF is seldom directed exactly southward. If, however, it has a southward component, then, as it is dragged past the Earth, reconnection takes place at some point on the sunward side of the magnetosphere and the process is qualitatively similar. If, on the other hand, it has a northward component then reconnection does not in general occur in this way, although there may be reconnection far back on the tail lobes. The process has also been idealized as happening steadily and uniformly. In reality the solar wind is gusty; the reconnection region is not stable. The process is very dynamic and can be better described as patchy and variable with our description representing an average picture.

The Antarctic and Arctic regions are ideally situated for observing these processes. It will be noted that magnetic field lines originating at high latitudes in Antarctica are directly connected to the solar wind. Those at lower latitudes may stretch into the deep tail. The convection processes in deep space map along the magnetic field lines to show effects in the Antarctic upper atmosphere. Energetic charged particles are constrained to move along the field lines and may be precipitated in the upper atmosphere where they collide with neutral atoms and raise their energy. When these atoms relax to their unexcited states they release this energy in the form of light, giving rise to the aurora.

The Regions of the Outer Magnetosphere

The processes described previously cause geospace to be divided into a number of regions, in each of which the magnetic field geometry and the particle populations are different. This is illustrated in Figure 4. This diagram is more nearly to scale than the previous figures. Again the solar wind blows from the left. Figure 4A shows the noon-midnight meridian, Figure 4B the equatorial plane, and Figure 4C a cross-section perpendicular to the Sun-Earth line on the plane *AB*. The various plasma regions are described next and can be located by referring to the diagram.

Magnetosheath. After the solar wind passes through the bow shock its density and pressure are increased and its velocity decreased. It flows past the magnetosphere. As a result of the passage through the shock it tends to be more turbulent. This region of turbulent flow at relatively small velocity is called the magnetosheath. It is confined to the region between the bow shock and the magnetopause. The plasma in the magnetosheath originates from the solar wind.

Cusp. In the closed magnetosphere of Figure 2 the magnetic field is confined to the interior of the magnetopause. None of the field lines are connected to the magnetosheath or the solar wind. The outermost field lines are parallel to the magnetopause. There is a critical field line that emerges from the polar regions on the day side and connects with these outermost field lines. At the point where it reaches the magnetopause the magnetic field is zero and its direction is indeterminate. At this point there is no bar to plasma entering the magnetosphere from the magnetosheath. In the more realistic case of Figure 4 this critical field line is connected to the solar wind and is surrounded by a roughly conical region of field lines that are connected to the magnetosheath and solar wind. This region is known as the polar cusp or simply the cusp. The plasma in the cusp originates both from the solar wind and from the Earth's atmosphere. Plasma from the atmosphere is lost upwards by a process akin to evaporation. The upward flowing atmospheric plasma is know as the polar wind. Energetic solar wind plasma can enter the cusp and be precipitated in the upper atmosphere. The cusp intersects the ionosphere in the northern and southern polar regions. Ground-based observations in Antarctica continue to lead to improved understanding of physical processes occurring in the cusp.

Regions of the magnetotail. The stretched out tail-like region drawn out from the magnetosphere behind the Earth is known as the magnetotail. The boundary region threaded by field lines originating in the cusp is known as the plasma mantle. These field lines are draped over the outer part of the magnetotail, their configuration determined by the details of solar wind flow. There are stretched-out portions of the magnetotail on either side of the equatorial plane in which the plasma density is relatively low. These are known as the tail lobes. In the southern lobe the magnetic field points away from the Earth and the northern towards it, as indicated in Figure 4C by the symbols $\otimes$ and $\odot$. At the equatorial plane there is an increased density in the region known as the plasma sheet. The equilibrium is maintained by currents flowing in the directions indicated by arrows in Figure 4C. These currents arise as a consequence of gradients in the pressure and self-consistently provide a magnetic force that balances the forces arising from the gradients of the plasma pressure.

These regions all map along the field lines to the polar caps in the Antarctic and Arctic. Ground-based observations of magnetic fields, energetic particles, and plasma velocity in the upper atmosphere have led to better understanding of physical processes in the magnetotail.

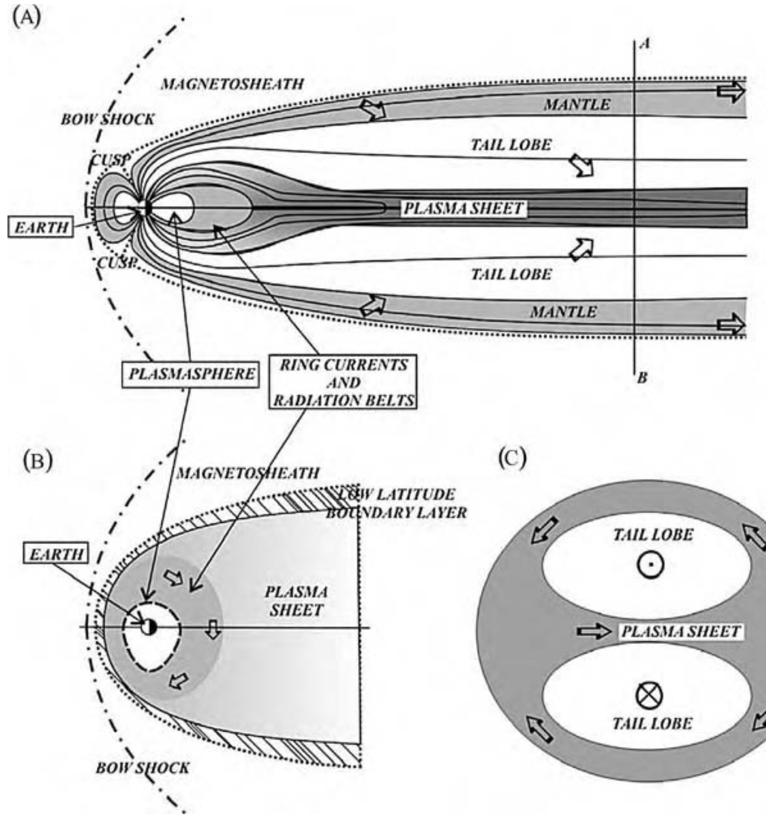

Figure 4 Open magnetosphere.

Regions of the Inner Magnetosphere

Ring current. In Figure 4A the plasma sheet is located in a region where the field lines are so stretched out that they point either directly away from or towards the Earth. As we move towards the Earth we encounter a region where the field lines are closer to the shape of the dipole field lines of Figure 1. In this region the plasma sheet merges into a plasma region known as the ring current region. This region surrounds the Earth. It is indicated by the shaded region shown in the equatorial plane in Figure 4B. It is called the ring current because the increasing inward gradient of plasma pressure leads to a westward current encircling the Earth, as indicated by the arrows in Figure 1B. This current leads to a small reduction of the Earth's magnetic field. This effect is seen at lower latitudes than in Antarctica. On the inner edge of the ring current region the pressure gradient is in the opposite direction and there is an eastward current, but this is small so that the overall effect is of a westward current. The ring current is variable. At times of low magnetic activity it may be negligible: at disturbed times its effects on the magnetic field at the ground are significant.

Radiation belts. In the same region as the ring current there are two regions of much more energetic charged particles. These are the inner and outer radiation belts. They were first observed by James van Allen using one of the earliest space probes and are also known as the van Allen belts.

Plasmasphere. As we move closer to the Earth we encounter a region where the density of plasma rises rapidly. It becomes more than a thousand times greater than in the region of the radiation belts. This region is shown unshaded in Figures 4A and 4B. It consists of plasma originating from the Earth's atmosphere, and constrained by the Earth's magnetic field to rotate with the Earth. Its outer boundary is called the plasmapause. The plasmapause is the boundary between the region where the geometry of the magnetic field constrains the plasma to rotate with the Earth and the region where magnetospheric convection (see later discussion) allows exchange of plasma with the solar wind. The plasmapause maps to the ground along magnetic field lines at a geomagnetic latitude of about 60°. Because of the tilt of the magnetic dipole this magnetic latitude crosses the Antarctic continent in the South Atlantic sector. On the other side of Antarctica this magnetic latitude lies in the South Pacific and Indian Oceans. As a result the stations well-equipped to observe the plasmapause are those such as Halley and Sanae, lying near the Greenwich meridian. The USA station Siple, now closed, played a very important part in the understanding of plasmapause phenomena in the 1970s and 1980s.

Magnetospheric Convection

The previous discussion indicates that there is a steady flow of solar wind plasma past the magnetosphere. At the reconnection regions there is an interaction between plasma within the magnetosphere and the solar wind. There is a motion of plasma out of the magnetosphere in the region *A* of Figure 3 and a motion into the magnetosphere in region *B*. This implies a circulation of plasma, known as plasma convection. We study this process and its effects in the Antarctic upper atmosphere in more detail.

Figure 5 shows various aspects of the convection process. Figure 5A shows a portion of Figure 3. The shaded region shows the magnetic field lines that originate in the Antarctic region and connect with the solar wind after reconnection in the region *A*. There is a similar region in the Northern Hemisphere. In this region the solar wind can be regarded as a conducting fluid moving through the illustrated magnetic field. When a conductor moves through a magnetic field it generates an electric field. This is the same process as that which drives an electric generator in a power station. In the power station, energy is extracted from whatever fuel is used to drive a motor that rotates conducting coils in a magnetic field, thus generating an electric field; in the solar wind a fraction of the energy associated with its motion is extracted to generate a field that is perpendicular to the plane of the diagram, and directed downwards.

The charges move freely along the magnetic field lines so there is no electric resistance parallel to them. As a result the electric field maps down to the upper atmosphere. Figure 5B is a map of this electric field in the Antarctic ionosphere. The shaded circular region is the region within which the magnetic field lines connect the Earth to the solar wind. The full lines show the direction of plasma flow in the ionosphere.

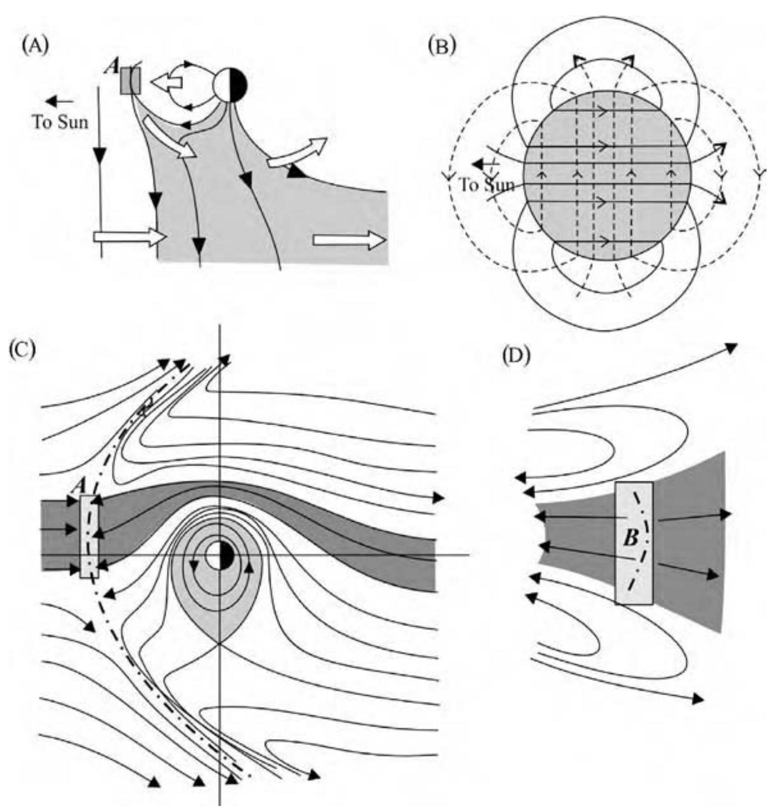

Figure 5 Magnetospheric convection. (A) Noon–midnight meridian over Antarctica. (B) Antarctic polar cap. Full lines represent direction of the flow in the upper ionosphere; dashed lines represent the direction of the accompanying electric field. (C) Motion in the equatorial plane. (D) Motion far down the tail in the equatorial plane.

The dashed lines show the direction of the electric field. Within the shaded area the plasma flows away from the Sun. The total voltage across this region arising from the electric field is large. During times of strong magnetic disturbances it may exceed 100,000 volts. At less-disturbed times it is a few tens of thousands of volts. There is a return flow outside the polar cap region in the direction shown, resulting in the formation of two cells of oppositely circulating flow. Currents in the lower ionosphere due to differential motion of positive and negative charges are associated with this flow. They give rise to magnetic perturbations of the ground. This picture is highly idealised to the case where the interplanetary magnetic field is southward. The Earth's rotation causes further modification. In other cases the reconnection region forms on different parts of the magnetosphere and leads to modified convection patterns in which the convection pattern may change and, indeed, the number of cells may increase.

Figure 5C shows the lines along which plasma flows in the equatorial plane near Earth, and Figure 5D shows the flow in this plane far down the tail. The magnetic field lines are perpendicular to the plane of the paper. The darker shaded regions contain plasma that emerges from the reconnection region *B* and enters the reconnection region *A*. The magnetopause is represented by a chain line. At the magnetopause, plasma inside the magnetosphere may be dragged along by the magnetosheath plasma by a viscous interaction. The viscous force is an additional driving force for convection. The relative importance of reconnection and viscous drag has been the subject of controversy. There is reasonable consensus that reconnection is far more important. Viscosity is not thought to provide more than about 15% of the drag. The paler shaded region represents the plasmasphere. Within this region the field lines remain approximately dipole shaped and rotate with the Earth's rotation. Outside this region the field lines are carried to the magnetopause and are either reconnected with solar wind field lines or dragged back by viscous interaction. Since the field lines inside the plasmapause remain connected to the atmosphere for long times this region is filled with ions of atmospheric origin, and the plasma is much denser than outside it, where the plasma is a mixture of ions of solar wind and atmospheric origin. This convection process can be observed in the Antarctic ionosphere. A map of the convection may be obtained by the international SuperDARN chain of radars. In the southern hemisphere these are located at Halley, Sanae, and Sjowa on the Antarctic continent, on Kerguelen Island, and in Tasmania. They are capable of measuring the plasma flow.

The Dynamic Magnetosphere

It must be emphasised that this steady state situation, described previously, is an idealised picture of a dynamic and rapidly changing situation. The structure of the magnetosphere is determined by the solar wind, which is variable and gusty. Solar flares can eject large quantities of high-speed plasma. Coronal mass ejections can occur in the absence of flares. The solar wind velocity, density, and magnetic field vary as conditions on the Sun change. The response of the magnetosphere is not instantaneous but depends on a variety of physical processes. These processes are important for the understanding of the space weather environment in which satellites and spacecraft operate. Observations on the Antarctic continent are crucial to this understanding.

Magnetic Storms

When sudden increase in the density and velocity of the solar wind, arising from a coronal mass ejection or similar phenomenon, arrives at the Earth, it leads to an immediate compression of the sunward side of the magnetosphere. This implies a sudden increase in the magnetic field. Information about this increase is transmitted throughout the magnetosphere by Alfvén waves in a matter of minutes. The resulting sudden increase in the magnetic field seen on the ground is called a sudden commencement. After the initial increase a number of effects lead to energization of magnetospheric particles and a variety of currents flowing within the magnetosphere. The electric field arising from the increased dynamo effect at the poles increases dramatically. The cross-polar potential difference may exceed 100 kilovolts. The initial increase of magnetic field may last for several hours. It is generally followed by a disturbed period, the main phase, during which the ring current, associated with the drift of energetic particles, is enhanced in the region near four Earth radii. This enhanced current provides an additional magnetic field that is directed northwards, roughly parallel to the Earth's axis. This leads to a reduction of the magnetic field at lower latitudes. This is followed by a recovery, at first rapid, then slower. During the recovery phase of the storm the energetic particles are slowly lost through precipitation into the atmosphere and charge exchange with neutral particles. The whole process typically lasts for several days.

Such storms can lead to surges in power lines (not a problem in Antarctica) and may cause severe damage to satellites and spacecraft through bombardment by energetic particles. Other effects are radio communication blackouts and severe magnetic disturbances, which may affect activities such as geophysical surveys. The understanding and prediction of the effects of magnetic storms is an important objective of Antarctic ground-based studies of the magnetosphere.

Magnetospheric Substorms

The magnetospheric substorm provides some of the most spectacular effects of magnetospheric activity in the auroral region. It is associated with dramatic auroral displays, and strong magnetic and electrical disturbances. At one time it was thought that magnetic storms were essentially composed of overlapping substorms, hence the name. While many substorms may take place during a magnetic storm, other effects that are not associated with substorms also occur. The aurorae associated with substorms were the subjects of the first studies. The name auroral substorm was applied to these phenomena. Later it was recognised that the auroral phenomena were part of a complex physical process involving nonauroral effects, and the name magnetospheric substorm was adopted.

A substorm arises as a consequence of stored magnetic energy in the magnetotail being released in a fairly local segment of the magnetosphere and energising charged particles, which in turn provide the enhanced currents and auroral effects associated with the substorm. The precise physical mechanisms are the subject of controversy. During a substorm, magnetic field lines that are stretched into the tail undergo a sudden collapse to a more dipolar shape over a relatively narrow longitude segment. In this process, particles are energised and injected into the ring current region. Their precipitation into the upper atmosphere leads to auroral displays; the enhanced ring current leads to magnetic disturbances. The pattern of convection over the polar caps is strongly affected. The substorm is preceded by a growth phase during which energy is being fed into the magnetotail. It is followed by an expansion phase during which the energy is released, and finally by a recovery phase. The expansion phase during which the most intense effects are observed lasts about half an hour. The whole process takes place within a few hours. While substorms are common during magnetic storms, they may also occur during otherwise quiet times.

Aurora

During a substorm there is a rapid collapse of part of the magnetotail. Field lines that were previously stretched out become less stretched. The plasma attached to the field lines is compressed and energised. Large currents flow along the field lines and through the ionosphere. As a consequence, these instabilities can allow a potential difference above the ionosphere along a field line. This accelerates and energises particles further. They may collide with neutral atoms in the upper atmosphere, raising them to larger energy levels. When they relax to the ground state they emit photons of visible light, leading to the formation of the aurora.

Magnetospheric Oscillations

The magnetosphere is very dynamic, changing on many timescales. For timescales that are long compared with those characteristic of the plasma medium the plasma motion is well described by magnetohydrodynamics. In this approximation, the characteristic waves are Alfvén and magnetosonic waves. When these have periods of a few minutes, their wavelengths are comparable with the scale of the magnetosphere itself. As a consequence they can set the magnetosphere oscillating in a variety of modes of oscillation. Such waves are an important mechanism for transferring energy between the magnetopause and the ionosphere. They are observed on the ground as oscillations of the Earth's magnetic field or as oscillations in the convection velocity of the ionosphere.

MAGNETOSPHERIC CONVECTION

The large-scale flow of rarefied plasma in the Earth's magnetosphere "is quite analogous to thermal convection" (Gold 1959); therefore, the term "convection" is commonly used to describe large-scale circulation inside the magnetosphere caused by the interaction of the solar wind (SW) with the geomagnetic field. This circulation results in the zero sum of electric fields $\mathbf{E} + \mathbf{v} \times \mathbf{B} = 0$, or $\mathbf{v} = \mathbf{E} \times \mathbf{B}/B^2$. Assuming that the electric field $\mathbf{E}$ is a gradient of a scalar function $\mathbf{E} = -\nabla \boldsymbol{\Psi}$, where $\boldsymbol{\Psi}$ is an electric potential imposed from the SW, then $\mathbf{v} \times \mathbf{B} = \nabla \boldsymbol{\Psi}$. The latter is a convective circulation of geomagnetic field lines in the crossed $\mathbf{E}$ and $\mathbf{B}$ fields. By analogy with the thermal convection in a nonconductive fluid $\partial \mathbf{B}/\partial t = \nabla \times (\mathbf{v} \times \mathbf{B})$, which means that the magnetic field is tied (frozen-in) to the corresponding plasma flow.

Two major forces control the large-scale magnetospheric convection: (1) transfer of a viscouslike momentum from the SW to adjacent regions of the magnetospheric tail (Axford and Hines 1961), and (2) front-side reconnection between the interplanetary magnetic field $\mathbf{B}_{\mathrm{IMF}}$ and geomagnetic field $\mathbf{B}_{\mathrm{geo}}$ (Dungey 1961). The SW flow around the magnetosphere carries magnetospheric "outer edge" plasmas with frozen-in geomagnetic field tubes tailward along the flanks; then returns these tubes with their plasma content by means of a sunward flow, skirting into the regions closer to the Earth. This generates a dawn–dusk electric field, $\mathbf{E}_{\mathrm{qv}} = -\mathbf{v}_{\mathrm{SW}} \times \mathbf{B}_{\mathrm{geo}}$, where $\mathbf{v}_{\mathrm{SW}}$ is the SW velocity in the magnetosheath: a region between the bow shock and the magnetopause. A similar flow pattern is formed in the magnetosphere due to the reconnection processes between the (oppositely directed) magnetic fields over the magnetosphere's front (sunlit) side, when the IMF is oriented opposite (southward) to the general (northward) direction of the geomagnetic field. This also imposes the interplanetary electric field $\mathbf{E}_{\mathrm{IMF}} = -\mathbf{v}_{\mathrm{SW}} \times \mathbf{B}_{\mathrm{IMF}}$ onto the magnetosphere in the dawn–dusk direction, which is then projected downward into the ionosphere along the geomagnetic field lines.

Magnetospheric convection in turn induces motions in the high-latitude ionosphere through linkages along the geomagnetic field lines, which carry a load of field-aligned currents and electromagnetic waves from the magnetopause down to the ionospheres of both the northern and southern polar caps. The magnetospheric convection produces the ionospheric plasma circulation in a form of two-cell convection pattern. This pattern maps down the magnetospheric "outer edge" field tubes flow over the geomagnetic pole in the antisunward direction and the return flow in the sunward direction along the lower-latitude, auroral zone.

Magnetospheric convection is a major driver of geomagnetic activity; it increases with faster SW and

larger southward IMF, causing more rapid stirring of the magnetospheric plasma. This triggers more charged particles to precipitate into the polar ionospheres and increases cross-polar electric fields and corresponding ionospheric currents. This activity is seen from the Earth's surface and space as magnificent aurora that illuminates the northern and southern polar skies.

MARGINAL ICE ZONE

The marginal ice zone (MIZ) forms the transition zone between the open, ice-free ocean and the continuous ice cover of the interior icepack. Ice conditions in the MIZ are continuously shaped by wave action, affecting both the growth and the breakup of ice floes. Average floe size increases across the MIZ, with the smallest floes (less than 1 meter diameter) at the edge. The MIZ is bounded seaward by the open ocean. The interior boundary is most commonly defined as the point at which incoming waves and ocean swell have diminished to the point that they have negligible influence on the character of the ice cover, or, alternatively, where ice divergence or concentration (the percentage of the sea surface covered with ice) is the same as that of the interior icepack. Wave penetration depends on the amplitude and period of the incident waves and on the nature of the ice cover, so that the width of the MIZ varies both spatially and temporally. This distance is typically about 100–300 km. Both broader and much greater in extent than its Arctic counterparts, the Antarctic MIZ is by far the largest in the world. In mid-winter it forms a continuous band stretching some 20,000 km around the continent. The total winter extent may be several million km^2, or perhaps 20% of the total sea-ice covered area. In areas of narrow pack ice extent such as in East Antarctica, the influence of ocean swell can extend almost to the continent. In summer, as the ice retreats to a narrow strip along the coast, the MIZ can be considered to comprise almost the entire width of the icepack.

The MIZ is dominated by strong spatial gradients. Seaward of the ice edge the ocean is relatively warm and moderates the near surface air temperature. To the south, the ice insulates the ocean, so that surface temperatures can drop well below freezing within a few tens of kilometers of the ice edge. There is, then, a tenuous balance between freezing and melting in the vicinity of the MIZ. Ice conditions may vary substantially with the position of the ice edge. The frequent passage of storms along the edge brings alternating incursions of warm air from over the ocean and outbreaks of cold air from over the ice, affecting the local position and shape of the ice edge and modifying freeze and melt cycles. The MIZ itself influences its local environment. Complex atmosphere-ice-ocean interactions associated with the strong gradients of the MIZ can generate a variety of mesoscale (having scales of tens to several hundred kilometers) phenomena that affect winds, currents, and ice drift. The ice responds rapidly to these forcings so that the MIZ is constantly changing in position, shape, and ice conditions.

While the ice edge may occasionally form a sharp transition from open water to close-packed ice, more commonly a diffuse edge forms where small floes and broken ice are aggregated into one or more long, linear bands. These are typically 1 kilometer or more wide and some 10 kilometers long, though a range of sizes occur. The bands may be separated from one another by several kilometers, and can range over many tens of kilometers before a more continuous ice cover is encountered. Mesoscale features are common along the ice edge. Meanders may form various promontories or embayments. Ice-edge eddies can form cusped protrusions, often giving the appearance of breaking waves in satellite imagery. Another common feature is long tongues of ice that jut out into open water, often with two counterrotating vortices at the head giving a mushroom-like appearance.

Ice Types and Characteristics

In winter, the ice edge advances at a rate greater than the northward drift speed of individual floes, so that the advance is primarily due to formation of new ice at the edge. Everywhere in the circumpolar Antarctic, the ice edge is exposed to the wide fetch and rough seas of the Southern Ocean, so the MIZ is continuously buffeted by significant wave action and swell.

Ice formation therefore takes place almost exclusively via the frazil-pancake cycle. Freezing begins through the nucleation of loose crystals known as frazil ice. Constant motion due to wave action prevents the consolidation of new ice crystals into an ice sheet. As freezing progresses, the frazil crystals form a loose soupy suspension known as grease ice that damps out the short capillary waves, giving the surface a matte appearance. As this soup thickens the frazil crystals will agglomerate into small pan-shaped discs of ice known as pancakes. As they are tossed about by the waves, cyclic collisions of individual pancakes promote adhesion of more frazil crystals and growth of the pancakes, and eventual consolidation of individual pancakes into large floes.

Seaward of the main ice edge, there are often one or more discrete bands of thin pancakes. At the main edge, the ice cover typically consists of thin pancakes 10–20 cm in diameter of moderate concentration embedded in an expanse of grease ice. Centimeter scale waves are damped by the viscous frazil slurry, but waves of several meters in wavelength may still be present. With increasing depth, the ice concentration increases as the pancakes gradually increase in size to 1–3 meters in diameter, reaching thicknesses of about 0.3–0.5 m. These larger pancakes will effectively attenuate all waves with wavelengths comparable to their size so that slow, rolling swell of several tens of meters or more in wavelength dominates. With deeper penetration, the individual pancakes begin to fuse together to form floes of gradually increasing diameter. As the floes grow, they will attenuate progressively longer wavelength swell. The transition to consolidated pack ice happens quite abruptly (diameters increasing from 20 m to greater than 200 m in about 25 km are typical) as even the longest waves are damped to the point that they can no longer break up vast floes (several kilometers in size).

As frazil and pancake ice form, a fraction of the ocean surface remains ice-free and is continuously exposed to cold air, maintaining a large heat flux from the ocean to the atmosphere and a high rate of ice formation. This permits rapid thickening of the ice cover even under relatively high temperatures. Pancakes only a few days old may reach thicknesses of about 50 cm. This is particularly important since, once a consolidated ice cover has formed, the ice insulates the ocean from the atmosphere and ice growth proceeds at a much slower rate. In much of the Southern Ocean, the weak surface stratification allows substantial heat from warmer, deeper water to reach the underside of the ice, thus inhibiting further growth. Despite the relatively narrow width of the MIZ, it is responsible for generating a significant fraction of the total pack-ice volume.

Several other processes contribute to ice thickening in the winter MIZ. As the ice concentration in a field of pancakes increases, individual pancakes will raft over one another due to wave action or compaction of the ice cover, effectively doubling or tripling the ice thickness. Enhanced thickening occurs when seawater and frazil crystals are thrust onto the surface of pancakes as they are jostled by waves or rafting, where they can more rapidly freeze. If snow is present on the surface, this wetting will create a slush that, upon freezing, forms ice of granular texture known as snow ice. It is unclear how important snow ice accretion is in the MIZ. Despite the young ice, snowfall is greater at the ice margin than deeper in the pack, so snow depths of several centimeters are common within the inner MIZ. Total ice thickness at the inner edge of the MIZ generally falls between 0.2 and 0.5 m. Congelation ice (ice formed during downward growth of crystals due to a vertical temperature gradient through the floe) is rare, but is occasionally found at the base of some floes.

The ice characteristics during the summer are quite different. Growth of new ice ceases and ice is advected from the south to melt at the retreating ice edge. Much of this ice will have developed away from the edge and so will have a structure typical of the interior pack, where congelation ice makes up roughly half of the total thickness. Some of the ice may be multiyear ice, having survived the previous summer melt season. Floes typically have angular shapes due to wave-induced fracture. Larger floes are interspersed with brash—small, irregular bits of ice broken from larger floes.

Wave–Ice Interaction

The greatest influence on the development and character of the ice margin is the action of ocean waves and swell. Waves control both the initial formation and consolidation of the ice, and the breakup of larger ice floes. This interaction is complex, as it is a function of ice thickness, floe size, and the incoming wave spectrum. Ice cover acts as a low-pass filter, so that shorter period waves are rapidly attenuated within a few kilometers of the ice edge. Long wavelengths, on the other hand, can penetrate loose-packed ice almost unimpeded. Swell of noticeable amplitude with a wavelength of several hundred meters has frequently been observed hundreds of kilometers from the ice edge.

The floe size and swell amplitude are tightly coupled. Wave energy attenuates exponentially with depth of penetration into the pack, generally increasing with increasing wave period and ice thickness. If the floes are much smaller than the wavelength, they will act as individual rafts riding on the swell, and damping is minimal—the wave does not "see" the floe and passes beneath it with little loss of energy. This accounts for the very deep penetration of swell into the Antarctic MIZ, where small pancake ice causes minimal decay of the long swell that often exists there. The mass of the ice does modify the propagation of the wave, however. At the ice edge, the incident wave is refracted perpendicular to the ice edge. The wavelength in the ice is less than in open water, decreasing with increasing ice thickness. The decrease in wavelength causes a steepening of the swell.

As the floe size approaches the wavelength of the swell, the floe will respond by bending. This forms an ice-coupled wave known as a flexural gravity wave. In this case, the wave is partly reflected from the floe. In a field of many floes, reflections from each floe will effectively scatter the wave energy so that the energy in the forward propagating wave attenuates rapidly. This occurs as the pancakes consolidate into floes of diameter of the same order as the size of the swell. The attenuation due to scattering increases with ice thickness.

Flexural gravity waves can cause the breakup of consolidated ice deep into the interior icepack. Large amplitude swell will strain a large ice floe due to bending. The maximum strain typically occurs between 20 and 100 m from the ice edge, increasing with the swell period and ice thickness. If the strain is sufficient to cause fracture, a new ice edge will be exposed to the swell, and the breakup can continue progressively deeper into the pack until the swell is diminished by scattering and viscous damping. The breakup of ice more than 500 km from the ice edge has been observed. The floes nearer the edge will be broken into still smaller floes as they are exposed to shorter period waves than ice deeper in the pack. The production of smaller floes alters the attenuation rate of the waves, allowing the shorter period waves to penetrate deeper, where they will break the ice into still smaller floes. There is thus a tendency toward a continuous gradation of increasing floe size with distance into the MIZ. The distribution is seldom uniform at any given location. Varying swell and collisions break some floes apart and create brash, and new pancakes may form in between the large floes, so that a broad range of floe sizes (typically 1–100 m) and thicknesses (typically 0.1–0.7 m) can occur.

The propagation of swell in the MIZ has been observed in high resolution synthetic aperture radar satellite imagery. As the change in wavelength upon entering the ice depends on ice thickness, there is an exciting possibility for the extraction of ice thickness information from space. This has been hampered by the lack of an adequate theory for the propagation of waves in a realistic MIZ, but it has shown promise for estimating the thickness of frazil-pancake ice.

Atmosphere-Ice Interaction

The sharp discontinuity between ice-covered and ice-free seas and the strong atmospheric temperature gradient across the MIZ play an important role in processes at the ice edge. The wind stress (the frictional force exerted by the wind on the surface) is greater over the rough, rubbly fields of pancakes and broken ice than over the ocean. This increases atmospheric turbulence and thickens the atmospheric boundary layer and surface winds. More importantly, it causes the ice to drift more rapidly than the ocean in response to the wind. These conditions can create a very different response of the MIZ depending on the prevailing wind direction.

Under on-ice winds, the action of both winds and waves will compact the ice. The locally increased wind stress over the pancake zone causes ice convergence. As loose pancakes have little resistance to compression, rafting of pancakes is common. Warm air incursions are often associated with stratus cloud formation as the moist air is cooled.

During off-ice winds, the ice often breaks up into a series of ice bands oriented perpendicular to the wind. The ice at the edge is generally rougher than in the interior pack due to the upturned edges of the pancakes. The wind will exert more force on these floes, so that they drift at greater rate than the rest of the icepack, and the MIZ will diverge creating small patches of open water. Within these patches, short-period wind waves will develop. The reflection of these waves from the ice floes causes a wave radiation pressure force on the floes that will push the band further from the main icepack, thereby increasing the expanse of open water. The increased force on the edges of the band due to waves compresses the individual floes into a tight band. As these bands drift seaward they will move into warmer water and melt, both cooling and freshening the upper ocean. The bands thus play a role in speeding the advance of the freezing ice edge.

Strong off-ice winds can create atmospheric roll vortices aligned along the direction of the flow. These are long, helical vortices that give rise to parallel lines of convergence at the surface, and divergence aloft. The surface convergence can herd ice into long streamers that run perpendicular to the direction of the ice edge bands. Along the lines of divergence, long, linear cloud bands may form as rising, moist air condenses. These "cloud streets" are a ubiquitous feature of the MIZ during strong off-ice flow.

For wind parallel to the ice with the ice to the left, the temperature gradient from the air over the ocean to the ice will be greatest, creating a strong boundary layer front—a sharp boundary between air masses of differing properties confined to the lower atmosphere. A pronounced cloud band is often associated with such a front. The thermally induced pressure gradient can create an along-edge, jet-like wind. An off-ice component, or "ice-breeze," akin to the sea-breeze familiar along coastlines at lower latitudes, can also develop. As the jet follows the ice edge, rotational circulation will develop in any meanders in the edge position. This circulation can form vortices that, under favorable conditions, may develop into polar mesocyclones (i.e., short-lived intense cyclonic systems with a typical scale of a few hundred kilometers). Through a similar process, the zonal asymmetry of the ice edge position contributes to the genesis of larger scale cyclonic storms.

Ice-Ocean Interaction and Mesoscale Features of the Ice Edge

Ocean fronts—regions of strong gradients in temperature and salinity—are often associated with MIZs. These are important for two reasons. First, they form a physical barrier to the advance of the ice edge, as ice advected across the front will melt rapidly as it drifts into warmer waters. Second, instabilities in along-frontal flow can generate meanders and eddies that influence the morphology of the ice edge. The ice acts a passive tracer as its drift mirrors that of the underlying ocean circulation, producing an array of features easily observable in satellite imagery. Eddies moving seaward carry ice into warmer water, while others carry warm water deeper into the ice. The net effect is to enhance the rate of melting at the ice edge.

In the Antarctic, the main polar front lies north of the furthest extent of sea ice, so that unlike Arctic MIZs, the influence of fronts is limited. Such processes are restricted to regions such as Drake Passage and the Scotia Sea where sharp frontal structures do exist in the vicinity of the winter ice edge and eddies have been widely observed.

In summer, melting ice will cool and freshen the surface waters north of the retreating ice edge. The contrast between this low density meltwater and surface waters to the north forms an ice-edge front. The density gradient across the front can also generate a current flowing parallel to the front known as an ice-edge jet. Instabilities in these currents may also generate eddies. Such fronts have been observed in the Ross and Weddell Seas, although with only weak frontal currents.

The extent to which either process of ice-edge eddy formation occurs in the Antarctic is unknown. Nevertheless, mesoscale ice-edge features are common in satellite imagery. Many of these features might also be caused by the complex wind driven interactions that occur along the ice edge. There is some evidence that some mesoscale features at the ice edge during the summer may be caused by ocean eddies associated with the Antarctic Slope Front.

Ecology of the Ice Edge

The MIZ has an ecological importance far beyond its limited size. During the melt season, fresh water input from ice melt leaves a stably stratified water column behind the retreating ice edge. The stratification confines phytoplankton to the well-lit surface waters, encouraging the development of highly productive ice edge blooms. It is believed that ice algae may provide a seed stock for ice edge blooms as they are released into the ocean from melting ice, as species in the blooms are often similar to those found in the melting ice. The ice edge also appears to be important to other organisms. Large krill swarms have been observed just inside the ice edge. Seabirds, seals, and whales have all been observed in increased numbers near the ice edge.

MARIE BYRD LAND, GEOLOGY OF

Marie Byrd Land is the large region within West Antarctica that borders the southern Pacific Ocean and eastern Ross Sea. Marie Byrd Land supports the northern part of the West Antarctic ice sheet, which is seated within a vast intracontinental rift that separates West Antarctica from the continental shield of East Antarctica. The predominant rock types exposed in coastal outcrops, narrow mountain ranges, and isolated nunataks are igneous and metamorphic. Consequently, the bedrock holds a wealth of information about geological processes that take place at depth below the Earth's surface. Moreover, since the crystalline bedrock is quite resistant to weathering and glacial erosion, the glacial landforms in Marie Byrd Land—horns, arêtes, whaleback ridges, and cliff-rimmed cirques—preserve a record of glacial advance and retreat of the West Antarctic ice sheet.

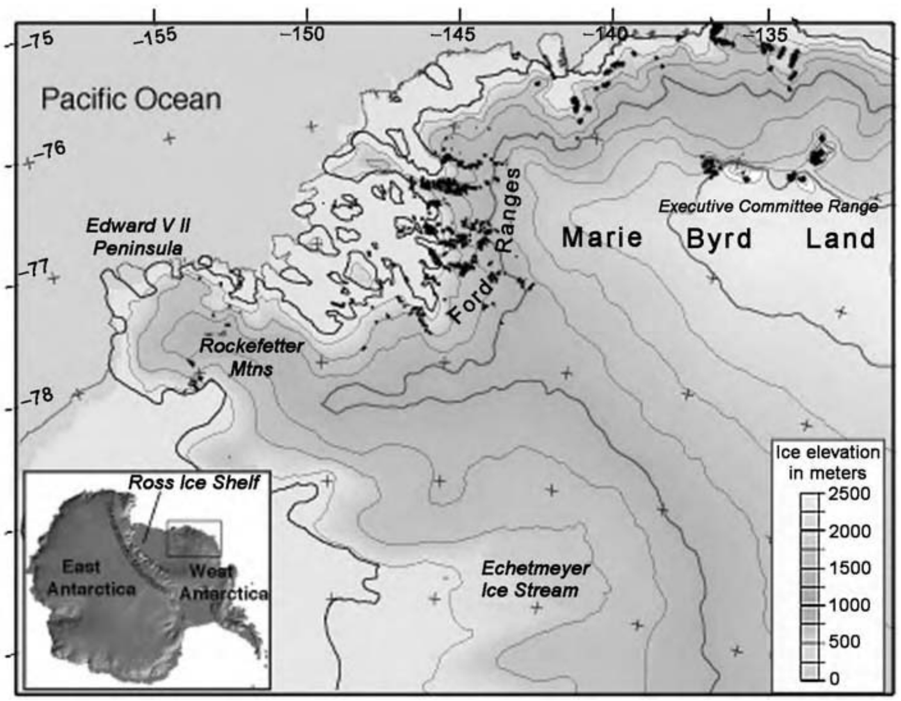
Plutonic and metamorphic rocks comprise the Ford Ranges and Rockefeller Mountains in western Marie Byrd Land, together with isolated ranges and scattered bedrock exposures along the coast, further east. Plutonism and metamorphism occurred at intervals from 375 to 98 Ma. However, the magnificent summits of the interior parts of Marie Byrd Land, rising to elevations of 3400 meters or more, are volcanic in origin. The isolated volcanoes and linear chains of volcanic summits are comparable in scale to features in the Cascade chain in North America. Previously nearly covered by the West Antarctic ice sheet, the ice-carved coastal landforms and big volcanoes have been exposed by deglaciation and lowering of the ice sheet, which commenced 10,400 years ago and continues today.

Plate Tectonic Setting

Marie Byrd Land's geological history is distinct from that of East Antarctica, and also differs from that of other geological provinces in West Antarctica. For example, Precambrian rocks are not known in Marie Byrd Land, and the Beacon Supergroup, the renowned sedimentary succession capping the Transantarctic Mountains, is nowhere found. Moreover, the timing and sequence of magmatism in Marie Byrd Land differs from that of Thurston Island or the Antarctic Peninsula, its nearest neighbors. Consequently, Marie Byrd Land is classified as a tectonic terrane: a fault-bounded block within Earth's crust that is made up of different geological units than neighboring tectonic blocks. Marie Byrd Land is one of four terranes that comprise West Antarctica. Discrete terranes commonly develop along subduction zones, or convergent margins, where oceanic crust converges with and sinks beneath continental crust. This is the case for Marie Byrd Land, which formed along the convergent margin of the Gondwana supercontinent. Materials of oceanic or magmatic arc character and sedimentary rocks derived from continental sources comprise the modern-day bedrock.

During early Paleozoic time, the margin of Gondwana underwent deformation and metamorphism due to convergence between tectonic plates, and experienced magmatism associated with subduction of oceanic crust. Mountain belts and magmatic arcs formed along the margin of Gondwana, and as they underwent erosion, they provided voluminous sediments that were transported and deposited along the extensive Paleozoic coastal margin. Marie Byrd Land was situated closer to East Antarctica at that time, and it received sediments from the mountains of the Ross Orogen. Intermittent subduction and magmatism continued in to the Mesozoic Era. Then, approximately 100 Ma, tectonic convergence gave way to extension and rifting of the continental crust.

A contemporary question in Marie Byrd Land geology is whether mantle plumes—upwellings of hot, rising material from deep within Earth—have played a role in the geological events of Mesozoic and Cenozoic time. The interplay of volcanism and glaciation is also of great interest. Marie Byrd Land's volcanoes arose 30 Ma, during the earliest stages of continental glaciation on the Antarctic continent. The coexistence of active volcanoes with the active West Antarctic ice sheet creates an opportunity to address questions about the onset of continental glaciation and the fluctuations in ice sheet volume during glacial cycles.



Marie Byrd Land supports the northern part of the West Antarctic ice sheet, which is seated within a vast intracontinental rift that separates West Antarctica from the continental shield of East Antarctica.

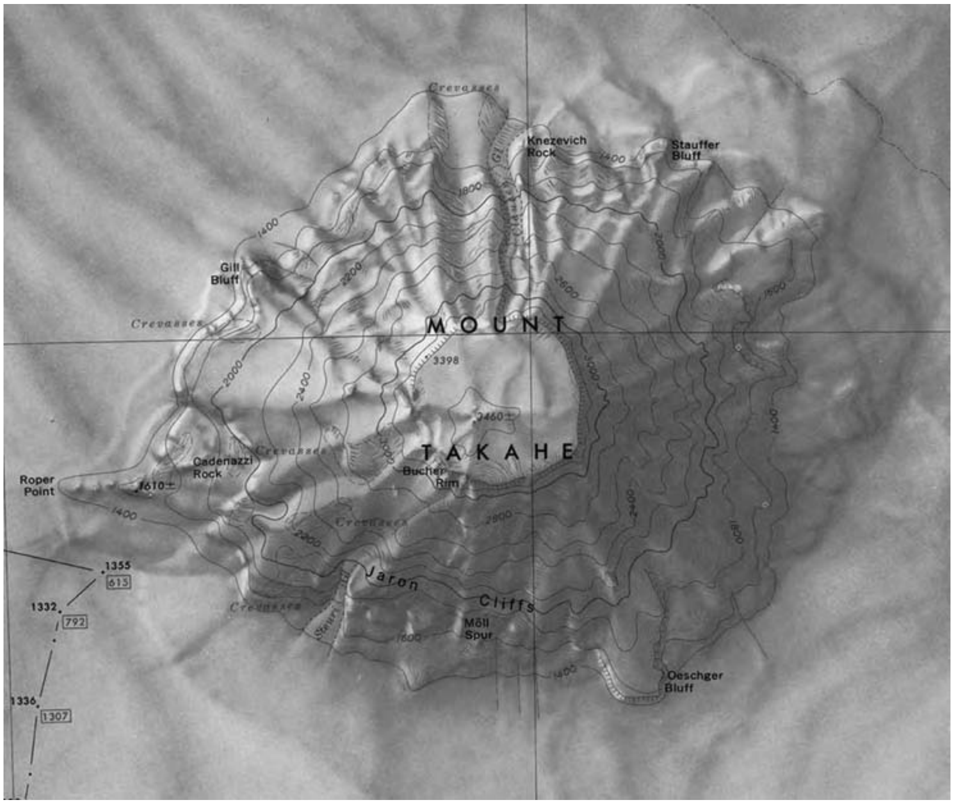
Geological History

Metamorphic and plutonic rocks of Cambrian to Cretaceous age comprise most of the mountain ranges and isolated nunataks near the Marie Byrd Land coast. These rocks provide a record of subduction along the margin of Gondwana in early Paleozoic and late Mesozoic time Volcanoes are the prevalent features in the interior of the terrane, and these have an alkaline chemistry, an indication that the volcanism, active from Oligocene (30–28 Ma) to Recent time, arises from depth in the Earth's mantle. Although no rocks of Precambrian age (>540 million years) are known, the isotope geochemistry of lower crustal xenoliths, or solid fragments plucked from depth by erupting magmas, suggests that Precambrian crust does underlie or adjoin the Marie Byrd Land terrane. Since the fossil record in Marie Byrd Land is meager, nearly all geochronological information for the terrane comes from isotopic mineral ages obtained from plutonic, volcanic, and metamorphic rocks. The mineral zircon is commonly used to determine the age of rocks and timing of events. Zircon forms as a crystal in igneous rocks, and upon erosion can become part of a sedimentary rock, where it is very resistant to weathering and chemical breakdown.

The sequence and timing of geological events determined for Marie Byrd Land are:

1. Sedimentation in early Paleozoic time, and formation of the oldest exposed rock unit, the Swanson Formation.
2. Deformation and metamorphism due to convergence along the Gondwana margin. Swanson Formation was folded into kilometer-scale folds and metamorphosed at low metamorphic grade.
3. Plutonism due to subduction of oceanic crust beneath the Gondwana margin. Ford Granodiorite plutons intruded the Swanson Formation.
4. Crustal stretching and thinning of Marie Byrd Land crust, accompanied by granitic plutonism. The Byrd Coast Granite was emplaced.
5. Alkalic volcanism from 30 Ma to Recent, with construction of large volcanoes.

The oldest rock formation in Marie Byrd Land, the Swanson Formation, is an immature sedimentary unit made up of greywacke and argillite. The Swanson Formation was deposited in early Paleozoic time, and preserves clear sedimentary layering and clastic textures that indicate deposition in a deep orogenic basin with a vast sediment supply. Detrital zircon grains within Swanson Formation suggest that the clastic materials were eroded from the early Paleozoic Ross Orogen of northern Victoria Land (Antarctica) and/or the Lachlan Orogen of Australia (Pankhurst et al. 1998). A subset of the zircons originally crystallized



The magnificent summits of the interior parts of Marie Byrd Land are volcanic in origin. Eighteen large volcanoes and diffuse smaller centers comprise the central Marie Byrd Land volcanic province. The volcano summits of the interior parts of Marie Byrd Land reach elevations as high as 4285 meters. Mount Takahe, shown here, rises to an elevation of over 3400 meters.

within granites of c. 500 Ma age, and another is of 1.1 to 1.2 Ga age. The granites were uplifted and eroded to provide sediment that accumulated in the Swanson Formation and other sedimentary formations in western New Zealand, Australia, and northern Victoria Land. The detrital zircon grains provide a "fingerprint" for the common source for the zircons and indicate that sedimentation occurred upon a continuous active margin of the Gondwana supercontinent.

At convergent tectonic margins, deformation and metamorphism typically occur, and those processes have affected the Swanson Formation. The Swanson Formation was folded into kilometer-scale, upright folds and was metamorphosed at low grade by 450 Ma. Presence of chlorite, a metamorphic mineral, gives the Swanson Formation a dark green color.

Plutonism began in Marie Byrd Land 375 Ma, with intrusion of Ford Granodiorite. The granodiorite has a calc-alkaline chemistry that indicates the presence of a subduction zone along the Gondwana margin during late Paleozoic time. The Swanson Formation–Ford Granodiorite association in western Marie Byrd Land has correlatives in the Paleozoic rocks of western New Zealand, northern Victoria Land (Antarctica), and Australia (Bradshaw et al. 1997), and is termed the Ross province (Pankhurst et al. 1998).

During the Mesozoic Era, subduction-related plutonism continued, but shifted to central and eastern Marie Byrd Land, where a magmatic arc developed (Mukasa and Dalziel 2000). Central and eastern Marie Byrd Land, with a Mesozoic record of arc magmatism, is termed the Amundsen province, and has geological affinities with eastern New Zealand, Thurston Island, and the Antarctic Peninsula.

About 100 Ma, in Cretaceous time, the Marie Byrd Land terrane underwent rifting and magmatism induced by the breakup of the Gondwana supercontinent. Intrusive rocks provide the record of this event, also. These are the Byrd Coast Granite in western Marie Byrd Land and mafic dikes intruded throughout the terrane. The plutonism coincided with stretching and thinning of the Earth's crust between East and West Antarctica, and formation of the Ross Sea portion of the West Antarctic rift system. The thinned continental crust subsided below sea level.

Fire and Ice

Volcanism in Marie Byrd Land began 36 Ma (Wilch and McIntosh 2000), and explosive eruptions continued until as recently as 7500 years ago (Wilch et al. 1999). Eighteen large volcanoes and diffuse smaller centers comprise the central Marie Byrd Land volcanic province. The volcano summits reach elevations as high as 4285 meters in the interior parts of Marie Byrd Land.

The cause of Marie Byrd Land volcanism is under debate. The alkaline geochemistry of the volcanic rocks is consistent with a rift or with a "plume" setting for volcanism. Consequently, one hypothesis, based on observations within Marie Byrd Land, is that a mantle plume, associated with a localized source of rising mantle, is present and centered beneath the high topography and large volcanoes of central Marie Byrd Land (LeMasurier 1998; LeMasurier and Rex 1991). An alternative hypothesis, which takes into account the broad distribution and contemporaneous development of volcanic centers throughout the southern Pacific Ocean, is that the magmatism arises from diffuse sources of melt from the underlying mantle (Finn et al. 2005).

The coexistence of active volcanoes with the active West Antarctic ice sheet creates an opportunity to address questions about the onset of continental glaciation and the fluctuations in volume of glacier ice during glacial cycles. Current indications are that thin glacial ice and alpine glaciers were present when alkalic volcanism began, 36 Ma (Wilch and McIntosh 2000). On volcano flanks and summits in central Marie Byrd Land, trim lines from glacial erosion record the waxing and waning of the West Antarctic ice sheet (Ackert 2000). In addition, the volcanic activity can be an aid to study of glacier ice for climate records. Layers of volcanic ash erupted from the high volcanoes, fell upon the ice sheet, and now form prominent dark layers within the glacier ice. The erupted materials can be dated with isotopic methods, so the ash layers now provide important time markers in the ice sheet that can be used to accurately determine ages for prior climate events (Dunbar et al. 2003).

Prior to 10,000 years ago, the West Antarctic ice sheet was at a maximum, but since then it has been in decline. Glacial geology research, including cosmogenic dating of glacial deposits upon granite bedrock in the Ford Ranges, indicates that since 10,400 ka, there has been continuous lowering of the ice sheet surface, with consequent exposure of the mountain peaks (Ackert 2000; Sugden et al. 2005). Overriding by a large regional ice sheet has given way to localized flow of ice within local glaciers, and melting of the ice sheet upon Marie Byrd Land continues today.

Geological Exploration

The first rock exposures discovered in Marie Byrd Land are those at Scott Nunatak and Prestrud Rock, on the coast of Edward VII Peninsula. The outcrops were charted in 1902 by the British National Antarctic Expedition. Samples of banded gneiss from these crags, collected in 1911 by Lt. Kristian Prestrud of the Eastern Sledge Party of Amundsen's Norwegian expedition, provided the first clues about the geology of Marie Byrd Land. Not until 1928 were nearby inland mountain ranges discovered during exploratory flights by Admiral Richard E. Byrd from the base at Little America. Byrd discovered the Rockefeller Mountains on Edward VII Peninsula and the Ford Ranges bordering the Saunders Coast. Byrd's second-in-command was Laurence M. Gould, a geologist, who was the first to examine the Byrd Coast Granite that makes up the Rockefeller Mountains (Gould 1931). During the geological sortie led by Gould in the year preceding Byrd's polar flight, one of the Byrd expedition's airplanes was lost in a severe wind storm. As a consequence of Admiral Byrd's air exploration of the area, the larger region was named Marie Byrd Land in honor of Byrd's wife.

The second Byrd Antarctic Expedition and the United States Antarctic Service Expedition ("Byrd III") of 1939–1941 investigated the geology and biology of the Ford Ranges in a systematic way. Topographic mapping was the objective the United States Navy's Operation Highjump, which acquired the high altitude aerial photography needed to develop the first accurate maps of the region. Notable scientists who participated in this and subsequent geology investigations in Marie Byrd Land, including traverses during the International Geophysical Year in 1957–1958, were Paul Siple and F. Alton Wade. Mt. Siple, a volcano located at 73°39′ S, 125°00′ W along the coast of central Marie Byrd Land, is named for Paul Siple. The US Antarctic Program Marie Byrd Land Survey of 1966–1967 made further progress in geological research. In the late 1980s, international (South Pacific Rim International Tectonics Expedition—SPRITE) and American (Ford Ranges Crustal Exploration—FORCE) geological research recommenced with new vigor and continues today. Current research focuses upon the transition from convergent to divergent tectonics along the margin of West Antarctica in Cretaceous time; character of the mantle and controls on volcanism; the climate record preserved in the ice of the West Antarctic Ice Sheet; and the processes and time frame for deglaciation.

MARINE BIOLOGY: HISTORY AND EVOLUTION

The present-day marine fauna of the Southern Ocean has been strongly influenced by plate tectonics, palaeoceanography, and the resulting global climate change. These historic processes had caused faunal extinctions of some animal groups, while others were able to survive or even thrive under the newly developed climatic conditions due to physiological adaptations.

The Mesozoic opening of the Southern Ocean and split-up of South America, Africa, and Antarctica is one of the largest gaps in knowledge on the evolution of this region. After the separation of Africa, the breakup between Australia and Antarctica started approximately 100 Ma ago and successively led to a beginning deepwater circulation between Australia and East Antarctica, which was not completely developed before Eocene or Oligocene (approx. 55–35 Ma). At that time, the complete development of the Antarctic Circumpolar Current (ACC) was interrupted only by the land bridge between South America and the Antarctic Peninsula. However, this large water mass already led to a successive climatic deterioration, cooling, and glaciation of Antarctica, especially in the east of the continent. Due to the opening of the Drake Passage approximately 32.5–34 Ma and the development of the Scotia Arc, the Circumpolar Current became effective and caused a further cooling of the Southern Ocean surface water. An extensive deepwater circulation formed between South America and the Antarctic Peninsula. These dramatic palaeoceanographic changes successively resulted in the generation of the psychrosphere, the cold world's deep-sea bottom water, which is linked to the surface water in polar areas. The cooling and glaciation of the continent is considered to be a key event for the evolution of many Antarctic marine species.

Today, the Southern Ocean is isolated by the Polar Front (PF, previously termed the Antarctic Convergence), which is the strongest jet of the ACC, which is characterized by high current velocities. Antarctic Bottom Water (AABW) is of special importance for benthic life in the deep sea both in Antarctica and in other oceans. It is generated at the Southern Ocean ice margins, is cold, is highly saline, and has been a factor in the isolation of the benthic faunas due to the Tertiary temperature changes. The Weddell Sea and the Ross Sea are the main sources of the AABW production. Because of its high density, this water mass sinks down the continental shelf and slope into the Southern Ocean abyssal zone, where it moves northwards, limited or diverted along ridges, troughs, and spreading zones towards other deep-sea basins. AABW generation depends on the sea-ice production, which in turn is dependent on atmospheric processes and temperatures. If AABW production was interrupted at any time in the past during interglacial periods, one barrier to colonisation would have been removed and benthic organisms from lower latitudes could have spread into the Antarctic. However, the interactions between sea-ice production and deep-water generation are complex, and the gradual changes of the recent glacial cycles are not yet completely understood. Until now, it was impossible to trace the influences of these historic changes on the evolution, development, zoogeography, and range extensions of pelagic or benthic organisms. A geography of the sea has recently been published for the pelagic realm. The fossil record of benthic organisms is very limited and the palaeontological record of deepwater taxa remains almost entirely unknown.

The cooling of the Southern Ocean approximates to an average temperature decrease of 0.003 °C per 1000 years, though evidence suggests this cooling has taken place unevenly in time, often in bursts over just a few million years. This has had a much less dramatic influence on the evolution and extinction of benthic species than on land organisms—the forests, land snails, amphibians, reptiles, and other groups have all gone. Many taxa also became extinct, especially in the Late Cretaceous, but some survivors underwent rapid radiations. The successive cooling, glaciation, and isolation of Antarctica and the subsequent extinction of faunal elements had a strong impact on the evolution and radiation (promoting rapid speciation) of many Antarctic marine species and resulted in the evolution of many key elements of the present-day benthic marine fauna. For example, krill, notothenioid fish, peracarid crustaceans, and pycnogonids radiated in the Southern Ocean like the marsupials in Australia, while decapod crustaceans (crabs and shrimps), cirripeds (barnacles), and teleostei (bony fish) are rare.

The near extinction of Antarctic reptant decapods in the Tertiary may be explained by physiological constraints related to haemolymph magnesium regulation capacities in the cold and by their reproductive strategies. The virtual disappearance of the Reptantia and the Teleostei caused the emergence of new adaptive zones previously occupied. These may have opened up opportunities for spectacular adaptive radiations, like for the brood-pouch-bearing Peracarida (Crustacea Malacostraca) and the notothenioid fishes. Such groups are considered to be "preadapted" to the climatic and biologic changes of the Southern Ocean. Notothenioidei thrive on the Antarctic continental shelf, probably because of the innovation of the glycopeptide antifreeze substances in their haemolymph.

Peracarida can be argued to have a variety of protective adaptations that help to reduce predation (such as by fish, which are especially speciose in benthopelagic or benthic environments). Larger species or species with a well-developed spine armature are not an easy prey for fishes (e.g., Epimediidae and Iphimediidae within the Amphipoda or Serolidae and Antarcturidae within the Isopoda). Some species use camouflage or mimesis (concealed mimicry) by having colourful pigment patterns on their cuticles. Spines can serve a similar function, blending their bearer into uneven backgrounds, such as algae, bryozoans, hydrozoans, or alcyonarians, as well as acting as protection against possible predators.

Radiations are the product of evolution in isolation over long periods of time and are connected with a high level (60%–90%) of endemism (organisms which have been reported in only that area) as is the case in sponges, bryozoans, and peracarid crustaceans, for example. However, these generalisations apply specifically to shelf faunas. It is currently unknown whether the often cited "typical" characteristics of the Antarctic fauna (e.g., the high level of endemism, gigantism, late maturity, decreased number of offspring, and high longevity, amongst others, also apply to Southern Ocean deep-sea fauna). Recent deep-sea expeditions (e.g., ANDEEP) have found endemism of deep-water isopod species to be ~85%, as high as on the shelf; however, this might be due to the still low sampling effort in the deep sea (of the Southern Ocean).

It was believed that many species had circumantarctic distributions, but there is growing molecular evidence that many of these actually comprise several cryptic species, presently undergoing speciation processes. For example, the isopod crustaceans *Ceratoserolis trilobitoides* (three cryptic species), *Glyptonotus antarcticus* (four species), and asellotes have all recently been described as having Southern Ocean species-complexes.

Many sessile suspension-feeding and other epifaunal groups have been particularly successful both ecologically (abundance) and evolutionary (species generation) on the Antarctic shelf in part due to the coarse-grained and poorly sorted, glacial-marine sediments. One might therefore wonder whether the Antarctic ice extension, followed by annual or cyclic retreats, has increased their success and the availability of hard substrates for them.

There are many hypotheses on the potential origin of the Southern Ocean fauna. It was first postulated that the ancestors of the Southern Ocean shelf species of isopod crustaceans evolved in the deep sea and migrated up onto the continental shelf (polar emergence). This would have been easier (than in other oceans) because of the absence of a thermocline. However, the contrary process, polar submergence of species from the shelf into the Southern Ocean deep sea has also been hypothesized. The ecological and evolutionary relationships of the faunas of southern South America and Antarctica were compared. This focussed on the possibility of species migration by island hopping via the Scotia Arc. If this was an important method, the Shackleton Fracture Zone in the Drake Passage might serve as a submarine bridge linking faunas of southern South America and the Antarctic Peninsula regions. The vicariance event of the fragmentation of the supercontinent Gondwana, into distant continents, has clearly led to disjunct distribution patterns within many faunal groups.

The present day Southern Ocean biodiversity is the result of different and simultaneously occurring biogeographic and evolutionary processes. These include the progressive retraction of taxa that used to have cosmopolitan distributions (established during the Jurassic and Cretaceous periods), disjunct distributions of genera or species due to continental drift vicariance, active migrations of taxa in and out of the Southern Ocean, and radiation events due to the emergence of new adaptive zones. As a proportion of the world, the Southern Ocean comprises ~8% by area, ~2% by coastline, and an intermediate level by shelf area. Whether the Southern Ocean marine ecosystem has a low or a high proportion of species relative to other regions depends on which of these figures is used for comparison. By ocean area, most higher organism groups are less rich than would be expected, a fact probably due to the low sampling effort below the continental shelf. By shelf area or coastline, many groups are richer than average across the world, especially the pycnogonids, polychaetes, ascidians, holothurians, amphipods, and bryozoans. Estimations of continental shelf biodiversity of the Antarctic are difficult because many geographic areas have not been sampled representatively, a huge number of new species await description, and the definition of shelf depth differs (it is unusually deep in Antarctica).

It is very probable that at no time during the Cenozoic did the Antarctic shelf ice sheet completely eradicate the Southern Ocean shelf fauna completely (there were probably refugia). However, during maximal ice extensions, ice masses would have extended to 1-km depth even north of the Antarctic Peninsula. Many Antarctic species investigated to date show wider bathymetric distributions compared with those in other seas, suggesting that many continental slope species found shelter in deeper waters off the shelf during glaciation events. The geological history of the breakup of Gondwana, the increasing isolation of Antarctica, and changes due to the Milankovitch (sun cycle) cyclicity have generated a cooling but fluctuating climate, and strongly determined the composition, distribution, and zoogeographic limits of organisms permanently. The subsequent changes in the ice-shelf extension probably led to speciation processes on the Antarctic continental shelf in some taxa, and to adaptive radiations. For this reason, some scientists refer to Antarctica as a diversity pump. It is unknown to what extent species have migrated up and down the Antarctic continental shelf and slope following ice extensions and retreats during glacial maxima and minima, but these processes are thought to have led to the high eurybathy that is characteristic for many Southern Ocean species today. Due to AABW production, the Weddell and Ross seas may have been an important source of taxa presently living in the Atlantic or Pacific deep oceans because the isothermal water masses surrounding the Antarctic continent provide an obvious conduit for the migration of shallow-water species into the Southern Ocean deep sea and further north. In this respect, the Antarctic shelf might indeed serve as a "biodiversity pump" conveying organisms or developmental stages from shallow to deeper sea areas of the Southern Ocean. Investigations on pressure tolerance, for example on the early larval stages of the sea urchin

Sterechinus neumayeri, have demonstrated theoretical ability to persist deeper than at 2-km depth.

Today, anthropogenic impacts, global climate change, natural selection, and evolution influence the biosphere. Southern Ocean shelf benthic communities have been reported to change due to increased physical disturbance, like iceberg scouring (which will be increased by global warming) or (on a local scale) sewage increase by humans. Climate models still have considerable levels of error associated with predictions of Southern Oceanic responses to global climate change, but increases in sea temperature, CO_2, glacial retreat, acidification of surface waters, UV-B, and precipitation all seem likely. Biological responses to these factors will affect, initially, the molecular level and determine population fitness and species interactions before it ultimately might affect biogeochemical cycling. Moreover, physical feedback of global climate change will regulate sea ice and primary production, winds, and thermohaline ocean circulation, all of which have further biological impacts and—like in the Late Cretaceous and Cenozoic—might force organisms to survive at greater depths in the Southern Ocean again.

MARINE DEBRIS

In the last few thousand years, humans have increasingly used the sea and launched floating material into it. About four decades ago, a new, most numerous and durable source of material started entering the oceans—plastics. Within this time the world's shores have revealed the changes in material afloat as plastic artefacts have rapidly accumulated on high-water marks. In Antarctica, a continent that has not had forests for a considerable period nor surface-dwelling (floating) animals, this has been particularly dramatic. A few years ago the first recorded visit took place to one of the remote South Sandwich Islands, but plastics had already covered a stretch of its shoreline. Natural flotsam does also occur, however. Tree trunks can occasionally wash up on Antarctic (mainly sub-Antarctic island) shores as do other biological propagules such as seeds. Unlike in other oceans, human (and other) debris is limited in its range; items rarely wash up on shores south of $\sim$63° S. In the Southern Ocean, the source of much marine debris are fisheries vessels, for example at Macquarie Island, Bird Island (South Georgia), and Livingston Island. However, a study of the annual debris accumulation patterns at Signy Island found little correspondence with the local krill fishery. At these localities and a few others (mostly sub-Antarctic and maritime Antarctic island sites), accumulation rates, and the nature and sources of debris are recorded at the request of CCAMLR. Where accumulation rates have been recorded (around Antarctica this ranges from 0.01 to 1 item/km/yr), there is mixed evidence of whether rates are still increasing. Dumping of plastics is now banned according to MARPOL Annex V, and in 1993, CCAMLR began applying conservation measure 63/XII phasing out plastic banding. Floating plastic debris is still relatively rare south of about 60° S.

There are a number of changes to the sea-surface and shore environments associated with man-made marine debris, such as plastics. Aside from aesthetics, it can poison, starve, and choke wildlife that swallow or become entangled in it, such as seabirds and seals. Plastic packaging bands can be regularly seen entangling and cutting into fur seals at the sites where there are large colonies. Below the surface, nylon fishing nets can "ghost fish" for considerable periods until they sink. A quite different issue is alterations to transport opportunities for organisms. In warmer waters, hitchhikers from microbes to iguanas travel on marine debris to colonise new coasts. Marine debris is now known to be able to cross the Polar Front, both northwards and southwards, enabling any attached organisms to reach new environments. The freezing surface of Southern Ocean waters were thought to be a barrier to floating colonists, but in 2003 several groups of organisms (namely polychaetes worms, bryozoans, hydroids, sponges and a mollusc) were found on a single plastic piece and some were more than a year old. Colonists can be so numerous that they can be important food sources. Birds have regularly been seen crowding to feed on stalked (pedunculate) barnacles attached to buoys and floating plastics washing ashore at Macquarie Island.

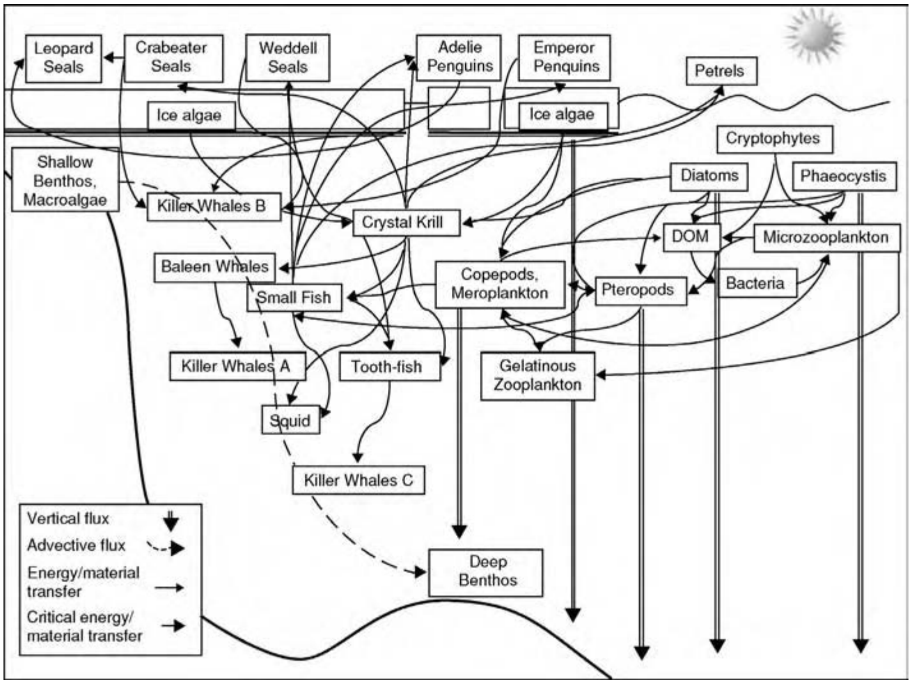
MARINE TROPHIC LEVEL INTERACTIONS

Ecological interactions among different trophic levels are critical connections that link the food web with the environment and material cycles. While the nature of these interactions is not different in waters of the Southern Ocean, there are species that exist in the Antarctic that are unusual in their importance to the food web. These species can occur at various trophic levels (the level within the food web at which an organism feeds), and their interactions with the environment and other organisms is critical in understanding their role in food webs. Food webs vary within the regions of the Antarctic, and the interactions between trophic levels is often poorly quantified.

At the first trophic level (that of the autotrophs), one critical interaction is the interaction of phytoplankton with the oceanic environment. This interaction controls the growth, abundance, and distribution of taxa (or of functional groups, related species that apparently occupy similar ecological niches). An example of this connection is that of the environment with an alga called *Phaeocystis antarctica*. This species apparently grows in waters with relatively deep mixed layers (and therefore relatively low irradiance levels) and elevated iron concentrations. This species is important because it has an unusual chemical composition, releases large amounts of volatile sulfur compounds (which enter the atmosphere and modify local climate), and in some locations is a poor food source for herbivores. Another important environment-functional group example is that of diatoms, which grow in high irradiances and slightly lower iron concentrations. Hence, in at least some locations in the Antarctic, there is a separation in time and space of these two functional groups.

Ice algae grow on and within pack ice throughout the Antarctic, and those groups have a strong linkage with their unique environment. For example, when pack ice begins to melt during the summer, ice algae (being highly colored) absorb solar energy and can enhance basal melt rates (and hence rates of algal release to the ocean). During melting, brine is released and creates a complex, three-dimensional matrix that provides refugia from predation for some organisms. Similarly, as frazil ice forms during austral autumn in the upper 10 m, it rises to the surface and many algal particles "stick" to the crystals, only to be incorporated into the pack ice.

Another important ecological interaction is that between the environment and Antarctic krill *(Euphausia superba)*, often called a keystone species of the Antarctic. Because of their size, krill (especially subadults) move with the water masses, and this large-scale



Representation of the food web of the continental shelf of the Ross Sea. (From Smith et al., in press.)

movement is a major factor in controlling their distributions. Krill also have a complex life cycle that includes laying of eggs at the surface, the obligatory sinking to depth (500–1000 m) to complete the larval development, and then their return to the surface by active swimming. If the eggs sink to the sediments, they are quickly eaten by benthic organisms, which means that krill development always occurs in waters off the continental shelf. If they sink to depths greater than 1000 m, their survival is reduced because they do not have internal food stores great enough to support metabolism prior to migration to the surface and subsequent feeding. Their development and vertical migration rates are also temperature dependent, and successful development is enhanced by passing through waters (>1°C) that are slightly warmer than those at the surface. Krill also require high concentrations of their phytoplankton food once they return to the surface, and utilize the complex circulation patterns to be advected to high-food regions to begin feeding.

Adult krill also form accumulations called swarms (densities up to 250 g m^{-3} and 20 m thick). These elevated densities are important in that they provide a concentrated food source for higher trophic levels (such as whales, seabirds, penguins, and seals), and also may serve as a protection against losses in a manner similar to fish schooling. The generation of swarms is due to the interaction between the vertical migration patterns of krill and the small-scale movement of near-surface water. Swarms will then be moved by the large-scale patterns of circulation over long distances as well. Other environmental factors such as food concentrations and irradiance also influence swarming behavior.

Feeding by a variety of species on krill demonstrates another critical feature of species interactions in the Southern Ocean. Many top predators, such as seals, seabirds, and penguins, nest on land and forage for food at sea. Thus they are spatially restricted to regions close to their colonies and nests. Yet there is specific foraging behavior of each group that separates them and reduces competition while searching for food. Such differences can include the depth of dives, the duration of dives, and the distance from nests. All of these also vary based on the amount of prey available as well; furthermore, prey availability is dependent on the season, their food, and other factors.

Perhaps the most important species interactions in the Southern Ocean are those involving man. In the past 100 years, whaling in the Antarctic dramatically reduced the populations of *all* species hunted: humpback, blue, fin, sei, and minke whales. Other species, such as fur seals, also were overexploited, as human technology allowed for rapid decimation of stocks. A number of fish stocks have been overharvested as well, and these fish species have slow growth rates; these populations have not returned to anything approaching preharvest levels. Finally, there has been and continues to be great interest in harvesting krill. Many problems exist with regard to the exploitation of this species, but if the economic need to catch krill increases, it is likely that the krill stocks could also be severely affected. Given the preeminent role of the species in Antarctic food webs, use of this species should be done with extreme caution, and the role of CCAMLR in ensuring trophic level sustainability will be crucial.

Trophic-level interactions occur between trophic levels, within trophic levels, between similar species, and within the same species. These linkages vary in space and time, and respond to other changes within the entire food web. They ultimately control the material and energy flows within the ecosystem; understanding those interactions provide a basis for understanding all food webs of the Antarctic marine ecosystems.

MARKHAM, CLEMENTS

Sir Clements Markham never went to the Antarctic. He nevertheless was a key figure in the history of the Antarctic because, as president of the Royal Geographical Society, he was the driving force that set in motion the renewal of British Antarctic exploration towards the end of the nineteenth century.

Born on July 20, 1830, at Stillingfleet in Yorkshire, the son of a clergyman, he entered the Royal Navy as a cadet in 1844, serving first on the Pacific Station, learning French and Spanish, as well as navigation and seamanship. It was from the decks of the wooden sailing warship HMS *Collingwood* in 1845 that he first set eyes on Peru, which was to become the first love of his life. (The polar regions were later to become the second.) He was allowed ashore with other midshipmen, and his fascination with the people and country led him to return to Peru in 1852–1853—soon after leaving the navy—to investigate its antiquities and to travel widely. He had learnt Quechua, the language of its people, during a winter in the Arctic, and he visited a number of priests in remote villages to learn about the history and literature of Peru. He returned again in 1859–1860 to procure young plants and seeds of the cinchona tree on the eastern slopes of the Andes. At his initiative, the newly established India Office had sent him and two others (one being Richard Spruce) to transplant these in India for the production of quinine, which would benefit both the Indian people and British officials and armed forces.

In 1850–1851, while still in the navy, he had played a small part in the search of Sir John Franklin, whose ships HMS *Erebus* and HMS *Terror* had disappeared in the Arctic during the last of the Admiralty expeditions to find the Northwest Passage. Markham's ship was *Assistance,* under Captain Erasmus Ommanney, part of a squadron commanded by Captain Horatio Austin. The first traces of Franklin were found on Beechey Island. Markham was a foremost contributor to the ship's winter newspaper, the *Aurora Borealis,* which was published on the expedition's return as *Arctic miscellanies*.

Throughout his life, Markham's literary output was considerable, beginning with translations from the Spanish of narratives relating to the conquest of the Incas and the history of Peru. These volumes were largely published by the Hakluyt Society, of which he became honorary secretary for 28 years, and later president for nearly 20. He wrote a short account of the Franklin search expedition, in which he had taken part, under the title *Franklin's Footsteps*.

Together with Sherard Osborne, who had also taken part in the Franklin search, Markham ran a campaign to renew Arctic exploration. This resulted in the British Arctic Expedition (1875–1876), commanded by Sir George Strong Nares in HMS *Alert* and HMS *Discovery*. Markham sailed as far as West Greenland in *Alert,* overstaying his allowance of leave and consequently having to resign his post as geographer at the India Office, during which period he had rescued from oblivion many historic records. He appears to have earned his living after that from his literary works, of which he published a prolific number.

He was installed as president of the Royal Geographical Society in 1893 and was knighted in 1896 for his "great services to geographical science." With the eminent oceanographer Sir John Murray, of *Challenger* fame, he opened the campaign to renew the exploration of the Antarctic regions. These had last been visited in the 1840s by three national expeditions. The government would not commit itself to financing another official undertaking, but did make a considerable grant towards the cost of what became the British National Antarctic Expedition of 1901–1904. A number of naval officers and ratings were allowed to join, among them the leader, Robert Falcon Scott. Markham had first noticed Scott as the youthful winner of a cutter race. He became Markham's protégé, but also received the recommendation of one of his old captains in the navy.

The Antarctic campaign broadened in its scope at the International Geographical Congress of 1895, held in London with Markham as its president. It passed the motion that the exploration of the Antarctic regions "was the greatest piece of geographical exploration still to be undertaken." Learned societies throughout the world should urge that the task should be begun before the end of the nineteenth century. It took years for Markham to amass funds enough to build *Discovery* at Dundee and for her to depart in August 1901 on a programme of Antarctic geographical exploration and scientific observations. He had brought in the Royal Society to cooperate in the organization of the expedition, but found relations with what he called "wild professors on the warpath" not at all easy. Their differences mainly concerned the geographical and scientific work on the expedition. In this, Markham triumphed: the exploration of the unknown interior of the continent was to be the main object (rather than what he called "mud larking": oceanography), and Captain Scott was to take charge of the scientific programme. The Royal Geographical Society became owner of *Discovery,* with Markham as her "Managing Owner." He chose the relief ship *Morning* in Norway and greatly appreciated the efforts of her master, Captain William Colbeck, during two Antarctic voyages, making a special presentation to him at the Royal Albert Hall on the occasion of Scott's lecture in November 1904.

Markham stood down as president of the RGS in 1905. He played little part in the organization of Scott's *Terra Nova* expedition, 1910–1913, but was greatly saddened by the deaths of the Polar Party in the Antarctic. He died on January 30, 1916, following an accident in which he set light to his bedding. A fine portrait in oils of him in old age, featuring the cinchona plant and the silver model of an explorer with his sledge, was painted by George Henry, ARA. It hangs, fittingly, at the Royal Geographical Society.

MARR, JAMES

James William Slesser Marr was born at Cushnie, Auchterless, Aberdeenshire, on December 9, 1902, and educated at Aberdeen Grammar School and the University of Aberdeen. At age 18, while at university, he was chosen from many volunteer Boy Scouts to accompany the Shackleton-Rowett Antarctic Expedition (1921–1922) aboard *Quest* to explore the coasts of the Weddell Sea and a number of little-known sub-Antarctic islands. From that time he acquired the nickname "Scout" Marr, which he resented. He was a young man of very powerful build, who quickly responded to Ernest Shackleton's great leadership and was held in high regard by all hands for his performance of duties. He was in the ship at Grytviken, South Georgia, in 1921, when Sir Ernest died.

On his return from the Antarctic, Marr graduated from the University of Aberdeen with an MA in classics in 1924, and then took his BSc in zoology in 1925. In that summer he took part in the British Arctic expedition in the ship *Island* under the leadership of Grettir Algarsson and Frank Worsley, which made a modest contribution to exploration and research, and circumnavigated Spitsbergen. Marr lost no chance to put out tow-net and dredge, and returned to the Marine Laboratory in Aberdeen to spend a year as a Carnegie scholar to work up his marine collections.

In 1927 Marr was appointed to the scientific staff of the Discovery Investigations. In this service he took part as marine biologist in three expeditions to the Antarctic—in *William Scoresby,* 1928–1929, and in *Discovery II,* 1931–1933 and 1935–1937. In 1929–1931 he was seconded to the British Australian New Zealand Antarctic Research Expedition under the leadership of Sir Douglas Mawson in *Discovery*. For all this service he was awarded the Polar Medal in Bronze, with clasps Antarctic 1929–1930 and 1928–1937. He later published his marine biological work in his definitive report, *Antarctic Krill.*

In 1939–1940 Marr again voyaged south as an inspector in the whaling factory ship *Terje Viken,* while seconded to the Department of Scientific and Industrial Research to investigate the possible use of canned and frozen whale meat to augment British wartime food stocks.

On his return from the Antarctic, Marr joined the Royal Navy as a lieutenant commander, RNVR, and saw service in Scotland, Iceland, South Africa, and Ceylon, until 1943, when he was recalled home to organize and lead the secret Operation Tabarin, designed to resume British activities in the Falkland Islands Dependencies (now British Antarctic Territory), and to safeguard British interests and sovereignty in that region. It thus fell to Marr to bridge the gap between the prewar British private expeditions and the new era of government-supported exploration and research.

Operation Tabarin was mounted in little more than 4 weeks, and involved huge problems in finding equipment, supplies, and shipping, so that it is astonishing that the two initial bases at Deception Island (South Shetland Islands) and at Port Lockroy (Anvers Island) were established so expeditiously. Marr himself was exhausted by this major effort, and was invalided home in 1945 at the end of the first winter at Port Lockroy, turning over to his second-in-command. For his service he was awarded the Polar Medal in Silver, being one of only eighteen men to receive both Bronze (abolished after 1942) and Silver Polar Medals. He is commemorated in two Antarctic place-names.

After the war Marr was able to resume his work as principal scientific officer at the National Institute of Oceanographic Research, an appointment he held until his death. He died on April 29, 1965, survived by his wife Dorothea Helene (Plutte) and five of their six children.

MAWSON, DOUGLAS

Douglas Mawson, Australia's greatest Antarctic explorer, was born May 5, 1882, near Bradford, Yorkshire, England, and immigrated to Australia in mid-1884 with his parents and elder brother. He was educated at the University of Sydney (BEng, 1902, focus on geology and mineralogy; BSc, 1905). His mentor was Professor (later Sir) T. W. Edgeworth David, a renowned geologist with inordinate political pull. During 1903, Mawson undertook a geological survey of the New Hebrides. In 1905, the University of Adelaide appointed him lecturer in mineralogy and petrology, and he began field studies of the geology (much of it glacial) of the region from the Flinders Ranges to Broken Hill.

When Ernest Shackleton visited Adelaide en route to Antarctica in 1907, Mawson asked to join his British Antarctic Expedition, to which David had already been accepted. Mawson's interest in glacial geology was a prime motivator, together with his adventurous spirit, and no doubt he thought that doing some Antarctic geology would further his career. He initially only wanted to travel south on the expedition ship *Nimrod* and then return when the land party was left behind. Shackleton, however, appointed him physicist for the duration of the expedition, and Mawson gained permission from the University to remain for the length of the expedition. Mawson was one of the party of six that first scaled Mount Erebus, the active volcano on Ross Island. The next summer, he was one of three (under David's leadership) who first reached the area of the South Magnetic Pole (summer, 1908–1909). Without the aid of dogs, Mawson, David, and Alistair Mackay dragged their sledges for 1260 miles (2030 km) on this trek. The route they chose for the return proved treacherous, food ran low, their survival was a near thing, and Mawson took over command from an exhausted David. They were only just rescued by *Nimrod,* when the first officer, John King Davis, convinced the captain to return to an area they had already searched, prior to leaving the party to their fate.

In Australia, Mawson and David were received as heroes, and Mawson began to conceive plans for an Antarctic expedition of his own. These took shape from February 1910. On a visit to England—having turned down an offer to join Robert Falcon Scott's expedition—Mawson won Shackleton's support, but not the large-scale funding Shackleton's connections had seemed to promise. While continuing his position at the University of Adelaide, Mawson found his own funding sources and proceeded with the planning of what became his Australasian Antarctic Expedition (AAE, 1911–1914).

The AAE received some government support but was largely a private affair. Conceived under the aegis of the Australasian Association for the Advancement of Science, from the outset it put science first. J. Gordon Hayes, writing of its scale and achievements, called it "the greatest and most consummate expedition that ever sailed for Antarctica" (Hayes 1928: 210). It was on a scale never before conceived for Antarctica: a serious scientific investigation with three continental bases stretched along a 2000 mile (3200 km) arc of coast, which would also be explored geographically, with each base sending teams east and west (hopefully to link up), and one party going south as well. In the event, Mawson was forced to reduce the continental bases from three to two.

The site for the Main Base was Cape Denison in Commonwealth Bay, Adélie Land. A second continental base was set up under Frank Wild some 1500 miles (2400 km) to the west, on the Shackleton Ice Shelf. Between the bases, seven major sledging trips were sent over entirely unknown territory, all in the face of extremely difficult weather. The Main Base, in particular, earned a reputation as the windiest place in the Antarctic.

The event that cemented Mawson's heroic reputation was his amazing return from the death of his two sledging companions. On November 10, 1912, he set out with Dr. Xavier Mertz, Lieutenant B. E. G., Ninnis, and two dog teams heading southeast, then east. A month out, 311 miles (500 km) from Main Base, Ninnis was killed when he fell into a crevasse, taking with him their best dogs and most of their food and equipment. With few supplies left, there followed a desperate return journey, on which Mawson and Mertz turned to their dogs for food. More than half way back, Mertz sickened and died; Mawson, also in terribly ill condition, continued alone. Finally, on February 8, Mawson reached Main Base, to find that the expedition ship, *Aurora,* had picked up most of the men and, after waiting weeks for his return, had sailed away only hours before to collect the members of the Western Base. With a small party that had remained behind to search for him, Mawson had to wait another year before he could return home. The next summer the party was relieved, and Mawson and the others arrived back in Australia in late February 1914. He was knighted later that year in London, and the following year his account of the expedition, *The Home of the Blizzard,* was published in two volumes. Mawson spent many years overseeing the publication of the scientific results of the AAE.

Mawson married his fiancé, Francesca Adriana ("Paquita") Delprat, soon after his return to Australia. After spending much of the following year travelling and lecturing in an attempt to repay the debts of the expedition, he served in the First World War, much of it with the Ministry of Munitions in England. He then returned to the Department of Geology at the University of Adelaide, where he was made professor of geology and mineralogy in 1921.

Mawson's British, Australian, New Zealand Antarctic Research Expeditions (BANZARE) of 1929–1931 were overtly imperial ship-based expeditions that also employed a seaplane. Among the discoveries were extensive regions between Adélie Land and Enderby Land, including Banzare Land, Princess Elizabeth Land, and Mac.Robertson Land (all named by Mawson). New features were charted, known features charted more accurately, new mountain ranges observed, and landings made on the mainland (at Scullin Monolith and Cape Bruce). Australia's Antarctic claims were direct results of Mawson's expeditions and his own efforts at science and exploration.

Mawson had a long career at the University of Adelaide, and his fieldwork in South Australia was extensive and important. He was a founding Fellow of the Australian Academy of Science, and played a significant role in the early planning of the Australian National Antarctic Research Expeditions (ANARE). Throughout his life he remained a figure of prominence and influence in scientific and Antarctic circles throughout the world. He died in Adelaide on October 14, 1958, and was given a Commonwealth state funeral.

McMURDO STATION

McMurdo Station is the scientific and operational hub of the United States Antarctic Program. Its location on the ice-free southern tip of Ross Island at the southwestern corner of the Ross Sea is geographically unique in ways that make it valuable for supporting scientific research:

- The high latitude of 77°51′ S—838 miles from the South Pole—has made it the compelling location for more than 100 years as a launching point for expeditions that have explored and studied much of the Antarctic.
- Its protected natural seaport—Winter Quarters Bay—accommodates deep draft cargo ships and tankers, enabling economical seaborne delivery of 95% of all fuel and cargo used by the United States Antarctic Program in continental Antarctica.
- Winter Quarters Bay is the world's southernmost port.
- Sea ice on adjacent McMurdo Sound and glacial ice of the nearby Ross Ice Shelf have proved practical for landing large transport airplanes with normal, wheeled landing gear arriving from overseas (Christchurch, New Zealand, 2350 miles to the north).
- The station site has several square miles of gently sloping, ice-free solid ground on which safe and efficient buildings have been constructed using techniques comparable to ordinary methods of the lower latitudes.
- The site is not and was not inhabited by wildlife colonies; ecological impact is minimal.

The locale is historic, having been discovered in 1839–1840 and used as the coastal base of expeditions toward the South Pole in the first decade of the twentieth century, most notably Robert Falcon Scott's British National Antarctic Expedition, which established the first hut there. The US Navy's Operation Highjump made reconnaissance flights over the Transantarctic Mountains from McMurdo Sound in 1946–1947. On 29 January 1948 during Operation Windmill, the US Navy icebreakers *Edisto* and *Burton Island* put parties ashore and studied the nearby ice shelf.

On 18 December 1955 the navy's icebreaker, *Glacier,* entered McMurdo Sound, beginning construction of McMurdo Station. The first function was as the logistics base from which to construct and support a research facility at the geographic South Pole for the 1957–1958 International Geophysical Year. After the IGY, McMurdo grew to be an operational and science center that now is the largest human settlement in Antarctica.

McMurdo's logistics centers on airlift within Antarctica and both airlift and sealift between it and the United States. This capability enables support not only of the year-round Amundsen-Scott South Pole Station, but also of the dozens of research camps established throughout the continent every summer and a complete program of waste management functions.

While McMurdo Station is occupied year-round, it has a distinctive annual cycle of population and activity that rises and falls with the Sun. In mid-August, McMurdo's Pegasus runway, on prepared glacial ice, receives several round-trip flights from New Zealand, ending the winter crew's isolation and nearly doubling McMurdo's population from 241 (in 2005) to about 400. From the beginning of October to the end of February, about three flights a week arrive from New Zealand on the Pegasus runway or on a temporary runway built each summer on the annual sea ice of McMurdo Sound. US Air Force C-17s make most of these intercontinental flights.

The McMurdo population rises quickly in October to about 1100, mostly Americans but including substantial numbers of scientists and support personnel from other Antarctic Treaty nations cooperating with their US counterparts. The South Pole population rises from eighty-six (in 2005) in winter to a summer peak exceeding 220, and the population of field camps rises from 0 in winter to a peak of about 136 in summer. Population drops quickly in late February to the winter level, at which it remains until August.

Substantial collaboration in air transport between Christchurch and McMurdo takes place with other Antarctic Treaty nations—particularly New Zealand, whose year-round Scott Base is 2 miles from McMurdo, and Italy, whose Terra Nova Bay station is 200 miles away.

McMurdo is the hub for US air transportation throughout the continent. In addition to the two runways described above, a skiway named Williams Field is near McMurdo on the Ross Ice Shelf; ski-equipped airplanes can use it at any time of the year. The airplane fleet for operations within Antarctica typically consists of six ski-equipped C-130s (designated LC-130s) and two or three ski-equipped Twin Otters. Helicopters, typically two AS-350B and two Bell 212 helicopters, operate from a heliport within McMurdo Station.

Satellite ground equipment at nearby Black Island, connected by microwave to McMurdo, provides the station with full-time telephone, e-mail, and Internet service as well as real-time access to some US radio and television broadcast channels.

Diesel engines generate electricity, and their "waste" heat warms buildings and helps desalinate seawater (using reverse osmosis) to make the station's water supply. Insulated and heat-taped pipes carry water and sewage throughout the station; sewage is treated before its remnant clean water is discharged into the sea.

The station's ninety or so buildings include a large multidiscipline science laboratory with aquaria, facilities for equipping field science parties, shops, a library, storage, and dormitories and dining areas.

Ross Island is ideally situated for Antarctic science. It is within helicopter range of southern Victoria Land, whose Transantarctic Mountains and McMurdo Dry Valleys have geological and biological complexities still not completely understood. It is not far from Weddell seal, Adélie penguin, and other wildlife colonies, whose documented behaviors and population changes offer insights into simple and remote ecosystems that manage to flourish in some of the planet's most extreme environments. It is within practical airplane range of the West Antarctic Ice Sheet, whose response to and influence on world climate and sea level are being studied intensively.

The functions of McMurdo Station are critical to most of the US Antarctic Program. The station in 2005 was expected to operate into the foreseeable future. However, an unprecedented array of large icebergs, stalled north of the station in the early years of the twenty-first century, complicated ship and icebreaker transit to the station and caused the National Science Foundation to consider alternatives to the McMurdo location.

McMURDO VOLCANIC GROUP

The McMurdo Volcanic Group is the formal stratigraphic name used by geologists to describe Cenozoic volcanic rocks erupted in the western Ross Sea and Central Transantarctic Mountain areas of Antarctica. The original definition included volcanic rocks at the Balleny Islands, but these are now excluded as they were erupted in an oceanic environment and not on continental crust, as was the bulk of the McMurdo volcanics. The Cenozoic is the period of geologic time ranging from 65.5 million years to the present day.

Some investigators refer to the McMurdo Volcanic Group as the McMurdo Igneous Complex. Geologic mapping of rocks in north Victoria Land has identified small early Cenozoic bodies of alkalic igneous rocks. They are likely to represent the subsurface remains of a volcanoes magma chamber. These rocks are known as the Meander Intrusives and represent the oldest McMurdo Volcanic Group rocks. The McMurdo Volcanic Group rocks are all within the continental part of the Antarctic tectonic plate. They lie within and adjacent to the Victoria Land basin, in the western Ross Sea, which started forming about 100 Ma during the final stages of the breakup of the Gondwana supercontinent. The continental crust still continues to be thinned by rifting. Lavas and eruptive products of the McMurdo volcanics typically have high contents of sodium and potassium giving them an alkalic compositions. Alkalic magma compositions are widespread in continental rifts.

The McMurdo Volcanic Group has been subdivided into the Hallett, Melbourne, and Erebus volcanic provinces. The Hallett volcanic province consists of a 260-km-long chain consisting of four major elongate shield volcano complexes (Adare, Hallett, and Daniell peninsulas and Coulman Island). They lie along the margin of the Transantarctic Mountains. Initial interpretations suggest the volcanoes were erupted in a subglacial environment when the ice sheets were larger. More recent work believes the volcanoes were erupted mainly under subaerial conditions. The Melbourne volcanic province consists of volcanic vents forming an arcuate band extending from the active Mount Melbourne on the coast to the large volcanic centers of Mt. Overlord, The Pleiades, and Malta Plateau lying on the Transantarctic Mountains. Small basaltic vents are widely distributed in the Melbourne province. The Erebus volcanic province is better studied and includes the numerous volcanic centers in McMurdo Sound, Beaufort, and Franklin Islands and marine volcanic centers in the southwest Ross Sea. Magnetic anomalies detected during geophysical surveys over the western Ross Sea are interpreted as small volcanic vents and included in the Erebus province. Ross Island is a coalescence of three major volcanoes (Mounts Bird, Terror, and Erebus) and is younger than 5 million years. In southern McMurdo Sound the Discovery subprovince is mostly older than 5 million years and includes the major volcanic complexes of Mounts Discovery and Morning and the linear fissure controlled vents on Minna Bluff and Brown Peninsula. Numerous other small basaltic centers are scattered along the foothills of the Royal Society Range and in the Dry Valley.

MEGA-DUNES

Mega-dunes were first described by Swithinbank (1988), who termed these features based on their likeness to transverse sand mega-dunes. These features are extensive on the remotest part of the East Antarctic plateau and occupy more than 500,000 square kilometers. The climatic conditions of mega-dune areas are characterized by low temperature, extremely small snow accumulation, and very uniform wind direction and speed. They are oriented perpendicular to the regional katabatic wind direction, amplitudes are small (about 3–4 m), wavelengths range from 2 to over 4 km, and mega-dune crests are nearly parallel and 10 to 100 km in length. Leeward faces are characterized by a flat smooth layer of cemented thin films of ice (wind crust), which cover extremely large snow crystals (up to a centimeter). Windward faces are covered by large rough surface morphology (sastrugi) up to 1.5 meters in height.

Mega-dunes rise only a few meters above the general surface level and are imperceptible to the surface traveller. The regular pattern of sastrugi and wind crust allows us to survey the mega-dunes by satellite observations. The study of mega-dune genesis indicates that the change of slope along the prevalent wind direction (from less of 0.5 m km^{-1} to 1–1.5 m km^{-1}) plays a crucial role since it generates a wave in the katabatic wind, of weak amplitude (3–4 m). Mega-dunes are formed by snow accumulation variability due to katabatic wind waves. This variability ranges between 25% (leeward faces) to 120% (windward faces) of the accumulation in adjacent non-mega-dune areas. Mega-dune internal structure suggests the sedimentary morphology of the windward face (sastrugi) migrates upstream with time, burying the wind crust of the leeward face. The velocity of migration is some meters per year but the ice is flowing downhill at about the same rate. So a century-long "movie" of satellite images would show the mega-dunes moving sideways across the face of the ice sheet. The reconstruction of past climates based on ice cores drilled in areas with high snow accumulation spatial variability is distorted. In mega-dunes areas the distortion of recordings is characterized by a snow accumulation periodicity of about 1500 years. The length of periodical variations due to mega-dunes is correlated with ice velocity and snow accumulation, and can therefore vary in space and time.

METEORITES

Very few extraterrestrial objects known as meteorites are recovered each year in the populated world. Only about 2000 stone or iron meteorites were known in 1970, either as observed falls or as later recognized finds. This number changed dramatically after Japanese glaciologists found nine meteorites of different types on a blue ice field near the Yamato Mountains, Dronning Maud Land. This high density of meteorites suggested the action of a concentration mechanism in the Antarctic and initiated systematic meteorite searches in the Antarctic, mostly along the Transantarctic Mountains and in Dronning Maud Land. By 2004, more than 30,000 meteorite fragments had been recovered, possibly representing as many as 6000–10,000 individual falls.

There are several reasons for high meteorite concentrations on some ice fields. (1) In visual surveys the recognition of meteorites is easy on blue ice fields. This is demonstrated by the mean mass of Antarctic finds, which is about 10 g, much smaller than the 1 kg or so of non-Antarctic meteorites. (2) Concentration mechanisms work by glacial movements, and ice flow is blocked or slowed by bedrock barriers. Where mountains or subsurface obstructions block the glacial flow and loss of ice is created by sublimation, meteorites fallen on the Antarctic continent are exhumed and stored on the ice surface together with direct meteorite falls. Small meteorites (<100 g) can be moved by strong winds from ice patches to surrounding snow areas. (3) Weathering of, and thus destruction of, meteorites is less severe under Antarctic conditions compared with more moderate climates with a greater concentration of liquid water available. This allows for the build-up of high meteorite concentrations on the surface of stagnant ice fields.

Mean survival times of meteorites recovered in Antarctica are much longer than those from warm or wet areas. Terrestrial ages (the time elapsed since a meteorite's fall to Earth) of up to 2 million years have been observed for Antarctic stone meteorites.

Before classification a name is given to each Antarctic meteorite. It consists of a geographical locality term, a two-digit number specifying the austral summer season of collection, and a number of two or more digits specific to the individual specimen (e.g., Allan Hills 84001).

During the last decades Antarctic meteorites became very important in the fields of cosmochemistry and planetology. The Antarctic collection represents a relatively unsorted and unaltered sample of what has fallen to Earth over a long time span. Several new meteorite types have been discovered. The most prominent example is the detection of the first lunar meteorite in 1981. By 2004 thirteen additional rocks from the Moon had been found on different Antarctic ice fields. Furthermore, eleven out of thirty-two known Martian meteorites were recovered in Antarctica.

There is no general agreement regarding the causes of differences in type frequencies, textures, terrestrial ages, and mass distributions among Antarctic and non-Antarctic meteorites. It is unclear whether these variations are due to terrestrial processes like weathering and contamination or whether they are of preterrestrial origin.

METEOROLOGICAL OBSERVING

Antarctica covers an area about the size of Europe. It rises steeply from sea level at the coast to a vast ice plateau reaching above 4000 metres and covering more than half the continent. Most manned stations are at coastal sites, so their weather is not a true representation of the continent as a whole, as they are much milder due to the influence of the sea. Automatic stations are much more widely spread across the continent and give a broader picture of the meteorology.

The weather varies enormously over this large area. Depressions cannot penetrate far inland and the interior receives the equivalent of only 50 mm rainfall each year—about as much as the Sahara desert. The high altitude of the Polar Plateau and the long winter night make it the coldest place on Earth. The northernmost coastal regions have mean summer temperatures just above freezing, whilst summer temperatures at Amundsen-Scott Station average –28°C. Even the warmest temperature ever reached there is only –14°C. Winter temperatures for the Antarctic Peninsula stations are highly variable depending on where the weather has come from. Northerly winds bringing down air from midlatitudes can push temperatures above freezing, whilst southerly winds from the continental interior can send the temperature plunging below –20°C.

Along the Antarctic Peninsula most stations have recorded significant warming over the last 50 years. Vernadsky station (formerly Faraday or Argentine Islands), with a continuous record going back to 1947 and further data back to 1944, shows the most significant trend. Here the average warming is 0.056°C per year. Elsewhere over the continent trends are variable, with perhaps a bias towards slight autumn cooling and slight winter warming. Global atmospheric models do not suggest that there should be any large warming over the Antarctic Peninsula in response to increasing greenhouse gasses, and it is suggested that the warming is a response to changing ocean currents, which have reduced the amount of sea ice on the western side of the Peninsula.

Meteorological observations are made regularly throughout the day at most manned stations. Surface temperature, humidity, sunshine, pressure, wind speed, and direction are largely measured by automated instruments, but an observer is needed to estimate the visibility and the amount, type, and height of clouds, although automatic instruments are being introduced. The observer also needs to keep note of the weather: rain, snow, fog, gale, etc., as well as more unusual phenomena: diamond dust, halos, mirages, and the aurora australis.

The cold atmosphere of the Antarctic makes it a good place to see some of the more unusual meteorological phenomena. Halo phenomena are caused by reflection and refraction of light from the Sun or Moon by ice crystals in the atmosphere. They may take the form of rings, arcs, pillars, or bright spots. Haloes can be seen from most countries and are normally formed by high, thin clouds. In the Antarctic, another phenomena called diamond dust also produces them. Here, because the air is so cold, ice can crystallize out of clear air near the ground. As the crystals tumble slowly to the ground they catch and reflect the sunlight like thousands of tiny diamonds.

At more than a dozen stations balloons are launched once or twice a day, each carrying a package of meteorological instruments known as a radiosonde. The instrument package signals back the temperature, humidity, and pressure to an altitude of over 20 km, with wind speed and direction found by tracking the package with GPS sensors. Special ascents are sometimes made to help study the lower part of the atmosphere called the troposphere, where weather systems are active. These include flights to investigate very stable conditions in the lowest layer, which mainly occur during the winter and other flights to study, for example, depressions forming in the Weddell Sea. Such studies are augmented by atmospheric profiles measured using captive packages carried aloft by kites or blimps. Further studies are made using instrumented aircraft, for example to study the composition of clouds in situ.

A meteorologist at an Antarctic station would start a typical day at 8 am, and complete a meteorological report during the morning. On an average summer's day at a coastal station it would be daylight and the weather might be slight snow or sleet, with overcast skies, light winds, and the temperature near freezing. By contrast, during the winter it would be dark, and with clear skies there would be a hard frost and temperatures around –30°C. The observations are checked, then coded into numeric form and sent via satellite to meteorological centres outside Antarctica. Other tasks are making measurements of snow accumulation, observing the ozone layer, and making measurements of atmospheric aerosol. All types of meteorological observations are conducted regularly throughout the day. In addition to the scientific work, the meteorologist has to help with the general base work.

History

Meteorological observation in Antarctica has a history as long as the exploration of the continent, and logs of the exploring ships and whalers give an early account of the continent's weather. For example, Edmund Halley in 1700 whilst off South Georgia encountered icebergs and noted that he was "In imminent Danger to loss our ship and lives, being Invironed with Ice on all Sides in a fogg soe thick, that we could not see it till [the ship] was ready to strike against it." James Clark Ross made the first systematic meteorological observations during his voyages with the *Erebus* and *Terror* in 1841–1843, and discovered that the mean atmospheric pressure was significantly lower than at the equivalent northern latitudes.

Continuous regular observation began at the beginning of the twentieth century with the establishment of a station at Scotia Bay, Laurie Island, in 1903. The Scottish National Antarctic Expedition, led by Dr. William S. Bruce, commenced observations in February 1903. The station was transferred the following year to the Argentinean Servicio Meteorologico Nacional, which has been running it ever since as the station Orcadas. In the following years further short-lived stations were set up as bases for exploration, for example Jean-Baptiste Charcot wintered at Petermann Island in 1909, and the British Graham Land Expedition (BGLE) set up several stations in 1935. The next big wave of station establishment came with the Second World War. Fears that the Germans might establish U-boat stations on the Antarctic Peninsula led to the establishing of British bases at Deception Island, Hope Bay (the record continues at nearby Esperanza), and Port Lockroy. All made meteorological measurements. Further stations around the continent were set up in the postwar period, such as Mawson, which was established by Australia in 1954.

The International Geophysical Year of 1957–1958 (IGY) provided a big impetus towards setting up continuously operated stations and more than forty were set up, of which more than a dozen are still operating today. This was the peak of manned observation in Antarctica, and since then the number of staffed stations has declined, though this is offset by an increasing number of automatic stations. A further boost to the observing network will take place for the International Polar Year of 2007–2008.

Research ships on their voyages to the coastal stations regularly make meteorological observations, usually every 6 hours. These are supplemented by drifting buoys that are often deployed to study the motions of ice floes. Further observations come from polar orbiting satellites; these can provide images in a variety of wavebands, and also provide temperature and other profiles. All types of observation are now used in global forecasting models.

Observational Problems

Although many of the observations made in Antarctica are done in exactly the same way throughout the world, some additional problems are encountered. Temperature measurements are often made using the Stephenson screen, or variations of it. These shield the thermometer from direct solar radiation and from precipitation falling on the thermometer. In low wind speeds in summer, the radiation reflected from the high albedo surface can give anomalously high readings, whilst under clear skies in winter the reverse can occur. Many stations use aspirated screens, where air is sucked over the thermometer bulb at a constant flow rate, to provide more consistent data. In blizzard conditions a screen can fill with drifted snow, giving a uniform temperature environment unless it is quickly cleared. Some protection can be afforded by the use of snow boards, which temporarily block the louvres whilst the blizzard is in progress.

Measuring the precipitation itself can be difficult. The snow is generally dry and what falls into a standard rain gauge just as easily blows out again. Similarly, precipitation that has fallen elsewhere or at a previous time can be blown around by the wind and into the gauge. Specially designed snow gauges provide a partial solution and another is to measure the depth of freshly fallen snow, and assume that in the long term there is a balance between transported and falling snow. Electronic precipitation detectors using scintillation in an infrared beam are now being deployed in Antarctica, and combination of the outputs of two detectors at different heights may provide the necessary discrimination between precipitation and transport.

Wind measurements were traditionally made using large, heavy-cup anemometers. These required a significant wind speed before they started turning and did not respond well to gusts. They were replaced by anemometers with lightweight plastic cups that performed better in these circumstances, but which

*Precipitation at South Pole is mostly in the form of diamond dust or ice crystals. The total snow accumulation is around 280 mm a year.

frequently became coated with rime deposited from fog, and hence underrecorded wind speeds. Propeller-type combined vanes and anemometers suffer less from rime, but can suffer mechanical failure. The modern replacement is the sonic anemometer, which can measure both wind speed and direction, can be heated to dispel any riming, and has no moving parts apart from the ultrasonic source.

Sunshine amounts are traditionally measured using the Campbell-Stokes recorder, a sphere of glass that focuses the sun's rays onto a fixed card where they burn a hole in bright sunshine. This suffers from a universal problem of overrecording in patchy cloud conditions, and also experiences another problem in polar latitudes, where there can be 24 hours daylight. In high southern (or northern) latitudes two recorders have to be mounted back to back to measure sunshine throughout the long day. Modern electronic records get around both problems and allow continuous recording.

MICROBIOLOGY

Microbiology is the study of microorganisms—microscopic forms of life that are ubiquitous in the biosphere and form an important component of Antarctic terrestrial, freshwater, and marine ecosystems. Their key functional role within Antarctic communities is in primary production, decomposition, and nutrient cycles. Microorganisms play an important role in global nutrient cycling, for example, in the nitrogen cycle. Abiotic transformation of nitrogen is extremely slow, whereas microbial oxidations and reductions are rapid, so microorganisms are responsible for the fixation of nitrogen and for the nitrification and denitrification of nitrogen compounds. They are also key components of the other nutrient cycles including the carbon and sulphur cycles and in the mineralization of organic waste, for example penguin and fur seal excrement.

Microbiology as a science has been conducted in the Antarctic since the first half of the twentieth century, although there has been significant understanding of Antarctic microbial ecosystems only in the last 20 years, as techniques developed elsewhere have been applied to Antarctic ecosystems. This is primarily because microbiology progresses in significant bursts largely associated with the development of new techniques and the application of new technologies, such as the invention of the microscope, the development of specific cultivation techniques, the invention of new methods for micromanipulation, novel biochemistry such as the polymerase chain reaction (PCR), or more recently through the application of *in situ* methodologies.

Microorganisms can be classified into a number of kingdoms or phyla. These classifications are not all universally agreed, but broadly consist of viruses, Archaea, Eubacteria, Fungi and Microsporidia, Alveolata, Stramenopila, Rhodophyta, green algae, and Protista. The viruses are relatively simple obligate intracellular parasites, and generally consist of either a single or double stranded DNA or RNA molecule, associated with a number of specific viral proteins. The Eubacteria are single-celled organisms lacking any membrane-bound organelles, including a nucleus, and are typically <10 μm in size. In the Antarctic, this group is largely represented by Cyanobacteria, Proteobacteria, and Gram-positive bacteria. The Archaea are another prokaryotic group like the Eubacteria but with uniquely structured membrane lipids; they are a very diverse group, both in terms of their morphology and their metabolic activity. The Fungi are nonphotosynthetic eukaryotes with chitin-containing cell walls, and include the generally unicellular yeasts. Algae have been separated into three phyla with the red algae placed in the rhodophyta, the green algae in the viridiplanta, and the brown algae in the stramenopila. This last phylum also includes a diverse range of microbial life, including the diatoms and water moulds. The classical protozoa are currently split between a number of phyla and unassigned subphyla. There appears to be considerably less endemism and geographic restriction of micoorganisms than there is for larger organisms, and in broad terms the colder regions of the world are populated by the same genera of microorganism as found elsewhere, and include all microbial processes, but these processes take place at a slower rate than in warmer environments—stopping altogether when cellular water freezes.

Microorganisms are very different from animals and plants, with a biomass many orders of magnitude smaller than any macroscopic metazoan or higher plant. However, an equally important characteristic of free-living microorganisms is their extraordinary abundance. Commonly, much greater numbers of bacteria and protozoa are found in natural systems than larger organisms. Microbial population sizes in the natural environment are, in relative terms, astronomically large, with more than 1,000,000 bacteria or 1000 flagellated protozoa per millilitre of freshwater. High abundance also has important implications for natural dispersal, because it raises the probability that representatives of each species may, for purely statistical reasons, be frequently transported—even over large distances. Microbial species may, potentially, be ubiquitous. They may be carried on the feet and damp feathers of penguins and other birds, or, like fungal spores, and even bacteria, be carried in wind or convection currents high into the atmosphere and transported thousands of kilometres. Less dramatically, microbes will be continuously transported in melt waters and in innumerable other ways. As has been found elsewhere, when there are no effective barriers to the dispersal of free-living microbes, speciation is rare. The total number of novel microbial species will be relatively small, and so local species richness will, as a general principle, reflect global species richness. However, this has yet to be established for the Antarctic, where the vast majority of microorganisms have yet to be identified.

Particularly abundant groups of microorganisms identified in microbiological studies in the Antarctic include the cyanobacteria (photosynthetic bacteria), lichens (symbiotic associations between a cyanobacterium or an algae and a fungus—particularly well adapted for life in the most extreme environments as the symbiosis makes them widely trophically independent of substrate type), psychrophilic bacteria (bacteria which grow between 0°C and 20°C and have an optimal growth temperature of 15°C or less), psychrotolerant bacteria (bacteria with an optimal growth temperature between 0°C and 5°C and at a maximum above 25°C), and psychrotrophs (can grow at low temperatures such as 0°C, but have an optimum in the mesophile range of 20°C–40°C). Obligate psychrophilic bacteria are unable to grow above 20°C, facultative psychrophiles are capable of growth at low temperature, but also grow above 20°C. Among cold-adapted microorganisms, psychrotrophs tend to dominate in environments that undergo thermal fluctuations. True psychrophiles have a more restricted growth range and are found in permanently cold habitats. However, even in permanently cold environments, >50% of the bacteria are not psychrophilic. In global terms, psychrotrophs are much more widely distributed than psychrophiles. From permanently cold habitats in the polar regions, the psychrophilic alga *Raphidonema nivale* and the fungus *Sclerotinia borealis* have been isolated. Among terrestrial psychrophiles are members of the genera *Pseudomonas, Cytophaga,* and *Flavobacterium* (each commonly encountered in the freshwater lakes of Signy Island).

Antarctic microorganisms include autotrophs (organisms that are able to use simple carbon compounds such as carbon dioxide gas as a source of carbon, and light as a source of energy), heterotrophs (feeding on living or dead organic matter), and chemoautotrophs (obtaining energy by oxidizing simple organic molecules). Many microorganisms, which grow and survive in extreme Antarctic environments, could be classed as extremophilic. Extremophiles are microorganisms that live under extreme conditions, where they not only tolerate the extreme but have an obligatory requirement for it, as they are frequently associated with adaptations to dry, nutrient poor, osmotic, and high light stress including high-ultraviolet-light environments, and compete badly with more cosmopolitan genera under more benign conditions elsewhere. Microorganisms show a variety of different tolerances to the degree of freezing and have evolved a number of different methods for dealing with the problem. These include spore formation (a more resistant form in the life cycle); influencing the external environment, such as the production of extracellular materials that reduce or prevent ice formation; increasing cell permeability and changing membrane fluidity to withstand expansion and contraction stress brought about by water loss; and rehydration or increasing solute concentration to depress the freezing point of intracellular fluid. Other factors that affect microbial growth in the Antarctic include substrate availability (including both growth substrates and terminal electron acceptor availability), the presence of competitors and antagonists, light availability (in terms of its intensity, spectral composition and duration—particularly for the autotrophs), high-energy ultraviolet radiation damage, temperature, pH (hydrogen ion concentration), pressure, osmotic potential and water availability, predation, dissolved gases, the presence of organic matter, micronutrients, and space available for growth.

A particularly important group of microorganisms that have not received much attention are the viruses. Considerable evidence exists to suggest that viruses are key components of many microbial communities, yet relatively little attention has been paid to their role in either terrestrial or aquatic Antarctic ecosystems. Elsewhere, studies of virus communities in microbial ecosystems have demonstrated that viruses can influence community structure, productivity, function, nutrient cycling, and food-web interactions. It has also been suggested that viruses have a role in the maintenance of biodiversity, the control of population size, the clonal composition of populations and genetic exchange. In spite of this, very few studies of viruses in Antarctic ecosystems have been conducted to date, yet the subject has enormous potential for answering some of the very fundamental questions of microbial ecology.

Habitats for microbial growth in the Antarctic are surprisingly diverse. The Antarctic continent is thermally and biogeographically isolated from the subtropics by the Antarctic Circumpolar Current, a global ring of cold water that contains complex frontal features and upwelling and downwelling cells. The Polar Front separates the Atlantic, Indian, and Pacific oceans from the Southern Ocean and the temperature discontinuity associated with it can be a barrier to migration and free flow of organisms. Thus, the Southern Ocean has its own unique characteristics; for example, upwelling of nutrient-rich water results in primary productivity that constitutes nearly one-third of the oceanic total. About two-thirds of the silica supplied annually to the ocean is removed by siliceous microorganisms in the Southern Ocean. The Southern Ocean can be subdivided into a number of characteristic environments: the pelagic and benthic environments, both deep-sea (with associated hydrothermal vents and cold seeps) and shallow areas including the sediment. The icebergs, seasonal and permanent sea ice, and ice shelves all contain microorganisms (for example, *Polaromonas vacuolata*) and harbour their own sets of microbial niches including melt pools. The bacterioplankton of polar seas is of about the same density as that of temperate waters, usually within an order of magnitude of 10^6 cells mL^{-1} and correlated with phytoplankton biomass. It consists of both psychrophilic and psychrotolerant bacteria. Organic substrate utilization increases by 30% when the temperature is raised from about 2°C to 5°C, but is inhibited above this. Although the overall metabolic activity of the bacterioplankton is heterotrophic, the biochemical details have yet to be established. The near-shore marine ecosystem includes shallow seas, nutrient upwelling, freshwater and nutrient run-off from the land, and includes rocks and rudimentary soils with varying degrees of salinity and marine nutrient input. On rocky shores, microhabitats may provide shelter from wave action, desiccation, predation, and insolation. Sediments may contain gradients of reducing activity if they become anaerobic. Marine mammals, such as fur seals, and birds, such as penguins, come ashore and deposit marine-derived nutrient into the Antarctic terrestrial system.

Terrestrial habitats for the growth of microorganisms are diverse and microorganisms have been found to exist in the upper layers of the ice sheet, and microorganism fossils have even been found in deep ice cores. Antarctica is the fifth largest continent, comprising about 10% of the Earth's land surface area. It is the highest, driest, windiest continent, yet contains a surprising diversity of habitats for microbial colonization and growth. Specific habitats include soils, some of which are saturated with minerals (soils can also be separated according to the presence or absence of vegetation—the microbiota of vegetated soils generally resembles the microbiota of soils everywhere), rocks, lithic, including hypolithic and endolithic communities (for example *Gloeocapsa* sp.), chasmolithic (in the cracks and fissures of weathered rocks), cryptoendolithic (in the interstices of porous rocks), sediments (both oxic and anoxic), cryoconite holes, ice, snow, meltwater, freshwater lakes, saline lakes, hypersaline lakes, streams and flowing waters, regions subject to volcanic activity (for example, Mount Erebus), and the air itself. Another notable habitat is subglacial lakes: accretion ice forms, and above Lake Vostok almost 4 km below the ice surface, both prokaryotic and eukaryotic microorganisms have been found in a spectrum of sizes and morphologies. These include heterotrophic bacteria in modest numbers, but with a comparatively low diversity including the alpha and beta proteobacteria; spore-forming bacteria, for example, *Bacillus* sp.; low and high G + C content Gram positives; Actinomycetes; Cytophaga-Flavobacterium-Bacteroidetes group; fungi; yeast; and microalgae. Strong gradients in both physical and chemical parameters within the environment produce sharply defined zonation in many Antarctic microbial communities. Superimposed on this spatial heterogeneity, there is also a temporal heterogeneity with a strong degree of seasonality (which can vary from 24 hours of daylight to 24 hours of darkness). Indeed, in many Antarctic limnetic systems, microorgansisms may be enclosed beneath an ice cover all year round (and therefore subject to a high degree of chemical and physical stratification, leading to a large number of potential microbial niches for colonization). The nutrient, poor status of the vast majority of Antarctic ecosystems, together with constant low temperatures, a short ice-free growing season and, of course, the Antarctic isolation factor, significantly influence microbial biodiversity in these systems.

Specific techniques used in the study of Antarctic microbiology are diverse and include direct microscopy, which can involve the use of specific stains, pure culture, direct isolation, isolation following enrichment, cultivation, preservation, direct culture under a variety of temperature regimes (which specifically excludes viable but yet to be cultivated microorganisms), serological methods, substrate utilization tests, antibiotic sensitivity and assay tests, molecular biology (particularly for taxanomic studies—the analyses of 16S rRNA and the use of PCR have become common in the investigation of the spatial distribution of microbial taxa in the natural environment that have not been grown in culture and is increasingly applied to Antarctic communities) and the use of fluorescent probes. With the advent of molecular identification techniques based upon the 16S rRNA gene, sequence information has become widely available for nearly all of the validly described prokaryotes. As this information grows, the understanding of evolution and potential endemism in Antarctic microorganisms is growing. Indeed, the importance of the cyanobacteria in Antarctica could be seen as an analogue for the early evolution of life on Earth and could thus be a good proxy for its study.

Key microbiological research sites in the Antarctic tend to be those readily accessible from established research stations, for example, Alexander Island from Rothera research station (UK), the Dry Valleys from McMurdo research station (USA), the Vestfold Hills from Davis research station (Australia), the Larsemann Hills from Zhongshan, Progress or Laws bases (China, Russia, and Australia respectively), King George Island (various) or from ships on marine cruises. An important feature of Antarctic microbial communities is that they form the end point of an environmental continuum from the tropics to the poles.

The microbiological research activity conducted in the Antarctic includes the impact of humans and human activity on the Antarctic environment (as humans have only recently been active to a significant degree on the continent), propagules from non-Antarctic sources can potentially arrive on the boots of expeditions and scientists, in the ballast tanks of ships, and through the waste material generated by human activity. In addition, human populations on remote Antarctic research stations can be used in medical research such as for epidemiological studies. Biotechnology is important in the potential for exploitation of Antarctic microorganisms or indeed microbial communities such as established biofilms for low temperature activity of enzymes, as a source of novel metabolism for bioremediation or low temperature biotransformations. A specific example is the mechanism by which bacteria from Antarctic sea ice produce polyunsaturated fatty acids. The study of Antarctic microbial communities may offer new insights into the molecular basis of cold adaptation, including cold-adapted enzymes such as psychrophilic carbohydrase and antifreeze proteins, a better understanding of the microbial cold stress response, overwintering strategies, protective pigment synthesis, and the response to ultraviolet radiation damage. The presence of the Antarctic ozone hole, which expands and contracts seasonally, ensures that Antarctic microorganisms receive unusually high doses of ultraviolet radiation for extended periods.

The relative isolation of the Antarctic continent makes it ideal for the study of microbial biodiversity, biogeography, evolution, migration and gene flow (for example, the transport of microbial inocula by birds), genetic variation, population genetics, and environmental genomics. It has been suggested that Antarctic ecosystems are of relatively low complexity with short food chains and limited biodiversity. Whilst this is still a subject of debate, if it is proved to be the case, Antarctic microbial communities would form ideal models with which to study ecological interactions, food web dynamics and microbial predator-prey interactions. In its most simplified case, the lakes on Signy Island, for example, do not contain fish (removing one of the key higher predators). Elsewhere there are no higher plants (such as trees) or in many cases animals. Such systems are dominated by the microbial loop.

It has been shown recently that the Antarctic Peninsula is subject to relatively rapid temperature rises, and so forms an ideal place to study the effects of global climate change, particularly with respect to changes in patterns of biodiversity and nutrient cycling. The conditions under which the microbial communities exist may act as a proxy for studies of the potential for life elsewhere in the solar system such as Mars or Europa, and indeed, for the development and testing of novel life detection systems. The potential exists within the Antarctic for the discovery of novel microorganisms. With an estimated 1,000,000–100,000,000 prokaryotic species believed to exist, to date less than 1000 have been described. So we are a very long way from a complete species inventory. The Antarctic provides a number of perhaps unique niches for the colonization of potentially highly specialized microorganisms, and these include subglacial lakes (such as Lake Vostok), microbial mats, endolithic communities, and even historic expedition huts (which have been found to harbour wood-decaying fungi). As evidenced by the discovery of Tomato mosaic tobamovirus in an ice core from Greenland, the Antarctic may act as a seed bank, the ice containing propagules of viable species that might be released following a rise in global temperature and an accelerated melting of the polar ice caps.

Bipolar comparisons in microbiology offer important insights into which species are ubiquitous in their global distribution or which might be endemic to a particular environment, especially as the Arctic consists of an ocean surrounded by land masses, whereas the Antarctic consists of a land mass surrounded by an Ocean. By understanding anthropogenic changes in the Antarctic ecosystem and comparing them to analogous communities elsewhere on the globe such as high altitude, Alpine, or permafrost environments, scientists can deduce whether particular human activities such as industrial processes and nuclear power are having a local or global impact (as there is no industry in the Antarctic). Bipolar comparisons have already been made between bacterial communities in pack ice, sea ice, marginal ice zones, sea water, mat forming cyanobacteria, and deep-sea sediments.

Antarctic microbiology, therefore, is a field that has been growing rapidly over the last 20 years, and as new studies are published, the subject is increasingly contributing to understanding the role and function of microorganisms in both low temperature and extreme environments, including information on nutrient cycling, gene flow, evolution, biogeography, biodiversity, and ecosystem function.

MINERALIZATION

Antarctica is often called the El Dorado or the treasury of the world. Why is there such a strong belief in the mineral wealth of Antarctica? Two reasons might be mentioned:

1. Antarctica ($\sim$11.9 million km^2) is larger than Europe or Australia. Theoretically, with respect to the size of other continents and the number of mineral deposits they have revealed so far, there should be more than 900 deposits in Antarctica.
2. Antarctica's mineral wealth is still untouched; the resources have not yet been mined as they have been for centuries on all of the other continents.

Human activity in the Antarctic is regulated. According to Article 7 of the Environmental Protocol to the Antarctic Treaty, *any activity relating to mineral resources, other than scientific research, shall be prohibited*. This is valid for at least 50 years after coming into force in 1998. Besides this political ban on mining, there are numerous reasons for scepticism concerning the feasibility of exploitation. At present, any mineral showings or deposits can only be appraised as not economically exploitable. The Antarctic is outstanding in many aspects: It is the coldest, windiest, most remote, inaccessible, and hostile continent. The shelf is very narrow and deep. For comparison: The Arctic shelf down to 500 m water depth is 4.4 times larger than the Antarctic shelf. Less than 2% of the Antarctic continent is free of ice: average ice thickness, 2100 m; maximum measured, 4776 m. Antarctica is the geologically least known and environmentally best protected continent. All these superlatives have a negative impact on any exploration and exploitation. As no exploration or mining can be conducted through the ice cap, the number of 900 theoretical deposits has to be reduced drastically to about 20 "ice free" deposits.

The Dufek Massif south of the Ronne Ice Shelf is probably the second largest layered intrusion (after the Bushveld Massif). It is thus prospective for nickel, cobalt, chromium, vanadium, and platin group elements (PGE), although the base of the intrusion, the most prospective part for these metals, is not exposed.

The Antarctic Peninsula, which represents geologically the southward extension of the Andes, is prospective for nonferrous metals like copper, silver, gold, and molybdenum. Small showings have been described from the Antarctic Peninsula (e.g., the low-grade porphyry mineralizations of copper, iron, lead, and molybdenum sulfides or oxides in alteration zones of the Copper Nunataks [Lassiter Coast], or gold and silver mainly as accessory minerals in stockwork and vein mineralizations on Stonington Island). Although the Antarctic Peninsula is considered part of the Andean province, where large porphyry copper deposits (e.g., El Teniente, Chuquiquamata) occur, one has to emphasize that the Cenozoic tectonic development of the Andes and the Antarctic Peninsula differs considerably.

Coal is known in the Transantarctic Mountains and the Beaver Lake area (East Antarctica), and iron ore in the Prince Charles Mountains. Both bulk commodities are of absolutely no commercial interest. Only large deposits with high-grade ores of high-value commodities could have a chance to be above the pay limit in future, but these deposits are not yet discovered.

MINKE WHALE (ANTARCTIC MINKE WHALE)

Name

Although minke whales had been classified as only one species of *Balenoptera acutorostrata* until the late 1990s, its taxonomy has recently been rearranged. Two separate species have now been recognized in the Southern Hemisphere. Minke whales in the Antarctic are now recognized as *B. bonaerensis* with the common name of "Antarctic minke whale." Elsewhere in the Southern Hemisphere, the dwarf minke whale is the recognized species, and this is currently classified as a subspecies of the Northern Hemisphere minke whale, *B. acusutara.* However the taxonomic status of these species is still pending. The dwarf minke whale can be recognized from white pigmentation on the shoulder that is absent from the Antarctic minke whale. The Antarctic minke whales are mainly reviewed here.

General Appearance

While Antarctic minke whales are the smallest species among rorquals (general name of genus *Balaenoptera*) in the Antarctic, they grow up to 10 m in body length. However, usually body lengths at attainment of physical maturity are 9.0 m and 8.5 m for females and males respectively. Approximate body weights at that stage are 8.0 and 7.0 tonnage for females and males respectively.

Compared with other rorquals, the minke whale has a relatively small, triangular-shaped head (25% to body length) and pointed rostrum. The body color is black or grey and white ventrally. A pair of crescent-like streamline marks of pale color runs from the ear to the anterior base of the flipper on both sides of the shoulders. Similar streaks of slightly weaker color can sometimes be seen above the posterior parts of fore-flippers. The most characteristic feature is that the Antarctic minke whales lack the white color patch on the fore flipper, which is common coloration in other minke whales of both hemispheres. The dorsal fin is large and curved. Tail flukes are half-moon shaped with a central notch on the posterior margin. The tail flukes are black on the dorsal surface and usually white on the ventral surface. On the throat, there are about forty-five ventral grooves that run from the tip of the lower jaw to just anterior of the umbilicus.

The Antarctic minke whales have a series of 260–360 baleen plates in the palate, on both sides of the inner surface of the rostrum. The maximum length of these plates is about 30 cm, with the longest plates occurring at about one-third along the length of the plate series from the posterior. The outer colorations of the plates are not bilaterally symmetrical. The plates are creamy white with a black belt at outer margins of all the plates on the left side and the posterior two-thirds of the plates on the right side. The plates of the first one-third of the right side are entirely creamy white.

Population Status, Distribution, and Habitat Use

The minke whale occurs mainly to the north of the Polar Front (located at 55° S–60° S) and the Antarctic minke whales is found to the south of the convergence, especially in the region 60° S to ice edge in the middle of summer. Although minke whales are especially highly concentrated in some localities such as the southern Ross Sea, they are found throughout Antarctic waters. Minke whales migrate regularly to high latitudes in summer, probably mainly to feed along ice edge where there are nutritionally rich areas. Mature/pregnant females have a greater tendency to be in waters close to the ice edge.

The population status has been assessed by scientific committee of the International Whaling Commission (IWC) through its international research project of IDCR (International Decade of Cetacean Research) and subsequently by SOWER project (Southern Ocean Whale and Ecosystem Research). Generally, the Antarctic minke whales are considered to be the most robust whale stock in the Antarctic. The IWC Scientific Committee agreed an abundance estimate of the Antarctic minke whales of 760,000 individuals south of 60° S based on the second circumpolar IDCR assessment cruises in 1985–1986 to 1990–1991. The third circumpolar survey was completed by the 2003–2004 season and the assessment is now being conducted using those data.

Life History

Breeding occurs at the low-middle latitudes in the austral summer. The breeding grounds are thought to be in waters off the northeastern coast of Brazil, western coast of South Africa, and northeastern and eastern coast of Australia. Antarctic minke whales are born at 2.85 m in average body length after 10.5–11 months gestation. There is no bias in the foetal sex ratio and the litter size (number of fetuses conceived) is invariably 1.0. The mean calving interval is 1.28 years (or annual pregnancy rate of 0.78). Most of the calves probably wean at about 3 to 4 months of age at a body length of about 4.5 m.

Lengths at sexual maturity are 7.9 m and 8.2 m for males and females respectively, which appear not to vary with respect to nutritional condition. Age at sexual maturity has changed with nutritional condition: in the 1940 cohort it was 11–12 years, but had declined to 7 years in the 1970 cohort. This decrease took place before exploitation in early 1970s and was thought to be the result of an increase in the growth rate of the minke whales due to declines of their ecological competitors including other rorquals. Growth of body length continues until 25 years for both sexes. The maximum known ages among the samples is 50 years.

Social Structure

There has been no direct observation on both mating and calving and therefore little is known about breeding behaviour, though minke whales are generally thought not to be highly social animals. In the Antarctic, the minke whales usually occur with a small school size consisting of two or three animals, although there are some reports of larger aggregations up to 400 individuals.

Diet and Tropic Interaction

The Antarctic minke whales mainly feed on euphausiids and are highly dependent on the Antarctic krill *(Euphausia superba)* in the main feeding ground. Their feeding activity is thought to peak in early morning, probably near daybreak. It is estimated the minke whales' daily food consumption corresponds to 4%–5% of total body weight.

As mentioned, minke whales may compete ecologically with other rorquals for food and habitat, and this may have been the underlying factor causing changes in the age at sexual maturity of the minke whales.

Economic or Nutritional Use

Exploitation of the Antarctic minke whales has been regulated by the IWC and there has been no sign of depletion. Although several countries such as Russia, Brazil, South Africa, and Japan have taken some minke whales in recent years, substantial exploitation occurred between 1971 and 1987. Japanese and Russian whaling fleets took annual catches of 4969–7900 through this period.

Because the IWC adopted a moratorium on commercial whaling for all stock of large whales in 1982, there were no commercial harvests of minke whales after 1987–1988 in the Antarctic. In that year, Japan started a specially permitted research program (JARPA) that included the harvest, for scientific purposes, of up to 330 minke whales per year. The number taken under the JARPA program was increased to 440 individuals after 1995–1996.

MOLLUSCS

Currently, more than 700 hundred species of molluscs are described from Antarctic waters, and, as Antarctic exploration continues, more species are discovered every year. All eight molluscan classes have been recorded. The pelagic realm is inhabited by squid, vampyrimorph octopodi, and a few ophistobranch gastropods, but those most commonly seen by human visitors to the region are likely to be pteropods swimming in surface waters. The benthic realm contains a diverse malacofauna: spiky, wormlike Caudofoveata and Solenogastres; eight-shelled, armour-plated polyplacophorans (chitons); limpetlike, multigilled monoplacophorans; shelled and shell-less gastropods, bivalves, and elephant tooth–like scaphopods; and eight-legged octopodi. Molluscs can be found from the intertidal, sitting on rocks and seaweed, to the deep sea. The deepest record for a living bivalve collected is from 6300 m. Their abundances can vary from one to several thousands per square metre.

Antarctic shells differ from those more familiar from low latitudes in a number of ways. More than 80% of the shelled species are less than 2 cm in size. The shells are very thin, in small species nearly transparent. One reason for these thin shells might be that shell-crushing predators such as crabs and lobsters are almost absent. Compared with tropical shells, their Antarctic cousins are missing prominent scales, spines, and patterns, not only in shell form but also in colour. Dominant shell colours are green-brown for protobranch bivalves and white for all others; colours like yellow, orange, pink, and purple, as seen in many temperate gastropods like in topsnails, are rare.

Most (~90%) molluscs that are known from the Southern Ocean occur only in this region, that is, they are Antarctic endemics. Molluscs are not evenly distributed around Antarctica. There are hotspots of species richness at the tip of the Antarctic Peninsula and on the eastern shelves of the Weddell and Ross seas. These patterns of species distributions are a result of evolutionary processes in relation to Antarctica's geological and climatological past. Since the cooling of Antarctic waters (about 35 Ma), groups like the edible bivalves Veneridae and Cardiidae (cockles) have disappeared and have only left their fossil remains. Other groups like the carnivore gastropod families Buccinidae (whelks) and Turridae evolved and split into several, specialised genera and species (adaptive radiation).

Typically, reproduction by Antarctic molluscs takes place over a considerable period, and they produce relatively few, large eggs. Many species brood their offspring in special brood pouches and release juveniles. Others, especially gastropods, attach egg masses to the substrate, in which the offspring develops until they hatch as young adults. While comparable reproduction processes take weeks to a few months in tropical and temperate regions, they take a year to several years in Antarctica. Freshly laid egg masses of the Antarctic whelk *Neobuccinum eatoni* were observed in aquaria more than 12 months before juveniles hatched. Antarctic molluscs invest a lot of energy into their offspring. Studying a 1-mm long specimen of the limpetlike monoplacophoran *Leavipilina antarctica,* three juveniles of 0.3-mm shell length were discovered in the tip of the shell. Famously, amongst marine biologists, Thorson's rule concerning the rarity of planktonic development at high polar latitudes was constructed from work on molluscs.

MOSSES

Mosses belong to the Plant Kingdom Division, or Phylum Bryophyta, which comprises six Classes, of which the Andreaeopsida, Polytrichopsida, and Bryopsida are represented in the Antarctic. Until a recent revision, mosses, and their close allies the liverworts, were both classified as comprising the Bryophyta. However, liverworts are now treated as a separate Division, the Marchantiophyta.

Mosses and liverworts belong to the group of spore-producing plants known as cryptogams (in contrast to the flowering and seed-bearing phanerogams). The fundamental difference between mosses and liverworts is that moss leaves, while tiny, are entire and those of liverworts are variously shaped, from entire and often rounded to bi- or many-lobed; in some genera they have a flat strap-shaped thallus rather than a leafy shoot. Moss leaves generally have a central strand of cells (midrib) that is absent in liverworts. The life cycle of both mosses and liverworts has two stages: a vegetative stage (gametophyte or leafy shoot), which bears the gametangia that give rise to the sexual stage (sporophyte). The latter comprises a spore-producing capsule borne on a short stalk (seta). It is the leafy shoot that is the typical "moss" or "liverwort" plant. Thus the capsule releases spores that germinate to form a branched filamentous protonema from which a leafy gametophyte develops. Male (antheridium) and female (archegonia) structures form on the shoot, sperm cells are released and fertilise the egg cell to form a zygote. This divides by mitosis to form the sporophyte. Meiosis occurs in the capsule resulting in the formation of spores. Bryophytes contain chlorophyll and assimilate carbohydrates for growth through the process of photosynthesis, just as flowering plants do. Their anatomy is very simple and most water uptake is by absorption through their leaves from both ground water and atmospheric water (precipitation and mist). While many species grow in wet or submerged habitats, many also occupy extremely dry habitats, obtaining their moisture from the very rare precipitation events. The latter category is well adapted to extreme conditions of temperature and desiccation.

Growth-Forms

Mosses have two principal morphological forms (growth-forms) comprising many individual leafy and usually branched shoots, the whole structure being referred to as a colony of shoots. Acrocarps (short erect colonies) tend to grow in drier habitats, while pleurocarps (prostrate spreading colonies) generally occupy moist or wet habitats. Amongst the much more prevalent acrocarps are several growth-form variants, such as cushions (with shoots radiating from a central point, typical of rock substrates) and turves (shoots arranged vertically and parallel, typical of soil). Most species are loosely attached to their substrate by a mass of rootlike rhizoids. The pleurocarps grow as a mass of intertwined shoots to form carpets (on wet ground) and finer wefts (in shaded wet rock crevices and overhangs), and usually lack rhizoids.

Physiology

Because of their simple anatomical structure without specialized water conducting tissues (a few species have a rudimentary conducting system), mosses and liverworts derive their water and nutrients passively and uncontrollably through their leaves and stems. Conversely, they have no control over water loss during dry or sunny weather. Nevertheless, Antarctic species are well adapted to their low-temperature environment, often with a very intermittent supply of liquid water, which is essential for fertilization and physiological processes. Carbon dioxide fixation (photosynthesis) and the formation of carbohydrates required for growth and reproduction can take place at low temperatures (the typical optimum being

10°C –15°C), in some species at or just below freezing point. During spells of brilliant sunshine the high solar irradiance, combined with high colony temperature and desiccation, photosynthesis ceases (photoinhibition). Growth is therefore continually being interrupted, and the annual shoot increment is seldom more than a few millimetres. While most mosses are a shade of green, some xeric species growing in very exposed (especially to solar irradiance) habitats are dark colored. These genera (notably *Andreaea, Ceratodon, Grimmia, Schistidium*) synthesise ultraviolet-protective pigments.

Moss reproduction responds to physiological and environmental stress by switching from sexual to asexual means when conditions become progressively less favourable. Relatively few species produce sporophytes, and even more rarely viable spores, although a few do so regularly. The more common method of colonization is by vegetative propagules varying from detached fragments of shoot to specialized structures which develop into new plants.

Species Diversity and Biogeography

Mosses, together with lichens, are the visually predominant terrestrial life form in the Antarctic, particularly in the wetter maritime Antarctic and coastal areas around the continent. However, many species are xerophytes (growing in extremely dry windswept habitats) colonizing rocks and arid soils. A recent revision of the moss flora of the Antarctic, including the South Sandwich Islands and Bouvetøya (climatically and biologically an extension of the maritime Antarctic) describes a total of 113 species, of which about 18 occur in continental Antarctica. Considering the area of the Antarctic biome (biological region), the moss flora is very small; a similar number could be found in 1 hectare of forest or mountain elsewhere in the world. As with the lichens, no Antarctic moss species have common names. Many species have a southern South American or New Zealand distribution, and a number are bipolar. Some of the commonest and most widespread have a cosmopolitan or global distribution (e.g., *Bryum argenteum, B. pseudotriquetrum, Ceratodon purpureus, Pohlia nutans, Sanionia uncinata,* several species of the family *Polytrichaceae*). Many species appear to be very rare in the Antarctic and several are restricted to the unique geothermal habitat associated with volcanic activity at a very few sites (see below).

Throughout the northern maritime Antarctic the current trend of regional climate warming has caused substantial recession of ice field and glacier margins and thickness since the mid-twentieth century. This has revealed many subfossil (a few hundred to several thousand years old) moss turf banks. These have retained their original structure and the component species are still readily identifiable. However, there is no evidence that any species existed earlier in the Holocene that do not occur at present.

Ecology of Moss-Dominated Communities

Few moss species develop pure stands of more than a few square metres, although different groups of mosses, often with associated lichens and occasionally liverworts, typically combine to form distinctive communities. These communities are dependent on the geological nature of the local rock and soils derived from them, degree of shelter and local microclimate, availability of moisture, and soil stability (i.e., free from frost heave activity, erosion, sea bird, or seal impact, etc.). Some species have a wide ecological amplitude (catholic in their habitat preference, such as *B. pseudotriquetrum, Pohlia nutans, Sanionia uncinata*), while a few are very selective and prefer specific environmental conditions or substrates (e.g., *Dicranella hookeri, Philonotis acicularis* associated with steam-emitting fumaroles in volcanic areas; *Muelleriella crassifolia* on rocks within the spray zone of coastal rocks; *Schistidium rivulare* on rocks in streams).

The most extensive stands of moss, sometimes covering more than a hectare, occur in the maritime Antarctic region, with the largest continuous expanse of closed moss vegetation (predominantly *Sanionia uncinata*) being on Aitcho Island, South Shetland Islands. Depending on habitat features, communities dominated by one or more species predominate. Here, in the absence of serious competition from other bryophytes and vascular plants, certain mosses attain virtually monospecific status and develop almost pure closed stands of several hundred m^2; elsewhere, two or more species may codominate. It is a feature of the Antarctic moss flora that no more than a dozen species frequently attain widespread dominance over more than about 25 m^2. However, many species may do so on a small scale by forming almost pure patches of a few m^2 within more complex communities. Habitats with relatively stable conditions tend to have low species diversity, but increasing habitat variability, such as typify fellfield or feldmark (rocky glacial terrain, typically windswept, dry and disturbed by freeze-thaw action, and sparsely colonized by vegetation), and sites of variable small-scale geology (e.g., at Signy Island), lead to increased species diversity both in bryophytes and lichens, and create the most complex communities of the biome.

Wet habitats with impeded drainage in the maritime Antarctic are typically dominated by three carpet-forming pleurocarpous species *(Sanionia uncinata, Warnstorfia fontinaliopsis, W. sarmentosa),* while mildly calcareous seepage areas support, in addition, *Campylium polygamum*. Habitats subjected to moving water (margins of melt runnels, wet rocks, etc.) support large loose cushions of *Brachythecium austrosalebrosum* and *Bryum pseudotriquetrum* and, occasionally in the more northerly region, *Syntrichia filaris*. Seepage areas below melting snow fields in coastal continental Antarctica sometimes support large stands of *Bryum subrotundifolium*.

A unique community type of moist, well-drained rocky hillsides in the northern maritime Antarctic is formed by the tall turf-forming mosses *Chorisodontium aciphyllum* and *Polytrichum strictum*. These species have developed deep accumulations of peat rising 1–2.5 m above the surface of the terrain, and possessing permafrost below a microbially active layer of 20–30 cm below the living moss surface. The integrity of these moss banks is maintained by the dense rhizoid systems of the two mosses, but particularly by the wicklike tomentum of the *Polytrichum*. The surface of these moss banks is usually colonized by various lichens.

The most diverse and disparate moss-dominated communities are those of fellfields, where environmental conditions fluctuate greatly both diurnally and seasonally. The principal species are mainly those of short cushion and turf growth-forms, with occasional small mats of liverworts. Because of the generally dry nature of the terrain, many lichens coexist with the bryophytes. There is considerable variation in the communities of the maritime Antarctic, usually dominated by species of *Andreaea,* but with numerous associated short acrocarpous species (*Bartramia patens, Bryum* spp., *Ceratodon purpureus, Hymenoloma* spp., *Kaieria pumila, Pohlia nutans, Polytrichum* spp., *Bucklandiella sudetica,* and others). On calcareous, sandstone, and volcanic fellfield soils and gravels, physiognomically similar but floristically different communities occur. These are usually dominated by species of *Schistidium* and *Syntrichia,* with *Bryum* spp., *Ceratodon purpureus, Distichium capillaceum, Ditrichum* spp., *Encalypta* spp., *Hennediella* spp., *Pohlia cruda,* etc. as subordinate associates. Equivalent communities on continental Antarctica are basically similar, but with restricted species composition (e.g., *Bryoerythrophyllum recurvirostre, Bryum* spp., *Ceratodon purpureus, Didymodon brachyphyllus, Hennediella heimii, Sarconeurum glaciale, Schistidium antarctici*).

Peat-Forming Mosses

The dead lower parts of some mosses accumulate to form a type of peat. Only those mosses in wet habitats undergo a significant degree of microbial decomposition and the peat thickness is seldom more than about 10–15 cm thick. However, the moss banks formed by *Chorisodontium aciphyllum* and *Polytrichum strictum* in the northern maritime Antarctic are a unique feature of the landscape. These tall turf-forming mosses grow on relatively dry well-drained hillsides. The rate of organic matter decomposition is very slow and this allows the moss turf to accumulate. Once this peat exceeds about 30 cm depth, permafrost develops and prevents further decay below that level, while the upper living moss layer remains microbially active. This is not a true peat as it has undergone very little loss of mass and the structure of the dead moss turf remains intact. These peat accumulations develop above the surface of the terrain, usually with eroding vertical edges that give the features a distinctive mound shape. In places, the peat thickness is up to 2 m, notably in the South Orkney Islands and a few sites on the midwestern Antarctic Peninsula. They are rare in the South Shetland Islands, yet the deepest known peat deposit formed by these mosses is on Elephant Island, surprisingly at about the altitudinal limit for these phenomena. Radiocarbon dating of peat from the base of the deepest deposits gives ages of 5000–5500 years since the mosses became established.

Mosses in Extreme Habitats

Most habitats in interior continental Antarctica can be regarded as extreme, in terms of low temperature, prolonged drought, rapidly fluctuating thermal and hygric regimes, high and continuous summer solar irradiance, high ultraviolet-B radiation levels, and prolonged winter darkness.

Epilithic (growing on rock) mosses are absent from continental Antarctica, except in the Antarctic Peninsula region. At high elevations and at far southern latitudes mosses occur only as chasmoliths (growing in rock fissures) or on soil adjacent to rock or stones where there is slight moisture retention. In such habitats, they are exposed for long periods to temperatures as low as –40°C to –50°C in winter (no sunlight to warm the substratum, and often only a thin insulating cover of snow) and, more critically, a summer diurnal range of from 15°C–20°C (colony and substratum microclimate) to –30°C. As a probable response to extreme conditions, especially high UV-B levels, most of the few moss species have dark photoprotective pigments.

Only five bryophyte species have been reported beyond 80° S, all in the Transantarctic Mountains, southern Victoria Land *(Bryum pseudotriquetrum, Ceratodon purpureus, Grimmia plagiopodia Sarconeurum glaciale, Schistidium antarctici)*. The farthest south record is of *S. glaciale* Cape Smith (84°42′ S).

Five mosses have been recorded above 1500 m altitude, although two of these occur in the unique habitat provided by geothermal activity near the summits (>2500 m) of the three active volcanoes in Victoria Land (Mt. Erebus, Mt. Melbourne and Mt. Rittmann, see below). The highest known occurrences of mosses in unheated habitats are in several of the mountain ranges in Dronning Maud Land where *Coscinodon lawianus* and *Sarconeurum glaciale* occur at *c*. 2220 m at a site in the Heimefrontfjella. *Bryum argenteum,* has been found at 1540 m on Mt. McGee in Victoria Land.

Active volcanic areas in Antarctica are few, but all possess a unique habitat for bryophyte colonization. The porous ashy soil and scoria, in places directly influenced by geothermal activity and active fumaroles, are kept permanently warm and moist in an otherwise inhospitable environment, thereby permitting some immigrant spores and vegetative structures (propagules) to become established that are unable to do so if they are deposited on unheated substrata. Soil temperatures beneath thermophilic (favouring heated substrates) bryophyte communities are frequently within the range of 25°C–50°C. Three areas in the northern maritime Antarctic possess volcanically heated substrata. These occur between sea level and *c*. 500 m altitude on Bouvetøya (54°25′ S), most of the South Sandwich Islands archipelago (56°–60° S), and Deception Island in the South Shetland Islands (62°57′ S).

In the South Sandwich Islands geothermal habitats occur on Bellingshausen, Candlemas, Leskov, and Visokoi Islands. Around many of the fumarole vents, bryophytes have developed distinct zones, each usually dominated by one to several mosses and liverworts with numerous associated species. Species composition of these zones appears to be dependent on the temperature of the substratum, thereby creating a series of communities along thermal gradients. When ambient air temperatures have been c. 0°C–2°C, temperatures of 50°C within turves of *Campylopus* spp. and *Sanionia uncinata* have been recorded, while at the moss-soil interface (c. 2.5 cm beneath the moss surface), they reached 85°C, rising to over 90°C at 5 cm depth. Those bryophytes most commonly or typically associated with heated ground include the mosses *Bryum dichotomum, Campylopus introflexus, C. spiralis, C. vesticaulis, Dicranella hookeri, Ditrichum gemmiferum, Leptobryum pyriforme,* and *Pohlia nutans,* and several liverworts.

Geothermal areas on Deception Island also possess distinct assemblages of mosses. In less than one year following the 1967 and 1969 eruptions on the island, the cosmopolitan weedy moss *Funaria hygrometrica* was found on steaming ashy soil near the eruption centres. This was its first known occurrence in the Antarctic, although it disappeared within a year or two when the geothermal activity ceased. Distinct but usually sparse communities of mosses occur around fumarole vents, usually dominated by *Dicranella hookeri* and *Philonotis polymorpha.* Steam emissions from fumaroles are about 85°C–95°C, and temperatures within moss turf close to the vents can reach almost 50°C when the air temperature a metre above the ground is around 0°C.

Similar geothermal habitats occur at high altitude near the summits of the volcanoes Mt. Erebus on Ross Island, and Mt. Melbourne and Mt. Rittmann in northern Victoria Land. Here, at altitudes of over 2500 m, ambient conditions are amongst the most severe for life on the planet, yet volcanic activity provides a microenvironment favourable for the development of a very few bryophytes and numerous microalgae. The substratum is maintained continually at temperatures well above freezing, and usually >25°C. With air temperatures permanently below about –20°C, the temperature differential at the soil-air interface creates high humidity, often in the form of steam, which condenses to provide a source of warm liquid water. Steam, often sulphurous or with high levels of CO_2, also emanates from fumarole vents. Although these sites are in total darkness for many months in winter, they either remain snow- and ice-free or are covered by hollow ice-towers up to 3 m high, formed by rime frost crystals, and serving as heated "greenhouses." *Campylopus pyriformis,* a moss typical of geothermally heated soil elsewhere in the world, occurs at c. 3500 m near the summit of Mount Erebus, and at c. 2700 m on Cryptogam Ridge, Mount Melbourne. Temperatures amongst the moss turf ranged from 14°C to 31°C; at 15 cm depth they increased to 40°C–60°C. These are the only sites where *C. pyriformis* has been recorded in continental Antarctica. The moss *Pohlia nutans* occurs at another heated site on Mt. Melbourne, and also on heated compact clay at c. 2600 m below the crater rim of Mt. Rittmann. Temperatures between 25°C and 45°C have been recorded within these populations.

In many continental Antarctic areas several mosses exist in a highly unstable soil environment. They are capable of colonizing loose, porous sandy soils during early summer when they become moistened by melt water sufficiently to afford temporary stability and establishment. The species of such communities (including *Bryoerythrophyllum recurvirostrum, Bryum pseudotriquetrum, B. subrotundifolium, Ceratodon purpureus, Hennediella heimii*) are often buried by water-borne and wind-blown silt and sand to a depth of several centimetres for much of each year. Growth and photosynthesis continue during summer, beneath this protective and insulating mineral layer, as very low levels of light can penetrate the loose crystalline structure of the sand.

Submerged Habitats

A few mosses are restricted to an aquatic environment attached to the bottom sediment of lakes, but some are terrestrial species that have been washed or blown into the water and succeeded in adapting to a submerged lifestyle in the relatively stable thermal conditions. Some of these cover large expanses and achieve shoot lengths of 30–50 cm, far greater than any moss in a terrestrial habitat. The exclusively aquatic species have a remarkable distribution around the continent. *Drepanocladus longifolius* is a wet habitat species of southern South America that occurs in some lakes in the South Orkney and South Shetland islands to 9 m depth. *Plagiothecium orthocarpum* and *Wollnya wilsonii* are terrestrial species, also of southern South America. The former grows to 32 m depth in several lakes in Schirmachar Oasis, Dronning Maud Land, while the latter is found only in a few shallow lakes in Enderby Land where it forms benthic moss "towers" up to 60 cm high. *Bryum pseudotriquetrum,* a terrestrial moss with a global distribution, occurs in several lakes around continental Antarctica and in the maritime Antarctic. Some of these lakes are permanently covered with several metres of ice, including in Lake Vanda in the Dry Valleys of southern Victoria Land, where it grows to a depth of 31 m.

MOUNT EREBUS

Mount Erebus (77°32′ S, 167°10′ E; 3794 m) is Antarctica's most active volcano and the southernmost active volcano in the world. It dominates the skyline in McMurdo Sound and is at the center of Ross Island, the home to the United States McMurdo Station and the New Zealand Scott Base. Mount Erebus was discovered in 1841 by British explorer James Clark Ross, who named the volcano after one of his two ships. Ross noted that Erebus was erupting, "... emitting flame and smoke in great profusion...some of the officers believed they could see streams of lava pouring down its sides until lost beneath the snow." Mount Erebus was first climbed in 1908 by members of the British Antarctic *(Nimrod)* Expedition (1907–1909). Erebus is one of the largest volcanoes in the world, ranking among the top thirty in size (1800 cubic kilometers).

It has many unusual features, the most notable being a permanent convecting lake of molten magma with a temperature of 1000°C. The lake was discovered in 1972. By late 2004, this had become two lakes, each about 50 m in diameter. The magma and many older rocks on the slopes of the volcano are rich in sodium and potassium and have phonolite compositions. Early geologists referred to the rocks as kenyte, after Mount Kenya in East Africa, but subtle differences in the mineralogical compositions make this name inappropriate. Large anorthoclase crystals are ubiquitous in the Erebus phonolite and are amongst the largest crystals found in volcanic rocks anywhere on Earth. The crystals can exceed 10 cm in length and they take many different crystal forms. They are easily eroded from the soft glassy matrix of volcanic bombs erupted from the volcano and the crystals litter the upper slopes of the summit crater. During the 1970s, most of the 1980s and 1990s small eruptions were common from the Erebus lava lake and adjacent gas vents, occurring two to ten times daily. The eruptions occasionally throw volcanic bombs onto the crater rim. Since early 2000 eruptive activity has declined. Exceptional Strombolian eruptive activity started on September 14, 1984, and lasted 4 months. Bombs over 10 meters long were erupted and some smaller bombs landed over 3 km from the eruptive vent. More than 100,000 cubic meters of bombs and ash were ejected and some of this partially buried the lava lake. A small research facility just below the crater rim had to be abandoned.

The summit plateau surrounding the active summit crater is dotted with fumarolic ice towers formed when warm volcanic gases (which are mainly water) freeze in the cold ambient air temperatures. Ice caves underlie some ice towers and occur where the warm gases have melted the snow and ice that underlies the ice towers. Small areas of warm ground, some with temperatures of 68°C at 10 centimeters depth, are too hot to sustain ice towers but they do contain thermophilic microbiota and moss.

The most tragic accident in Antarctica's history occurred on November 28, 1979, low on the north slopes of Mount Erebus, when an Air New Zealand DC-10 aircraft on a sightseeing flight crashed, killing all 257 people on board.

MUSIC, ANTARCTIC

There is a limited range of Antarctic music, with very little written by those who have actually been there. The earliest music composed and performed *in situ* was on the British National Antarctic Expedition (1901–1904). "Songs of the *Morning:* A Musical Sketch" was composed on board the relief ship *Morning* by Lieutenant Gerald Doorly and Chief Engineer Morrison. Published in a small edition after the expedition, it has now been recorded.

More serious music had to wait until 1948, when the British classical composer Vaughan Williams composed the music for the film "Scott of the Antarctic." The film score faithfully follows the action of the film and ends in a triumphant outburst after the death of Scott. Later, Vaughan Williams revisited the story and decided to recast the music into a symphony. *Sinfonia Antarctica* (Symphony no. 8, 1952) used many of the original melodies, but the composer decided to end it differently, with a much lower key finale in which the wind howls outside the tent as nature reigns supreme. Vaughan Williams included extracts of Scott's last journal in his score, as well as parts of the Psalms and poetry by Donne, Shelley, and Coleridge. Some performances include these texts, spoken by a narrator.

The British composer Sir Peter Maxwell Davies was at the premiere of *Sinfonia Antartica* in 1953. Nearly 50 years later, he visited the Antarctic at the invitation of the British Antarctic Survey to experience it firsthand, as a condition of his commission to write a sequel to *Sinfonia Antartica. The Antarctic Symphony* was completed in December 2000 and had its broadcast premiere in London on May 6, 2001. The single-movement work offers jagged contrasts—suggesting, for instance, the crashing of icebreaking ships through the frozen sea set against the whisper of snowy avalanches. These contrasts are achieved through a balance of varied tempos and dynamics, with rumbling climaxes of brass and timpani alternating with long-phrased passages, some with shining strings over pizzicato cellos and others featuring a succession of woodwind solos. Sir Peter also fulfilled another commission with Antarctic music. Commissioned to compose for the fortieth anniversary of the National Association of Youth Orchestras, he did so with another "chilling" piece—*High on the Slopes of Terror*—the title coming from a line in the diary of Captain Scott. The score had its premiere in Glasgow on August 31, 2001, with Chethams Symphony Orchestra. Despite performances around the world, it is still not available on CD.

The *Antarctica Suite* by the Australian Nigel Westlake is perhaps more accessible than the music of

Maxwell Davies, being originally composed as film music. Part of the last movement ("The Ice Core/Finale") depicts the scientific study of ice, and the final coda is said to reflect the optimism attending the signing of the Protocol on Environmental Protection to the Antarctic Treaty. One of the strengths of Westlake's piece is the way the guitar, not naturally a *fortissimo* instrument, is balanced against the larger orchestral forces.

The centenary celebrations of the Scottish National Antarctic Expedition in 2004 included some new Scottish music. The Scotia Suite of Scottish Country Dances was devised by Roy Goldring and set to music by Muriel Johnstone. It includes seven dances: "Antarctic Bound," "Scotia Sea," "The Ice Cap," "Coats Land," "Bruce's Men," "The Piper and the Penguin," and "Spiers Bruce—The Pole Star." Music for the dances has been recorded by Neil Barron and his Band, and the accompanying CD also includes pipe music performed by Ian MacInnes and a musical suite "South," performed by the National Youth Orchestra of Scotland.

There are two other forms of Antarctic music—that based on natural sounds and popular music by a wide variety of singers and musicians meant to evoke aspects of the cold continent. Chris Cree Brown is a New Zealand composer whose two works—*Icescape,* for orchestra, and *Under Erebus,* an electroacoustic work—both resulted from a trip to Antarctica in 1999 supported by Antarctica New Zealand, and published by the University of Waikato under the CD title of *the New Zealand Sonic Art Vol II* (MDWU1201).

Music of the environment has been composed by Douglas Quin. His music and soundscape *Australis/Borealis: Sounding Through Light* combines the sound recordings and a chamber ensemble complete with chorus. Similarly, *Antarctica,* by the Canadian folk-singer Ian Tamblyn, uses true-life sounds as integral parts of his tracks, accompanied by piano, guitar, synthesizer, double bass, organ, and a variety of other instruments. His sounds include the wind, Weddell seal pups, Adélie penguins, a variety of birds in flight, the cracking of ice, and the much less natural shuddering and booms of icebreakers and helicopters.

Another piece of music entitled *Antarctica* is an electroacoustic composition realised in 5.1 cinema surround sound by the British percussionist Craig Vear. Vear spent the summer of 2003–2004 in Antarctica as the Arts Council and British Antarctic Survey artist in residence. *Antarctica* is a unique and intriguing combination of a nature documentary, an interwoven experience of wildlife and voices, a radio performance, and a film soundtrack.

Amongst the popular music is that from Koreyoshi Kurahara's film "Antarctica," composed and recorded by Vangelis in 1983. His "Theme from Antarctica" is very floating, symphonic, ethereal, majestic, and emotional, and provides the basis for many of the other tracks on the CD, which are essentially variations on this theme. John Cale composed "Antarctica" for the 1995 film by Manuel Huerga, *Antarctica as a State of Mind.* Valmar Kurol made three visits to the continent before composing, with Marc-Andre Bourbonnais, the CD *Antarctic Arrival*. The compositions are serene, peaceful, and unaffected: much like the frozen south the images convey.

N

NANSEN, FRIDTJOF

A pioneer Arctic hero, Fridtjof Nansen never went to the Antarctic. However, his influence and inspiration within polar science and exploration made him a major figure in those arenas in the far south. In addition to his status as a polar hero, Nansen was a best-selling author, capable artist, statesman, humanitarian worker, and winner of the Nobel Peace Prize in 1922.

Fridtjof Nansen was born on October 10, 1861, just outside the Norwegian capital Christiania (now Oslo). His father was a lawyer, and his mother came from one of Norway's few aristocratic families (Wedel-Jarlsberg). Nansen took to skiing, including ski jumping, and other sports from an early age and was a pioneer of skiing as a sport. His interest in nature and the outdoors led him to zoology studies at the University of Christiania, and particularly, 4 months on a sealer, *Viking,* in 1882 in order to collect marine specimens in the Arctic. A glimpse of the snow-covered mountains of East Greenland and finds of silt and drift logs in the ice off the coast were both to prove crucial to his later career.

Nansen completed his doctoral thesis in 1888 at the Bergen Museum, writing on the nervous system of lower animals, notably the hagfish. His research was a significant contribution to the subject at that time. By now the idea of crossing the unknown interior of Greenland had taken root and Nansen's daring plan was to ski from east to west, with hope of rescue and a ship home in front of the expedition and not behind. An insistence on science as the prime motive for expeditions was important for Nansen, and was also expressed in his expectations of the younger Roald Amundsen's expeditions. Nansen's attention to detail was revealed in the planning of his Greenland expedition, when he thoroughly tested, invented, and modified equipment, clothing, and food beforehand. Some of his patents, such as a sleeping bag, Nansen sledge, cooking apparatus, and layered clothing, became prototypes for later expeditions in the Arctic and Antarctic.

Nansen took five others with him across Greenland in 1888, including two Sami from northern Norway whom he thought would be excellently adjusted to such an expedition. This proved to be not quite true, but instead Nansen used the winter spent in Godthåb (Nuuk) after the crossing to study thoroughly the Greenlanders' adaptations to a harsh polar climate. The notion of learning from polar people was picked up by Amundsen, who used techniques learned from the Inuit on his successful South Pole expedition.

Nansen was feted as a hero on his return to Christiania in 1889 with his position as a polar authority and expedition hero now established. He married the singer Eva Sars and was appointed conservator at Christiania University. The theory of an east–west drift across the Arctic Ocean now intrigued him. Meteorology professor Henrik Mohn had first voiced this on the basis of artefacts from the US ship *Jeannette* found off southwest Greenland in 1884. *Jeannette* had been crushed in the ice north of the New Siberian Islands in 1881. Nansen's finds of silt and drift logs off the East Greenland coast were further indications.

Against the advice of many international polar authorities of the time, Nansen devised the plan of drifting with the presumed current in a specially designed ship that would withstand the force of the pack ice.

The drift in the ship *Fram* east to west across the Arctic Ocean in 1893–1896 was a great success and yielded a huge amount of scientific data as well as increasing Nansen's polar expertise and reputation. He was now indisputably the polar expert of the time, not least for his ability to understand and formulate scientific challenges in the polar areas. Having discovered that the Arctic is a deep ocean surrounded by land, and understanding that the Antarctic on the other hand appeared to be land surrounded by sea, his next wish was to attempt to reach the South Pole to investigate the unknown continent. He already had *Fram* available to get him down south. However, Nansen's worth for Norway, struggling to leave the union with Sweden and establish itself as an independent nation, was too great for him to be able to disappear into the polar wastes again. He became fully engaged in political and diplomatic missions, assisting in bringing a new royal family to Norway in 1905 and becoming Norway's first envoy to London 1906–1908.

The decision of the Sixth International Geographical Congress in London in 1895 to encourage Antarctic research was given impetus by Nansen's Arctic Ocean discoveries, and the way was opened for the Heroic Era in Antarctic exploration to begin.

In 1907 Roald Amundsen approached Nansen to ask for advice concerning his plans to repeat the drift across the Arctic Ocean, but this time to reach the North Pole. Nansen recommended *Fram* as the only suitable ship, but stated that he himself would be using it for a South Pole expedition. When he finally conceded that this was not to be, Amundsen was allowed to take it on his expedition that actually went to the South Pole (1910–1912). Amundsen was asked to take Nansen's experienced companion from the *Fram* expedition, Hjalmar Johansen, with him. Because of their support, Nansen and King Haakon of Norway were the two persons that Amundsen most feared when he announced his change of plans, to go to the South Pole instead of the North Pole. Nansen was disappointed by this change, but defended Amundsen in public.

Nansen's advice was sought by many others with interest in or plans for polar work and expeditions. Ernest Shackleton talked with him in London in 1907, and asked Nansen to see the expedition off. Robert Falcon Scott met Nansen in Norway in March 1910 to test equipment, and was advised to use dogs. Nansen suggested that Scott take the young Tryggve Gran with him to the Antarctic as a ski expert.

After World War I, Nansen turned to humanitarian work with the League of Nations, working particularly with Russian refugees and the Soviet famine crisis. For this he received the Nobel Peace Prize. Nansen was a prolific writer and speechmaker. He died at his home outside Oslo in 1930.

NATIONAL ANTARCTIC RESEARCH PROGRAMS

This entry describes, in alphabetical order, the national Antarctic research programs of those countries whose programs do not have a separate entry.

Czech Republic

Czechoslovakia acceded to the Antarctic Treaty on 14 June 1962. The Czech Republic and the Slovak Republic have maintained their accessions individually since they separated on 1 January 1993. The Czech Republic is expected to become an Associate Member of the Scientific Committee on Antarctic Research (SCAR) in 2006.

Czech scientists were active in Antarctic research during the 1950s and 1960s, mainly in the fields of astrophysics, geophysics, meteorology, and geology, working with the scientific programmes of other nations. A renewal of research activity in the 1990s gave rise to a determination to establish a Czech station in Antarctica to carry out research independently. Czech scientists visited Antarctica in several seasons to prospect for a site that would be appropriate for continuing their current scientific interests, including terrestrial biology.

In February 2005, construction of the Mendel station began at a site on the northern shore of Ulu

Peninsula (63°48′ S, 57°53′ W), between Bibby Point and Cape Lachman at the northern end of James Ross Island, northeastern Antarctic Peninsula, and several buildings were erected before the end of the season. The building work was completed in the 2005–2006 season. Research programmes are planned in the following fields: geology, geomorphology, climatology, terrestrial ecosystems, and freshwater ecosystems.

Ecuador

Ecuador acceded to the Antarctic Treaty on 15 September 1987, became an Associate Member of SCAR on 12 September 1988, became a Consultative Party of the Antarctic Treaty on 19 November 1990, and became a Full Member of SCAR on 15 June 1992.

The Ecuadorian navy operates the RV *Orion* for marine research and the support of the summer-only station Vicente (62°8′ S, 58°22′ W) close to Point Hennequin on the eastern shore of Admiralty Bay, King George Island, South Shetland Islands.

Estonia

Estonia became an Associate Member of SCAR on 15 June 1992, but withdrew from SCAR on 22 August 2001. Estonia acceded to the Antarctic Treaty on 17 May 2001.

Estonian scientists were active in Antarctic research for many years within the program of the Soviet Union. Some of these have continued their research in the 1990s by working with other national programs.

Estonia is planning to erect a small summer-only station in the general vicinity of Terra Nova Bay, Victoria Land, from which a limited program of research will be conducted.

Malaysia

Malaysia became an Associate Member of SCAR on 4 October 2004 and is expected to accede to the Antarctic Treaty in 2006.

Malaysian scientists have been active in Antarctic research for several years, working within other national programs, particularly those of Argentina, Australia, and New Zealand. The main field of interest has been in meteorology and other aspects of atmospheric sciences, but this will expand into biological sciences, including the biodiversity of benthic invertebrates, microbial studies, and genetic studies. Currently, there are no plans to build a station.

Pakistan

Pakistan became an Associate Member of SCAR on 15 June 1992 but has not acceded to the Antarctic Treaty.

Pakistan despatched an expedition to Greater Antarctica in January 1991 under the auspices of the National Institute of Oceanography. A few small buildings were erected, on stilts, on the surface and partially dug into the snow to determine the drift characteristics of each structure. These constituted Jinnah Antarctic Research Station, located at 70°25′ S, 25°46′ E on the Prinsesse Ragnhild Kyst of Dronning Maud Land. In addition to research facilities, the station houses a sophisticated unmanned Automatic Weather Station from which weather data are transmitted to Pakistan via the Argos satellite system. The station was revamped during the second Pakistan expedition to Antarctica during the 1992–1993 austral season. There have been no reports of further activities.

Peru

Peru acceded to the Antarctic Treaty on 10 April 1981, became an Associate Member of SCAR 14 April 1987, became a Consultative Party to the Antarctic Treaty on 9 October 1989, and became a Full Member of SCAR on 22 July 2004.

The Antarctic Program of Scientific and Technological Research (PROANTARCYT) of Peru in Antarctica works in close cooperation with the Scientific Subcommission of CONAAN, comprising Peruvian universities and the National Research Institutes.

Peru established a small summer-only station, Machu Picchu (62°05′ S, 58°28′ W), near the head of Admiralty Bay, King George Island, South Shetland Islands. The station opened in February 1989 and can accommodate a maximum of twenty-eight personnel. The principal scientific activities include environmental monitoring, geomagnetic observations, human biology, meteorology, offshore marine biology, onshore geology/geophysics, stratospheric ozone monitoring, terrestrial biology, and tidal measurements.

Marine science and station resupply are carried out by the research vessel *Humbolt*.

Sweden

Sweden acceded to the Antarctic Treaty on 24 April 1984, became an Associate Member of SCAR on 24 March 1987, became a Full Member of SCAR on 12 September 1988, and became a Consultative Party to the Antarctic Treaty on 21 September 1988.

The Swedish debut in Antarctica was the Swedish South Polar Expedition (1901–1903) of Otto Nordenskjöld, which established a base on Snow Hill Island, off the northeastern tip of the Antarctic Peninsula, and explored in that general area.

In the 1987–1988 summer season, Svenska Antarktisforskningsprogrammet (SWEDARP) (Swedish Antarctic Research Programme) personnel, transported aboard the German vessel *Polarstern,* established a field station, Svea (74°35′ S, 11°13′ W), in Heimefrontfjella, Dronning Maud Land, to undertake glaciological, survey, and geological studies. In the 1988–1989 summer season, a new larger station, Wasa (73°03′ S, 13°25′ W), was established in Vestfjella, Dronning Maud Land, adjacent to the Finnish station Aboa. Since this time the Nordic Antarctic operators—Finland, Norway, and Sweden—have taken annual turns to provide logistic support for scientists of all three countries to work in Dronning Maud Land. Swedish scientists also are active in other Antarctic areas, working in collaboration with the other national programs.

Swedish Antarctic research priorities include deep water formation and interaction among sea, ice, and air in the Weddell Sea; atmospheric composition and processes; marine ecosystems related to global change and commercial use; mass balance of ice sheets and glaciers, related to climate change and sea-level fluctuations; participation in international deep drilling/ice coring programmes, for reconstruction of past climate and atmosphere composition, and for using the ice sheet as a detector medium in astrophysics; geological and tectonic development; and satellite techniques for remote sensing of ice sheets and for geodetic purposes.

Switzerland

Switzerland became an Associate Member of SCAR on 16 June 1987, acceded to the Antarctic Treaty on 15 November 1990, and became a Full Member of SCAR on 4 October 2004.

Swiss scientists have been active in Antarctic research since 1968, particularly in the field of glaciology, working with scientists in other national programs, notably those of the United States, Italy, and New Zealand. The analysis of deep ice cores from Antarctica, most recently in the programme of European Polar Ice Coring in Antarctica (EPICA), has been a major focus in glaciology, but fieldwork has also been conducted in glacial geology. There are currently no plans to build a station in Antarctica.

Uruguay

Uruguay acceded to the Antarctic Treaty on 11 January 1980, and became a Consultative Party on 7 October 1985. Uruguay became an Associate Member of SCAR on 29 July 1987, and a Full Member on 12 September 1988.

The initial involvement of Uruguay with the Antarctic was in April 1916 with the despatch of the *Instituto de Pesca No. 1* in the second unsuccessful attempt to rescue the men of Sir Ernest Shackleton's Imperial Trans-Antarctic Expedition, who were stranded on Elephant Island in the South Shetland Islands.

In January 1984 a reconnaissance visit was made to King George Island, South Shetland Islands, to search for a suitable site for a scientific station. In December 1984 Artigas station (62°11′ S, 58°57′ W) was established on Fildes Peninsula, King George Island. On 8 December 1997, the hut of the former British Base D at Hope Bay, northeast-most Antarctic Peninsula, was transferred to Uruguay and refurbished as a summer-only station, Ruperto Elichiribehety (63°24′ S, 56°54′ W). The navy vessel *Vanguardia* provides logistic support and station resupply and acts as a platform for marine science.

Research activities include ornithology, geodesy, tidal studies, meteorology, glaciology, psychological and medical studies, and ozone measurements.

NATIONAL INSTITUTE OF POLAR RESEARCH, JAPAN

The National Institute of Polar Research (NIPR) has its head office complex in Tokyo. Three buildings with a total floor area of 11,177 m^2 occupy 5945 m^2 of land area. The complex contains various facilities, such as offices, wet and dry laboratories, a computer room, and a library.

The "Polar Department" was established in April 1962 in the National Science Museum, Tokyo, to promote the Japanese Antarctic Research Expedition (JARE). The Department was enlarged in several steps. NIPR in its present form was established on September 29, 1973 as one of the Inter-University Research Institutes of the Monbusho (Ministry of Education, Science, Sports, and Culture). In April 2004, NIPR was detached from the government and became a public corporation, sponsored by the former Monbusho, which had also changed its own structure and become the Monbu-Kagakusho (Ministry of Education, Culture, Sports, Science, and Technology, or MEXT).

NIPR's annual budget was 3951 million yen in fiscal year 2003. (All the figures hereafter refer to those of 2003.) One hundred forty-nine personnel were employed in the year, under the Director-General, Prof. Okitsugu Watanabe: sixty-nine researchers, fourteen engineers, twenty-nine administrators, and thirty-seven expedition members. (Researchers included five visiting professors, seven visiting associate professors, and an adjunct research fellow.)

The function of the NIPR was assigned at the time of the establishment of the institute in 1973, and is still effective: it shall conduct polar research for Japan. The task takes various forms.

1. Research activities of the permanent staff cover a wide range of scientific disciplines, including upper atmosphere physics, meteorology, glaciology, earth sciences, biological sciences, and polar region engineering.
2. NIPR is in charge of implementing the scientific and logistics programs of the Japanese Antarctic Research Expedition, which is under the authority of JARE Headquarters, chaired by the minister of MEXT. NIPR is responsible for maintaining four Antarctic stations: Syowa Kiti (Syowa Station) on East Ongul Island; and Mizuho Kiti (Mizuho Station), Asuka Kiti (Asuka Station), and Dome Fuji Kiti (Dome Fuji Station) on the mainland.
3. NIPR carries out many national and international cooperative projects with research organizations outside the institute. Currently 500 Japanese investigators are affiliated with NIPR.
4. NIPR provides postgraduate students with the opportunity to conduct their doctoral thesis research using relevant Antarctic data and analytical facilities.
5. NIPR is responsible for collecting, processing, and utilizing data and samples obtained by Antarctic and Arctic investigations. Data and specimens in the fields of biology, glaciology, and aurora physics are dealt with at the Division of Polar Information of the institute. These data and specimens are used for joint research programs with other institutions at NIPR, or are distributed to qualified scientists based on advice from advisory committees such as the Antarctic Meteorite Research Committee and Ice Core Research Committee. Aurora data are preserved at the World Data Center for Aurora. The Computing and Communication Center is equipped with powerful data-processing facilities, a Multipurpose Satellite Data Receiving System, and a polar information retrieval system. The Arctic Environment Research Center operates an Arctic field laboratory in Ny-Alesund, Svalbard. The Polar Research Resources Center studies the Antarctic environmental system in conjunction with the global system. NIPR established an Antarctic Meteorite Research Center in 1998. The library is responsible for collecting literature relevant to polar research. It also publishes about 3000 pages of scientific papers annually.
6. Permanent members of NIPR represent various national and international polar research organizations. NIPR established and continues to operate national Antarctic data centers for aurora, biology, glaciology, solid earth geophysics, geology, upper atmosphere physics, and logistics in cooperation with Working Groups of SCAR of the International Council of Scientific Unions.

7. NIPR invites visiting professors and provides research fellowships for visiting investigators from abroad. In addition, each year NIPR invites several scientists from abroad to participate in its annual symposia.

Antarctic and Arctic Stations

Four scientific stations (Syowa, Mizuho, Asuka, and Dome Fuji) in the Antarctic and a station in Ny-Alesund in the Arctic are affiliated facilities of NIPR and are maintained and managed by NIPR.

Syowa Station was established by Japan's First Antarctic Expedition, on January 29, 1957, near the eastern shore of Lützow-Holm Bay, East Antarctica. The station is located on Ongul Island, about 4 km west of the edge of continental Antarctica. The station is a straight-line distance of approximately 14,000 km from Tokyo. Its coordinates are 69°00′ S and 39°35′ E, and it is 29 m in elevation. The base is built directly on bedrock, and consists of an administration building, an electric power plant, living quarters, observation and research buildings, environmental protection facilities, satellite telecommunications buildings, and warehouse facilities, with a total floor area of 6100 m^2. Approximately forty people winter at the base each year to conduct research and observational activities.

Dome Fuji Station was established on January 29, 1995 by the 35th and 36th Antarctic Expeditions. It is located approximately 1000 km south of Syowa Station at the highest point on the Dronning Maud Land ice sheet. The station is situated at 77°19′ S and 39°42′ E at an elevation of 3810 m. The station consists of an electric power plant, dining hall, residential facilities, laboratory, combined medical and residential building, drilling workroom, excavation control room, passageways, and evacuation facilities, all with a combined floor area of 386 m^2. Additionally, the station has a 4-m-deep by 22-m-long trench for deep layer excavation, an ice-core processing and experimentation facility, and other facilities that are dug into the snow. It was here at Dome Fuji Station that the 36th Expedition wintered over and excavated the ice sheet to a depth of 2500 m. Core samples thus obtained enabled researchers to study 340,000 years of global climate and environmental change. The expedition also conducted monitoring in the study of atmospheric and material circulation systems, the chemical properties of snow accumulation, and the dynamics of ice-sheet movement.

Dome Fuji Station is located at high altitude, and its weather is characterized by extremely low temperatures and light winds.

Weather Statistics at Syowa Station

Average temperature	–10.5°C
Recorded maximum temperature	10.0°C (January 21, 1977)
Recorded minimum temperature	–45.3°C (September 4, 1982)
Average wind speed	6.5 m/s
Recorded maximum instantaneous wind speed	61.2 m/s (May 27, 1996)
Average sea-level air pressure	986.6 hPa
Average relative humidity	66%

Weather Statistics at Dome Fuji Station

Average temperature	–54.3°C
Recorded maximum temperature	–18.6°C
Recorded minimum temperature	–79.7°C
Average wind speed	5.8 m/s
Average sea-level air pressure	598.4 hPa

NEMATODES

Nematodes (phylum Nematoda) are unsegmented, vermiform animals with adults ranging in length from 0.3 mm to over 8 m. Nematodes are the most abundant multicellular animals on earth, and their distribution and abundance in Antarctica reflects the same physical, chemical, and biological factors that affect their populations elsewhere. To feed, grow, and reproduce they require free water. Nematodes inhabiting soils and aquatic sediments typically feed on microbes, plants, or other microfauna, and populations may reach millions m^{-2}, containing over 200 species. Their feeding activity enhances nutrient cycling and other ecosystem processes. Nematodes living in plants, invertebrates, and vertebrates may affect host condition, particularly when infestations are great or the host is stressed. The juvenile stages of these "parasites" may develop in inert sediments, invertebrates, or vertebrates.

Air, water, and animal movement aid nematode dispersal. But colonisation of habitats, the establishment of ongoing populations, requires nematodes to survive local conditions—in continental Antarctica they face dual stresses of low temperature and desiccation. Terrestrial nematodes survive freezing and desiccation in a dormant state but grow and reproduce when conditions are favourable. In *Panagrolaimus davidi* (order Rhabditida), the sugar trehalose and ice-active proteins may inhibit crystallisation that would otherwise cause cell damage and death on rapid freezing; under slow freezing it shows dehydration and anhydrobiosis, perhaps accompanied by trehalose synthesis. *Ditylenchus parcevivens* (order Tylenchida) and *Teratocephalus tilbrooki* (order Chromadorida) are, in contrast, fast dehydration strategists. The adaptations required to meet these conditions increasingly restrict the diversity of terrestrial nematodes at higher latitudes; more than twenty-five nematode species are known from Signy Island, approximately five on Ross Island and the Dry Valleys of Victoria Land, and only a single species on Steinnabben nunatak in East Antarctica.

In their coastal colonies, penguins, through excreta, moulting, and death, transfer nutrients from marine to terrestrial environments. Thus, at least during the summer, colonies are the scene of significant biological activity because nematodes, along with microfauna such as tardigrades and rotifers, use this resource and the microbes associated with it. Four soil nematode species occur near Ross Island penguin colonies, but only *Panagrolaimus davidi* has been collected within colonies, and high salinity is thought to exclude the other bacterial-feeding nematodes (*Plectus antarcticus,* Plectidae; *Scottnema lindsayae,* Rhabditida) and omnivorous nematodes (*Eudorylaimus antarcticus,* Dorylaimida) found in the vicinity. Apparently the adaptations that enable *P. davidi* to survive freezing and desiccation also confer resistance to severe osmotic stress.

The nematodes known from the vicinity of Adélie penguin colonies are those that occur in the Dry Valleys of Victoria Land, where diffuse aerial input of organic matter supports simple terrestrial food webs. Habitat patches supporting *S. lindsayae* over several years seem least suitable for *P. antarcticus* and *E. antarcticus,* suggesting that variation in soil conditions (e.g., moisture, pH, salinity, ratio of carbon to nitrogen) on the scale of tens of metres, rather than dispersal, controls the distribution of these nematodes. This suggests that both idiosyncratic variation in snowdrifts and climate change may significantly impact these populations. Knowledge of factors influencing these distributions will prove useful in understanding the spatial heterogeneity of nematode populations in more complex ecosystems.

At least twenty-five nematode species, together with rotifers and tardigrades, have been collected from nunataks, with *Eudorylaimus nudicaudatus* (Dorylaimida) and *Chiloplacoides antarcticus* (Rhabditida) being known only from such sites. However, only four species have actively growing populations and are clearly established. On nunataks, the largest nematode populations, including *Panagrolaimus* sp., are found in association with colonies of snow petrels *(Pagodroma nivea),* and generally more nematodes are recovered from samples with moss, blue-green alga *(Nostoc),* or green alga *(Prasiola)* than from material with lower organic matter content. Collection of individual or small numbers of nematodes from such localities may indicate that they have dispersed but have not colonised; records from continental Antarctica of nematodes such as *Helicotylenchus, Tylenchorhynchus,* and *Rotylenchus* (Tylenchida) that feed on higher plants probably belong in this category.

Nematode assemblages in soils around mosses and vascular plants in the maritime Antarctic (e.g., Signy Island) are functionally and taxonomically comparable with those of nearby more temperate sites. In maritime Antarctica, nematode-trapping fungi (e.g., *Arthrobotrys, Monacrosporium, Harposporium*) are widespread; related forms have been found in continental Antarctica (Ablation Point, Alexander Island; Victoria Land).

Lake systems in East Antarctica have yielded five nematode species, with many lakes having only one species. Nematodes have long been known to be abundant and diverse in Antarctic marine sediments, and at 200- to 2000-m depth on the Weddell Sea shelf their diversity may surpass that of the Arctic bathyal assemblage. As for the Arctic, some marine nematodes (e.g., *Geomonhystera*) are found in sea ice, and marine invertebrates (e.g., *Diplopteraster perigrinator,* Echinodermata; *Eulagisca gigantea,* Polychaeta) may be parasitised by nematodes.

Among nematode parasites of vertebrates, adults of *Pseudoterranova decipiens* (Ascaridida, Anisakidae) have the Weddell seal *(Leptonychotes weddelli)* and the elephant seal *(Mirounga leonina)* as the main final hosts, being found in the stomach. Third-stage juveniles of *P. decipiens* occur predominantly in fish that feed on benthic nototheniid fishes; pelagic or euphausid feeding fish species are less infected, indicating a benthic life cycle. Earlier developmental stages infect crustaceans. Adults of other nematode species occur in the stomach and intestine (e.g., *Anisakis physeteris* with euphausids and fish as intermediate hosts) or urinogenital system (e.g., *Crassicauda crassicauda, Placentonema gigantissima*) (Spirurida, Tetrameridae) of various whale species.

As in the rest of the world, nematodes are abundant and diverse in the Antarctic. They show a range of adaptations to permit their dispersal, survival, and the utilisation of a range of terrestrial and marine food resources, as well as parasitising invertebrates and vertebrates.

NEOTECTONICS

Neotectonics (active or recent tectonics) is a broad field of study examining geologically recent movements of the Earth's surface. Earthquakes (seismicity) and fault slip, volcanic activity, and the response of the solid Earth to the fluctuations of ice sheets and glaciers (glacial isostasy) contribute to neotectonic activity in Antarctica. Antarctica is unique—it is nearly completely covered by ice (98%) and almost entirely surrounded by oceanic spreading ridges—and this gives rise to exceptional neotectonic activity. This focus is on active tectonics.

The detection and location of earthquakes in Antarctica has been hampered by the limited number of seismometers, most of which are located on the periphery of the continent. Until recently, no earthquakes had been observed for large interior regions. This led to the suggestion that these regions might be aseismic—that is, that they experience no earthquakes at all. This was ruled out only recently, when small earthquakes were detected by temporary networks of seismographs in the continental interior. Nevertheless, even with the newly observed earthquakes, Antarctica has a low level of seismicity.

Unlike most continents, which have zones of tectonic convergence (compression) where mountains are built and earthquake activity is frequent, Antarctica is almost completely surrounded by oceanic spreading ridges. This may put the continent in a relatively low state of stress and could explain the limited occurrence of earthquakes. As well, the weight of the ice sheets and glaciers squeezes and compresses the underlying bedrock, and this is thought to suppress earthquakes. The largest observed earthquake had a magnitude of less than 5, which is small compared to the earthquakes with magnitudes of 6 and 7 observed in other intraplate continental settings.

The Transantarctic Mountains (TAM) are a major structural feature separating East and West Antarctica. Their formation is linked to the Cenozoic rifting that formed the West Antarctic Rift System (WARS), a major geological structure. The TAM contain some of the oldest surfaces on Earth, aged many millions of years, yet surface uplift may be presently occurring at a low rate due to basal erosion by cross-cutting outlet glaciers originating in East Antarctica.

Much of the sparse continental seismicity occurs along the TAM and adjacent WARS. Crustal extension of a few millimeters per year has been observed in some parts of the TAM by Global Positioning System (GPS) measurements. Field observations indicate possible recent slip on faults. The crustal extension could be tectonic, could originate in the Earth's response to ice-sheet changes, or could be a combination of the two.

Tectonically mobile West Antarctica also features a mantle plume centered beneath Marie Byrd Land, which is thought to be responsible for crustal doming and volcanism. Active volcanoes in Antarctica, such as Mount Erebus, generate local crustal deformation and small earthquakes, or tremors. In contrast to West Antarctica, East Antarctica is considered to be a stable cratonic region, although recent observations suggest low levels of crustal deformation in some localities.

Regions with active tectonics frequently exhibit high geothermal heat flow. Low heat flow promotes a frozen glacier bed, while high heat flow promotes basal sliding and faster glacial flow. Subglacial lakes are unique environments that are sensitive to heat received from the underlying crust. The habitat of the largest of these, Lake Vostok, may be influenced by its location on a seismically active geological structure.

The ice sheets and glaciers that cover nearly all of Antarctica have fluctuated in their extent and thickness and are presently changing in size. The changing weight of the ice drives a complex pattern of crustal uplift and subsidence known as glacio-isostatic adjustment that is still poorly discerned. Unlike the Northern Hemisphere, where the history of crustal uplift and subsidence after deglaciation is preserved in numerous raised beach deposits, relatively few observations are available for Antarctica because most shorelines are covered by ice. The limited available observations show that sea level has generally not fluctuated by more than about twenty meters in the past 5000–6000 years. Modern space-based geodesy, including satellite gravity missions and GPS, is increasingly being used in Antarctica to determine the earth's present-day response to tectonic forces and changes in ice mass.

NETHERLANDS: ANTARCTIC PROGRAM

The Netherlands Polar Programme (NPP) has existed since 2002. It is a merger of the Netherlands Antarctic Programme (NAAP, in existence since 1985) and a conglomerate of Arctic projects financed and administered through NWO (Netherlands Organization for Scientific Research). The funding for polar research in the Netherlands comes from five ministries: (1) Foreign Affairs, (2) Housing, Spatial Planning, and Environment, (3) Transport, Public Works, and Water Management, (4) Agriculture, Nature, and Food Quality, and (5) Education, Culture, and Science. The department of Foreign Affairs chairs this Interministerial Polar Committee and deals with Antarctic Treaty matters.

Polar research proposals are judged on five policy criteria in order to be funded: (1) scientific quality, (2) political and social relevance, (3) international links, (4) relation to the research themes of the Netherlands Polar Programme (Glaciology and Climatology; Marine Sciences; Ecology; Man and the Polar Environment), and (5) the urgency and especially the feasibility of the proposal.

Any member of the research community can submit proposals for Antarctic research, but they are generally associated with one of the four leading research institutes in this field: the Institute for Marine and Atmospheric Research (IMAU, of the University of Utrecht), the Royal Netherlands Institute for Sea Research (RoyalNIOZ), the Netherlands Institute of Ecology (NIOO-KNAW), and the Arctic Centre (of the University of Groningen). These four institutes are regularly consulted as to what the research themes of the country's polar programme should be. The proposals for research are submitted to the Committee on Polar Research (part of NWO), which evaluates and prioritizes them via an international panel of referees. The proposals then go to the Interministerial Polar Committee. This committee makes the final assessment of the proposals and hands out funding.

The current budgets per annum are €140,000 for Arctic research and €2.7 million for Antarctic research. This money is divided fairly evenly between logistics and research.

The Netherlands has no Antarctic infrastructure of its own—that is, no ship, no research station, no aircraft. It does, however, have memorandums of understanding (MOUs) with several international organizations, such as the British Antarctic Survey and Germany's Alfred Wegener Institute. A yearly amount is paid to the international partner to use their logistical facilities, regardless of how many Dutch scientists go to Antarctica in a given year. The MOUs stipulate that the Dutch projects should be in collaboration with those of the host country. Advantages of this type of system include that the Netherlands spends less on logistics (40%–50% versus 80% by some other countries) and that research is not restricted to a single location.

NEUMAYER, GEORG VON

Georg Balthasar von Neumayer was born on June 21, 1826, at Kirchheimbolanden, and died on May 24, 1909, at Neustadt/Pfalz.

In 1849, Neumayer finished his studies at the Engineering School and Polytechnical School (today Technical University) at Munich. He then became the assistant to Johann von Lamont (1805–1879), director of the observatory at Bogenhausen/Munich and leading authority in terrestrial magnetism. Within several months Neumayer was introduced to meteorological and magnetic measurements.

When he was not accepted to join the navy in 1850, Neumayer bought a berth on a barque from Hamburg to South America to gain practical experience in seamanship and navigation. After his return to Hamburg he passed his mate's certificate under the director of the observatory and school of navigation, Carl Christian Ludwig Rümker (1788–1862) in May 1851. He then went to Triest, where he tried in vain to join the newly established Austrian Navy.

Back in Hamburg, Neumayer lectured some months at Rümker's school, introducing Matthew Fontaine Maury's (1806–1873) new hydrographical method of preparing sailing directions from the analysis of winds and currents recorded in special ship logs. In 1852, Neumayer sailed to Australia, serving before the mast. He came back to Germany in 1854 with the plan to establish a geophysical observatory at Melbourne that could serve as a base for a later expedition to Antarctica. Following Lamont's advice, Neumayer first gained practical experience during extended magnetic surveys in Germany. When the Bavarian king granted financial support to buy the newest instruments, he founded the Flagstaff Observatory at Melbourne in 1857, directing it until 1864.

After his return to Germany, Neumayer plead in vain for a German Antarctic expedition during the first meeting of German geographers at Frankfurt/Main in 1865. He ultimately was named leader of an Austrian Antarctic expedition, which could not be realized due to the death of its major supporter, Admiral Wilhelm von Tegetthoff (1827–1871).

After the foundation of the German Reich, Neumayer moved to Berlin to become hydrographer of the Admiralty (1872–1875). He was in charge of the scientific program of the *Gazelle* expedition (1874–1876), during which the transit of Venus was observed at Îles Kerguelen in the Southern Indian Ocean in 1874. From 1875 until 1903 he directed the newly established Deutsche Seewarte (Naval Observatory) at Hamburg. In this position he influenced nautical and geophysical techniques of measurement and used his talent as an organizer of scientific research.

Neumayer was a key figure in the realization of the first International Polar Year (1882–1883). One of the consequences of that international program was the foundation of the German Meteorological Society in 1883, over which Neumayer presided until 1888. He continued to emphasize the advantages that could accrue through international cooperation in Antarctica, and much of the joint international program conducted in the period from 1901–1904 was organized following his concepts. He was the guiding force during the preparations for the first German Antarctic expedition (1901–1903), playing a similar role to Clements Markham's in Great Britain. In 1900, Neumayer was raised to the Bavarian nobility.

NEW ZEALAND: ANTARCTIC PROGRAM

On July 30, 1923, Britain claimed the Ross Dependency, and placed it in the care of New Zealand. The dependency lies between 150° W and 160° E, and includes Ross Island, the site of New Zealand's Scott Base, built in 1957 to support the Commonwealth Trans-Antarctic Expedition (CTAE) and the International Geophysical Year (IGY) scientists. Successful international cooperation in the IGY led to the signing of the Antarctic Treaty, with New Zealand an original signatory.

Scott Base became a permanent base in 1959–1960 and was managed by the New Zealand Antarctic Programme (NZAP) under the auspices of the Department of Scientific and Industrial Research (DSIR). In 1992, NZAP became the responsibility of the Ministry of Foreign Affairs and Trade (MFAT). In 1994, there was a further review of New Zealand's involvement in Antarctica, resulting in the establishment of Antarctica New Zealand.

Based in Christchurch, Antarctica New Zealand is a Crown Entity, established under the *New Zealand Antarctic Institute Act 1996*. It has a board appointed by the Minister of Foreign Affairs and Trade, twenty-six staff in Christchurch, and an annual summer staff of twenty to thirty at Scott Base, with ten wintering over in Antarctica each year. Through Scott Base, access, services, and accommodation are provided to all people who travel to Antarctica under the New Zealand Antarctic programme.

Antarctica New Zealand's key functions are as follows:

- Develop, manage, and execute New Zealand activities with respect to Antarctica and the Southern Ocean.
- Maintain and enhance the quality of New Zealand Antarctic scientific research.
- Cooperate with other institutions and organisations, both within and outside New Zealand, that have objectives similar to those of the Institute.

Supporting Science

Antarctica New Zealand supports a range of activities in Antarctica and the Southern Ocean every year. Thirty to forty science projects involving around two hundred researchers from throughout New Zealand are supported each season, including collaborations with scientists from other countries.

New Zealand's influence in Antarctic issues is built on scientific understanding and the ability to predict impacts, direct and indirect, on Antarctica and the Southern Ocean. Antarctica New Zealand's science strategy—*New Zealand Science in Antarctica and the Southern Ocean (2003–2008)*—provides a framework to manage national research in the region.

Antarctica New Zealand's three major initiatives are the Latitudinal Gradient Project (LGP), Biodiversity of the Ross Sea (BioRoss), and an international drilling project, ANDRILL.

LGP takes advantage of the "natural laboratory" in the latitudinal gradient offered by the Ross Sea sector. The project combines many scientific disciplines to address biological responses to a changing environment and expand our knowledge of the coastal marine, inland aquatic, and terrestrial ecosystems in the region. This collaborative project is spread over a 10-year period; the first research work was begun at Cape Hallett in October 2003.

BioRoss was developed by the Ministry of Fisheries, Antarctica New Zealand, and the Ministry of Foreign Affairs and Trade as part of New Zealand's Biodiversity Strategy process. The objective is to develop a more complete inventory of the biodiversity in selected marine communities in the Ross Sea region and to enable better state-of-the-environment reporting.

New Zealand is the project manager for ANDRILL, a multinational drilling project aimed at improving understanding of Antarctica's role in global climate change from 65 Ma to the present. ANDRILL will provide records critical to understanding fundamental ice sheet behaviour and its influence on the global climate. The ANDRILL consortium comprises the USA, Italy, Germany, and New Zealand.

Environmental Stewardship

Antarctica New Zealand works closely with other countries and operators in the Ross Sea region and elsewhere, in order to minimize the environmental impact in Antarctica.

All activities in Antarctica are managed under the Protocol on Environmental Protection to the Antarctic Treaty, which Antarctica New Zealand translates into appropriate environmental standards for the activities it supports. An Environmental Management System based on ISO 14001 assists compliance with New Zealand legislation.

In 2001, Antarctica New Zealand published *Ross Sea Region 2001: A State of the Environment Report for the Ross Sea Region of Antarctica.* This is the first comprehensive stock-take of the region. It reports on the pressures human activities are placing on the environment and details the current management of these pressures. The report concludes that the Ross Sea region, despite a history of human involvement of nearly five decades, generally remains in a pristine condition. Developing priorities and potential projects from the report is now an important focus for Antarctica New Zealand.

Public Awareness and Education

The public awareness and education programmes are designed to increase awareness of New Zealand's activities in Antarctica.

The Artists to Antarctica Programme, partnered with Creative New Zealand, provides opportunities for artists to explore Antarctica in their work and increase understanding among New Zealanders of the values of Antarctica and its global importance.

Active education networks facilitate the development of curriculum-based education resources as well as increasing awareness of the importance of Antarctica to students at all levels.

Media visits to Antarctica inform the public about current activities in the New Zealand programme. The Invited Visitor Programme increases knowledge and understanding of the importance of Antarctica and the role of New Zealand.

Operations

Antarctic logistics is an integral aspect requiring ongoing cooperation with other Treaty partners. Antarctica New Zealand works cooperatively with the US and Italian Antarctic programmes to plan and coordinate the movements between Christchurch and McMurdo and on the ice.

International Representation

New Zealand is committed to the Antarctic Treaty and is a consultative party. Antarctica New Zealand is involved as part of New Zealand Government delegations to international forums and specialist networks, including the following:

- Council of Managers of National Antarctic Programmes (COMNAP)
- Antarctic Environmental Officers Network (AEON)
- Committee on Environmental Protection (CEP)
- Antarctic Treaty Consultative Parties (ATCM)

NORDENSKJÖLD, OTTO

Nils Otto Gustaf Nordenskjöld was born in Sweden on December 6, 1869, and as a schoolboy he expressed an interest in the geography of distant sites. His uncle, Adolf Erik Nordenskiöld, the leader of the first expedition to navigate the Northeast Passage, in *Vega* (1878–1880), provided further inspiration. In 1894, Nordenskjöld completed his doctoral degree at Uppsala University and held parts of a chair in mineralogy and geology, through which his interest in landscape formation and geohistory developed.

In 1895–1897, Nordenskjöld organised an expedition to Patagonia and Tierra del Fuego, partly to compare the biological, geological, and ice conditions of the northern and southern hemispheres. In addition to this, he carried out extensive mapping and studies of the Ona, one of the area's indigenous peoples. In 1898, Nordenskjöld visited the Klondike in Alaska, without any major financial or scientific success. Thereafter, he finalised his plans for an expedition to Antarctica, but was flexible as to timing and scientific objectives. Inspired by the 1895 and 1897 geographical congresses highlighting the need for exploration of Antarctica, Nordenskjöld engaged in fundraising and began to look for suitable expedition members. Meanwhile he prepared himself further with regards to organisation, logistics, and equipment. In the summer of 1900, he joined the Danish expedition to East Greenland under the leadership of Lieutenant Georg Carl Amdrup, in which Nordenskjöld accompanied the ship party led by Nicolaj Hartz. The ship was the whaler *Antarctic,* which Nordenskjöld shortly afterwards purchased.

From the beginning, Nordenskjöld planned an expedition with dual functions, enabling both scientific endeavours and whaling, and as a result he hired the experienced Norwegian whaling master Carl Anton Larsen as captain of *Antarctic*. With the Swedish South Polar Expedition, Nordenskjöld became the first Swede to carry out an expedition to the Antarctic mainland, 1901–1904. Nordenskjöld had, with some difficulties, found a suitable scientific team to work with studies in meteorology, geology, botany, zoology, and oceanography as well as mapping. Larsen was entrusted with the job of finding most of the crew members, amongst them several experienced whalers. To a certain extent, the sealing and whaling operations intruded on the scientific work, and consequently the ship party was relatively inactive for some periods of time. Nevertheless, valuable mapping, biological, and oceanographic work was carried out. At the land station, Snow Hill Island, systematic studies of climatic and ice conditions were pursued, fossils were collected, and contributions were made to the understanding of global ice conditions and land formation. Furthermore, the results foreboded theories on continental drift. Nordenskjöld and some of his fellow expedition members also made an attempt to establish the first Swedish whaling/science consortium for the Antarctic in 1911–1912, in cooperation with Great Britain (including the British Museum and the Royal Geographical Society) and Norwegian whaling interests.

In 1905, Nordenskjöld became professor in Economic Geography and Ethnography, and in 1923, he became the founder and head of the Gothenburg School of Economics. In 1913–1918, he was chairperson of the International Polar Commission and he was also elected as a member of several scientific societies in Sweden and abroad, where he developed his interest for scientific work in the Arctic. Nordenskjöld died on June 2, 1928, due to injuries incurred after being hit by a bus close to his home.

NORTHERN GIANT PETREL

The northern giant petrel, *Macronectes halli* (order Procellariiformes), is a large, surface-nesting fulmarine petrel common to the sub-Antarctic region, that is remarkably similar to southern giant petrels *(M. giganteus)* in terms of life history, ecology, and breeding biology. Northern giant petrels also resemble southern giant petrels in that both species have large wingspans (1.5–2 m), stocky builds, and wings that are pointed, somewhat narrow, and designed for effortless soaring. Unlike southern giant petrels, however, northern giant petrels do not have a light or white phase, although their plumage may become lighter, especially on the neck and head, as individuals age.

Northern giant petrels have a circumpolar, exclusively peri-Antarctic breeding distribution between 44° S and 55° S, a zone between the Subtropical Convergence to the north and the Polar Front to the south. Only on the island of South Georgia do northern giant petrels breed south of the Polar Front. Juveniles of the species, however, disperse widely outside this breeding range, with individuals commonly occurring near the coastlines of the three southern continents (Africa, South America, and Australia) during the 5- to 11-year interval between fledging and recruitment into the breeding population. The breeding population is currently estimated at c. 11,200 pairs, with numbers increasing at some localities, and decreasing at others in response to anthropogenic factors such as disturbance, mortality due to commercial fishing bycatch, and variability in resource availability.

Foraging strategies are generally gender specific, with males and females showing greater tendencies towards land-based and oceanic feeding, respectively. Studies based on satellite telemetry demonstrated that male northern giant petrels tended to forage almost exclusively near Antarctic fur seal *(Arctocephalus gazella)* colonies, especially during the peak in seal carcass availability, while females during the same period generally continued to forage at sea, thus providing a variety of prey species to developing chicks. Because giant petrels are opportunistic predator–scavengers, the availability of carrion due to increasing seal and penguin populations near some breeding localities, especially at critical periods during chick growth and development, has likely contributed to localized population increases of northern giant petrels. It has been speculated that this dichotomy in resource use due to on-shore scavenging for carrion by males and pelagic foraging by females has effectively decreased the potential for breeding failures due to starvation, which is seen in other seabird species that specialize in fewer types of prey.

Northern giant petrels tend to nest in sheltered locations amongst tussock grass or on vegetated slopes. Individuals of this species lay a single egg between mid-August and mid-September, or approximately 6–8 weeks earlier than do southern giant petrels. Thus, although the two species may breed sympatrically at several locations, the timing of their breeding cycles ensures very little interbreeding. Eggs are incubated for approximately 60 days, with males taking a slightly larger share of incubation duties. Chicks fledge within 110–120 days and weigh 4–6 kg, with male fledglings often leaving the nest slightly heavier than females.

Despite what appears to be a relatively stable global breeding population of northern giant petrels, the proximity to, and increase of, commercial longline fishing still poses a significant threat to the species. This is due especially to the fact that young prebreeding individuals may repeatedly come in contact with fishing vessels during their many years spent at sea before they join the breeding population while they mature. Thus, despite an abundant prey base near breeding localities, mortality due to fishery bycatch may still seriously compromise the future stability of northern giant petrel populations throughout their range.

NORWAY: ANTARCTIC PROGRAM

Norway has a long history of whaling, exploration, scientific activity, and surveying in the Antarctic. Such activities motivated Norway's annexation of Bouvetøya in 1930, Peter I Øy in 1931, and Dronning Maud Land in 1939. Paralleling these territorial claims, Norway has played an important role in Antarctic cooperation, through long-term research and active participation in the development of the international legal framework concerning the management of Antarctica within the Antarctic Treaty System. Two of the postwar milestones in Norway's Antarctic research were the Norwegian-British-Swedish Antarctic Expedition (1949–1951) to Maudheim in Dronning Maud Land and the establishment of the Norway Station in Dronning Maud Land. This station was manned in the period 1956–1960 in support of the International Geophysical Year (IGY).

Following a 15-year hiatus, during which Norwegian activity was restricted to participation on expeditions organised by other nations, the first Norwegian Antarctic Research Expedition (NARE) took place in the austral summer 1976–1977. Three more NAREs followed in 1978–1979, 1984–1985, and 1989–1990. The summer station Troll Station, erected at Jutulsessen in Gjelsvikfjella in Dronning Maud Land in the austral summer 1989–1990, was the first Norwegian base established in Antarctica after the Norway Station. Since 1991–1992, following an agreement between Norway, Sweden, and Finland that committed each nation to organise an expedition every third year, Norwegian research and monitoring within fields of marine biology, geology, glaciology, and physical oceanography have been carried out annually during austral summers. Since 2000–2001, the Nordic collaboration has benefited from intercontinental flights between South Africa and Dronning Maud Land. Norway is now entering a new era in terms of logistics in Antarctica, through the establishment of a blue-ice runway at the research station Troll in Dronning Maud Land, and through an upgrade of Troll to winter-activity status from 2005.

Norway has, as a claimant state in the Antarctic, a responsibility for science-based management of the natural resources. Norwegian research activities are fundamental for the management of the natural resources in Norwegian Antarctic territories. In the coming years special focus will be on understanding the fundamental processes in Antarctic environments in relation to environmental variability and human impacts. This includes studies of topics such as climate modelling, paleoclimate, ocean circulation, marine ecosystems, the carbon cycle, tourism, and cultural heritage. Monitoring programmes including atmospheric studies, marine living resources (CCAMLR), meteorology, and human impacts will also be given high priority. Further, topographical and geological surveying in the Norwegian claimant areas will be continued.

The Norwegian Polar Institute is the principal supplier of scientific information on Norwegian polar regions for the central government administration, acting as its consultant on polar matters and helping to ensure that the environment is managed as efficiently as possible, in keeping with international efforts to promote sustainable development. The institute is the national manager and operator for the Norwegian Antarctic Program. It has the status of a directorate, and is responsible to the Norwegian Ministry of Environment, which is funding Norwegian Antarctic activities with about US$2.5 million per year.

NORWEGIAN-BRITISH-SWEDISH ANTARCTIC EXPEDITION (1949–1952)

The Norwegian-British-Swedish Antarctic Expedition (NBSAE) was the first Antarctic expedition to be organized by a tripartite consortium. The idea for an expedition to Dronning Maud Land in the South Atlantic sector originated with Hans Ahlmann, professor of geography at the University of Stockholm. Ahlmann had observed that many glaciers in countries bordering the North Atlantic had been in retreat during the first half of the twentieth century, and wondered whether this was a local trend or perhaps part of some global change. In 1942, he had seen aerial photographs taken in 1939 by a German expedition to Dronning Maud Land in which ice-free areas appeared to have been recently exposed. Aware that glaciers are sensitive to climatic change, Ahlmann conceived the idea of an expedition to study the area.

Norway had formally claimed the sector between 20° W and 45° E. Inspired by Ahlmann, the Norwegian government decided in 1946 to mount an expedition, although not even 1 year had elapsed since the surrender of German forces in Norway at the end of the Second World War. Sweden agreed to participate, and Ahlmann approached the Royal Geographical Society in London with a view to British participation. This was forthcoming, and a tripartite committee began planning for a 2-year expedition to start in 1949.

The scientific objectives included glaciology, meteorology, geology, and mapping. As the first expedition to winter in the Atlantic sector of the continent between 57° W and 95° E (nearly half the coastline of Antarctica), it was felt that the program should be as broad as possible within the constraints of a small land party. Inland exploration would depend on dog transport supported by three Weasel tractors.

The expedition traveled in two ships. The 24,000-ton *Thorshøvdi* was a whaling factory ship on her way south for the 1949–1950 season whale fishing. *Thorshøvdi* sailed from Sandefjord, Norway on October 25, 1949, with five members of the expedition, sixty-two sledge dogs, and the tractors. *Norsel,* a sealer one-fortieth the size of *Thorshøvdi,* left Oslo on November 17, 1949 with the bulk of the expedition's cargo and the remainder of the staff. She also carried a five-man Royal Air Force group with two small Auster aircraft for reconnaissance. *Thorshøvdi*'s cargo, with her five expedition members and the dogs, were transferred to *Norsel* near the edge of the pack ice on January 14, 1950.

Under the command of Guttorm Jacobsen, *Norsel* spent 2 weeks working through pack ice before approaching the coast, which was found to consist of ice cliffs 20 m high. It took a week of searching with an aircraft on floats to find an ice dock low enough to unload the ship. Four hundred fifty tonnes of cargo were landed and then hauled to a point 3 km from the ice front, after which the ship departed with the air unit on February 20. Maudheim base was established on a floating ice shelf at 71°3′ S, 10°56′ W. A wintering party of fifteen men under the leadership of Norwegian John Giæver included six Norwegians, four Swedes, three Englishmen, one Australian, and one Canadian. Of these, the scientific staff comprised three glaciologists, two meteorologists, two geologists, and a surveyor.

While the meteorologists spent the following 23 months at Maudheim studying weather systems and the energy balance from the snow surface to altitudes of 20 km, glaciologists spent the first winter drilling to study the structure of the ice at depth. A local survey network was established to study the deformation of the ice shelf.

After the winter, a route-finding party traveled 300 km inland to a mountain area. On their return, all three Weasels were used to carry 10 tonnes to establish an advance base from which field parties would travel onward by dog sled. A four-man geology/survey party with three dog teams and a four-man glaciology party with two dog teams left Maudheim on December 19, 1950. The glaciologists determined ice temperatures at 10 m depth and the annual rate of snow accumulation at every camp site; and in several places they established survey networks to measure the rate of glacier flow. The geologists traveled far and wide to sample outcrops for geological mapping, and the surveyor developed a triangulation network to provide ground control for topographic mapping from aerial photographs.

A visit by *Norsel* after the first year brought a Norwegian aviation group and three new wintering staff. Survey flights were made to the inland mountain areas. One member of the first wintering party returned home with the flying group at the end of *Norsel*'s visit.

On February 24, 1951, 3 weeks after the ship left, one of the Weasels with four men on board accidentally drove over the ice front in a fog. Bertil Ekstrøm, John Jelbart, and Leslie Quar drowned. Stig Hallgren swam to an ice floe and was rescued 13 hours later after a dinghy was launched to recover him. Now only six men remained to man the base at Maudheim.

The last field party returned to Maudheim with their dogs on May 30 after living in tents for 24 weeks without a break. However, Alan Reece, one of the geologists, was now blind in one eye after being hit by a rock fragment on March 11. Ove Wilson, the young Swedish doctor, was advised by radio to remove the damaged eye as a precaution against infection of the patient's good eye. After the training of four assistants, none of whom had ever seen an operation, the damaged eye was successfully removed.

During the second winter, the glaciologists obtained ice cores to a depth of 100 meters in the ice shelf, a world record at the time, and resurveyed the ice deformation network. Preparations were made for the second sledging season, during which, in addition to continuing the first summer's work, a party of three men would penetrate as far inland as possible to measure ice thickness by seismic sounding. In the event, the seismic party reached a point 620 km inland. Ice thicknesses greater than 2500 m were found, indicating that in this area, a fjord landscape extended far inland under the ice sheet.

Norsel returned to Maudheim for the last time on December 22, 1951, bringing a Royal Swedish Air Force flying group to complete the aerial surveys. Maudheim was abandoned on January 14, 1952, and the expedition reached Southampton, England on February 18.

The scientific results of the expedition exceeded expectations. The glaciological studies showed that the ice sheet was neither in retreat nor advancing. The finding that the inland ice was much thicker than expected led to the conclusion that the amount of ice on Antarctica must represent the principal factor controlling world sea level. The geological work found evidence (interpreted decades later in the light of the new science of plate tectonics) that indicated that Dronning Maud Land had once been joined to southern Africa. The meteorological studies showed the extent to which the Antarctic ice sheet affects world climate. The survey triangulation covered an area of some 60,000 km^2, and aerial photography extended this to about 100,000 km^2. Finally, medical research on expedition members led to a new understanding of the effects of prolonged isolation.

Six volumes of scientific results were published, together with a set of topographic maps and many papers in scientific journals. The success of the expedition helped to end the series of competing national expeditions that had characterized the first half of the twentieth century. It paved the way for continued international cooperation and laid a foundation for the Antarctic phase of the International Geophysical Year of 1957–1958.

NORWEGIAN *(FRAM)* EXPEDITION (1910–1912)

Roald Amundsen's ambition in life was to be a feted and successful polar explorer, and the climax of his career was to be the expedition to the South Pole, 1910–1912, an expedition that came about as a result of a quirk of fate.

After his successful traversal of the Northwest Passage, 1903–1906, the North Pole was Amundsen's next obvious goal. He announced that he would carry out a repeat and extension of Fridtjof Nansen's famed drift over the Arctic Basin. Nansen had intentionally let his specially constructed ship, *Fram,* freeze into the ice to drift through the Arctic Ocean from east to west in 1893–1896. The expedition had not, however, quite attained the Pole, something that Amundsen now intended to accomplish. He obtained Nansen's permission for the use of *Fram* on the condition that scientific research be given a key role. In 1909, the Norwegian Storting (Parliament) granted Amundsen 75,000 kroner to prepare *Fram* for the new North Pole expedition. King Haakon agreed to be the expedition's patron, and a number of wealthy private donors contributed, but Amundsen still had to seek Nansen's help to obtain loans for the remainder of the expenses.

Amundsen's plan was upset in September 1909, when both Frederick Cook and Robert E. Peary claimed that they had reached the North Pole, Cook in 1908 and Peary earlier in 1909. Interest in sponsoring Amundsen's expedition dwindled, and he realised that he had to achieve another major goal—becoming the first man to reach the South Pole—in order to generate interest for his Arctic drift plans. Arriving second was not in his nature. The change of plans was kept secret, including from Nansen, whose backing had been crucial, and from most of the participants, until the ship arrived at Madeira, which was the last stop before the Antarctic. The men were given the choice to continue to the Antarctic or to return home; they all stayed. The subsequent announcement of Amundsen's change of plans caused an international sensation not only because he had withheld the information from the king and Nansen, but because a British expedition led by Robert Falcon Scott was also planning an attempt on the South Pole. Amundsen's short telegram to Scott—"Beg to inform you Fram proceeding Antarctica. Amundsen"—shocked the British, and his choice to establish his winter base in the same general region of the Antarctic as Scott's earlier and intended site came to be interpreted as unfair play.

Amundsen's greatest attribute as a leader of polar expeditions was his meticulous attention to detail in planning. His time on the Belgian Antarctic Expedition, 1897–1899, and with the Netsilik during his navigation of the Northwest Passage had given him ideas and practical experience with regard to optimal equipment for long dog-sledge journeys. Reading previous Antarctic expedition reports gave him warnings and advice, including the fact that the Bay of Whales at 78°38′ S seemed to be a stable part of the Ross Ice Shelf (or Great Ice Barrier, as it was known at the time) on which to establish his base, thus putting him closer to the South Pole than Scott at his base in McMurdo Sound. All his equipment was specially made according to detailed specifications, and both provisions and participants were carefully chosen.

Fram was to deliver the shore group and spend the Antarctic winter on a scientific cruise in the southern Atlantic under the command of Captain Thorvald Nilsen, before fetching the shore party the following southern summer. On shore for the South Pole expedition would be nine men, including Amundsen, most of them with the title of general workers. Two men from his previous expedition were included, the dog driver Helmer Hanssen and the cook, Adolf Lindstrøm. Sverre Hassel had learned dog driving with Otto Sverdrup in northeast Canada on the second *Fram* expedition, and Olav Bjaaland was an excellent skier, while Hjalmar Johansen had accompanied Nansen when he left *Fram* on his "sprint" toward the Pole in 1895–1896. Oscar Wisting, Kristian Prestrud, and carpenter Jørgen Stubberud completed the wintering group.

When *Fram* left Kristiania (Oslo) on August 9, 1910, most of the crew still thought they were sailing round South America to reach the Bering Strait and a drift over the Arctic Ocean. Many wondered at the 100 Greenland dogs onboard—why take them over the Equator when they could be fetched from Alaska? The large prefabricated cabin was also puzzling for a drift in Arctic ice. At Madeira, on September 6, they were told of the "detour" to the South Pole, and on January 13, 1911, they reached the Bay of Whales. It took a month to unload and establish the shore base, Framheim, with the dogs transporting goods between the ship and the base site. On February 2, Scott's *Terra Nova* sailed up beside *Fram* and could see how efficient this means of transport was. *Fram* sailed to 78°41′ S in the bay before leaving, thus becoming the ship that at that point had been both farthest north and farthest south.

During the autumn, large food and fuel depots were established by dog-sledge and ski journeys at each degree of latitude up to 82° S, and these were marked by an almost foolproof system of flags planted east to west out from the depots, so that they could hardly be missed even in poor weather. At the same time, valuable travel experience was acquired. The winter was spent perfecting and modifying equipment and extending the base with snow tunnels and rooms for various storage and work purposes, while Amundsen worked on the question of rations. Seals and penguins provided a fresh meat supply, not least for the dogs, while the dogs in their turn were carefully calculated to become a meat supply themselves on the trip to and from the Pole. In this way the weight of food to be taken was cut down, and scurvy was made less likely.

Amundsen's only grave mistake during the expedition was to try to start too early for the Pole, occasioned by a fear of losing the prize to Scott. September 7 was too early for travelling: the temperature was down towards –50°C and both men and dogs froze. The return to base a week later was a rout, with Amundsen running first. He could have lost men, but Johansen "swept them up" from behind and rescued both them and ultimately the Pole expedition. Heavy criticism from Johansen, particularly in front of the others, was not tolerated by Amundsen, who demoted him from the Pole group and sent him on a mapping expedition under Prestrud to King Edward VII Land instead. It was a clear snub for the experienced Johansen, who had brought the younger Prestrud home from the early start. Amundsen's revenge was underlined by his sending Johansen off in disgrace when the expedition returned to civilisation.

A new start was made on October 19, with Amundsen, Hanssen, Hassel, Bjaaland, Wisting, and fifty-four dogs. Only Amundsen did not drive his own sledge. The use of skis, dog sledges, experienced men, dogs for food, and carefully established and marked out depots made the perfect combination, and the journey to the Pole and back was carried out without significant problems. When Amundsen departed his first depot at 81° S, Scott was just leaving his winter base. By November 16, Amundsen's group was across the Ross Ice Shelf and had the Transantarctic Mountains in front of them. Ernest Shackleton had already shown a way to the South Pole, but by starting farther west on the Ross Ice Shelf, Amundsen had to find a new way up to the Polar Plateau. He chose the glacier that he named after one of the sponsors, Axel Heiberg, and 4 days later, with forty-two dogs, they reached the Plateau. The names "The Devil's Glacier" and "The Devil's Dance Floor" show, however, that the route was not easy. The dogs had done the worst part of their job. The group was at 85°26′ S, with 440 km left and no more heavy climbs. Twenty-four dogs were shot, some for food immediately and some for later. The eighteen best were kept for the next part of the journey. After 4 days stuck in their tents because of a snowstorm, the party continued, although still in bad weather and sledging conditions. At 87° S the conditions improved, and on December 14 they reached their goal. Here Amundsen declared how strange it was to stand at the South Pole, when his real goal was actually the North Pole.

The group had beaten Scott by a month. Together they planted the Norwegian flag and called the expanse around them Haakon VII's Plateau. Neither this claim nor Prestrud's at King Edward VII Land was followed up by the Norwegian government. Amundsen noted the day of arrival as December 15, since he had forgotten that they had crossed the International Date Line on their voyage. They stayed there for 3 days, in order to observe the position as correctly as possible, making ski trips from the Pole in the other three directions to be sure that they had actually reached the spot, and moving their camp slightly farther south. When they headed north, they left behind a small tent containing some extra equipment and letters to King Haakon and Scott. Scott was asked to take the King's letter back with him. The photograph Scott's party took of Amundsen's tent at the Pole a month later would ultimately prove that both expeditions had actually reached the spot.

Amundsen's group now had sixteen dogs pulling two sledges. By January 6, 1912, they were back on the Ross Ice Shelf after an exciting skiing experience back down the glacier. They had more than enough food for the return journey, and the clothes and equipment functioned well. They arrived back at Framheim on January 25, earlier than expected after a total journey of c. 3000 km in 99 days. *Fram* had already arrived on January 8, after her oceanographic expedition in the southern Atlantic, and the shore party, including the remaining thirty-nine dogs, left on January 30. It took 5 weeks to reach Hobart, Tasmania, where the news of the expedition's success could be released.

Prestrud, Johansen, and Stubberud had left Framheim on November 8, 1911, and had reached King Edward VII Land on December 2. They were back at Framheim on January 10, after mapping and making observations in the previously unknown territory. This side expedition and its results were, however, not of great interest to Amundsen. Five days later the Japanese *Kainan Maru* expedition surprised them by visiting the Bay of Whales.

Amundsen was now supposed to continue with his expedition to the North Pole, as he had promised Nansen. However, time passed as he held lectures in Australia, New Zealand, Europe, and America, which helped to cover old debts and new expenses. *Fram* was left too long in the warm waters off South America, and was too worm-eaten to survive a new battle with the ice in the Arctic Ocean. Then WWI broke out. It was not until 1918 that his next expedition finally left in *Maud*.

Amundsen had not made any pretence of conducting scientific research in the Antarctic. It was the conquest of the Pole alone that was his motivation, and being the first there. Time was, therefore, essential, as he had no idea of Scott's progress. The expedition did have other significant results, however: it proved the superiority of ski and dog-sledge expeditions in polar areas, it opened and mapped a different route to the Polar Plateau from Shackleton's and Scott's, and it gave knowledge to future expeditions about equipment, nutrition, and travel planning. On the home front, Amundsen's success also gave the new independent nation of Norway a world-famous name and a deed to be proud of.

NORWEGIAN (TØNSBERG) WHALING EXPEDITION (1893–1895)

Henrik Johan Bull (1844–1930), a Norwegian who emigrated to Australia, read the report by James Clark Ross of numerous right whales in the Ross Sea and became convinced of the commercial possibilities of whaling in Antarctic seas. After 3 years of unsuccessfully trying to raise funds for a whaling expedition to the Ross Sea, Bull visited Svend Foyn, the pioneer of modern whaling, in Norway. Within 15 minutes, the 84-year-old Foyn had agreed to provide funding and a ship, a 226-ton whaler originally named *Kap Nor* but to be renamed *Antarctic*. Foyn appointed Leonard Kristensen captain, with Bull as manager.

Unfortunately, the division of duties was not properly established, which led to subsequent problems between the two men.

William Speirs Bruce, who subsequently joined the Dundee Whaling Expedition (1892–1893), and Eivind Astrup, who had travelled with Peary in Greenland, asked to join as naturalists, but were unable to reach the ship in time. Carsten Borchgrevink, another Norwegian who had emigrated to Australia, also applied for the post of naturalist, but was shipped as seaman.

Antarctic sailed from Tønsberg, Norway on September 20, 1893, and headed for Îles Kerguelen, where oil and skins of 1600 elephant seals were taken. After calling in at Melbourne, where Bull remained behind to finalize preparations for the voyage to the Ross Sea, *Antarctic* went whaling. One right whale was taken, but the ship ran aground at Campbell Island and repairs were needed on its return.

On September 26, 1894, *Antarctic* set sail again and headed south via Campbell Island, where a few fur seals were taken. Svend Foyn Island was named, but it proved to be a huge iceberg. On the following day, November 7, the propeller worked loose and the ship made for Port Chalmers, New Zealand, under sail.

The final departure from New Zealand was on November 30, Victoria Land was sighted on January 17, 1895, and a landing was made on Possession Island, where Ross had landed 53 years earlier. Borchgrevink discovered a lichen, the first plant to be found south of the Antarctic Circle. *Antarctic* achieved a farthest south of 74°00′ S, and, on January 24, 1894, a boat party landed at Cape Adare. At the time this was believed to be the first landing on the continental mainland of Antarctica, but American sealers had already done so in the 1820s.

The expedition now returned northward. Attempts to go sealing at the Balleny Islands were prevented by bad weather. One sperm whale was caught off Tasmania, and Melbourne was reached on March 12.

Commercially, the expedition had been a failure. It was equipped to catch slow-moving right whales, and attempts to catch fast rorqual whales were unsuccessful. No right whales were found in the Ross Sea, and it has been suggested that Ross had been mistaken in his identification. The expedition is best known for the apparent "first landing on the continent." Kristensen claimed to have been the first ashore, but Borchgrevink maintained that he had leaped out as the boat grounded on the beach. Later, Alexander von Tunzelman, a seaman, declared that he had held the boat steady while the others disembarked. Bull and Borchgrevink started to plan a second expedition, but Bull withdrew after he found Borchgrevink claiming credit for the first expedition's achievements.

O

OASES

Antarctic oases are variably sized ice-free areas on the coast of Antarctica. The term started use in October 1936 at an ice-free area that was analogous to a desert oasis. Alfred Stephenson, a meteorologist with the British Graham Land Expedition, camped on the eastern side of Alexander I Island at Ablation Camp, wrote: "It seemed we had suddenly come into an oasis, for instead of the usual mass of snow with occasional patches of rock there were large valleys of exposed rock with scarcely any snow to be seen" (Stephenson 1938: 194–195).

Since then, the term oasis has been refined by Shumskiy (1957) to incorporate a meteorologically based meaning that emphasised the presence of an ablation zone between the land and surrounding ice. An Antarctic oasis, therefore, is a substantial ice-free area that is separated from the ice sheet by a distinct ablation zone and is kept free from snow by ablation due to low albedo and positive radiation balance. This meaning was permanently enshrined by Solopov (1967) in his monograph *Oazisy v Antarktide (Oases in Antarctica)*. This definition of oasis thus excludes nunataks (even comparatively large massifs), coastal bluffs, peninsulas, off-shore islands, and areas where topographic damming of ice (rather than ablation) has led to their ice-free nature. The Victoria Land Dry Valleys and the Amery Oasis/Beaver Lake area of Mac.Robertson Land fall into this last category. The formation or presence of oases has no relationship with a "local paucity of precipitation" reported by Bölter et al. (2002: 8). Smith (1988, 1997) also developed a biological definition of oasis that is not in common usage.

In addition to these constraints, most oases have four other geographical traits in common. First and most importantly, they lie beside a deeply incised outlet glacier that creates substantial drawdown in the ice surface. This drawdown reduces the flux of the ice sheet over a potential oasis, allowing deglaciation to occur. Second, all oases have erosional (e.g., striation) and depositional (e.g., till and moraine) evidence indicating former cover by an ice sheet. Third, because of the typically disorganised drainage patterns, there are abundant lakes. Fourth, because of the habitat afforded by rock crevices, sediment, and shallow ponds, the oases are home to abundant terrestrial, lacustrine, and marine life. Most oases, including Vestfold, Larsemann, and Stillwell, abut the open ocean, but Bunger and Schirmacher oases lie behind ice shelves.

Bunger Hills ($\sim$950 km^2, max 160 m asl) is bounded by the ice sheet to the east, glaciers to the south and west, and the Shackleton Ice Shelf to the north and northwest. Within these boundaries lie $\sim$480 km^2 of land and a number of marine inlets. The hills were first sighted from a distance by members of the Western Base of the Australasian Antarctic Expedition (1911–1914), but they were thought to be an island. The true nature of the hills was discovered by the 1946–1947 US Navy Operation Highjump, and the first visitation was made by navy pilot, David Bunger, who landed a seaplane on one of the lakes in February 1947. Richard E. Byrd (1947) described the area as "an island suitable for life...in a universe of death." The First Soviet Antarctic Expedition visited the oasis in 1956, with the establishment of Oasis (Oazis) Station at the end of that year. At the end of 1958, Oasis Station was transferred to the Polish expeditions, under which it was renamed Dobrowolski. This facility has operated intermittently since that time, including the construction in 1987 of additional buildings a few hundred metres to the west of Dobrowolski. In 1985–1986, Australian expeditioners established Edgeworth David Base, which consisted of a small number of fibreglass shelters, a few kilometres west of Dobrowolski. There are contrasts in the geography of Bunger Hills. To the south and east, the rock is less weathered, the terrain is more rugged, sediments are fewer, plants are more abundant, and the lake water is fresher. To the northwest, sediments are much more abundant, rock is strongly weathered in places, and there are brackish lakes. Less than 5% of Bunger Hills is covered by snow and ice. The presence of dozens of Weddell seals in the marine inlets implies that the sea ice breaks out annually, and most freshwater lakes thaw annually. Saline lakes are rare in Bunger Hills, and the few that exist are frozen during winter. Birds, particularly snow petrels and skuas, are abundant.

The largest truly coastal oasis is Vestfold Hills (420 km^2, max 170 m asl). Vestfold Hills is bounded by Sørsdal Glacier to the south, the ice sheet to the east, and the ocean to the west. Discovered and photographed from the air in February 1935 by the captain and crew of the Norwegian whaling vessel *Thorshavn,* this area of rolling brown hills with striking mafic dyke swarms was named after Vestfold County, in southern Norway. This section of Princess Elizabeth Land was named the Ingrid Christensen Kyst, in honour of the wife of the whaling magnate Lars Christensen. Caroline Mikkelsen has the distinction of being the first woman to step ashore at Vestfold Hills, even though it was a small island just offshore. There was a long absence until 1955–1957, when both Soviet and Australian expeditioners visited Vestfold Hills, the latter to establish Davis Station on January 13, 1957. Apart from a 4-year hiatus from January 1965 to February 1969, Davis has operated continuously. Like Bunger Hills, less than 5% of Vestfold Hills is covered by snow and ice. While eastern Vestfold is rugged and sediment poor but rich in vegetation, western Vestfold has subdued topography and abundant sediment, but is poor in vegetation. Sea salt drives this pattern. Vestfold Hills hosts a Pliocene diatomaceous sediment in Marine Plain that contains *in situ* whales and other vertebrate fossils. Vestfold Hills is renowned for its hypersaline lakes, including Deep Lake, which has a salinity nine times that of seawater and a lake surface nearly 50 m below sea level. Some hypersaline lakes, including Club, Deep, and Lebed, do not freeze, even in mid-winter. Freshwater lakes are also common, but perennially frozen lakes are rare. Vestfold has abundant wildlife, including Adélie penguin rookeries, elephant seal haul-out beaches, snow petrels, Wilson's storm petrels, South Polar skuas, and rare giant petrel nests.

Larsemann Hills (50 km^2, max 180 m asl) was discovered and photographed by the Lars Christensen expedition of 1936. Consisting of two main peninsulas, Larsemann is bounded by the ice sheet to the south, Dalk Glacier to the east, and ocean elsewhere along its irregular boundary. The hills were visited again by Australian surveyors in 1957, but it was not until 1987 that the summer-only Law Base (Australia) was established. The Soviet stations Progress 1 (1988–1990; site now remediated) and Progress 2 (1990–), and the Chinese Station Zhong Shan (1989–) followed. Glacial erratics are relatively rare in Larsemann Hills, and moraines, while present, are few. Hilltops are typically bare and strongly eroded. Terrestrial plants, penguins, and seals are rare, while the numerous rock crevices host snow petrels. Skuas are found particularly around station buildings. Most lakes are freshwater and annually frozen, and host relatively rich ecosystems of algae and aquatic moss. Lakes near to the ice dome on Stornes (the western peninsula) appear to be perennially frozen and almost devoid of the rich growths of plants found on Broknes (the eastern peninsula).

Stillwell Hills ($\sim$96 km^2, max 340 m asl) is a coastal area of rugged, low hills forming a peninsula and a number of smaller islands. The Hills are bounded to the south by the ice sheet, to the west by a small outlet glacier, and to the north and east by sea. The outlet glacier calves into sea ice that is pinned in behind small islands. Fold Island ($\sim$40 km^2) lies immediately to the north of the main peninsula of Stillwell Hills and is separated from it by a narrow channel only a few hundreds of metres wide. An emperor penguin rookery beside Fold Island indicates the presence of perennial sea ice there. The main peninsula is 18% covered by icefields, which fill the valleys and abut lakes that appear to be perennially frozen. Geological investigations were carried out by D. S. Trail in 1961. While there are no bases at Stillwell Hills, proximity to Mawson Station (Australia) means that summer access is straightforward.

Schirmacher Oasis (34 km^2, max 220 m asl) lies in an embayment in the ice sheet, with the Novolazarevskaya ice shelf to the north. The oasis probably owes its existence to Wohlthat Massif, some 80 km to the south, diverting continental ice from the area. The oasis is elongated east–west, and is only a few kilometres wide in several places. Numerous ponds and lakes are dammed behind snow and firn fields, and most lakes thaw annually. The oasis was first discovered from the air in February 1939 by pilot Richard Heinrich Schirmacher, and the first station to be built there was Novolazarevskaya (USSR) in 1961. German scientists, supported by the Soviet Antarctic Expeditions in Schirmacher since 1976, established a laboratory that became Georg Forster Station (Germany) in 1987. In 1989, Maitri Station (India) was built a few kilometres from Novolazarevskaya Station. Georg Forster Station was closed in 1993. The oasis is frequented by nesting seabirds, including skuas, snow petrels, Wilson's storm petrels, and Antarctic petrels. Adélie penguins have been known to attempt to nest but are rarely successful.

OASES, BIOLOGY OF

An oasis is generally defined as a fertile area in a desert, occurring where the water table approaches or reaches the ground surface. However, in an Antarctic context, oases have been variously construed by scientists as being either dry or wet and either large or small snow-free areas on the continent. The most widely accepted concept is based on local climatic, topographic, geomorphologic, and hydrologic criteria, the most important being that they remain largely snow free due to negligible precipitation and high ablation rates in summer. Most of the larger oases are at or near the edge of the continental ice sheet near the coast, some being separated from the sea by ice shelves. Smaller oases occur at higher altitudes far inland. However, not all ice-free areas constitute oases. If such areas are extensively colonized by vegetation, this implies that the local climate, environment, and water availability are suitably favourable for widespread plant development, and thus do not comply with the concept of Antarctic oases. Some scientists use the term "oasis" to describe a wide range of ice-free sites surrounded by permanent ice, particularly in the region of the Antarctic Peninsula and offshore islands, and often with prominent vegetation. However, such areas are not oases in the conventional sense, and are not considered here.

From a biological or ecological point of view, it is the wet area within an otherwise desert-like environment that is the oasis, and not the ice-free desert *in toto*. This concept may be defined as follows: "An area of restricted size where there is surface water, at least for part of the summer, and where local topography provides a favourable microclimate, allowing a concentration of microbial and plant species to develop relatively complex communities in an otherwise arid and barren desert landscape."

The McMurdo Dry Valleys of southern Victoria Land is the largest ice-free area in Antarctica, covering c. 4000 km^2, and comprises a complex system of broad valleys separated by high mountain ranges and surrounded on all but its coastal boundary by glaciers. The Dry Valleys experience very low summer temperatures and negligible precipitation, although occasional snowfall occurs on the upper slopes of the valleys, permitting very sparse lichen growth. Although it is essentially a desert, there are several large and small lakes ranging from seasonally ice-free to permanently frozen to a depth of many metres, while others are highly saline, especially at depth. During summer, streams flow from melting glaciers towards some of the lakes, although many fail to reach them before drying up. Away from these water sources, the coarse, sandy, gravelly, porous soils are extremely dry and largely incapable of sustaining life in any form. The most biologically rich habitats are the seepage areas below some of the glacier snouts. Here melt water spreads out over the adjacent ground, at some sites covering up to several thousand square metres, and maintaining a wet substrate for a short period during mid- to late summer. These areas support a diversity of plants and microorganisms, and an associated invertebrate fauna. By far the greatest biodiversity is found in the aquatic environment, where algae and cyanobacteria predominate. One of the most intensively researched sites is the Canada Stream, a diffuse area of melt water flowing from the Canada Glacier to Lake Fryxell in Taylor Valley. Here, and in other temporary streams entering the lake, there are several distinct algal communities. The central areas of the channels are dominated by orange-brown mats of the cyanobacteria genera *Oscillatoria* and consolidated mats of *Phormidium*. The edges of these channels are usually dominated by loose black mats of another cyanobacterium genus, *Nostoc*. Filamentous growths of the green alga *Prasiola* form green-colored mats in some of these streams. In all these communities diatoms are also abundant.

Beyond the wettest areas several simple communities of terrestrial vegetation are formed by small patches of diminutive species of moss (notably *Bryum* spp., *Hennediella heimi, Sarconeurum glaciale*). The drier short turves and cushions of moss are sometimes colonized by a few species of crustose lichens as well as by black encrusting cyanobacteria. Crustose lichens also occasionally colonize stones at the margin of the wet areas. However, within a metre or two of this marginal zone the ground becomes extremely dry and visibly barren. Within the moss, algae, and cyanobacteria communities there are associated microfauna. The only macroscopic invertebrates are occasional mites and springtails associated mainly with moss or beneath stones where they feed on algae and fungi. At the microscopic level, nematode worms, tardigrades, rotifers, and protozoans may be locally frequent amongst moist moss and associated with algae and cyanobacterial mats in aquatic habitats.

Other extensive (c. 100–500 km^2) ice-free areas include Bunger Hills (Queen Mary Land), Vestfold Hills, and Larsemann Hills (Princess Elizabeth Land). These have an undulating topography of low hills, broad valleys, and basins with many streams and freshwater and saline lakes and ponds. As with the Dry Valleys, wet areas adjacent to some of the lakes and below glaciers and ice fields provide a habitat for mosses, algae, and cyanobacteria. Because the climate in these areas is less severe than in the Dry Valleys, some 7–10 degrees of latitude farther south, biological diversity is greater. Extensive stands of *Nostoc* and *Phormidium* dominate seepage areas, and stands of moss can reach 100 m^2 or more and may comprise one or several species, including *Bryum* spp., *Ceratodon purpureus,* and *Schistidium antarctici,* with a few less frequent species occasionally associated. Rocks in melt channels sporadically splashed by water sometimes support thalli of the foliose lichens *Umbilicaria aprina, Physcia caesia,* and *Xanthoria elegans,* and occasional crustose species. Beyond the influence of ground water, vegetation becomes restricted to epilithic lichen communities, but these are not strictly components of the oases.

There are many small (10–100 km^2) ice-free sites where life is restricted mainly to isolated seasonal wet areas (e.g., Ulu Peninsula, James Ross Island; Seymour Island; Ablation Valley and Mars Oasis, Alexander Island; Edmonson Point and Beaufort Island, Victoria Land; Schirmacher Oasis, Dronning Maud Land; Langhovde and Skarvsnes, Enderby Land). Even at this level the oases are discrete, and some have more complex biological communities (e.g., Ulu Peninsula, the northernmost of the Antarctic biological oases).

On a much smaller scale there are other types of biologically rich microsites within arid, barren landscapes. Although not strictly oases, they do fulfill some of the criteria that permit a diversity of life to exist. One of these categories is the nutrient-enriched cliffs and screes (talus) below breeding colonies of sea birds, notably snow and Antarctic petrels, in inland mountain ranges. Such areas can cover several hundreds of square metres and support several species of brightly coloured nitrophilous lichens, especially species of *Acarospora, Caloplaca, Candelariella, Rhizoplaca,* and *Xanthoria,* occasional mosses, and the green alga *Prasiola crispa*. Being well adapted to drought and low temperatures, these lichens are dependent more on the nutrients than on free water, as they have the capacity to absorb moisture from the atmosphere. A similar type of microoasis occurs on James Ross Island, where many ancient carcasses and skeletons of seals occur up to several kilometres from the shore. The low nutrient status, dryness, and instability of much of the island's terrain prevent plant colonization, but nutrients leaching from these cadavers permit numerous mosses and lichens to grow on and around them. Geothermal ground near the summits of the three active volcanoes in Victoria Land (Mount Erebus, Mount Melbourne, and Mount Rittmann) also act as microoases where a very few bryophytes and algae have established. Here, the warm ground and steam provide a favourable habitat, sometimes <1 m^2, while beyond these hotspots conditions are too severe for colonization.

OATES, LAWRENCE EDWARD GRACE

Captain L. E. G. Oates holds a unique place in the history of Antarctic exploration, due not only to being part of Robert Falcon Scott's party who died after attaining the South Pole, but because of the way he sacrificed his life on the tragic return journey in order to help save his comrades. He was immortalised by his laconic final words: "I am just going outside, and may be some time."

Lawrence Edward Grace Oates was born on March 17, 1880, at Putney, London, the eldest son of William and Caroline Oates (née Buckton). Although more popularly known as "Titus" after the infamous anti-Catholic conspirator, relatives called him Laurie. He was a member of a distinguished and wealthy family that lived at Gestingthorpe Hall, the manor house at Gestingthorpe, Essex, from 1891, and can trace its lineage back 1000 years.

Oates was a sickly child who was dominated and spoilt by his formidable mother Caroline. He was given a fine education, including a brief spell at the Remenham Place preparatory school and 2 years at Eton (1894–1896). But he failed miserably at school and never passed a single examination, largely because of dyslexia. After numerous futile attempts to pass entry exams into the army, in 1898 he enlisted in the militia corps, the Prince of Wales's Own West Yorkshire Regiment.

Oates was subsequently gazetted to the 6th Inniskilling Dragoons, the elite cavalry regiment, on April 6, 1900, after the outbreak of the Boer War. He was recommended for the Victoria Cross, the highest military honour, for one act of courage that left him badly wounded and with one leg shorter than the other. However, Oates grew disenchanted with the army during peacetime duties in Ireland, Egypt, and India (1902–1909). He was an expert horseman and an adventurous, old-style cavalry officer more suited to a chivalrous age, and he struggled to come to terms with the military reforms and the changing face of warfare in the early twentieth century.

Oates was promoted to the rank of captain in November 1906, but was anxious to leave the army when he learned about Scott's South Pole expedition in 1909. In his eagerness, he paid £1000 (approximately £50,000 in today's terms) to the expedition's funds and was given responsibility for the horses, which were central to Scott's plans. But he was not asked to select the poorly suited animals, which he described as the "greatest load of crocks I have ever seen." Oates proved to be one of the most popular men on the expedition, but he clashed a number of times with Scott over the purchase and deployment of the inadequate ponies.

Oates, a reserved, aristocratic man of great courage, was an outsider as the only solider in the navy-dominated expedition. But he worked tirelessly on the march toward the South Pole, getting the last of the horses 400 miles (640 km) across the Great Ice Barrier (now known as the Ross Ice Shelf) to the foot of the Beardmore Glacier. He was selected for the final Polar Party because Scott wished to see the army represented at the South Pole. But Oates was already in serious decline from fatigue and frostbite when Scott made his selection and wanted to return to base camp. A closer inspection of his fitness might have excluded him from the final party.

With his comrades, Oates reached the South Pole on January 17, 1912, but weakened rapidly on the return journey. Initially he kept his condition hidden, but in early March he revealed badly frostbitten feet and hands. He deteriorated rapidly during the next two weeks, with his feet swollen by acute frostbite and worsening gangrene. He begged to be left behind and on March 16 or 17, 1912, he crawled from the tent to commit suicide, unable to cope any longer. It was his thirty-second birthday, and Scott wrote: "We knew it was the act of a brave man and an English gentleman." His body was never found, but his death became a symbol of noble sacrifice.

OCEAN RESEARCH PLATFORMS AND SAMPLING EQUIPMENT

Throughout history, scientific research in the Southern Ocean has been limited by the remoteness of the region, its severe weather, and the presence of ice. Once on site, scientists have typically sampled the ocean by lowering selected instruments on appropriate wires, but a frozen surface can complicate this process or render it dangerous, particularly during winter months. In spite of these problems, early explorers nearly always sampled the ocean, taking cores of the sediments; collecting fish, invertebrates, and benthic (bottom-dwelling) fauna; and measuring temperature and salinity to characterize the physical state of the seawater. Although simple equipment was employed, the data provided a first glimpse into the sub-ice environment and the ecosystems functioning there. Much of the knowledge gained about the Southern Ocean through the middle of the twentieth century was obtained on the *Discovery* investigations.

The advent of icebreakers in the latter half of the twentieth century made it feasible to work in the pack ice, but mostly in the austral summer and with a primary mission of supporting coastal stations. As such, scientific sampling was a relatively low priority, although those ships were outfitted with rudimentary laboratories, winches, and sampling equipment. Shortly after the International Geophysical Year, the US National Science Foundation converted a military transport ship into a full-time research vessel, the USNS *Eltanin,* from which multidisciplinary surveys were made over broad areas of the Southern Ocean during the 1960s and 1970s. Subsequent demand for more knowledge finally resulted in the construction of a new breed of ship, ice strengthened but lacking the power of turbine- and nuclear-driven icebreakers. These research vessels included *Polar Duke, Nathaniel B. Palmer,* and *Laurence M. Gould* (US), *Aurora Australis* (Australia), *James Clark Ross* (Great Britain), and *Polarstern* (Germany). These ships can stay at sea for 50+ days, can berth and feed 25+ scientists plus crew, and have modern laboratories and sampling equipment, along with a capacity to load and deliver substantial quantities of supplies to stations and field camps.

The equipment these vessels carry on a given expedition will depend on the type of research to be conducted, but a primary tool for many oceanographers is the CTD/rosette, which measures *c*onductivity (salinity), *t*emperature, and *d*epth (pressure), and can also retrieve samples of water from any depth. As this package is lowered on an electrically conductive cable, the data from these measurements are fed to the operator's console, where they are plotted versus depth as the CTD descends or returns to the ship. Water samples are acquired using plastic "Niskin" bottles attached to the circumference of the rosette and triggered from the surface when the desired depths are attained, usually on the return trip to allow a rapid and continuous sampling of physical parameters during the descent. Once on board, the seawater is drained from the bottles and analyzed using standard laboratory procedures for salinity (to monitor the conductivity probe), nutrients (mainly nitrate, phosphate, and silicate), suspended particles, or a variety of dissolved ions, metals, gases, and organic compounds. Additional devices can be plugged into the CTD package for concurrent data display and recording. Many of these instruments are optical, sensing the total clarity of the water, the amount of phytoplankton (microscopic suspended algae), chlorophyll fluorescence, and the natural light transmitted into or scattered within the water. Other types of samples are acquired with a variety of bottom corers, nets, and trawls for collecting swimming, drifting, and benthic organisms. Surface seawater is commonly pumped aboard for laboratory analyses while ships are underway.

Most ships are equipped to sample the water column and seafloor using acoustic devices. The most basic of these is the simple echo sounder, which measures the time delay between transmission of a "ping" of sound into the water and its arrival back at the surface, having been reflected by organisms in the water and from the seafloor. The frequencies employed vary according to the task, with high frequencies (100 kHz or above) used to assess fish and krill populations, and low frequencies (12 kHz) used to measure the water depth. Even lower frequencies, less attenuated by seawater, are used to investigate the layering of sediments within the seafloor. Good resolution of the upper layers is provided by 3.5 kHz, but in order to see deep into the sediments, geophysicists utilize "airguns" to generate pulses of sound in the 100-Hz range. These pulses echo back from the seafloor, from structures deep within the sediments, and from bedrock below the sediments, and are recorded using a towed array of hydrophones. More sophisticated echo sounders utilize multiple sound pulses and phased detection of the returns to acquire three-dimensional images of a swath along the seafloor. Geophysicists also use ship-borne gravimeters to measure local gravity anomalies caused by embedded masses or isostatic disequilibrium caused by plate tectonic motions, and towed magnetometers to map anomalies produced as the oceanic plates spread apart and the Earth's reversing magnetic field is recorded in the solidifying igneous rocks.

Another instrument mounted in most ships' hulls is the Acoustic Doppler Current Profiler (ADCP). This device consists of three or four transducers facing downward but mounted at slight angles relative to one another, sending out pulses of high-frequency sound (usually 150–1200 kHz) into the ocean and receiving the returns from particles suspended in the water. From the timing (distance from the source) and frequency shift (due to the Doppler effect of the moving particles), an instantaneous profile of the three-dimensional flow is recorded. To obtain absolute flow values, the ship's motion relative to the water and its pitch, roll, and heave must also be separated from the signal using data from sensors for that purpose. In regions of extensive sea-ice cover, these and other instruments are often deployed on bottom-moored arrays, with recorders that must be recovered at a later date. The instrument array typically consists of a heavy anchor (sometimes one or more steel train wheels), an acoustic release, wire or synthetic rope, and hollow glass spheres at the apex of the mooring to provide the buoyancy necessary to keep the array upright and facilitate recovery. The array is deployed by streaming the flotation spheres behind the ship while paying out the wire with its attached instruments, and finally dropping the anchor over the intended deployment site. Recovery is accomplished by sending a coded command to the acoustic release, causing it to release its grip on a chain attached to the anchor and allowing all but the anchor and chain to rise to the sea surface.

Instrumentation on moored arrays can include most of the equipment normally associated with ship-based sampling, or more specialized equipment. One common item is the sediment trap, which can collect either a single, time-integrated sample, or multiple, sequential, time-series samples. Particles are intercepted as they settle from the upper water column toward the seafloor where they would become sediment, and the biogenic components are analyzed for plankton and nekton activity. Some instruments are capable of measuring dissolved nutrients and other parameters, or preserving samples of the seawater and its contents. The latest development in this field is the cabled observatory, where a suite of instruments is installed on the seafloor and connected by a cable to a research station ashore. The cable provides power to the underwater package and delivers data from it to the land station and from there via the internet to computers in scientists' laboratories. Researchers can control the instruments and receive data in real time from anywhere in the world, while educators, students, and the general public can experience the Antarctic environment without the need to travel there.

Some sampling requirements demand instrumentation that moves independent of a ship or fixed mooring, and this can be free drifting, tethered, or autonomous. Drifters are used either to track the motion of the water itself or to acquire time-series measurements in a parcel of water as it circulates, and periodically transmit location and measurements to orbiting satellites. Tethered remotely operated vehicles (ROVs) are often used to provide the scientist with a virtual presence in the ocean where manned submersibles are impractical or unsafe (e.g., beneath sea ice, icebergs, and shelf ice). ROVs incorporate thrusters, video systems, and sensors that are manipulated by a technician aboardship through the vehicle's tether. These vehicles have been used to study organisms feeding on algae embedded in the ice and living on the sea floor, and regions where glacier calving fronts interact with the ocean and seabed. Where the tether presents an unacceptable hindrance to maneuverability or range, autonomous undersea vehicles (AUVs) are used. These rovers incorporate large battery packs and thrusters, and range in size from small enough to be operated from an inflatable boat to very large, requiring a crane and special handling system. AUVs that lack any mechanical means of propulsion are referred to as gliders. A buoyancy regulation system causes the vehicle to alternate between heavier and lighter than seawater, while movable "wings" cause the vehicles to be propelled forward during descent and ascent. This porpoising motion allows data collection in two dimensions: along a prescribed course using only the energy required by the buoyancy system, and that associated with data transmission through a satellite during surfacing intervals.

Satellites are also used to acquire sea-surface data such as passive radiation emitted from the ocean and sea ice, and ocean color related to plankton biomass. Much of this type of data can now be acquired in real time aboard ship, and is increasingly relied upon by modern expeditions for navigation in ice and weather, and for the location of choice sampling sites. These are all examples of technologies now being applied in studies aimed at better understanding the Antarctic environment, as well as in pressing concerns related to the increase in carbon dioxide in the atmosphere and oceans. Since this increase impacts seawater chemistry and organisms living in the sea, measurements are particularly needed in the remote Southern Ocean to adequately determine baseline values and monitor changes over time.

OFFICE OF POLAR PROGRAMS, NATIONAL SCIENCE FOUNDATION, USA

The Office of Polar Programs is the day-to-day manager of the United States Antarctic Program. Some thirty of the office's scientific, engineering, and managerial staff work full time on the Antarctic (others are involved in the National Science Foundation's Arctic research program). The Antarctic staff represents 2.5% of the foundation's roster; the program it administers spends about 5% of the Foundation's $5.7 billion annual budget (2004 figures).

Dividing its time between the Antarctic and the seventh floor of the National Science Foundation headquarters building in Arlington, Virginia, the Antarctic staff manages the USA's scientific research and operational support in Antarctica and the Southern Ocean. But neither the Office of Polar Programs nor its parent foundation is an Antarctic institute. The field work is performed mainly by university scientists who have been awarded foundation grants and by operational support specialists who are employed with firms that have won National Science Foundation contracts. The US military has a substantial logistics role.

Responsibilities of the Office of Polar Programs include these functions:

- Annual preparation of plans and budget for consideration within the executive branch of the US Government and for review and appropriation by the US Congress
- Development of scientific goals for Antarctica, obtaining advice from the science community, and communicating these goals to the community
- Receipt of proposals for research and education projects from US universities, other research institutions, and federal agencies; evaluation of these proposals for relevance to program goals,

scientific merit, and logistics feasibility; and granting of funds (as available) to these institutions for performance of the projects in Antarctica and completion of analysis upon return
- Detailed planning of logistics, and transmittal of logistics requirements and funds to elements of the Department of Defense and to the US Coast Guard
- Facilities management, design, planning, engineering, construction, and maintenance
- Development and management of a contract with a commercial firm for operation of Antarctic stations and research ships and related services, including construction
- Development and implementation of safety, environment, and health programs for US activities in Antarctica
- Arrangement of cooperative scientific and logistics programs with other Antarctic Treaty nations
- Designation of a senior US representative in Antarctica and on-site management of the field programs in Antarctica
- Serving as a clearinghouse of information regarding Antarctic records, files, documents, and maps maintained within agencies and nongovernmental organizations.

In fiscal 2002, the office made 228 new grants to start Antarctic research projects, workshops, or analyses. In the 2001–2002 season, seventy-eight research institutions (mainly universities) throughout the United States were involved in field investigations in the Antarctic; scientists from these institutions conducted 148 research projects during the austral summer, and some of the projects continued through the 2002 austral winter. These numbers are roughly typical for any given year. Additional projects not involving fieldwork were conducted at the grantee research institutions in the United States.

The scientists obtained the grants (which were awarded, actually, to their employing universities) through a competitive process involving anonymous review by scientific peers and review by operational experts to establish the feasibility of supporting the research out in the field. This evaluation typically begins when proposals written in response to a foundation program solicitation arrive 15 months before a project goes to the Antarctic. A proposal received, for example, in June 2006 normally would be considered for support in the Antarctic no earlier than the 2007–2008 austral summer.

Operational support in the Antarctic is provided by a major contractor to the foundation; for the years 2000–2010 it is Raytheon Polar Services Company, Centennial, Colorado, other contractors, and the US military.

While the United States has no central Antarctic institute, the Office of Polar Programs does fund specialized Antarctic facilities whose counterparts in another nation might be part of that nation's Antarctic institute. These facilities include the National Ice Core Laboratory, Denver, Colorado; the Antarctic Marine Geology Research Facility and Core Library, Florida State University, Tallahassee, Florida; the Antarctic meteorite collection at the Johnson Space Center, Houston, Texas; a polar rock repository at The Ohio State University, Columbus, Ohio; an Antarctic Resource Center (maps and aerial photographs) at the US Geological Survey, Reston, Virginia; and the Antarctic Bibliography at the American Geological Institute, Alexandria, Virginia.

The National Science Foundation can commit funds for US participation in international Antarctic research only after peer review of proposals that it has received. Funds normally are not awarded to non-US institutions.

Other Participating Federal Agencies

Several other US agencies support Antarctic research—notably the National Aeronautics and Space Administration (satellite operations, satellite-derived and balloon-launched research); the National Oceanic and Atmospheric Administration (ozone research, climate monitoring at the South Pole); and the US Geological Survey (mapping). The agencies coordinate their Antarctic operational requirements with the Office of Polar Programs.

The Department of Defense provides military logistics, reimbursed by the foundation, comprising shipborne cargo between the United States West Coast and McMurdo Station (Military Sealift Command), shipborne fuel delivery to McMurdo (Military Sealift Command), airlift (primarily C-17) between Christchurch, New Zealand, and McMurdo (Air Mobility Command), LC-130 Hercules (ski-equipped) airlift in Antarctica (109th Air Wing, Air National Guard), cargo ship loading and unloading (Navy Cargo Handling and Port Group), and the aviation technical services of weather forecasting, air traffic control, and ground electronics maintenance (Space and Naval Warfare Systems Center).

The Department of Homeland Security (through the US Coast Guard) provides icebreaker services, reimbursed by the foundation: channel breaking of sea ice in advance of the fuel and cargo ships, escorting the supply ships into and out of McMurdo, and other assistance, including science project support.

The Department of the Interior's Office of Aircraft Services provides procurement assistance, contract administration, and inspection for commercial aircraft services contracted to the US Antarctic Program.

The Department of State formulates foreign policy direction relating to the US program and conducts foreign relations regarding Antarctica. It chairs the Antarctic Working Group—a subgroup of the Interagency Working Group on Global Environmental Affairs that formulates policy guidance for US activities under the Antarctic Treaty. Other members of the group are the National Science Foundation, the Department of Defense, and other federal agencies as appropriate.

Historical Development of the Office

The National Science Foundation's first Antarctic assignment was for funding of US planning and scientific participation in the 1957–1958 International Geophysical Year. Starting with fiscal 1954, only 4 years after it was established, the Foundation provided these funds to the National Academy of Sciences, a longstanding advisory body chartered by the US government, which in turn awarded them to participating scientists. The US Navy separately funded and managed operational support and logistics.

In 1959, the government decided to continue its support of Antarctic research indefinitely and formed the United States Antarctic Program, asking the foundation to manage it. The foundation set up an Office of Antarctic Programs; it began awarding research funds directly to scientists and coordinating operational needs with the Navy. The Academy started a Committee on Polar Research (later renamed the Polar Research Board), which the foundation funds, to advise the foundation.

In 1970, the President centralized government funding of the Antarctic program, including the Navy's role, at the foundation. About then, also, an Arctic responsibility was added and the office name was changed to Office of Polar Programs.

With centralized management came a gradual shift from military to civilian performance of many of the Antarctic operational functions. A Presidential memorandum in 1982 formalized the change. Over the years, consolidation increased the effectiveness and efficiency of research, for the military units were able to focus on their strengths and turn over the functions of science support and station operations to foundation contractors specifically oriented to these specialized tasks. The US military itself consolidated its remaining Antarctic functions. In 1998, the Navy withdrew from a long and distinguished career in the Antarctic as it turned over its then-principal Antarctic duty—flying ski-equipped LC-130 airplanes—to the New York Air National Guard, which already had a similar mission in Greenland.

Formal reviews in 1996 by the President's National Science and Technology Council, and in 1997 by a National Science Foundation external panel, revalidated the President's 1982 decision. The reviews recommended indefinite continuation of the United States Antarctic Program, along with its centralized management by the foundation's Office of Polar Programs.

OPERATIONAL ENVIRONMENTAL MANAGEMENT

Focus on the environmental aspects of Antarctic operations has increased significantly during recent decades. This has happened in parallel with the general increase in global environmental awareness. It also reflects a greater understanding of the impacts that operations have on the science that they support. The managers of Antarctic programmes have instituted operational procedures to minimize these impacts and provide Antarctic researchers with the best possible conditions. These efforts have been guided by the Antarctic political and legal system, which has placed environmental management high on the agenda during recent years.

The Legal and Political Framework for Operational Environmental Management

The desire to minimize environmental impacts from operations has been a concern from the start of scientific research in the Antarctic and has been clearly reflected in the many recommendations adopted by the Antarctic Treaty Parties through the years. Many of the recommendations have been developed on the basis of advice from the Scientific Committee on Antarctic Research (SCAR), which has ensured that the needs of the scientific community have been heard in the effort to maintain the value of the area for scientific research.

Already in 1961, the parties to the Antarctic Treaty had agreed to measures to conserve flora and fauna (Recommendation I–VIII), including, for example, recommendations regarding operations of aircraft and vehicles near concentrations of seabirds and marine mammals. In 1975, the Antarctic Treaty Parties adopted Recommendation VIII–11 (Man's Impact on the Antarctic Environment), containing a code of conduct that set minimum environmental standards for operations in Antarctica, including specifying standards for waste disposal. It also provided Antarctic operators with guidelines for the planning of major Antarctic projects, in essence stipulating the first environmental impact assessment requirements in Antarctica.

With time, the initial basic recommendations were further developed and tightened. Recommendation XII–3 (1983), for instance, gave national organizations responsible for Antarctic activities a clear obligation to scrutinize the plans for any scientific activity they planned to conduct, including the planned provision of logistic facilities to support such activity, in order to determine whether the planned activities were likely to have significant impacts. Recommendation XV–3 (1989) built on and tightened the earlier waste-disposal requirements and stipulated that the amount of wastes produced, or disposed of, in Antarctica should be reduced to the maximum extent possible so as to minimize impact on the Antarctic environment and minimize interference with scientific research or other legitimate uses of the Antarctic.

In October 1991, the Antarctic Treaty Consultative Parties adopted the Protocol on Environmental Protection to the Antarctic Treaty (the Protocol). The Protocol incorporated a number of the earlier recommendations regarding environmental management, including provisions for environmental impact assessment (Annex I), the conservation of Antarctic fauna and flora (Annex II), waste disposal and waste management (Annex III), the prevention of marine pollution (Annex IV), and area protection and management (Annex V). The Protocol provides a comprehensive legal and political framework for environmental operational management in Antarctica. The comprehensiveness of the Protocol and the overarching aim it sets out gave impetus for a whole new thinking with regard to operations in the Antarctic, and operators have seen further merit in reducing their impact in Antarctica.

The coming into the force of the Protocol prompted many operators to review their ongoing activities in Antarctica with the aim of improving operations and procedures affecting the environment, such as those related to waste management, fuel storage, and sewage treatment (see, for example, Argentina, 1998).

The Operational Framework for Environmental Management

In 1988, more or less parallel to the development and adoption of the Protocol, the national Antarctic programme operators joined forces and established the Council of Managers of National Antarctic Programmes (COMNAP) to facilitate liaison between the managers of national agencies responsible for the conduct of logistics operations in support of Antarctic science. One of COMNAP's aims is to enhance the national Antarctic programs' environmental stewardship in Antarctica through exchange of information and experience, development of manuals and guidelines, and consideration of common operational problems.

In the 1990s, many Antarctic operators appointed or identified persons within their organizations who would have special responsibility to follow up on the application of the provisions of the Protocol in the operations of their programme. In 1996, these Environmental Officers (EOs) moved COMNAP to form the Antarctic Environmental Officers Network (AEON) in order to provide a forum for the exchange of information, experience, and ideas about practical environmental management issues. The objectives of AEON are primarily information exchange and the promotion of a mutual understanding on the practical application of the Protocol in Antarctic operations.

During the past decade or so, COMNAP has developed comprehensive procedures and guidelines on operational aspects that are relevant in the context of Antarctic operational environmental management. Some examples of these guidelines include the following:

- Guidelines for Oil Spill Contingency Planning (1992)
- Recommended Procedures for Fuel Oil Transfer at Stations and Bases (1992)
- Recommendations for Spill Prevention and Containment of Fuel at Stations and Bases (1992)
- Guidelines for the Reporting of Oil Spill Incidents which Occur in Antarctica (1993)
- Antarctic Environmental Monitoring Handbook (2000)

Practical Aspects of Operational Environmental Management

Permits and Environmental Impact Evaluations

Those responsible for operations in Antarctica must normally report any new activity to the appropriate national authorities. Permit and authorization requirements vary between countries, depending on the specifics of their national legislation. Common for all are the environmental impact assessment (EIA) requirements provided for in the Protocol, which requires that all activities in Antarctica be planned and conducted so that they inflict as little as possible negative impact on the environment. EIA procedures are detailed in Annex I of the Protocol. Such procedures ensure that appropriate environmental management and mitigation procedures are identified for the activity. Since the coming into force of the Protocol, most Antarctic operators have put in place procedures for environmental impact assessments and are actively pursuing these requirements.

Activities that are likely to have little if any impact on the environment (including most science events) require a preliminary assessment procedure before they are allowed to proceed. For more substantial activities likely to have some environmental impacts associated with implementation, an initial environmental evaluation (IEE) is normally required. Although all activities are assessed on an individual basis, the types of activity that trigger the IEE level are often similar between operators, and usually encompass activities such as removal of stations, fuel storage instalments, upgrading of stations, installment of larger equipment (e.g., scientific, communication), and transport upgrading.

When an activity is expected to have more than minor or transitory impact, a comprehensive environmental evaluation (CEE) is required. Only a handful of CEEs have been developed to date. The types of activities considered have so far been mostly related to construction of new stations and large-scale research activities. Examples since 1998 include the following:

- Scientific ice drilling and construction of a field camp (Germany)
- Project Ice Cube at South Pole Station (United States)
- Upgrading of the Norwegian summer station Troll to a permanent station (Norway)
- Construction and operation of a Czech scientific station (Czech Republic)
- Water sampling from the subglacial Lake Vostok (Russia)
- Development and implementation of surface traverse capabilities (United States)
- Scientific drilling and infrastructure provision for the Cape Roberts (CRP) and ANDRILL Projects (New Zealand)

The process of assessing environmental impacts is complex and challenging. To aid operators in implementing the assessment process in a coherent manner, the CEP adopted "Guidelines for Environmental Impact Assessment in Antarctica" in 1999, which set out a step-by-step approach to the assessment process. The guidelines are meant to aid operators in their endeavours to assess the environmental impacts of their operations in a methodological and structured manner, identifying impacts and dealing with mitigation issues.

In 2001, COMNAP, through its AEON, analyzed a number of IEEs developed by national operators in order to achieve a better understanding of how the EIA process is being used by national Antarctic programmes, and to identify strengths and weaknesses in the preparation of IEEs (COMNAP 2001). Through the analysis it was found that different aspects of the EIA processes are being done well while other aspects can be further improved. The analysis noted, in particular, weaknesses with regard to the actual evaluation of environmental impacts, the key component of the EIA process. Establishing a methodological approach to evaluation of environmental impacts is therefore recognized as a particular challenge that operators will continue to consider. Despite the challenges still remaining, the environmental impact assessment process has nevertheless clearly aided operators in considering environmental aspects of the operation, and how these best can be dealt with.

Waste Management

Until relatively recently, waste-disposal practices in Antarctica were more or less similar to those elsewhere in the world, with open dumps, landfills, and burning, and, more particular for Antarctica, dumping of waste on the sea ice during winter, as it would float away and sink during the summer. Sewage was normally burned or discharged with little or no treatment straight into the sea. With the adoption of the Protocol, the focus on waste management increased significantly. Annex III of the Protocol sets waste management standards, including waste minimization; consideration of waste storage, disposal, and removal; returning waste to the organising country; and cleaning up sites of past activities. Operators have, over the last 2 decades, developed stringent procedures and routines to handle waste in accordance with these standards, and have developed detailed waste-management strategies. For example, the short summary of Antarctica New Zealand's waste strategy states that the organization "will minimize, reuse and recycle waste generated by its activities as far as practicable and will ensure that waste is disposed of with minimal environmental impacts. Waste management planning will examine the use, where appropriate, of alternative technologies, materials and disposal options, and identify areas of past activity which require future clean up and/or remediation" (Antarctica New Zealand 2004).

Strategies and policies have been developed into plans, guidelines, and handbooks to provide practical procedures for the handling, storage, and disposal of waste and to provide procedures for the day-to-day implementation of the strategies and policies developed. Plans typically include detailed procedures for the proper separation, handling, storage, transport, and disposal of all wastes generated, including field activities. Policies are also in place to promote waste minimization and increase waste recycling. The complexity of the waste strategies varies from operator to operator and according to the complexity of the operations. Comprehensive waste-classification schemes have been developed, both to promote recycling of the waste and to enable recording of amounts to facilitate studies aimed at evaluating the environmental impact of the operations.

Today all operators remove most of the waste from Antarctica. However, sewage and food wastes still remain a challenge and are often treated and disposed of at the site. At the coastal stations such waste is often discharged untreated (or only macerated) into the sea or into ice pits. Studies have shown that such effluent can have some local impact. Thus, aiming at minimizing the impacts even further, more and more operators are installing sewage-treatment plants for treatment of the sewage before discharge, and collection of sludge/dried solid matter for removal from Antarctica.

Discharge of sewage at inland stations has proven to be more challenging. At some of these stations such waste is discharged into cavities, so-called "sewage bulbs," in the ice. Other stations have installed incinerator toilets, from which the remaining ash is removed from Antarctica. Although the Protocol specifically prohibits it, several inland stations have found it necessary, due to operational challenges, to discharge wastewater directly on ice-free ground, normally after some treatment. The challenge of handling liquid waste at inland bases has been noted, and COMNAP has, on this basis, investigated the question of best practice, reaching the conclusion that the proper treatment of wastewater depends on the specific situation and that therefore there is no single "best practice."

Fuel Use, Storage, and Management

Virtually all operators in Antarctica operate a range of vehicles for transport of personnel and materials, as well as for mechanical works. Most stations are also supported by vessel operations, and some by aircraft. Ships, aircraft, and vehicles, as well as stations and field camps, operate predominantly on fossil fuels. With the large quantities of fuels being stored, transported, and consumed, fuel spills constitute one of the highest operational environmental threats to the Antarctic environment (COMNAP 2002). Operators endeavour to minimize the threat by limiting consumption, ensuring appropriate storage and handling, and establishing response mechanisms in the event of spills.

At stations and in the field, leaks from hosing, fittings, and seals are a common cause of fuel spills. A rupture/breach of an uncontained fuel-storage tank has the potential to cause major spills. The worst-case scenario for a sea-based environmental emergency would be a vessel that sinks, and breaks up, releasing its bunkers or cargo fuel.

Many operators have, within the new environmental framework, over the last decades evaluated and improved their fuel-storage and -handling systems. When systems are upgraded, secondary containment at fuel-storage sites are normally installed. For example, at McMurdo Station, the US program has recently upgraded fuel-storage facilities so that most bulk-storage tanks now have some form of secondary containment. At nearby Scott Base all single-skinned fuel-storage tanks were replaced with double-contained tanks between 1998 and 2000. Electronic fuel-leak monitoring systems have been installed at some stations (e.g., the South African Base SANAE IV).

Aware that the reduction of risk of emergencies or accidents is best achieved through effective measures on preparedness, emergency response action, and contingency planning, the Antarctic Treaty Consultative Parties agreed in 1998 to adopt the numerous COMNAP guidelines on fuel oil handling, spill prevention and containment, contingency planning, and reporting of oil spills as a framework for fuel management for operations in Antarctica.

Energy Management

In addition to the risk of fuel spills, the use of fossil fuels entails the release of both greenhouse gases and pollutants into the atmosphere. An aim for Antarctic operators is therefore to reduce fuel consumption through conservation and use of alternative energy sources. The use of alternative energy sources is on the increase. Solar energy is used in several places, mostly at the smaller stations, such as Lake Hoare Camp (US) in the Dry Valleys and Wasa Station (Sweden) in Dronning Maud Land. Wind energy is also used, although mostly on a small scale, at several stations, for example, Neumayer Station (Germany), Juan Carlos I (Spain), and Syowa (Japan). In 2004, the Australian Antarctic Division initiated the first serious attempt by any operator to use wind power generation in Antarctica on a large-scale basis when the installation and commissioning of two wind turbines was completed at Mawson Station.

Flora and Fauna, and Introduction of Microorganisms

Harmful interference with flora and fauna, for example flying or landing helicopters, using vehicles or vessels, or using explosives in a manner that disturbs concentrations of birds and seals is, in accordance with Annex II of the Protocol, prohibited. On this basis, operators have instituted procedures to ensure that flora and fauna are not disturbed as a result of their operations. Environmental codes of conduct have been developed by most operators, covering issues such as vehicle use, pedestrian traffic, camping, etc. Several operators have also instituted guidelines for aircraft operations in order to minimize environmental impact from such operations. At ATCM XXVII in 2004 it was noted that the potential for harmful disturbances to concentrations of birds makes it important to provide pilots with guidelines that would prevent or minimize the damaging impact, and on this basis the Antarctic Treaty Consultative Parties adopted "Guidelines for the Operation of Aircraft near Concentrations of Birds in Antarctica," which will provide operators with further guidance in minimizing environmental impact from their operations.

Annex II of the Protocol also requires operators to take necessary precautions to prevent the introduction of microorganisms not present in the native flora and fauna. Introduction of exotic organisms such as plants, seeds, insects, spiders, and microorganisms is a potential threat to the Antarctic environment, and could irrevocably change the natural environment and wildlife. Some operators, such as the Australian Antarctic Division, have instituted extensive procedures to prevent the introduction of microorganisms through quarantine practices based on inspection measures, administrative measures, and on-site management activities, while others are still in the process of assessing the risk and the necessary precautionary procedures.

Monitoring

Monitoring of the impacts of activities in Antarctica is an integral part of environmental operations. The Protocol is an important basis for determining monitoring requirements. The most common types of monitoring studies being undertaken by Antarctic operators include (1) contamination in near-shore coastal ecosystems; (2) atmospheric pollutants associated with station activities; (3) quantity and quality of sewage and waste-water discharges, (4) levels and fate of hydrocarbons in soil and/or water; and (5) population counts and/or breeding success of Antarctic birds (COMNAP 1998). Many national programs have developed systematic monitoring programs that are specific to their operations. Other operators have not begun or are only in the early stages of program development. COMNAP, through its AEON, is developing practical guidelines to assist operators in developing and designing monitoring programs for particular operations, and has also developed a technical monitoring handbook (2000) to facilitate comparative studies across operators.

Training

Operators in Antarctica recognize that education and training are essential in improving the environmental management in operations, and most operators have included environmental management in their training framework, although the extent, form, and content vary between operators. Training and education are often multitiered, conducted both before departure, while travelling, and on arrival in Antarctica. A number of tools are used for training/education purposes, such as printed codes of conduct, videos (such as *Caring for the Environment in Antarctica—A Guide to Your Responsibilities,* produced by Antarctica New Zealand), web-based training tools, and specialized training courses for specific (high-risk) activities (e.g., the Antarctic Oil Pollution Control Course, organized by Oil Spill Response Ltd. (OSRL) and the British Antarctic Survey). COMNAP has adopted a voluntary checklist for environmental training to assist operators in developing the environmental aspects of their training program.

Operational Environmental Management in the Tourism Industry

The Environmental Protocol also applies to tourism and nongovernmental activities. Environmental awareness has always been a key element of tourism operations in Antarctica, and already in the 1970s operators active in the region recognized the need for standardisation of operating procedures that would protect the vulnerable environment and initiated relevant codes of conduct. In 1991, the International Association of Antarctica Tour Operators (IAATO) was formed to promote the highest possible standards of travel in Antarctica, and is today invaluable in providing an operational environmental management framework for tour operators in the region. IAATO has over the years developed an extensive number of procedures and guidelines in order to assist their members to practice appropriate, safe, and environmentally sound activity in the Antarctic in accordance with the Environmental Protocol. The IAATO framework rests on, and further specifies and develops the provisions of, Recommendation XVIII–1, *Guidance for Visitors to the Antarctic and Guidance for Those Organizing and Conducting Tourism and Non-Governmental Activities in the Antarctic,* adopted by the Antarctic Treaty parties in 1994 (and developed on the basis of IAATO's original operating guidelines from 1991).

To minimize impacts of activity on shore, IAATO has instituted, amongst other things, regulations and restrictions on the number of people that can be ashore at a site at the same time, guidance with regard to staff-to-passenger ratios, and restrictions on the size of vessels that can visit particular sites. IAATO has also developed site-specific guidelines for sites that are visited regularly to ensure that activity at these sites takes into account the particular sensitivities of these sites. A set of marine wildlife–watching guidelines to provide guidance to operators with respect to minimizing impact on the marine fauna due to cruise activity has been developed, as well as have guidelines for helicopter operations in order to minimize impacts on sensitive bird and mammal populations. IAATO is notably in the forefront in promoting practical practices for boot and clothing decontamination in order to reduce the risk of introducing nonnative species and of transmission of disease to the sites visited by tourists.

IAATO requires extensive postvisit reporting from members and maintains an extensive database with information on tourism activities in Antarctica over the last 15 years. This is one of the most important information bases the Antarctic Treaty parties have at their disposal in the context of assessing human pressure on the Antarctic environment and monitoring environmental impacts.

OZONE AND THE POLAR STRATOSPHERE

Ozone is a compound of oxygen containing three atoms, instead of two as in the oxygen gas that sustains life. It was discovered in 1839 by a Swiss chemist, Christian Friedrich Schonbein. In high concentration, ozone is a bluish-green gas, with very strong oxidising properties. It is a toxic, irritating gas, often encountered in surface air pollution episodes, when it can trigger asthma and irritate mucous membranes. Dry air consists of 78% nitrogen and 21% oxygen and normally trace amounts of other gases, principally argon, water, and carbon dioxide. The concentration of ozone is usually only a few parts per million and even in the ozone layer it is only one part in 100,000.

The atmosphere can be split up into several regions from the surface to the fringes of space. The lowest part of the atmosphere, the troposphere, is where weather systems occur. Here the atmosphere is moist, generally gets colder with height, and is characterised by convection. The next region is the stratosphere, where temperatures increase with height, creating a stable, layered structure. Here the atmosphere is dry, and this is where the majority of the ozone lies. The boundary between these two regions is the tropopause, which in the Antarctic is at 10–12 km altitude. Above the stratosphere lie the mesosphere and thermosphere, with corresponding boundaries, the stratopause at around 45 km and the mesopause at 80 km.

Ozone concentrations at the surface were first measured reliably by Robert Strutt (later Fourth Lord Rayleigh) in 1918 using spectra of a hydrogen lamp recorded through 5 kilometres of air. These measurements showed that ozone concentration could not be uniform throughout the atmosphere, as a higher concentration was required to explain the sharp cutoff at around 300 nanometres (nm) seen in stellar spectra. Three years later, Fabry and Buisson used spectrographic techniques to demonstrate that its principal atmospheric location is in the stratosphere, though it was not until the 1930s that the actual vertical distribution was first measured. It was soon recognised that measuring the variation in the total ozone column was of meteorological interest, and Professor G. M. B. Dobson developed a prototype ozone spectrophotometer in the 1920s. His instrument is still the standard today, and around 120 Dobson spectrophotometers have been built.

Dobson's instrument measures ozone by comparing the intensities of two wavelengths of light from the sun, one of which is absorbed quite strongly by ozone, whilst the other is only weakly absorbed. The ratio of the intensities varies with the amount of ozone present in the atmosphere, and a well-calibrated instrument can measure ozone amounts to within a few percent. The instrument uses wavelengths between 305 and 340 nm, and these are selected by means of prisms and a series of slits. It was initially a photographic instrument, but photocells were introduced in the mid-1930s and a photomultiplier in 1946.

The sun emits radiation in all parts of the electromagnetic spectrum, roughly 7% in the ultraviolet between 200 and 400 nm, 41% in the visible between 400 and 760 nm, and 52% in the infrared. The ultraviolet part of the spectrum is further divided into UV-A, UV-B, and UV-C. UV-A lies between 315 and 400 nm and gives rise to a suntan and aging of the skin. UV-B lies between 280 and 315 nm and is the damaging part of the spectrum. UV-C, which is totally absorbed by the atmosphere before it can reach the ground, lies between 200 and 280 nm.

Ozone is created by the photochemical destruction of oxygen, which liberates a free oxygen atom that can then combine with an oxygen molecule to create ozone. A third molecule is required to take away excess energy. The dissociation requires ultraviolet light of wavelength shorter than 240 nm. Sidney Chapman gave the first description of the photochemistry in 1930:

$$O_2 + hf -> 2O$$

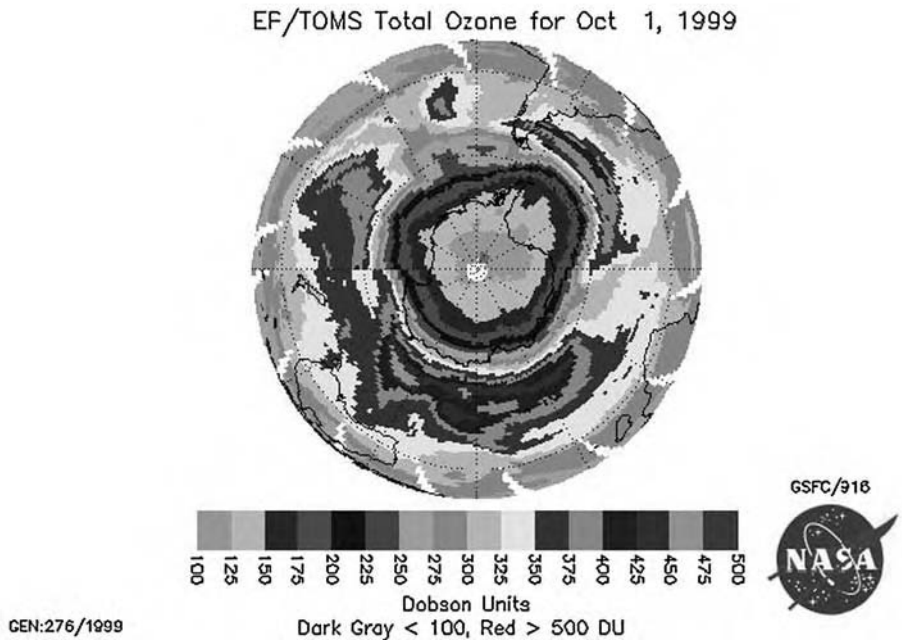
$$O_2 + O + M -> O_3 + M$$

Ozone can be dissociated by light of wavelength shorter than 1100 nm:

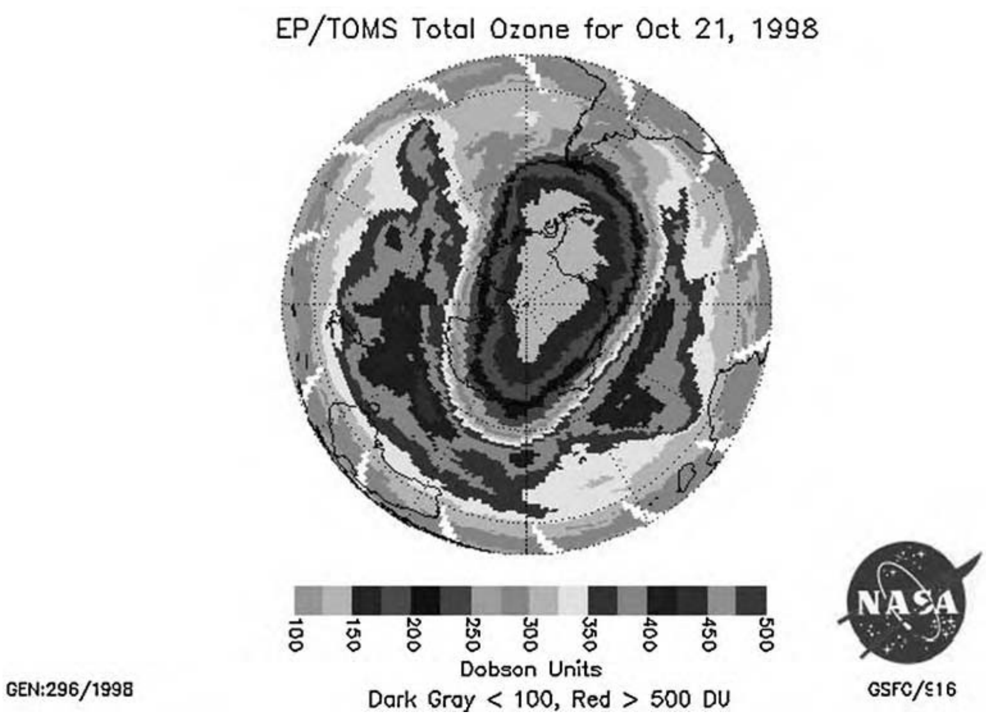
$$O_3 + hf -> O_2 + O$$

The free oxygen atom thus created quickly finds another oxygen molecule and the ozone is reformed with the net result of absorbing the solar radiation and inputting the energy into the atmosphere as thermal energy. The process is very efficient and virtually all radiation between 200 and 310 nm is absorbed, despite the relatively low concentration of ozone. The main ozone absorption bands in the ultraviolet are the Hartley (around 200–300 nm) and Huggins (around 300–350 nm), and there is the weak Chappuis band in the visible range (440–740 nm). In the lower stratosphere, below about 30 km, ozone has a long lifetime, and the ozone mixing ratio can be used to trace atmospheric motions.

A typical value for the total amount of ozone in a vertical column of our atmosphere is around 300 Dobson Units (DU), or 300 milli-atmosphere-centimetres, which corresponds to a layer of ozone 3 mm thick at



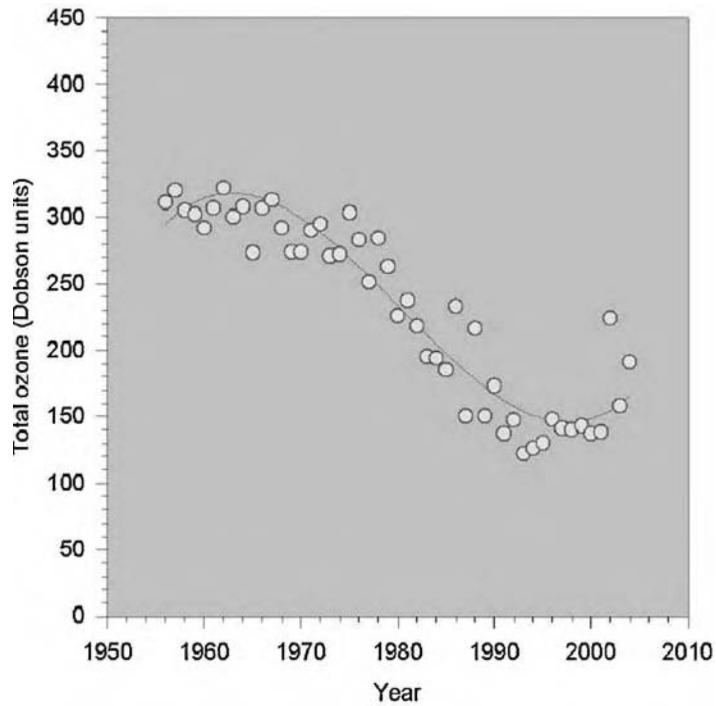
Satellite image showing the ozone hole in early October (1999). (From NASA/GSFC.)



Satellite image showing the ozone hole extending towards South America. (From NASA/GSFC.)

the Earth's surface. This 3 mm is in reality spread through the column, with the bulk of it lying in the stratosphere, with a maximum at around 17 to 25 km altitude depending on location.

Early studies of the ozone layer suggested a good correlation between changes in the total ozone column and synoptic-scale weather systems. The prospect of being able to use this in weather forecasting



Mean October ozone at Halley Station. (British Antarctic Survey.)

encouraged the setup of a global network of ozone monitoring stations; however, this was a blind alley. Developments in computer power have led to the use of numerical modelling as the key tool in weather prediction.

Day-to-day changes in ozone concentration are governed by motions in the stratosphere. These movements are a combination of horizontal and vertical transport. The ozone creation region above 50 km acts as a source or sink, so that descent of air acts to increase the total ozone column, whilst ascent of air acts to reduce it. Sustained ascent can lead to significant apparent ozone depletion and is responsible for some of the so-called mini ozone holes.

The longest-running ozone data set in the world is that from Arosa in Switzerland, going back to 1926. It shows a downward trend of a few percent per decade since 1970, with the depletion mostly occurring during the winter and spring. The Antarctic record is shorter, and in common with most Antarctic data sets begins in 1956 when stations began to be set up in Antarctica as part of the International Geophysical Year (IGY) of 1957–1958. Observing stations using the Dobson ozone spectrophotometer were set up at Argentine Islands (which later became Faraday and is now Vernadsky) and at Halley, and these have continued without interruption. In the 1960s, further measurements were begun at Amundsen-Scott, King Baudouin, Byrd, Hallett, and Syowa, although only the first and last of these continue today. In the 1970s, ozone measurements from polar orbiting satellites began, and a variety of satellites continue to make measurements. A few stations have made ozone profile measurements using chemical sondes, and this is also possible from ground-based measurements using the Umkehr technique.

The long record from Halley and its location within the winter polar vortex made it the best site for discovering what is now known as the Antarctic ozone hole (Farman, Gardiner, & Shanklin 1985). The seasonal pattern of the total ozone column in Antarctica is linked to the development and breakdown of the winter circumpolar vortex.

Historically ozone values were around 300 DU at the beginning of the winter (March in Antarctica), and similar at the end. During the winter, ozone amounts build up in a circumpolar belt just outside the vortex, due to transport of ozone from source regions in the tropics. Very high values, occasionally exceeding 500 DU, may be seen in this belt, which typically lies between about 60° S and 40° S. When the polar vortex breaks down in the spring (October), this belt of high-ozone column air sweeps across Antarctica, typically reaching the area around the central

Pacific sector first and the Atlantic sector last. Peak values used to exceed 450 DU, and then slowly declined back to 300 DU during the summer and autumn.

Since the mid-1970s, an increasingly different pattern of behaviour is seen—the Antarctic Ozone Hole. At the end of the winter, values are around 10% lower than they were in the 1970s and drop at around 1% per day to reach around 100 DU at the end of September. Values then slowly begin to recover, but the spring warming in the stratosphere is often delayed to the end of November or into December. Peak values in the spring warming are now substantially lower than in preozone hole times, and a decline in late spring and early summer values since about the early 1970s is very evident, as is the presence of very low October values since about the 1980s.

Ozone profiles can be measured using chemical sondes, which record the ozone concentration as the balloon rises through the atmosphere. The most frequent technique is to bubble air through a potassium iodide concentration cell, which generates a current that is proportional to the ozone concentration. These sonde profiles show that ozone concentration is low in the troposphere, but normally rises from the tropopause to reach a peak at around 17 to 22 km, thereafter falling. During the spring depletion, the majority of the loss occurs between 12 and 20 km altitude and virtually all ozone within this layer is destroyed. Although the peak ozone concentration is around 20 km altitude, the maximum absorption of short-wave solar radiation takes place at a much higher altitude of around 50 km. This absorption gives rise to the temperature maximum in the upper stratosphere.

The mechanism that controls the development of the Antarctic ozone hole is linked to the dynamics of the winter polar vortex. During the winter, lower stratospheric temperatures drop below –80°C, and at these temperatures stratospheric clouds can form. Observers at stations along the Antarctic Peninsula regularly see these clouds during the late winter as nacreous or mother-of-pearl clouds, created by lee-waves off the mountains of the Peninsula. More southerly stations sometimes report them as "ultra-cirrus," which may cover the entire sky in a faint milky veil. Occasionally there are reports of clouds that resemble noctilucent clouds, and it is just possible that such mesospheric clouds are seen in the Antarctic winter; these reports need further investigation. Once the clouds have formed, chemical reactions take place on the cloud surfaces, which together lock up nitrogen oxides and water and liberate chlorine and bromine (from CFCs, Halons, and other similar chemicals) in an active form. When exposed to sunlight, catalytic reactions take place, which rapidly destroy ozone. The simplest catalytic cycle that destroys ozone involves chlorine with chlorine monoxide (ClO) as an intermediary:

$$\mathrm{Cl} + \mathrm{O_3} \rightarrow \mathrm{ClO} + \mathrm{O_2}$$

$$\mathrm{ClO} + \mathrm{O} \rightarrow \mathrm{Cl} + \mathrm{O_2}$$

The same amount of chlorine is present at the beginning and end of the reaction and is the catalyst for the reaction to take place. Bromine can take part in similar cycles. More complex reactions also take place and together they can destroy ozone at around 1% a day until the catalytic cycle is broken, usually by other species reacting with the chlorine or chlorine monoxide to convert it into an inactive form. Paul Crutzen, Mario Molina, and Sherwood Rowland carried out pioneering work on these catalytic cycles in the 1970s, and in 1995 they received the Nobel Prize for their work.

Satellite images give a global picture and show the formation of the ozone hole within the strong winter polar stratospheric vortex. Globally, ozone amounts are generally lowest at the equator and highest at subpolar latitudes. The polar vortex acts as a barrier and hence, ozone-rich air builds up around it, in subpolar latitudes. Inside the vortex, ozone depletion is enhanced by chemical reactions on polar stratospheric clouds, which form in the very cold vortex. When the circumpolar vortex is at its strongest, the ozone hole tends to be roughly circular, but as it weakens, the vortex often becomes strongly elliptical and often offset from the Pole towards the Atlantic. At these times the northern edge of the vortex can reach as far north as 50° S in the Atlantic sector, posing a risk of increased UV exposure for the inhabitants of southern South America and the sub-Antarctic islands. The wave rotation period of the vortex is typically around a fortnight and this can be used to give rough forecasts of the period when such areas are most at risk. As the vortex warms, the clouds begin to disappear and chemical depletion ceases. With further warming the vortex begins to break down and the subpolar ozone-rich air sweeps across the continent.

The lower stratospheric temperature is strongly correlated with the total column ozone at any one location, a relationship first described by Reed and Normand in 1950. The mean 100 hPa temperature over Antarctica during October to December is now significantly lower than it was 30 years ago. This is due to a combination of the delayed spring warming and the lower amount of ozone in the stratosphere. The decrease in October ozone at Halley since the mid-1970s is very marked. This stratospheric change has potential implications for the surface climate, though the direct coupling between stratosphere and troposphere is weak.

The first signs of ozone depletion can, in retrospect, be seen from the mid-1970s, but the change did not become significant enough to be noticed until the early 1980s. Since then the ozone hole has grown deeper and lasts longer. In addition, the late-spring maximum has become much reduced and there are signs of depletion in the autumn. During the late 1990s, the maximum depth of the ozone hole stabilised, reflecting the nearly complete destruction of ozone in the vulnerable part of the atmosphere.

The size and depth of the ozone hole at its maximum extent now seem to be near their peak. The 2000 and 2003 ozone holes were the largest yet seen and reached an area of 28.4 million square kilometres. The ozone hole in 2002 was anomalous as a result of unusual stratospheric conditions and does not represent a recovery. The size of the hole is constrained by the circumpolar vortex, which in turn is constrained by the size of the Antarctic continent. The depth of the hole is constrained by the height range where temperatures are cold enough for the stratospheric clouds to form. A very slow return to the pre-1970 situation should be attained, provided that the Montreal Protocol is adhered to, and that there are no other changes to the atmosphere.

The Montreal Protocol is an international agreement that is designed to reduce the total chlorine and bromine load in the stratosphere. These gases largely reach the stratosphere in the form of CFCs and Halons, which were liberated in the troposphere from aerosol, refrigeration, foam-blowing, and fire-extinguishing systems. They have a typical stratospheric lifetime of 50 years, hence the expectation of a return to pre-1970 conditions on that timescale. The protocol was first drawn up in September 1987 and subsequent reviews have made it ever more stringent. The original agreement was to halve the use of CFCs by 1999, with the 1990 amendment agreeing to a complete ban by 2000. The developed world achieved the target well in advance of this date and production of other ozone-depleting chemicals will stop in the early years of this century. The developing countries were allowed a longer timescale to cease production and some took full advantage of this to continue production. This has delayed the timing of the maximum halogen loading of the atmosphere into the twenty-first century.

Other changes are, however, happening to the atmosphere, in particular the rising level of greenhouse gases. These act to warm the lower troposphere, but also act to cool the lower stratosphere. This may prolong the period when stratospheric clouds can form, and hence enhance ozone depletion. This may delay the recovery of the Antarctic ozone hole past the middle of the twenty-first century. It also raises the possibility of an Arctic ozone hole forming in the next 20 years. At present the northern polar vortex is relatively weak and usually breaks down in January or February, much earlier in the corresponding season than in the Antarctic. The combined effect of slowly declining ozone throughout the Northern Hemisphere and the increase in concentration of greenhouse gases is leading to a cooling of the Arctic stratosphere. The colder stratosphere and the increased temperature gradient between equator and pole increase the strength of the circumpolar vortex, making it more stable. Because it lasts longer, the spring warming is delayed, stratospheric clouds are present into the spring, and photochemistry rapidly destroys ozone.

Other short-lived events can also affect the ozone layer. Space shuttle launches briefly perturb the stratosphere, but their effect is soon past. Major volcanic eruptions, such as Mt. Pinatubo in the Philippines, which put several cubic kilometres of material into the stratosphere in 1991, can affect the ozone layer for a few years and can trigger depletion in parts of the layer that are not normally affected by the stratospheric clouds. The greatest Antarctic depletion yet seen occurred in 1992; however, turbidity measurements show that the material had largely dissipated by the mid-1990s. A major meteorite impact or atmospheric fireball, such as occurred over Siberia at Tunguska in 1908, could also damage the ozone layer.

All living cells contain DNA, a complex molecule that carries the genetic code, which describes the structure and biochemistry of the organism. UV can harm living things by damaging their DNA, which readily absorbs high-energy UV-B radiation. Many plants contain the pigment chlorophyll, which absorbs visible light as the energy source for photosynthesis. It also absorbs UV-B light and becomes bleached and nonfunctional. Living things must therefore protect themselves from UV-B. Many microbes, plants, and animals can synthesise protective pigments, for example, the brightly coloured lichens found encrusting rocks.

P

PACK ICE AND FAST ICE

Introduction

Sea ice is frozen sea water. Each year in March, following the brief Antarctic summer, the surface of the ocean around the Antarctic coast cools to the point of freezing. This occurs at a temperature of approximately –1.8°C, lower than the freezing point of fresh water because of the ocean's salinity. The first evidence of freezing is an unconsolidated layer of tiny ice crystals, called frazil ice, that give the surface an oily appearance. These crystals quickly coalesce to form a more consolidated cover that thickens as the air temperature drops, eventually creating a solid interface between the atmosphere and ocean.

Unlike the continental ice mass covering Antarctica, which has formed by millions of years of accumulated precipitation, most of the sea ice around Antarctica is less than 1 year old, waxing and waning on an annual cycle. At minimum extent in February, sea ice covers an area of approximately 4 million km^2. Then, at maximum extent in September, the sea ice cover has expanded to almost 20 million km^2, an area 1.5 times that of the Antarctic continent (13.2 million km^2), and slightly greater than the area of South America (17.8 million km^2). This annual change from open ocean to ice cover represents one of the greatest seasonal changes in physical properties anywhere on earth, and has an extraordinary influence on oceanic and atmospheric circulation and marine ecosystems.

Sea Ice Extent and Concentration

Since the early 1970s, satellite sensors have provided global, daily coverage of the sea ice zone in both hemispheres. The most reliable data on sea ice extent are from November 1978 through to the present, and over this period a slight increase in Antarctic sea ice extent has been reported. This is in stark contrast to the Arctic, where a significant decrease in summer sea ice extent over the past several decades has been observed. Regional changes in Antarctic sea ice extent have been reported, particularly in the peninsula region where there has been a sustained increase in air temperature over the past several decades, but these have not reflected a change in total extent because of compensating changes in other regions. These anomalies reflect, at least in part, teleconnections to lower-latitude climate phenomena such as the Southern Oscillation, and highlight the sensitivity of sea ice to anomalies in climate forcing. There is substantial evidence that year-to-year variations in sea ice cover in the Bellingshausen, Amundsen, and Ross Seas are linked to variations in surface air pressure, air temperature, and sea-surface temperature that occur during El Niño events. On much shorter time scales, the location of the sea ice edge is influenced by wind and ocean currents, and may move northward or southward by tens of kilometers per day under strong wind conditions. Over the longer term, however, the mean location of the ice edge reflects the location of the freezing isotherm, which is influenced by longer-term changes in oceanic and atmospheric temperature and circulation. The only sustained change observed in Antarctic sea ice extent is in the Peninsula region, where a decrease in mean air temperature of approximately 0.6°C per decade has been observed since 1950. Trends in sea ice extent may be linked to climate change, or to changes in oceanic and atmospheric circulation in the polar regions.

The sea ice extent varies not only seasonally but also from year to year and on much longer geological timescales. During the last glacial maximum, for example (i.e., the period 25,000 years ago when the average temperature of the earth was approximately 5°C cooler than at present), the sea ice around Antarctica in winter covered approximately twice the area of the Southern Ocean today. Evidence for this comes from diatom assemblages in deep-sea sediment cores, which are representative of ice-covered seas, and can be used to identify seasonality as well as total extent. The more northerly extent of sea ice would almost certainly have influenced the circulation pattern of the Southern Ocean at that time as well as the climate of the mid- and high-latitude regions. Another proxy for sea ice extent may be the amount of methanesulfonic acid (MSA) measured in glacial ice cores. MSA is an oxidation product of dimethylsulphide (DMS); it is produced by sea ice algae and may be found in higher concentrations in the atmosphere (and therefore glacial ice) during periods when sea ice extent is greater. This holds true for one area off East Antarctica dating back to 1841 and is currently under investigation in other areas around the continent.

Unlike the Arctic, which has an indigenous native population and is surrounded by countries with active military and economic interests in the sea ice zone, the Antarctic is far more isolated and has subsequently received far less attention. Captain James Cook, the first explorer to circumnavigate the Antarctic in 1773, was unable to penetrate far south of the sea ice edge, and wrote in his log book, "should anyone possess the resolution and fortitude to...[push] yet further south than I have done, I shall not envy him the fame of his discovery, but I make bold to declare that the world will derive no benefit from it." However, in the early 1900s expeditions by explorers including Douglas Mawson, Robert Falcon Scott, Roald Amundsen, and Ernest Shackleton did venture farther south, obtaining the earliest scientific discoveries from the Antarctic. Perhaps most famous is the drift track of Shackleton's ship *Endurance,* which provided some of the first information on the strength and drift patterns of Antarctic sea ice after it was trapped and subsequently crushed by ice in the Weddell Sea in 1915. Whalers and sealers, who were active in the Southern Ocean between the 1920s and 1950s, also kept logs of their encounters with sea ice, particularly the location of the ice edge, where blue, fin, and minke whales were commonly found. These records have also been used as a proxy for ice-edge location in the presatellite era; however, questions remain about the accuracy and consistency of the data, and their suitability for comparison with the modern satellite record.

The International Geophysical Year in 1957–1958 saw a significant increase in scientific activity in Antarctica, and the establishment of a number of national Antarctic research programs that are still active today. For the most part, however, sea ice was not a focus of Antarctic research at this time, and was primarily regarded either as a hindrance to shipping operations or a means of transport around the coast. It was not until the 1970s that research began to focus on the structure and properties of Antarctic sea ice and its role in the global climate system, with dedicated scientific expeditions to examine the sea ice environment. This coincided with the advent of satellite remote sensing, which provided complete daily coverage of the sea ice zone in both hemispheres, using a passive microwave radiometer. This instrument measures the "brightness temperature" (which is related to the physical temperature) of the earth's surface, enabling it to differentiate the colder ice and snow surfaces from relatively warm sea water. It has a distinct advantage over visible band imagery in that it can obtain data regardless of cloud conditions and darkness, although there are circumstances (particularly in summer, in regions of thin ice, and in coastal zones) when ambiguities arise. As well as being able to identify the location of the sea ice edge, passive microwave data are also very useful for determining the concentration, or compactness, of the sea ice cover. In most of the Antarctic, the sea ice zone is a complicated mixture of different ice types and open water, and the ice concentration (given as the percentage of a particular area covered by sea ice) may vary significantly on subdaily timescales. The passive microwave instrument has geophysical products that range from 12.5 to 25 km^2 on the ground, which means that the ice conditions are averaged over this area to provide a mean value. Other satellite sensors, each designed for a specific purpose, have different surface footprints and measure different surface properties, and may be affected differently by clouds, darkness, or other atmospheric conditions.

Antarctic Sea Ice Terminology

Most of the sea ice around Antarctica is known as "first-year" ice, having formed since the previous summer. First-year ice is regionally variable, but on average grows to approximately 0.5–1.0 m thick, significantly less than in the Arctic. In coastal regions the ice may become "landfast" and continue growing up to 1.5–2.0 m thick. Dynamic or mechanical processes play a far greater role in the development of the drifting pack ice north of the landfast ice zone. Pack ice floes often do not grow to more than a few tens of centimeters thick before being deformed by the action of wind, waves, ocean currents, and tides. The net result is a complicated mixture of different ice types, different ice thicknesses, and open water that is constantly in motion and changing in thickness and morphology. The processes of mechanical redistribution are called "rafting" and "ridging"; rafting describes the action of one floe riding up over another, effectively doubling the thickness of ice each time it occurs, while ridging describes the convergence of floes that buckle and break to form pressure ridges of ice blocks that may reach 10 m or more in thickness. The subsequent changes in surface and bottom topography cause increased drag with the ocean and atmosphere, and influence processes such as ice motion, snow accumulation, light penetration, and the mechanical strength of the ice.

The motion of sea ice is extremely complicated. It is primarily influenced by wind and ocean currents, but tides, the Coriolis force (the influence of the rotation of the earth), atmospheric pressure gradients, the tilt of the ocean surface, and internal ice stresses all play a part. On a large scale the ice cover can be regarded as a continuous medium, and most sea ice computer models treat it as a viscous–plastic material that behaves as a viscous fluid for small strain rates and flows in a plastic manner for large strain rates. Sea ice with high compactness will resist more compression and shearing than that with low compactness, and thick ice will resist deformation more than thin ice. Ice deformation may create open water areas between ice floes, where ocean–atmosphere heat exchange may be several orders of magnitude greater than through a consolidated ice cover, and where new ice often reforms. These areas are known as "leads" because of their suitability for navigation, and they provide access between the ocean and ice for wildlife. The new ice formed in leads can be crushed into ridges when the surrounding thicker floes converge, transforming thin ice into thick ice much more quickly than would occur simply by freezing. The prevalence of leads determines the ice "concentration," which is a measure of the ratio of ice cover to open water. During the ice growth season, leads facilitate new ice formation and increased ice mass, while in summer they absorb solar radiation, warming the surface layer of the ocean and contributing to ice decay.

Sea ice that survives the summer melt season is known as "second-year" ice, unless it survives more than one summer, in which case it is referred to as "multiyear" ice. The Weddell Sea, Bellingshausen/Amundsen Seas, and eastern Ross Sea are the areas where second-year ice is common around Antarctica. These are not only the southernmost waters around the coast, they are also areas where ocean circulation pushes ice toward the coast and causes it to pile up and thicken. Multiyear ice (surviving two or more summers) is found in limited quantities in the Antarctic; it is more common in the Arctic, where the sea ice cover is older and thicker and may survive for several decades. Surface melt can occur on the surface of multiyear floes in the Antarctic, creating widespread areas of slush. As a result, melt-water can percolate down to the surface of the sea ice and refreeze to form "superimposed ice," which is effectively a fresh ice layer.

Sea ice is further classified as either "pack" ice, which under the influence of wind and ocean currents may drift up to tens of kilometers per day, or "landfast" ice (commonly referred to simply as "fast" ice), which is attached to the coast and immobile. Fast ice is common in coastal bays and around grounded icebergs, where it typically grows to a uniform thickness of between 1 and 2 meters. Its maximum thickness is usually reached in September, and depends on the balance between the atmospheric and oceanic heat fluxes at the top and bottom surfaces of the ice, respectively. It creates an important transition between the Antarctic continent and the drifting pack ice, particularly for wildlife that use it as a breeding ground, or for a location to haul out of the water. Most fast ice is eventually broken up by waves, which penetrate to the coast once the pack ice to the north has melted. The fast ice floes then become an integral part of the pack ice, drifting and deforming with the wind, waves, and currents.

Sea Ice Drift

To measure sea ice drift and deformation, scientists use satellite-tracked drifting buoys that are placed on ice floes and monitored remotely. These provide regular (usually hourly) updates of their position and have shown average daily drift speeds in some areas of the Antarctic pack ice as high as 15–20 km/day. Around most of the continent the ice drift along the coast is towards the west, driven by the East Wind Drift. Further north the net drift is to the east as a result of the eastward-flowing Antarctic Circumpolar Current (ACC). Gyre circulations at various locations around the continent connect the eastward- and westward-flowing regimes, such as in the Weddell and Ross Seas, or where bottom topography diverts ocean currents toward the north or south. Drifting buoys are often also equipped with air temperature and pressure sensors that provide near-real-time data for weather forecasting models. These data are extremely valuable in data-sparse regions where there may be no other observations for distances of hundreds to thousands of kilometers.

The drift of sea ice contributes to the redistribution of fresh water around the Southern Ocean. First-year Antarctic sea ice has a salinity of about 6–8 parts per thousand (ppt), compared with seawater, which has a salinity of approximately 33 ppt. The salt that remains in the ice is trapped in tiny brine channels between ice crystals that are completely fresh, while the rest of the salt is deposited into the ocean. The subsequent drift of sea ice results in a net transport of freshwater away from the area of ice formation. This is particularly the case in some coastal features known as "polynyas," where sea ice growth rates are high but the ice is quickly advected away from the coast. Polynya is a Russian term, adopted as part of the common sea ice nomenclature, for an area of open water surrounded by ice. They can be up to several tens of thousands of square kilometers in size and are maintained by particularly cold katabatic (gravity-driven) winds that drain off the Antarctic continent. Total ice growth in the more active polynyas may be on the order of 10 meters per year, although the ice thickness in these polynyas at any one time is never more than a few centimeters.

Ocean–Sea Ice–Atmosphere Interaction

The salt deposited into the ocean as a result of sea ice formation drives a vertical circulation process between the surface and deeper layers of the ocean. Salt added at the surface by sea ice formation makes the surface water more dense, and therefore heavier, causing it to sink toward the bottom. There it may accumulate in depressions on the continental shelf and eventually spill over the sill, mixing with warmer, saltier water masses over the continental slope. This is a key process in the formation of Antarctic Bottom Water, and an important link in the ocean "conveyor belt" responsible for redistributing heat between the equator and the poles and maintaining our current climate system. The formation of Antarctic Bottom Water is known to occur only in the Weddell and Ross Seas, and off the Adélie Land coast, where the necessary combination of bathymetry, high ice production, and water mass mixing occurs. The properties of bottom water can be observed well north of the equator in the Atlantic and Pacific Oceans. The deeper waters being brought to the surface as part of the vertical convection beneath the ice are warmer and rich in nutrients, facilitating high biological productivity in the surface waters. This is enhanced during summer when sea ice melting has the dual effect of releasing algae into the water column and establishing a stable, low-salinity surface layer that inhibits mixing. Any change to this vertical circulation would therefore have serious implications for the Southern Ocean ecosystem.

Sea ice affects the interaction between the ocean and atmosphere in a number of other important and complex ways. For example, depending on its thickness and snow cover, sea ice can be up to an order of magnitude more reflective than the ocean; therefore, it reflects much more of the sun's incoming energy back into the atmosphere. This causes a "positive feedback" with the climate system, whereby the changed conditions that result from the formation of sea ice enhance the likelihood of more sea ice. That is, the surface becomes more reflective, therefore less heat is absorbed at the surface, and therefore more ice is likely to form. The reflectance (or albedo) of open water is 7% of the incoming radiation from the sun, compared to 49% for ice >70 cm thick. The addition of a 3-cm snow cover increases the albedo even more, up to 81% for ice >70 cm thick.

The accumulation of snow on sea ice also contributes to the redistribution of fresh water around the Southern Ocean. Precipitation that accumulates on an ice floe might only be deposited into the ocean when the ice melts, which could be hundreds to thousands of kilometers away, and many months later. Snow falling on sea ice also drives another important process in the Antarctic, which is the formation of "snow ice." This occurs when snow accumulates to the point where it overloads the sea ice and pushes the ice surface below sea level. Sea water then floods the base of the snow layer, creating slush, which subsequently refreezes to form an additional layer of ice between the sea ice and the snow. This new layer is called "snow ice" and can often only be identified separately from sea ice by measuring the ratio of ^{18}O to ^{16}O isotopes in the melted samples. The formation of snow ice is important because it increases the volume of ice present in the pack ice without having the same input of brine to the ocean that occurs when sea ice forms. Studies indicate that snow ice formation is prevalent in all areas of the Antarctic pack ice and therefore is an important consideration in mass balance studies of the sea ice zone.

Sea ice is thought to be intimately related to biological productivity in the marine ecosystem, providing a refuge for some animals and a platform for others. Microorganisms are trapped in the sea ice structure as it forms, often in higher concentrations than occur in the water column, and then released again when the sea ice melts. During their time within the ice environment, some species thrive while the growth of others is either inhibited or stopped completely. Gradients of temperature and salinity within the ice dictate the living conditions for organisms trapped there. The amount of snow cover will also largely dictate the amount of light available. Near the top of the ice, conditions will typically be colder, with a higher concentration of salt within the brine channels, while the bottom of the ice will be warmer with larger, less-saline pores in the ice. This may change in the summertime when the surfaces of floes become saturated with melt water and algal communities near the ice–snow interface flourish. When this happens, the organisms within the ice may become sufficiently concentrated that the ice turns brown, decreasing its albedo and resulting in more light absorption and enhanced melt. High concentrations of organisms also occur near the bottom of the ice and there is considerable evidence that krill utilize these communities for food, particularly during late winter. Krill is a key component of the food chain and a primary source of food for baleen whales and various species of seals, penguins, and other birds. Both adult krill and larvae have been observed feeding on the under-ice communities.

As well as reflecting incoming energy at its upper surface, sea ice also has an insulating effect on the ocean—an effect that is further enhanced by the addition of snow cover. Heat in the ocean, which would normally be given up to the atmosphere, therefore remains trapped within the upper layer of the ocean. This is an example of a "negative feedback" process, whereby heat trapped in the ocean as a result of sea ice formation may limit or prevent further ice growth.

Sea Ice Thickness

Measuring Antarctic sea ice thickness is a problem of great topical interest, as long-term changes in the sea ice thickness distribution are likely to be a sensitive indicator of global climate change. The sea ice thickness distribution is also an important input parameter to computer models of global climate, and is important for efficient planning of Antarctic shipping operations. Recent technological advances using satellite-based radar and laser altimetry offer some hope that satellite data may soon provide broad spatial coverage for sea ice thickness by converting measurements of freeboard (the height of the ice or snow surface above sea level) into total ice thickness by assuming bulk densities for the ice and snow cover. Until such satellite-based data are available it will be impossible to measure or monitor sea ice thickness on basin-wide scales. In the meantime, however, efforts continue using other technologies that have, to date, provided a valuable inventory of Antarctic sea ice thickness data. These range from sophisticated measurement devices such as upward-looking sonar (ULS) and electromagnetic (EM) techniques to simple drilled measurements and estimates of sea ice thickness from ships. While each technique has its merits, none provides the continuity of large-scale spatial measurements required for comprehensive sea ice thickness monitoring.

Upward-looking sonars are instruments moored below the ocean surface that measure sea ice draft by recording the response time of an acoustic signal transmitted by the instrument and reflected off the underside of the ice. The ice draft measurement is then used to determine ice thickness based on assumptions of the water column properties (which affect the speed of sound) and the ice and snow density. The instruments have been quite successful in some regions, but a high percentage of those deployed have never been recovered, as a result of either equipment failure or destruction by icebergs. Most instruments are moored at least 170 m below the surface to avoid iceberg hits; however, even at this depth they may still be destroyed by large icebergs that have a draft significantly greater than this. There are also significant unknowns that affect data processing, such as the snow cover on the ice, and seasonal changes in water column properties that cause seasonal changes in the speed of sound and the measured response of the instrument.

Electromagnetic techniques have been used extensively in both hemispheres. Until recently, their use in the Antarctic has been limited to ship-based surveys and thus has been limited to thinner ice areas accessible by ship. This problem has been overcome by the use of airborne EM systems, which can yield regional-scale estimates of sea ice thickness. The technique utilizes the large (2–3 orders of magnitude) contrast in electrical conductivity between sea ice and seawater. Consequently, the conductivity of the sea ice is negligible in comparison to the seawater conductivity, effectively making the ice transparent to a low-frequency EM field generated by the transmitter coil of an EM instrument. The instrument then measures the quadrature component of the secondary magnetic field, normalized by the primary field, which yields the height of the instrument above the ice–ocean interface. Sea ice thickness can then be calculated by subtracting the height of the instrument above the ice surface, which is typically measured using a laser. It is widely accepted that EM methods provide reliable estimates of the thickness of level sea ice; however, estimating sea ice thickness near three-dimensional structures such as pressure ridges is difficult because of the presence of conductive seawater or slush layers, and the smoothing of the observed response over the "footprint" of the instrument. Consequently there are regions and seasons when the technique is not suitable, and its use is limited to within flying range of coastal stations or research vessels in the sea ice zone.

Ice-thickness estimates from research (and other) vessels in the Antarctic have also yielded extremely valuable ice-thickness information in recent years. This technique relies on trained observers taking regular (usually hourly) estimates of sea ice conditions from the ship's bridge as it moves through the pack ice, and recording them in a common database. Observations of sea ice thickness are made as ice floes are broken and turned sideways along the hull of the ship, using a measuring stick or buoy of known diameter suspended close to the sea ice as a guide. More than twenty thousand such records of sea ice type thickness, floe size, and snow cover characteristics have now been compiled into a single database that provides valuable first-order estimates of these properties for the Antarctic. Additional information on sea ice topography is used to account for the mass of sea ice in ridges.

Field Studies and Future Work

Field studies in the Antarctic have also provided a great deal of information on the characteristics of sea ice. Experiments such as Ice Station Weddell in 1991 and Ice Station Polarstern in 2004/2005 have been dedicated experiments that have followed the evolution of a particular ice floe over a period of weeks to months. Experiments conducted at these drifting ice stations have yielded extremely valuable information on the seasonal changes in ice conditions, ice dynamics, and biogeochemistry of the sea ice zone. There have also been many other ship-based experiments and field sampling by different countries involved in Antarctic sea ice research. These include process studies that have focused on polynya processes, ice deformation using satellite-tracked drifting buoys, validation of remotely sensed data using field measurements, and the effect of sea ice formation on water mass modification. The collected data can provide insights into ice properties that help scientists to interpret satellite imagery, and can improve the way in which physical processes are parameterized in climate models. Sea ice core sampling is usually an integral part of any field experiment, and the data from these samples have collectively yielded information on regional and seasonal differences in the crystal structure and therefore the development of the sea ice. By examining thin sections of the ice cores between cross-polarized filters, it is possible to identify different ice types, such as frazil crystals, columnar ice crystals, snow ice, and superimposed ice, each of which indicates a different process of floe development.

In the future, monitoring changes in the properties of Antarctic sea ice will be of great importance. There is unequivocal evidence of change in the Arctic region, and some suggestion that similar change is occurring in the Antarctic Peninsula region. If the sea ice environment changes in the future, this may well be associated with changes in oceanic circulation and will undoubtedly influence the ecosystems of the Southern Ocean and the wildlife resident there. While field studies have yielded extremely valuable information on sea ice characteristics, and satellite data have provided a detailed record of ice extent and concentration since the 1970s, the Antarctic sea ice zone remains the most data-sparse region on earth. A great deal more data are needed to monitor this area for change; in particular, long time-series data on sea ice thickness are of key importance, but will only be available through improved satellite technology that is not currently available.

PALEOCLIMATOLOGY

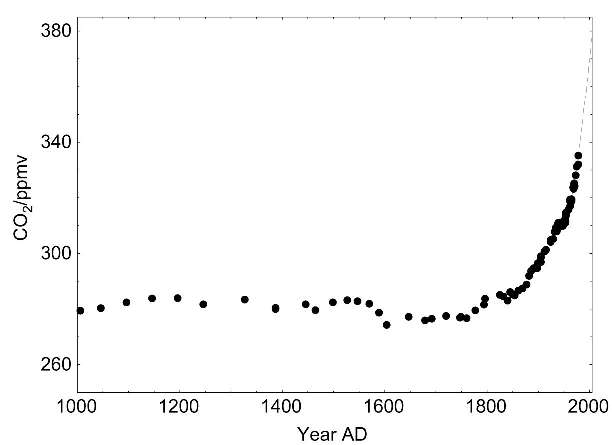
Paleoclimatology is the study of past climate. The climate of Antarctica over very long timescales can be studied in the geological record, and it reveals that the continent has not always been the cold place it is now. The ice sheet first appeared around 40 Ma, and the causes of this glaciation are the target of both data collection and modelling studies. However, most Antarctic paleoclimate studies cover a much shorter period, within the late Quaternary period (the Quaternary is approximately the last 2 million years). Although marine and lake sediment records are available, ice cores are at the centre of such studies, and now cover a period of over 800,000 years. They reveal that Antarctic climate has varied with a dominant period of 100,000 years, in concert with the ice ages and interglacial periods that dominated the climate of the northern hemisphere. However, ice cores also show that the major greenhouse gases, carbon dioxide (CO_2), and methane (CH_4), varied in a pattern similar to Antarctic climate, as did many other environmental parameters. In this way, the study of Antarctic paleoclimate actually contributes key datasets for our understanding of global climate change.

Paleoclimate Records

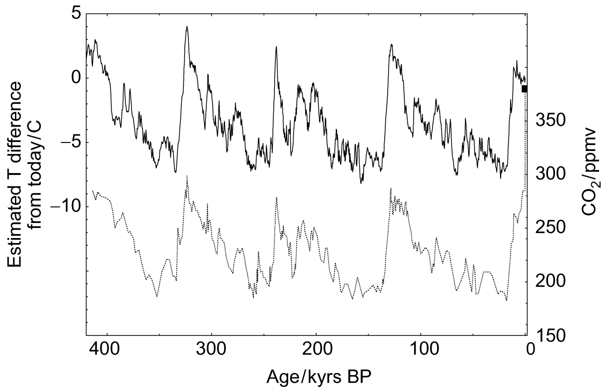
Past climate is documented mainly by making measurements of the physical, chemical, or biological properties of some type of sedimentary sequence. The main requirements are that the sequence be laid down in a monotonic order (so that the order of events is preserved) and that some property of the sequence be controlled by one of the environmental variables that we wish to know about (for example, temperature). Among the archives that can be used in various parts of the world are marine sediments, lake sediments, peat bogs, corals, ice cores, speleothems (stalagmites and stalactites), and tree rings. Over longer time periods, fossils found in sedimentary rocks can indicate the environment at a past time.

In Antarctica and the Southern Ocean, many of these archives are not available, and paleoclimate studies have been confined to ice cores, marine sediments, and lake sediments (as well as geological records for longer time spans). Lake sediments are mostly confined to the last few thousand years (partly because some records are obliterated by advancing ice from time to time). Marine sediments can span much longer periods, although nearshore records can also suffer from the effects of ice advances. Ice cores in Antarctica now span a period of over 800,000 years (800 kyr), although there are also numerous datasets that span only a few centuries.

Marine sediments consist of rock fragments and preserved biological remains that fall through the ocean column and are accumulated at the ocean floor. They can be recovered using shipboard corers

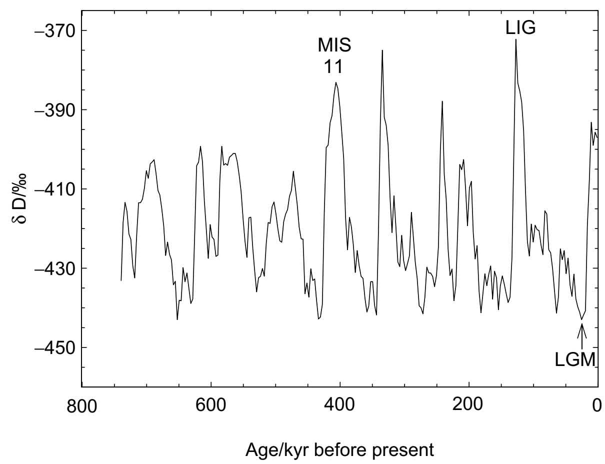


Atmospheric carbon dioxide from the Law Dome (Antarctica) ice core over the last millennium (Etheridge et al. 1996). Modern measurements in the atmosphere are shown as a line for the last 50 years, while the ice core data are shown as symbols.



Estimated temperature (based on deuterium values, solid curve, left axis), and carbon dioxide concentration (dashed curve, right axis) from the Vostok ice core, Antarctica, for the last 420,000 years (Petit et al. 1999). The current CO_2 concentration, based on atmospheric values measured at Mauna Loa, has been added as a symbol. The original deuterium data have been corrected to allow for the temperature of the source water (Vimeux et al. 2002).

that penetrate the sediments and return cylinders of mud to the surface. In the continental shelf regions of Antarctica, glacial debris is a particularly important part of the sedimentary record, and its study can indicate the style of glaciation and the timing of transitions between ice sheets, ice shelves, and open conditions. Elsewhere, assemblages of biota (for example, diatoms) can be identified as being associated with particular conditions (for example, sea-surface temperature values, or cover by sea ice). Sediments up to about 50,000 years old can be dated by radiocarbon dating methods, which involve measuring the ^{14}C content. Older sediments can often be dated by other radiometric methods.



The deuterium (representing temperature) record from the EPICA Dome C core covering the last 740 kyr (EPICA Community Members 2004). LGM: Last Glacial Maximum, LIG: Last Interglacial, MIS11: Marine Isotope Stage 11. The temperature difference between the LGM and the present is estimated as 9°C.

Lakes are rather rare in Antarctica, and confined to a few warmer parts of the continent and sub-Antarctic islands. The sediments at their bed can also be recovered by techniques similar to those for marine cores, with generally hand-held corers deployed from small boats or platforms, or from solid lake ice surfaces. They likewise contain sediments derived from surrounding surfaces, as well as biological material from the lake itself and from its catchment area. These can indicate, for example, the climatic conditions at the surface of the lake. In some cases, lakes can change from fresh to marine depending on relative sea level at a site, and these changes are recorded as changes in biota.

Most of Antarctica is covered in cold ice, permanently below 0°C, and ice cores can be collected from any such area. As snow builds up to form an ice sheet, it collects a record of (mainly) atmospheric conditions at the time. Ice cores are cylinders (typically 10 cm in diameter) of ice retrieved from the ice sheet. Drills are cylinders with metal cutting teeth on the end; the barrel is rotated to collect the core. For depths to about 20 m, hand drills are used. Beyond that, an electromechanical drill, consisting of a barrel on the end of a cable, must be used. In the deepest drills, lengths of up to 4 m are retrieved on each "drop" of the drill. By repeating this many times one can penetrate deep into the ice sheet. Because of the importance of ice cores in Antarctic paleoclimate, I will describe the formation of the ice-core record in more detail in a separate, later, section, but for now I note that ice cores can tell us about many parameters in the environment; the surface temperature, the greenhouse-gas content of the atmosphere, and the occurrence of explosive volcanism are three examples.

Antarctica over Geological Time

Before proceeding to the shorter timescale that is the main focus of this article, I will briefly summarise what we know about the long-term environment and climate history of Antarctica over many millions of years. Within the fossil record and offshore sediments of Antarctica, there is a history of the climate that Antarctica itself has experienced. Geologists can learn there about the breakup of the supercontinent of Gondwana. About 200 Ma, this supercontinent included South America, Africa, India, Australia, and

New Zealand, with what is now Antarctica at its centre. Gondwana broke up over a period of about 160 million years, with South America the last fragment to separate from Antarctica.

At times in this past Antarctica was a warm continent, supporting a rich flora and fauna. Fossil leaves and wood, dinosaurs, and even marsupial mammals have been found in the geologic record. The earth as a whole, and Antarctica in particular, seem to have been on a long overall cooling trajectory throughout the Cenozoic Era, the last 65 million years.

Sometime around 40 Ma, the warm "greenhouse world" really ended with the appearance of the first ice sheet on Antarctica. The history of the extent and persistence of this ice sheet is uncovered not only in Antarctic studies but also by looking at the history of past salinity that can be deduced from marine sediments around the world. When snow falls on Antarctica, it consists of freshwater taken from the ocean. This has various effects as successive snowfalls build up to form an ice sheet: it lowers sea level; it makes the remaining ocean more salty; and because there is less of the heavier isotope of oxygen in the snow than there is in ocean water, it changes the isotopic content of the ocean. By measuring the isotopic content of shells in marine sediments, this ice-sheet growth can be documented and the climate history of the last 65 million years summarised (Zachos et al. 2001).

According to this summary, small ice sheets were intermittently present in Antarctica from just after 40 Ma. This is about the time that the Tasmania-Antarctic Passage opened, although it is a matter of debate whether this is significant. Later, the Drake Passage opened, separating South America from Antarctica. Around 15 Ma, the East Antarctic ice sheet became persistent. The appearance and growth of the ice sheet are clearly related to an increased cooling of the Antarctic continent. There is debate about the exact causes of this cooling, with two favoured ideas, of which one or both may be important: (1) the opening of ocean gateways between Antarctica on the one hand and South America and Australia on the other hand led to the development of circumpolar ocean currents that isolated the continent from warm northern waters, and (2) decreasing levels of CO_2 from the high levels at the start of the Cenozoic likely caused a global cooling trend.

The oxygen isotope data only give an indication of how much ice there was in the world, but not where it was. They have been supplemented by evidence derived from sediment cores from the Antarctic continental margin. The most ambitious project (the Cape Roberts Project) was an international initiative that retrieved some 1500 m of strata from 3 cores in the western Ross Sea. The drilling took place from a platform on the sea ice. The cores encompassed the period from 34 to 17 Ma, and give further evidence of the extent of glaciation during this period. From 34 to 25 kyr, this sector of East Antarctica seems to have had tundra vegetation and a subpolar climate. From 24 to 17 Ma, there is evidence of more extensive grounded ice, and the sector seems to have been cooler.

Ice-sheet expansion in West Antarctica probably occurred some 6 Ma, and the appearance of the first ice sheets in the northern hemisphere continents around 2 Ma heralded the start of the Quaternary period. It is in the later part of this period that we pick up the story of the more detailed paleoclimate records found in Antarctica.

Ice Cores

The first deep ice core to bedrock was the 1390-m Camp Century (Greenland) core, completed in 1966. Two years later, bedrock was also reached at Byrd Station in West Antarctica, at 2164 m. Since then, a huge number of shallow cores and a handful of bedrock cores have been completed in both Greenland and Antarctica. Ice cores can be thought of as containing information in three different forms.

Firstly, the water molecules themselves contain climatic information. The isotopic signature of ice is formed by evaporation and condensation of water, starting over an ocean source and ending up during snowfall over an ice sheet. There are two stable isotopes of hydrogen (^1H and ^2H [or deuterium, D]), and three stable isotopes of oxygen (^{16}O, ^{18}O, and ^{17}O, although we will only be concerned with the first two of these). Thus, water consists mainly of $H_2{}^{16}O$, but with a small proportion of the heavier forms, HDO and $H_2{}^{18}O$. The lighter forms of water have a higher vapour pressure. As a result, air masses become increasingly depleted in the heavier isotopes as more water is removed from them, which occurs as they get colder. The result is that colder site temperatures lead to water that is more depleted in the heavier isotopes (this is expressed as departures from a standard in parts per thousand, and labelled as $\delta^{18}O$ or δD). In reality the processes are more complex than this simple explanation would suggest (Jouzel et al. 1997), but as a general rule, lower values of the two isotope ratios indicate a colder air temperature.

Aerosol particles, as well as some gases that can become attached to ice surfaces or enclosed in the ice structure, form the soluble and insoluble chemical content of the ice. They are either enclosed in falling snow or deposited dry to the snow surface. Components of this part of the ice-core record include terrestrial dust from other continents, sea salt, and volcanic sulfate. Because aerosol is relatively short-lived in the atmosphere, interpreting some of these species in terms of quantitative changes in aerosol source and transport is difficult, but on the other hand they contain regional information that can assist in deciphering patterns of atmospheric transport.

Finally, snow at the surface is compacted and metamorphosed, first into firn, and then (at a depth typically of 60–100 m) into solid ice. Air bubbles get trapped in the solid ice, and they contain samples of the ancient atmosphere, which can be analysed to give the concentrations of stable trace gases in past times. Of particular interest is the ability to measure the past atmospheric concentration of carbon dioxide and other greenhouse gases. These measurements are rather unique in that they are not "proxies," as are almost all other paeoclimatic signals—what is measured really is the concentration of the gas in a sample of old air. The air component of ice cores forms at depth. For this reason, the air enclosed just below the bubble close-off depth in central Antarctica is from the late twentieth century, but the ice (containing the climate record) at the same depth is hundreds or even thousands of years old (depending on how much snow falls each year). To determine any time lag between a climate change and a trace-gas change, this ice age–air age difference must be accounted for.

As a result of all these different signals, ice cores should contain information about past temperature, atmospheric transport, greenhouse gas concentrations, volcanic eruption frequencies, pollution, and numerous other parameters.

Ice cores covering shorter time periods, and at sites with high snow-accumulation rates, may be dated rather accurately by counting annual layers, using the winter–summer contrast in many properties of the cores. At the sites with the oldest ice, snow accumulation is very low, and annual layer counting is not possible. Here dating relies mainly on glaciological modelling, constrained by a number of fixed points derived from comparison with other records where absolute dating may have been possible.

Ice cores range from numerous very shallow (10 m) cores containing just a few years of snowfall at high resolution, up to the longest cores (Vostok [Petit et al. 1999], at 3623 m currently) and the oldest cores (currently estimated at 890,000 years [although only 740 kyr is published at the time of writing] at Dome C [EPICA Community Members 2004]). The very long cores require multinational, multi-institute efforts: for example, the Dome C core is one of two deep cores being drilled by the European Project for Ice Coring in Antarctica (EPICA) in East Antarctica; it has combined the scientific, drilling, and logistic input of ten nations.

Climatic Information of Recent Centuries from Antarctic Records

In most cases, instrumental records of climate in Antarctica extend back only a few decades, with very sparse and limited information before that. We therefore have to rely on paleoclimatic evidence for even recent centuries.

Numerous ice cores exist from across Antarctica that cover the last few centuries up to about 2000 years. A particular focus for producing such records has been the International Trans-Antarctic Scientific Expedition (ITASE), which in practice is a series of traverses in different parts of Antarctica, on which shallow cores have been collected. The ice core data are supplemented by a very few lake and marine records. In general, the ice core data show few significant changes in climate indicators over recent centuries, implying that Antarctic climate has been reasonably stable over this period. In this section, we highlight just two particular results from Antarctic records covering this period.

The first one is an Antarctic result with global significance. As already discussed, the air bubbles in ice cores retain a record of the past concentration of stable atmospheric gases. The major greenhouse gases (especially CO_2 and CH_4) have been measured routinely in the atmosphere only for a few decades, and we are entirely reliant on the direct measurements available in ice cores for our knowledge of what happened before that. Sites with very high snow-accumulation rates can give the highly resolved records needed for recent centuries: the Australian site of Law Dome has provided particularly important records of greenhouse-gas concentrations (e.g., Etheridge et al. 1996).

The ice-core records show that the year-2005 atmospheric concentration of CO_2 is about 380 ppmv (parts per million by volume) and is about 30% higher than the preindustrial value of about 280 ppmv. This value was stable to within 10 ppmv for the previous millennium before about AD 1830. For methane the situation is even starker, with a preindustrial value of 0.7 ppmv, less than half the present concentration of 1.75 ppmv. Thus, from these Antarctic measurements we have clear evidence that current concentrations of greenhouse gases are highly unusual, with (as it turns out) no analogue in at least the last 450 kyr. This is one aspect of the debate about climate change that is settled and beyond dispute.

The second issue that can be addressed is that of whether any change, perhaps due to human influence, can yet be seen in the Antarctic climate itself. In general, ice cores do not provide a clear answer to this question: the expected signal is small compared to the noise in the proxy used for temperature, and across most of Antarctica we already know that no clear change is so far seen in surface temperature from the instrumental records. One intriguing result from ice cores has been a suggestion that there has been a significant reduction in sea ice extent, at least in the Indian Ocean sector of East Antarctica, since the 1950s. This is based on a decrease in the concentration of methanesulfonic acid (MSA) in an ice core (Curran et al. 2003): production of this chemical, via biogenic emission and atmospheric oxidation, is believed to be indirectly related to the ice extent in winter. Much more work is needed before it can be established whether this change is widespread, and whether it is really related to a change in climate.

The one region in which a warming has certainly occurred over the last few decades is the Antarctic Peninsula. In this region, there is some sign that the temperature proxy (oxygen isotope ratio) is high in recent decades in some cores, but it is not yet clear how unusual this is in the context of previous millennia.

Climate of the Holocene: The Last Ten Thousand Years

The Holocene is the period since the end of the last glacial period; it is considered to have a rather stable and relatively warm climate in many, but not all, regions of the world. For this period, in the Antarctic we have ice core, lake sediment, and marine sediment datasets, as well as some information on past glacier retreat in portions of the continent.

Ice cores show that, on the East Antarctic plateau, the early Holocene, from about 11–9 kyr before present (BP), was warmer than the present (Masson et al. 2000). The remainder of the period shows no obvious and significant changes across most of the continent. It is clear that the much larger ice sheets of the last glacial maximum (about 21 kyr BP) were still retreating in the early Holocene, so coastal cores can show a more confusing picture.

A complex picture of Holocene climate comes from the Antarctic Peninsula region, where a wide range of evidence exists, although so far no long ice core has been drilled for this region. However, a marine core from Palmer Deep, on the west side of the Peninsula, shows a rather complete record of Holocene climate for this ocean region. The abundance of diatoms in the core suggests that the area underwent a mid-Holocene climatic optimum between around 8.7 and 4.4 kyr BP (Sjunneskog and Taylor 2002). The cold Neoglacial period that followed seems to be significantly earlier than that indicated by terrestrial records elsewhere in the Antarctic Peninsula, and it remains difficult to reconcile the dates of different climate events along the peninsula.

Innovative studies of marine and lake sediments show that ice shelves may have retreated to, or beyond, their present positions at times during the Holocene. In the northern Antarctic Peninsula, marine cores from areas that have recently been uncovered by retreating ice shelves show that a similar retreat happened probably about 4000 years ago. There is other evidence from this area of warmer conditions at this time, although dating control on the different signals is poor. Further south, evidence from around George VI Sound suggests that the ice shelf there was absent about 8000 years ago, suggesting that this region experienced conditions warmer than the present at that time. It is not yet clear how to synthesise all these findings into a story that explains the Holocene changes in climate in the Antarctic Peninsula in relation to the rest of the world and to the climate forcing factors.

Although this section has concentrated on the climate of Antarctica itself, ice cores have provided important information for global climate studies over this time period also. In particular, records of many of the factors that force climate are most easily obtained from ice cores. The changes in greenhouse gases over this time are again taken from ice cores: both the major gases show changes, with minima in the mid-Holocene for CH_4 and in the early Holocene for CO_2, but the changes are small in comparison to those that preceded this period. Ice cores can also provide data on past changes in volcanic sulfate (from spikes in sulfate concentration in ice cores), and in solar activity (based on fluxes of the cosmic-ray-produced ^{10}Be); both datasets are essential input for attempts to model natural climate change during this period.

Glacial-Interglacial Cycles: The Last Eight Hundred Thousand Years

Ice-core climate records from central Antarctica have become iconic, as standard records showing the major climate shifts of the late Quaternary period. The main features of the records are similar right across the continent, as shown by the similarities in their common period of the three longest records, the 420-kyr Vostok core (Petit et al. 1999), the 340-kyr record from Dome Fuji (Watanabe et al. 2003), and the (so far) 740-kyr ice core from Dome C (EPICA Community Members 2004).

The most obvious feature of the temperature (deuterium) record is that warm and cold periods recur with roughly a 100,000-year period. This is the familiar pattern of warm and cold also seen in climate and sea-level data recorded in marine and terrestrial records worldwide. The cold periods are the times when large ice sheets covered much of North America and northern Europe; in the coldest parts (glacial maxima) sea level was as much as 120 m lower than it currently is. The warm periods are known as interglacials. The ice-core record shows that central Antarctica was also much colder (by between 8°C and 10°C) in glacial maxima compared to interglacials. The record shows that generally, in the last four glacial cycles, long glacial periods gave way rapidly to relatively short, sharp interglacials that lasted for only 10–30 kyr of the 100-kyr period.

The new EPICA Dome C core shows that, although the 100-kyr pattern persists throughout the record, the amplitude of change was much less in the earlier period (before 450 kyr BP). Interglacials in that period were much less warm than the current one; however, they persisted for a larger proportion of each cycle.

The underlying cause of the 100-kyr cyclicity is believed to be changes in the shape of Earth's orbit around the Sun. Aspects of Earth's orbit change on timescales around 20 kyr, 40 kyr, and 100 kyr (Milankovitch cycles). The 100-kyr period is that of changes in the eccentricity of the orbit. However, it is not yet clear why the relatively small changes in the pattern of solar energy receipt implied by Milankovitch cycles (and by the 100-kyr cycle in particular) lead to such major changes in Earth's climate. Ice cores provide some clues to this, by showing how some of the amplifying features of climate behaved.

In particular, the Vostok core shows clearly that the greenhouse gases, CO_2 and CH_4, increase and decrease in close concert with Antarctic climate. The changes in CO_2 look particularly similar to those of Antarctic climate, probably because it is Southern Ocean processes that play the largest role in the transfer of CO_2 between the atmosphere and long-lived reservoirs in the deep ocean. In the most recent glacial cycles, the CO_2 concentration is typically 180 ppmv in full glacial conditions and 280 ppmv in interglacials (remember that the present-day concentration is much more—about 380 ppmv in the year 2005).

Other aspects of climate recorded in ice cores also change on glacial–interglacial timescales. Sea salt, possibly related to sea-ice extent, and micron-sized dust, probably related to climate in southern South America, are two examples.

Most terrestrial records from the Antarctic continent are extremely sparse for any period beyond the Holocene, although various lines of evidence, including glaciological modelling, suggest that the Antarctic ice sheet was considerably larger at the last glacial maximum (perhaps by about one-third in volume). The direct evidence comes from examples from cosmogenic exposure ages of rocks above the present snowline (the amount of cosmogenic isotopes depends on how long the rocks have been exposed to cosmic rays, and thus indicates when they were last covered in ice). Other evidence comes from survey evidence of glacial scour marks indicating the past extent of ice streams, and from marine sediments showing that open areas were previously ice covered. Some scientists believe that the West Antarctic ice sheet may have partially collapsed during the last interglacial some 120 kyr BP, but this remains controversial.

Marine cores can also extend through the period that the ice cores cover. Compilations of the last glacial maximum indicate that sea-ice extent in winter was about double that of today (Gersonde et al. 2005). Summer sea-surface temperatures appear to have been lower by as much as 4°C–5°C in parts of the sub-Antarctic zone of the Southern Ocean. A very limited number of marine cores from the Southern Ocean cover longer timespans, even as much as the entire Quaternary, but more are needed before we can get a good representative picture of either sea-surface temperatures or sea ice extent over the longer period.

The Importance of Antarctic Paleoclimate Records

While it is interesting to observe the evolution of Antarctica itself, I will finish this article by emphasising the importance of Antarctic climate records for understanding global climate. The late Quaternary ice-core records have become the standards to which other Southern Hemisphere data are keyed. From them, despite some difficulties in synchronisation of different records, we can see the relationship in time and space between Antarctic climate, Southern Ocean temperature, CO_2 concentration, and ice volume. By comparing Antarctic and Greenland ice-core records, we can see the phasing of Northern and Southern Hemisphere climate. In particular, during the last glacial period (and probably earlier ones), the north shows massive and rapid millennial-scale climate changes (Dansgaard-Oeschger events), which are seen only in very subdued form in the south. At the transition from the last glacial period to the Holocene, the south shows a rather gradual change, while the north has most of its temperature increase in very large steps, quite late in the transition. These contrasts are also giving clues about mechanisms of climate change, probably related to the partitioning of ocean heat transport.

The Antarctic records are also giving key data about climate forcings and feedbacks that must be used if we are to understand past climate. Since we cannot expect to accurately predict future climate until we can reproduce that of the past, this is rather vital knowledge.

PALMER, NATHANIEL

American sealer Nathaniel Brown Palmer (born August 8, 1799, Stonington, Connecticut) became one of the first people to see Antarctica in 1820. He was preceded by two others earlier that year: Fabian von Bellingshausen (on January 27) and Edward Bransfield (on January 30).

Palmer, whose father was a shipyard owner in Stonington, went to sea at the age of 12. He first sailed to the Antarctic in 1819, as second mate on the brig *Hersilia* (James Sheffield, master), which operated in the newly discovered South Shetland Islands, the first US vessel known to have visited the archipelago. The voyage brought home 8868 skins of fur seals, spurring other New England ship owners to outfit sealing expeditions.

Palmer commanded the 47-foot (14.3-m) sloop *Hero* on another sealing voyage in 1820. Among *Hero*'s five-man crew was Peter Harvey, born in Philadelphia in 1789, one of the first black persons to reach the Antarctic. *Hero* sailed with four other Stonington vessels in a group led by Benjamin Pendleton. After arriving in the South Shetlands, Palmer took *Hero* southward to search for a better anchorage. He moored inside the flooded caldera of Deception Island—almost certainly the first to do so. On November 16, 1820, either from Deception's southeast coast or from *Hero*'s mainmast, Palmer is said to have sighted Trinity Island to the southeast and the Antarctic Peninsula beyond. The next day, he sailed to investigate, but heavy ice prevented him from making a landing. In January 1821, while searching for seal rookeries, Palmer took *Hero* along the western side of the Antarctic Peninsula as far south as Marguerite Bay.

Later that year, commanding the sloop *James Monroe,* Palmer was sealing in the South Shetlands as part of another Stonington fleet led by Pendleton. In company with British Captain George Powell of *Dove,* Palmer sailed east; together they discovered a large island of a new group on December 6, 1821. Because there were no seals to harvest, Palmer had little interest in the island, but Powell went ashore the next day and claimed it for the British crown, calling it Coronation Island, and the group "Powell's Group," now known as the South Orkney Islands.

Palmer made a final Antarctic voyage from 1829 to 1831, commanding the brig *Annawan* and sailing in company with his brother, Alexander S. Palmer, master of the schooner *Penguin,* in a voyage from Stonington led by Pendleton aboard the brig *Seraph*. The private sealing and exploration voyage was the first to earn sanction by the US government. It included the first American scientist to visit the Antarctic, physician and geologist James Eights, who published seven papers on his findings, including his discovery of fossil wood in the South Shetlands, the first fossil discovery in Antarctica.

"Captain Nat," as Palmer was widely known later in life, became wealthy as a ship designer, owner, and master, particularly of the Yankee clipper ships used in the China trade. He died in San Francisco, California, on June 21, 1877, the day after returning from a voyage to Asia.

PARASITIC INSECTS: LICE AND FLEAS

Lice (order Phthiraptera) and fleas (order Siphonaptera) are the only two groups of parasitic insects known from the Antarctic continent. Lice are wingless and flat-bodied, living as permanent parasites on warm-blooded vertebrates and feeding on the host blood, skin products, or feathers. Three suborders of Phthiraptera are represented: the Anoplura or sucking lice, with five species (family Echinophthiriidae) living on seals; the Amblycera (family Menoponidae) and Ischnocera (family Philopteridae) or chewing lice, with more than sixty species in eighteen genera, living on birds such as penguins, albatrosses, petrels, and skuas. Phthiraptera is the insect order with the greatest number of species in Antarctica.

Being permanent parasites, the habitat of lice is the skin and the plumage or pelage of their hosts. Moreover, the geographical ranges of lice, with very few exceptions, match those of their hosts. However, each species of louse occupies a distinct ecological niche on the body of the host. In the case of bird lice, there is usually a stout "head and neck" louse species on each species of albatross, petrel, and skua, coexisting with elongate "wing" lice and round "body" lice. Each Antarctic seal species is parasitised by its own unique species of sucking louse, with most specimens located on the hind flippers, tail, ankle, and hip of the host. Seal lice have special morphological adaptations, such as a thick skin covered with large scales that trap host sebum, to withstand cold temperatures and long submersion periods.

Among bird lice, the most speciose genera in the Antarctic are *Austromenopon* Bedford, 1939, represented by ten species of body lice; *Austrogoniodes* Harrison, 1915, represented by seven species exclusively parasitic on penguins; *Quadraceps* Clay and Meinertzhagen, 1939, represented by six species of wing lice; and *Saemundssonia* Timmermann, 1936, with nine species of head and neck lice. The remaining fourteen genera contain from one to four species each. *Pseudonirmus* Mjöberg, 1910, is the only Antarctic-endemic genus and contains three species, each parasitic on a separate host species (Cape pigeon, snow petrel, and Antarctic petrel).

The order Siphonaptera is represented by a single endemic genus and species: *Glaciopsyllus antarcticus* Smit & Dunnet, 1962 (family Ceratophyllidae), the Antarctic flea, parasitic on three species of petrels. A study of the biology of *Glaciopsyllus antarcticus* associated with Antarctic fulmars (*Fulmarus glacialoides* [Smith]) showed that its life cycle is closely synchronised with the breeding of its host. Unremarkably in such a cold place, fleas need the warmth of the host bodies to reproduce. Eggs are laid by adult Antarctic fleas when the host is incubating its own eggs, and immature stages (larvae and pupae) only develop when the host's chicks appear. Adult fleas overfeed on the chicks to produce large quantities of blood faeces, on which the larvae feed to complete development and pupate, all within the host plumage. Unlike all other known fleas, the Antarctic flea is remarkable in that pupae remain on the host body and, although not yet proven, pupae and adults appear to overwinter on the host while the latter migrates during its nonbreeding period.

PARASITIC INSECTS: MITES AND TICKS

Mites (Acari or Acarina) are small arachnids (phylum Arthropoda), usually less than 0.7 mm in body length, that live freely or in association with other animals. In the Antarctic regions, they inhabit ice-free terrestrial or marine ecological systems, in which their functional role is often important. This is especially the case for decomposer mites (which feed on decaying matter or fungi); others are herbivorous (feeding on algae or lichens) or predacious (feeding on other mites or small invertebrates). One mite group, the ticks (Metastigmata), is entirely parasitic of vertebrates. Mites are among the relatively few animal groups represented in all three Antarctic geographical regions, the continental, the maritime (Peninsula and nearby islands), and the sub-Antarctic (near and outside the Polar Frontal Zone). In the physically harsh continental Antarctic habitats, mites constitute (along with collembolans) the highest taxonomic level of living organisms. No vertebrates feed in these habitats, which support other lower invertebrate groups, such as nematodes, tardigrades, rotifers, and amoebae. The mite diversity of continental and maritime Antarctica is expectedly low, and these regions respectively comprise 29 and 54 species, compared to the more than 450 known species for the sub-Antarctic. A single sub-Antarctic island (Marion Island) may support more than seventy mite species. While five mite orders (Mesostigmata, Metastigmata—ticks, Prostigmata, Oribatida, Astigmata) are represented in the Antarctic regions, only the Prostigmata and Oribatida are known from continental Antarctica.

Continental Antarctic mites occur on nunataks (rocky peaks that protrude through the ice sheet) in the higher latitudinal zones, or along the coastal regions of east Antarctica. Their habitat comprises rocks or gravel that support patches of moss, alga (such as *Prasiola*), or lichens (such as *Usnea* and *Umbilicaria*). All continental Antarctic mites are free-living and, with the exception of one predacious prostigmatid genus (*Coccorhagidia,* Rhagidiidae), herbivorous, and they feed on algal and or fungi elements. Given the isolation and extent of glaciation of the continent, the origin of continental Antarctic mites has been a question of much interest. The oribatid mites (five species) are thought to have originated when the continent was part of Gondwana and to have survived the effects of the Neogene glaciation. This suggestion stems from the endemism of the family Maudheimiidae (*Maudheimia,* four species), and the exclusive distribution of the genus *Antarcticola* (Ameronothridae, one species) on islands having a Gondwanan association (South Georgia, Îles Kerguelen). The distribution of each of the four *Maudheimia* species, in relation to their phylogeny (evolutionary history), suggests that speciation resulted from isolation of populations during glaciation of the continent. The Prostigmata (twenty-four species) are hypothesised as having colonised the continent subsequent to glaciation, considering that close relatives (from the same genus) are found on surrounding islands. The prostigmatid mite families found in the region are Eupodidae, Nanorchestidae, Penthalodidae, Tydeidae, and Rhagidiidae.

Detailed ecological studies on Antarctic mites have typically been restricted to Signy Island (maritime Antarctic), South Georgia, and Marion Island. Analogous to the climatic conditions, the habitat conditions of the Maritime Antarctic are intermediate of those for the continental Antarctic and sub-Antarctic. The sub-Antarctic embraces the best-developed terrestrial systems, comprising a variety of habitat types and consequently supporting a high mite-species diversity, including numerous predacious mites. The habitat types are broadly grouped under epilithic (dominated by mosses and lichens) and vegetative (dominated by ferns and angiosperms) biotopes. The former biotope constitutes inland rock and gravel fields, as well as coastal rocky shores. Community studies suggest that the epilithic biotope has served as a glacial refuge, from which the vegetative biotope has become recolonised. Evidence for this derives from the epilithic biotope's having a higher mite diversity and supporting mites with specific habitat requirements. This is especially well exemplified by the supralittoral zone (just above the intertidal zone) of many sub-Antarctic islands, which contains principal Antarctic mite genera, including *Parasitiphis* (Mesostigmata), *Neocalvolia, Algophagus* (Astigmata), *Halozetes,* and *Alaskozetes* (Oribatida). These usually inhabit the lichens *Turgidosculum* and *Caloplaca*.

The marine zone comprises two evolutionarily distinct mite groups, referred to as primary and secondary marine mites. Primary marine mites constitute a single family, the Halacaridae (Prostigmata), with more than fifty known coastal species in the Antarctic region. They show a complete transition to the marine environment by the capacity for aquatic respiration and continuous submersion. Secondary marine mites are confined to the intertidal zone, and those that show a partial marine transition by feeding on marine lichens or algae belong to the Ameronothridae (Oribatida: *Halozetes* [twelve species], *Alaskozetes, Podacarus*) or the Hyadesiidae (Astigmata: *Hyadesia, Neohyadesia*). Because of the occurrence of ameronothrid mites in marine, supralittoral, and terrestrial biotopes, which were differentially affected by glaciation, these mites have been fundamental to understanding the evolutionary (historical) ecology of sub-Antarctic island invertebrate faunas. Regarding other aquatic systems, the astigmatid mite genus *Algophagus* is important from an ecological and evolutionary perspective. While they primarily inhabit freshwater bodies, some species occur in supralittoral and terrestrial habitats.

The mechanisms whereby mites disperse and colonise in the Antarctic remain speculative. Aerial dispersal seemingly imposes a level of desiccative and thermal stress beyond the physiological capacity of mites. Bird transport or oceanic dispersal, especially by means of rafting (on seaweed, for example), is a more probable mechanism of dispersal between islands. The numerous Cosmopolitan and European (Boreal) mite species found on islands in the region (approximately seventy) is evidence of human introduction, and some mites (such as *Tyrophagus*) are typically present where there is human activity. Although no obvious ecological threats have arisen from mite introductions, the situation could change in the future.

Because of its relevance to understanding issues such as ecological conservation, global warming, and species introductions, research has focussed on free-living mites, rather than on mites that live in association with animals. Ticks (*Ixodes,* Metastigmata [four species]) and some mesostigmatid mites *(Rhinonyssus)* are common parasites of penguins and other seabirds. A variety of seabirds are home to feather mites, which complete their lifecycles on or in the feathers (thirty-seven species are known from the Antarctic regions; Astigmata). *Halarachne* mites (Mesostigmata) live in the nasal passages of elephant or leopard seals. At least two cases of phoresy (a mutual association that functions in mite dispersal) are known for the Antarctic. Of particular interest are the phoretic nymphs of *Psylloglyphus* (Winterschmidtiidae, Astigmata) and *Glycacarus* (Glycacaridae, Astigmata) that attach to the tergites of a flea *(Notopsylla),* which in turn parasitizes grey-headed or white-chinned petrels of the sub-Antarctic.

PELAGIC COMMUNITIES OF THE SOUTHERN OCEAN

Pelagic communities include animals and microalgae that spend at least a part of their life suspended or swimming within open-ocean or coastal waters. In the Antarctic, the definition also includes species that interact with pack ice or ice floes.

Over the ~35-million-year existence of the Southern Ocean, some animal groups have adapted to the icy and homogenously cold conditions to a greater extent than others. Particularly striking is the dominance, in some areas, of Antarctic krill *(Euphausia superba),* which belong to a group (the euphausiids) that make up only a minor component of pelagic communities in other ocean systems. In other less-coastal areas, copepods dominate numbers, and at depth, species of zooplankton. The pelagic fish, by contrast, are rather underrepresented in the Southern Ocean. Animals capable of exploiting krill, such as whales, seals, and penguins, have flourished in this environment as seen nowhere else.

The Southern Ocean is bounded to the north by the Polar Front and by the Antarctic continent to the south. It comprises 10% of the world's oceans and is predominantly very deep (3000–4000 m). It contains two major features that dominate the biology of its pelagic communities: (1) the Antarctic Circumpolar Current (ACC) and (2) the seasonal ice zone (SIZ). The ACC is the strongest oceanic current in the world since the lack of any continental barriers allows the wind to drive the flow continuously around the globe. The current flows from west to east (clockwise) and contains numerous water masses separated by a series of oceanic fronts. The water masses in the northern regions are generally ice free and mainly differ according to their temperatures, salinities, and levels of nutrients. The differing types and prevalence of ice cause further zonation to the south.

The marginal ice zone (MIZ) is the first type of ice encountered when leaving open waters. The MIZ is 100–200 km wide and consists of small ice floes broken up by swell. The location of the MIZ depends on the extent of the SIZ, which, at its maximum, covers almost 19 million km^2, some 8% of the southern hemisphere. The SIZ advances and retreats at a rapid rate (up to 1.6 km h^{-1}) over the course of the year, shrinking to just 5 million km^2 by the end of the summer. The high level of biological activity in these zones matches the dynamic physical nature of the MIZ and SIZ. By contrast, the permanent pack-ice zone, which is sandwiched between the SIZ and the Antarctic continent, changes little over time and supports very few pelagic communities.

All Antarctic food chains are ultimately fuelled by the development and growth of phytoplankton (microscopic single-celled algae) that accumulate at the ocean's surface or on surface-dwelling ice. Phytoplankton growth (primary production) depends on light to drive photosynthesis, and these organisms thrive when conditions in the water column stratify, preventing them from being mixed too deeply. This stratification may be caused either by the warming of surface waters, as observed in northern regions, or by the melting of ice, as occurs in the retreating SIZ. Phytoplankton also need sufficient nutrients and trace elements in order to grow. When all conditions are satisfied, phytoplankton taxa, such as diatoms, dinoflagellates, and *Phaeocystis antarctica,* are capable of forming large blooms. However, the lack of trace elements, particularly iron, results in primary production being constrained in many areas of the Southern Ocean. Smaller species (picophytoplankton and nanophytoplankton) dominate the relatively low levels of primary production in these areas.

The primary productivity regime of a region makes a large difference to the type of pelagic community that can prosper. Regions where phytoplankton blooms occur regularly often support populations of Antarctic krill and their predators. A large part of these blooms remain unconsumed and the dying cells frequently form aggregates *(marine snow)* that descend rapidly. When this occurs in the open ocean, it provides food for deep-living pelagic organisms; in coastal waters, benthic communities will often consume it. In regions of low primary productivity, small organisms such as dinoflagellates and foramaniferans consume the dominant picoplankton and nanoplankton. These in turn are eaten by copepods (e.g., *Oithona*) that have small enough filters to capture them, or pteropods (Thecosomata) and salps *(Salpa thompsoni),* which use a mucus trap for the same purpose. Salps reproduce asexually and attain large levels of biomass when conditions are favourable. Although not strictly gelatinous (they consist of a transparent cellulose cuticle with an internal filtering chamber and muscles), they are considered to have low nutritional value and are rarely found in the diets of large predators. Their major consumer is probably *Themisto gaudichaudii,* a hyperiid amphipod that is much smaller ($\sim$20 mm long) than the salp itself ($\sim$60 mm). *T. gaudichaudii* is found in the diets of some large vertebrates.

The open ocean is a homogenous environment devoid of protective structures such as reefs. However, vulnerable pelagic organisms can use other strategies to reduce their risk of being eaten. Krill and *T. gaudichaudii* form large swarms in which individuals can forewarn each other of the advance of predators. Other organisms change their vertical location in the water column over daily or seasonal cycles. This is because most food items (particularly phytoplankton) are located in the sunlit surface layers where the risk of being detected by visual predators is the greatest. Visiting these layers only during the nighttime, or during limited times of the year, reduces this risk.

Although the vertical migration range of pelagic organisms such as krill, salps, and *T. gaudichaudii* remains within the epipelagic zone (0–250 m), other species start their journey from the mesopelagic zone (250–1000 m). These include the lanternfish (myctophids) and hatchetfish (argyropelecids), which are adorned with numerous photophores (light organs) that can be both a camouflage and a means of communication. Animals in the bathypelagic zone (1000–3000 m) do not make a daily journey to the surface but feed either on marine snow or on each other. Such animals are mainly jellyfish (such as comb-jellies and siphonophores), shrimps (penaeids and carids), and bioluminescent fish. Other organisms, such as the copepod *Calanoides acutus,* enter this zone during the wintertime in a state of diapause and so rely on their reserves of body fat to keep them alive until they ascend the following spring. Very few organisms are found in the deepest layers (the abyssopelagic zone, >3000 m) although shrimp-like crustaceans called mysids become relatively abundant at the interface with the sea floor (the benthopelagic zone).

Humans have exploited several animal groups in the Southern Ocean pelagic community over the past two centuries, including Antarctic fur seals *(Arctocephalus gazelle),* baleen whales (e.g., the Antarctic blue whale, *Balaenoptera musculus;* the fin whale, *Balaenoptera physalus;* and the humpback whale, *Megaptera novaeangliae*), toothed whales (the sperm whale, *Physeter macrocephalus*), icefish *(Champsocephalus gunnari),* Patagonian toothfish *(Dissostichus eleginoides),* and krill. With the exception of krill, the populations of each species were lowered to levels that threatened their extinction. This also upset the balance of other species within the ecosystem. Laws (1977) proposed that the near extinction of baleen whales in the early part of the twentieth century meant that 150 million tons of surplus krill became available for other predators such as crabeater seals *(Lobodon carcinophagus)* and penguins like the Adélie *(Pygoscelis adelie)* and macaroni *(Eudyptes chrysolophus)*. Many of these species increased in abundance over the mid-twentieth century. Since the moratorium on whale hunting was enforced in 1986, the populations of some whale species are thought to have recovered at a rate of 10% per annum while a simultaneous decrease in the population sizes of penguins and seals has been reported.

Meanwhile, krill populations have gone through periods of high and low abundance over the course of the twentieth century. Some say that the high levels of biomass reported earlier in the century were a result of the species moving towards its carrying capacity as the level of whale predation fell. The gradual decline in krill numbers since then is a result of, initially, the increase in the numbers of seals and penguins exploiting the krill surplus and, subsequently, the recovery of the whale population. However, others have proposed that the recent decline in krill numbers has been caused by the partial demise of their major habitat, the SIZ. Krill-rich areas, such as the Antarctic Peninsula, have recently undergone rapid warming and the extent of the SIZ has decreased in this region. Ice is particularly important to krill larvae, especially over winter, where it provides a refuge and source of food (ice algae). Krill also rely on blooms that occur at the retreating ice edge during the summer to fuel reproduction. The decline in krill has been accompanied by a simultaneous increase in the numbers of salps, which prefer open waters without blooms. Climate models able to predict the future extent of the SIZ in the Southern Ocean are still in their infancy and still have considerable error margins. However, it is likely that any further decrease will make this region less habitable for krill and less sustainable for large populations of their vertebrate predators.

PENGUINS: OVERVIEW

Penguins are marine flightless birds, different enough from all other birds to merit an order (Sphenisciformes) of their own. Within the order are eighteen extant species and approximately forty fossil species, all similar enough in size, shape, and ecology to be included in the single family Spheniscidae.

Distinguished on land by their stocky build, upright stance, and narrow flippers, modern penguins are found almost exclusively in the Southern Hemisphere. Contrary to popular belief, they are not predominantly polar or even subpolar birds. They are found along cool and warm temperate coasts of South America, South Africa, Australia, and New Zealand and on the cool temperate islands of the Southern Ocean and the Antarctic and sub-Antarctic islands. The most northerly breeding population occurs on the Galapagos Islands, where a few individuals live north of the Equator. The genera and species are distinguished by their size, shapes of bill, and colour patterns of head and neck. The largest (emperor penguin) weigh some thirty times more than the smallest (little penguin).

All known fossils occur within the geographical ranges of modern species. In age, the species range from late Palaeocene or early Eocene (50–60 million years) to Miocene (5–10 million years). Most are represented by single tarso-metatarsi (ankle) or humerus (upper forelimb) bones, or fragmented skulls; in relatively few have even partial skeletons been identified. Measurements of these bones indicate that most fossil species lay within the size range of modern penguins. A few were much larger, standing up to 1.6 m (5 ft) tall and weighing up to 80 kg (176 lb). At least one species was notably smaller, standing only 33 cm (13 in) tall.

In skeletons and musculature, penguins show ample evidence of having evolved from flying birds, though the earliest known representatives of the family were already flightless. Once committed to swimming and diving, they were able to diversify in size; among modern penguins, the smallest feed mainly in surface waters, while the largest appear to be the deepest divers. Their evolution from relatively small flying birds, possibly akin to petrels and similar in size to the smallest modern auks, occurred in warm seas, before the presence of an Antarctic ice cap chilled the Southern Hemisphere. Only during and after the Pliocene period (2–3 Ma) were some of the southernmost species likely to have encountered icy seas. However, the insulation (overall feathering and subdermal fat) required to keep swimming and diving birds warm in temperate seas was a useful preadaptation for colder conditions. Currently the greatest concentrations of penguin species occur in cool temperate waters: New Zealand and its southern islands alone support seven breeding species, the Falkland Islands five species. The Antarctic region, including the continent and islands within the Polar Front (the northern limit of Antarctic surface waters), also supports five species, of which three (emperor, Adélie, and chinstrap) breed only south of the Polar Front.

The penguin body is almost completely feather covered, with only a narrow naked brood patch on the lower abdomen present during the breeding season. Tropical Humboldt, Galapagos, and African penguins have conspicuous bare patches on the face, possibly to shed surplus heat. All species are counter shaded (i.e., they have dark feathers on the head and back, white underneath). Newly grown dorsal feathers are black or dark brown, with a blue or grey spot that in some species (king and little penguins)

Species	Body Length, cm (in)	Mean Body Mass, kg (lbs)	Geographical Range
Emperor, *Aptenodytes forsteri*	115 (45)	30.0 (65)	Antarctica, including the Antarctic Peninsula
King, *Aptenodytes patagonicus*	94 (37)	15.0 (33)	Macquarie I., Prince Edward Is., Heard I., Îles Kerguelen, Îles Crozet, Falkland Is., South Georgia, South Sandwich Is.
Adélie, *Pygoscelis adeliae*	71 (28)	5.0 (11)	Antarctica, Antarctic Peninsula, South Shetland Is., South Orkney Is., South Sandwich Is., Bouvetøya, Peter I Øy, Balleny Is, Scott I.
Chinstrap, *Pygoscelis antarctica*	69 (27)	4.5 (10)	Antarctic Peninsula, South Shetland Is., South Orkney Is., South Sandwich Is., Bouvetøya, Peter I Øy, South Georgia, Balleny Is.
Gentoo, *Pygoscelis papua*	76 (30)	5.9 (13)	Antarctic Peninsula, South Shetland Is., South Orkney Is., South Sandwich Is., South Georgia, Falkland Is., Heard I., Macquarie I., Prince Edward Is., Îles Kerguelen, Îles Crozet,
Yellow-eyed, *Megadyptes antipodes*	66 (26)	5.4 (12)	Southeastern New Zealand, Campbell I., Auckland Is.
African, *Spheniscus demersus*	71 (28)	2.7 (6)	Southern Africa
Magellanic, *Spheniscus magellanicus*	71 (28)	5.0 (11)	Southern South America, Falkland Is.
Humboldt, *Spheniscus humboldti*	66 (26)	4.1 (9)	Northern Chile, Peru
Galapagos, *Spheniscus mendiculus*	53 (21)	2.3 (5)	Galapagos Is.
Fiordland, *Eudyptes pachyrhynchus*	56 (22)	3.6 (8)	Southwestern New Zealand
Erect-crested, *Eudyptes sclateri*	66 (26)	4.5 (10)	Antipodes Is., Bounty Is.
Macaroni, *Eudyptes chrysolophus*	71 (28)	4.5 (10)	Southern South America, Antarctic Peninsula, Falkland Is., South Shetland Is., South Orkney Is., South Sandwich Is., South Georgia, Prince Edward Is., Îles Crozet, Îles Kerguelen, Heard I., McDonald I., Bouvetøya
Rockhopper, *Eudyptes chrysocome* (three subspecies)	56 (22)	2.7 (6)	Tristan da Cunha, Gough I., Falkland Is., Tierra del Fuego, Prince Edward Is., Îles Kerguelen, Îles Crozet, Heard I., Île St. Paul, Îles Amsterdam, Macquarie I., Campbell I., Auckland Is., Antipodes Is., Bounty I.
Snares, *Eudyptes robustus*	53 (21)	3.0 (6.5)	Snares Is.
Royal, *Eudyptes schlegeli*	61 (24)	4.5 (10)	Macquarie I.
Little blue, *Eudyptula minor*	41 (16)	1.1 (2.5)	Southern coasts of Australia, New Zealand
White-flippered, *Eudyptula albosignata*	41 (16)	1.4 (3)	Banks Peninsula and Motunau I., New Zealand.

Figures are based on Stonehouse (1967) and Williams (1995). Body masses of all species vary widely according to breeding condition, gender, moult, etc. "Standing height" can be estimated as roughly 90% of body length.

dominates to provide an overall impression of silver-grey. After several months, the feather tips erode, darkening the dorsal plumage overall. Ventral feathers are white in most species, but emperors and kings are markedly yellow-to-gold on the upper abdomen, chest, and throat, merging into conspicuous yellow or golden-orange auricular patches. *Eudyptes* penguins have species-specific gold or yellow crests above the eyes; *Megadyptes* penguins have a bright-yellow coronet encircling the head. *Spheniscus* penguins carry distinctive black bands encircling the chest and throat. Bill colour varies from black to bright orange; in kings and emperors vivid coral or lilac plates line the lower mandible.

Individual body feathers on the midback and abdomen grow at a density of about 11 per cm^2 and range in length from 2 cm in the smallest species to 4.5 cm in emperor penguins. In all species, they are curved and flattened to overlap like roof tiles. Body feathers include aftershafts of down, which mat together to form a dense underlayer. Body feathers can be raised or lowered. When raised, the feathers part and permit air to circulate; when lowered they form an effective windproof and waterproof covering. Flippers are covered with tiny scale-like feathers; tail feathers in most species are short and stiff. Penguins spend much of their time ashore preening, oiling the feathers from a preen gland above the tail. All species undergo an annual moult, in which all the feathers are replaced simultaneously over a period of 2 to 3 weeks.

Additional insulation is provided by a layer of subdermal fat, barely present in warm-climate species and thickest in polar penguins. On the back and abdomen of emperors at the start of winter it may be 2.5 cm thick; on Adélies it may be up to 2 cm (0.8 in). On calm days in winter or early spring, with air temperatures around –40°C, snow may settle on the surface of an emperor or Adélie penguin. Despite the bird's high core temperature (c. 38°C), fat and feathers combine to ensure that very little heat escapes through the surface. Penguins are indeed so well insulated that, when active, they require radiating surfaces to shed heat to the environment. This function appears to be undertaken by the flippers, which are relatively uninsulated yet well supplied with blood vessels. Their white undersurfaces often appear pink (i.e., flushed with blood) in birds emerging from the sea. The bare faces of *Spheniscus* penguins may similarly act as radiators.

Most penguins are likely to spend the majority of their lives in the sea, emerging onto land (or sea ice) only to rest, preen, moult, and breed. *Eudyptes* penguins undergo long distance dispersions between breeding seasons, requiring them to spend at least 6 months continuously at sea. Penguins float low in the water, using flippers for propulsion and steering, with feet and tail combining to form a rudder. Underwater, the flippers are extended and appear to vibrate, moving the birds forward at speeds of 60–100 m per min. They feed exclusively in the sea, on a range of foods including planktonic crustaceans, fish, and squid. Swimming and diving abilities enable them to feed at depths below those of most flying birds. The smallest penguins (little and rockhoppers) feed almost entirely on plankton within a few metres of the surface. Those of intermediate size (gentoos, chinstraps, macaronis) dive to depths of as much as 100 m and can stay submerged for 3–5 minutes. The largest penguins (emperors, kings) dive regularly to 50–100 m in search of larger fish and squid. Emperor penguins have been recorded diving to 500 m, on hunting forays lasting more than 15 minutes.

Though sometimes described as clumsy on land, penguins can move fast over a variety of surfaces. Small and intermediate-sized species emerge through heavy surf to land on rocky shores or beaches, running, hopping, and if necessary climbing steep slopes to reach their nest sites. The larger species are less agile: kings land only on beaches, emperors almost exclusively on sea ice, both avoiding steep slopes. Species that encounter soft snow toboggan on their bellies, propelling themselves with toes and flippers. In early spring, Adélie and emperor penguins may have to walk 70–80 km over sea ice to reach their breeding grounds; gentoo and chinstrap penguins may scramble through snow to nest in colonies over 150 m above sea level.

Most penguin species nest in dense colonies, on beaches or cliffs within a few hundred metres of the sea. The largest colonies, for example of *Pygoscelis* penguins, may include hundreds of thousands of nests. Yellow-eyed and Galapagos penguins, by contrast, breed in solitary pairs, or in small groups of nests, well spaced apart. Like most other warm-climate penguins, they nest under cover of vegetation or in caves. *Spheniscus* and *Eudyptula* penguins typically nest in burrows. All but two of the known emperor penguin colonies form on sea ice; the others are on land.

Polar and subpolar penguins breed once yearly, returning *en masse* to their traditional colonies in early spring, and nesting, laying, incubating, and rearing their chicks simultaneously during the brief summer. Subtropical and tropical species are less tightly coordinated, and with breeding seasons that may extend throughout the year. Emperors and kings lay a single white egg that they incubate on their feet, warmed by a fold of abdominal skin. All other species lay two (rarely three) eggs, chalky white or bluish, which they incubate in nests made of pebbles, moss, and the bones of their predecessors. *Eudyptes* penguins lay one smaller egg that they usually discard, followed by a larger one that they incubate to full term. In emperors, only the males incubate, for a total of 64 days. In all other species, incubation is shared, for periods ranging from 54 days in kings to 33–36 days in the smaller species. Both parents brood and feed their young, bringing food and regurgitating it to their own offspring, which they find and identify by calling. Growing chicks are covered in dense woolly down, which they moult into juvenile plumage before leaving the nesting grounds. Those of the smaller species are ready for the sea some 7 to 9 weeks after hatching.

Chicks of emperor and king penguins, taking longer to rear, require anomalous breeding cycles. Emperors lay in mid-winter so that their chicks, which take 20 or more weeks to grow, are ready for the sea by mid-summer. Kings lay over an extended period in spring and summer, then retain their chicks in the colonies throughout the subsequent winter, when the chances of their survival at sea would be much reduced. King chicks may thus be a year old on first entering the sea.

Predators on land include skuas (*Catharacta* spp.); southern giant petrels *(Macronectes giganteus)* and leopard seals *(Hydrurga leptonyx)* are predators at sea.

PETER I ØY

Peter I Øy (Island) lies in the Bellingshausen Sea only 280 miles (450 km) off the Antarctic coast at 68°50′ S, 90°35′ W. Shaped approximately like an egg, its area of 60 square miles (156 km^2) is 95% glaciated, with a 131-ft- (40-m-) high ice wall or, in parts, steep cliffs, plunging into the sea. The island has volcanic origins and the highest peak, Lars Christensentoppen at 5381 ft (1640 m) asl, is an extinct and ice-capped volcanic crater.

The climate is hard, with strong winds, low temperatures, and snow. For much of the year thick pack ice encircles the island, making landing very difficult. On the west coast the rocky promontory Kapp Ingrid Christensen divides the bays Norvegiabukta and Sandefjordbukta with their narrow (c. 4-m-wide) strips of beach, and most landings occur here.

The vegetation is dominated by specialised hardy mosses and lichens. A few seabirds, particularly several hundred pairs of southern fulmars *(Fulmarus glacialoides),* nest in the cliffs, and small Adélie and chinstrap penguin rookeries exist on Framnesodden. Large numbers of seals, particularly crabeater and leopard, inhabit both the shore and particularly the surrounding waters.

Peter I Øy was first sighted in January 1821 by Thaddeus von Bellingshausen, commanding the *Vostok* and *Mirnyy,* and was named after Czar Peter the Great (1672–1725). However, pack ice prevented approach nearer than c. 16 miles (25 km). Ninety years later the island's existence was confirmed when Jean Charcot in *Pourquoi Pas?* sailed to within 3 miles (5 km). In 1926–1927, a Norwegian expedition led by Eyvind Tofte on the *Odd I* circumnavigated and surveyed the island without managing to land. Finally, the Norwegian second *Norvegia* expedition, captained by Nils Larsen and led by Dr. Ola Olstad, made the first landing on February 2, 1929. With a ceremony on Framnesodden in Sandefjordbukta, the island was claimed for Norway. Surveying work was done and a small hut built to house a depot for a future expedition. This was probably destroyed very quickly by the elements, although it is listed as no. 25 on the Antarctic Treaty Historic Sites and Monuments List. Larsen revisited in 1931 on *Norvegia,* but was unable to land. In May 1931, a Norwegian Royal Proclamation announced that the island was placed under Norwegian sovereignty, and in March 1933 it was declared a Norwegian dependency. In 1935, when a royal resolution was passed to prohibit sealing on Bouvetøya, Peter I Øy was included as a similarly protected area.

A second landing was made at the same spot in February 1948 by a Norwegian expedition on the *Brategg,* captained by Nils Larsen. Scientific investigations were carried out for 3 days until ice forced them to leave. A new hut was erected and a copy of the occupation document from 1929 placed inside. Again the hut was probably soon destroyed. Since then, sporadic landings have been made by various nations, mostly for short scientific investigations, and there have been a few tourist visits since 1980. In January 1987, five Norwegian scientists spent 11 days at the island for extensive investigations and surveying.

PETERMANN, AUGUST

The German cartographer and publicist August Petermann (b. Bleicherode, April 16, 1822, d. Gotha, September 25, 1878) had an important role as a promoter of the geographical exploration of Africa and the polar regions. The popularization of his conceptions of the physical geography of the Arctic Ocean encouraged European countries to take an active part in the exploration of the polar seas in the second half of the nineteenth century (Tammiksaar et al. 1999). Although Petermann had no ambition to be involved in the organization of the exploration of the southern polar regions, he had indirect, but considerable, influence on it, most notably due to his compilation in 1863 of the first special map of the physical geography of the Antarctic (Petermann 1863a). This was based on only the scanty observation data available.

Petermann's career as a scientist (1839–1845) started with taking part in the compilation of *Physikalischer Atlas* (1837–1848) with the cartographer Heinrich Berghaus. This provided geographical information in a novel way—on thematic maps. In 1845–1848, in Edinburgh, Petermann helped Alexander Keith Johnston, geographer to the Queen, to compile the English version of *Physikalischer Atlas* (1848) of Berghaus. After that (1847–1854), Petermann worked as an independent cartographer in London and became known as a promoter of geographical investigation in Africa. In 1854, he moved to Gotha in Germany and founded the geographical journal *Mittheilungen aus Justus Perthes' Geographischer Anstalt über wichtige neue Erforschungen auf dem Gesammtgebiete der Gerographie,* which quickly became the leading geographical journal in the world. The key to the success of the journal lay in the expeditious publication of the most recent geographical information and the use of it in maps (Wichmann 1888; Weller 1911). This made Petermann an influential man. He used his authority to promote the investigation of little-studied regions and to disseminate his geographical hypotheses.

In addition to the journal, Petermann was active in compiling atlases (for example, the highly valued *Stieler Handatlas*). He began to construct maps of the Arctic in order to depict the entire Russian Empire. His first innovative map in conical projection, entitled "Süd-Polar-Karte," was published in the *Stieler Handatlas* of 1863 (Petermann 1863a). A similar projection enabled him to delineate the routes of all known expeditions in the region of the Antarctic Circle without large deviations, by using the data collected on the border of drift and pack ice and hypothetical land sights. On the basis of the diverse data obtained and published on his maps, Petermann determined that the name "Antarctic continent" was used too frequently in Mercator projection maps, as the connecting of pack ice, ice walls, and observed lands with a line did not necessarily indicate the existence of a continent surrounding the South Pole (Petermann 1863b).

Although there were very few reliable observation data available on the Antarctic, Petermann concluded that the border of drift ice was changeable and varied regionally and yearly by approximately 1000 miles (1610 km). Despite the temperature isotherm of the Antarctic water discovered by James Clark Ross, he believed that the physical-geographical border of the Antarctic waters was constant and coincided with the northernmost border of drift ice at 55° S. This, according to Petermann, was the key to helping explain the movement of currents in the Antarctic, which in summer carried the drift ice to much farther north latitudes. Comparing these data and the air temperatures recorded in the Arctic and Antarctic, Petermann determined that due to the cold summers in the Antarctic—in contrast to the warm summers in the Arctic—there could not be a continent in the region of the South Pole, as continents accumulate warmth. According to Petermann, the cold summer and lack of living organisms in the Antarctic indicated that there was an ocean covering most of the area; he further believed that, having passed the drift-ice belt on a steamer, one could discover new lands and reach the South Pole (Petermann 1863b).

Petermann's conception of the physical geography of the Antarctic seems bizarre today, but in the 1860s—when scientists had not unanimously accepted or rejected the theory of continental freezing, had not yet been to the inner regions of Greenland, and had not yet investigated its ice cap—Petermann's hypothesis was considered feasible by many individuals who interpreted the numerous theories (often proceeding from the scientific knowledge of the eighteenth century) supposedly supported by the scanty factual data on the Antarctic. Alexander von Humboldt and Georg von Neumayer, for example, agreed with parts of Petermann's theory that an extensive Antarctic Ocean existed, and the instructions to the First German South Polar Expedition (1901–1903) even included the task of crossing the hypothetical Antarctic

Ocean. As often happens in science, the observations carried out during this expedition not only did not confirm the presence of the Antarctic Ocean, but helped establish just the opposite, the presence of an Antarctic continent under the continental ice.

PETRELS: PTERODROMA AND PROCELLARIA

The birds discussed in this article are in the order Procellariiformes and family Procellariidae.

Kerguelen Petrel *(Lugensa brevirostris)*

This is an ancient species of petrel, possibly 40 million years old, from which the fulmarine petrels evidently descended, and perhaps with an ancestral connection to shearwaters. It is uniformly slate grey with paler undersides of the primary feathers and inner leading edge of the underwing, a narrow black bill, and pale purplish-grey feet. It is large-headed and about 35 cm long with a mass of about 350 g. It flies with a characteristic swift flight, often towering high above the sea. Nonmigratory and normally restricted to Antarctic and sub-Antarctic seas, it reaches the edge of pack ice apparently circumpolarly, but ranges to 30° to 40° S in winter–spring, this northern limit associated with mortalities mainly of young birds on southern coasts (South Africa, Australia, New Zealand) after storms. Total populations have never been counted but may exceed 1 million and, apart from decreases on a few islands infested with rats *Rattus* spp. and feral cats *Felis catus,* seem relatively stable. Breeding sites are restricted to sub-Antarctic islands in the Atlantic Ocean (Gough and Inaccessible) and Indian Ocean (Prince Edward Islands, Îles Crozet, and Îles Archipelagos), but it disperses to the South Pacific Ocean.

Kerguelen Petrels visit their colonies nocturnally, breeding in 1- to 3-m-long burrows, usually in waterlogged habitat, which avoids competition with most other burrowing petrels. The nest is built up with mud and vegetation. Breeding occurs in spring–summer with pairing and mating in September, the single white egg laid in October, and hatching in December after about 49 days of incubation by both parents in long shifts. The chick is left unguarded from 2–3 days old while both parents range widely at sea but there is no data on their foraging ranges. After 60 days of rearing, the chick departs in late January to February. After breeding, the adults disperse to moult at sea but nonbreeders, which have been visiting through the summer, visit the colonies intermittently throughout the nonbreeding season of March to August. These petrels are relatively silent at colonies but occasionally utter sharp, wheezy, three-syllabled calls in flight. Nothing is known of their longevity, presumed to be some decades, or of their social structure, presumed to be in long-lasting, monogamous pair bonds. Their burrows are widely dispersed within colonies and they are solitary at sea, typically not following ships.

Large, red, mesopelagic crustaceans (decapods, amphipods, and mysids) are a major component of their diet, with tunicates possibly secondary, and mesopelagic squid and fish as minor items, indicating that much of their feeding may be at night. Their large eyes would assist such nocturnal feeding. They do not dive but catch their prey at the surface, sometimes associating with smaller toothed whales.

Mottled Petrel *(Pterodroma inexpectata)*

Similar in size to the Kerguelen Petrel at 35 cm long and a mass of about 325 g, this gadfly petrel is grey above with a transverse M-mark formed by the blackish outer primaries, greater upperwing coverts, and lower back. The crown and tail tip are darker grey, and there is a black eye patch. Underparts are white but for the brownish-grey belly, and a prominent black underwing stripe along the leading edge inwards to the wrist and then diagonally inwards almost to the axillaries. The stubby bill is black and the feet flesh-coloured with blackish extremities.

This species is endemic to New Zealand, but ranges widely in Antarctic seas, reaching the pack ice from 70° E to 75° W during summer months (December to March). Many if not all of these Antarctic foragers may be immature or nonbreeding. Its breeding grounds formerly included many colonies in hills and mountains of the North and South Islands, but human exploitation followed by depredations by introduced predators led to the extirpation of all colonies. It now breeds only in southern New Zealand in Fiordland, on islands around Stewart Island and at Snares Islands, where populations are now stable. The largest colony on Whenua Hou (Codfish I) has 1–2 million birds and is increasing after removal of predacious Weka *(Gallirallus australis)* and rats. After breeding, the whole population migrates to the North Pacific Ocean, reaching Alaskan seas and the Bering Sea. It is found in the North Pacific Ocean from late February to early November, with some remaining there through the northern winter.

Breeders return to their colonies in October to November, visiting nocturnally and nesting in 1- to 2-m-long burrows in quite dense colonies under tussock grassland, scrub, or low forest, sometimes alongside Sooty Shearwaters *(Puffinus griseus)*. Their habit of visiting colonies abundantly on wet nights led to the name Rainbird. The single white egg is laid in December to early January; it hatches mainly in February and the fledgling departs after about 90–105 days, rearing in May to early June. There are long incubation spells by both parents and absences of many days at sea finding food for their chick. Nonbreeders visit the colonies from November to early March and are very vocal in flight, uttering a complex variety of calls.

The diet of breeding birds is dominated by mesopelagic fish, particularly lanternfish of more than ten species, supplemented by small cephalopods and a few crustaceans. There are few Antarctic species among these prey, so the birds seen in Antarctic seas in summer, which feed mainly on squids, fish, and euphausiids, are presumably nonbreeders. They feed solitarily by surface-seizing, probably mainly at night, and sometimes associate with shearwaters *Puffinus* spp. when feeding. They ignore ships, usually being seen flying swiftly past.

White-Headed Petrel *(Pterodroma lessonii)*

The largest gadfly petrel, 45 cm long and about 600 g in body mass, its upper parts are grey from crown to tail with blackish wings and lower back. Head and nape become white as the plumage wears. There is a black eye patch. The underparts are white contrasting with the dark grey underwings. The bill is stout and black, and the feet are pale pink with black distal third of webs and toes. This species ranges circumpolarly in Antarctic and subantarctic seas from its breeding colonies on Possession Island (Crozet group), Kerguelen Archipelago, Macquarie, Auckland, and Antipodes Islands. It is an abundant species, although introduced predators have caused population decreases on Crozet, Kerguelen, Macquarie, and Campbell Islands (possibly extirpated). This petrel is nonmigratory, but range to the edge of the Antarctic pack ice, keeping south of about 45° S during the summer breeding season but reaching to 30°–35° S in winter, when longitudinal dispersal from the colonies is much greater. Its breeding grounds are at lower altitudes (0–300 m above sea level) and usually in tussock grassland on slopes or in dry, peaty herbfields.

Birds visit land nocturnally only, and nest in 1-2-m-long dry burrows. The breeding grounds are deserted for only 2 months of the year. Breeding birds begin to arrive back in August and, after mating, seem to have a long prelaying exodus, but its length is unknown. The single, white egg is laid from late November to December; it hatches after 55–60 days, and the chick is left alone after 3 days. The chick departs after about 102 days in May to early June, its parents also departing then or some days earlier, and the breeding grounds are deserted by late June. Nonbreeders also visit the colonies from about October to May and are responsible for most of the aerial calling, which comprises a variety of repetitive, sharp calls and softer cooing notes. Brown (sub-Antarctic) skuas *(Catharacta lonnbergi)* prey upon these petrels at nearly all of their colonies.

Little is known of the species' longevity, breeding age, and social structure, but, like other gadfly petrels, birds probably live potentially over 30 years, begin breeding at about 6 years, and form long-lasting, monogamous pair bonds. The burrows are quite dispersed within colonies and it is solitary at sea. Though slightly attracted to ships, it does not usually follow in their wake.

The diet of this petrel has been little studied, but mesopelagic cephalopods and crustaceans (mysids, amphipods, and decapods) are evidently important, and some lanternfish are also taken. They feed by seizing prey at the surface, detecting it while in flight, and do not dive. Most feeding may be at night. They loosely associate with prions *Pachyptila* spp. and shearwaters *Puffinus* spp. when feeding.

Soft-Plumaged Petrel *(Pterodroma mollis)*

Individuals are 35 cm long and weigh 300 g, somewhat like a small white-headed petrel; the two species belong in the same group within the genus. It is slate grey above with a blackish M-mark across outer primaries, greater upper-wing coverts, and lower back, and a grey tail. There is a black eye patch and the underparts are white but for a grey collar and dark grey underwings. The bill is black and the feet flesh-coloured with blackish extremities. There is a rare, entirely dark grey morph.

This is a nonmigratory, predominantly sub-Antarctic species but it encroaches into Antarctic seas in the South Atlantic Ocean, particularly in the Weddell Sea to 60° S in summer months. In the Indian Ocean, birds range mainly north of their colonies in sub-Antarctic and sub-Tropical seas. This is a very abundant species, with breeding colonies at Gough Island, Tristan da Cunha, Prince Edward, Îles Crozet, Îles Kerguelen, Île Amsterdam, and the Antipodes Islands. It is scarce in the South Pacific Ocean, but is increasing at the Antipodes Islands. Breeding takes place from September to June, with the single egg laid in 1- to 2-m-long dry burrows mainly in December, hatching in February, and the fledgling leaving in May to June. Colonies, which can be quite dense under tussock grassland and fernfield, are deserted only in July–August, with nonbreeders active there from October to June. The diet is dominated by mesopelagic crustaceans (decapods, amphipods, and mysids), with squid, fish, and offal also eaten. They feed by surface-seizing, are solitary at sea, and do not follow ships.

Grey Petrel *(Procellaria cinerea)*

This is a large petrel, 50 cm long and weighing about 1.1 kg, and it belongs to a group of petrels anciently related to shearwaters. It is grey above, the contour feathers edged paler, the crown, wings, and tail appearing darker, and the plumage browning slightly with wear. The underparts are white except for the dark-grey underwings. The bill is greenish-yellow with black on top; the feet are flesh-coloured with darker outer sides and yellowish webs. Its flight is strong and direct; more shearwater-like than that of its black relatives. It is circumpolar, breeding at Tristan da Cunha and Gough Island, and at the Prince Edward, Crozet, Kerguelen, Campbell, and Antipodes archipelagos. It ranges into Antarctic seas, farthest south in January to June to 62° S in the Pacific and Indian Oceans but only to 54° S in the Atlantic. The range is farther north in June to October, to about 33° S, but even farther to 6°–15° S off the west and east coasts of South America, respectively. Its populations have suffered from introduced cats and rats on Tristan da Cunha, Marion, Crozet, Amsterdam, Macquarie, and the Campbell Islands, but large populations persist on Gough Island and on the Kerguelen and Antipodes archipelagos. Recent removal of predators from Marion, Macquarie, and the Campbell Islands will benefit those population remnants. It suffers little mortality from brown (sub-Antarctic) skuas.

This is a winter breeding species, returning to colonies from February. It is active over land day and night, returning to colonies particularly in afternoons (breeders) and probably after 0300 h local (nonbreeders). Calls, mainly a pulsating bleat, are given by nonbreeders from the ground, usually near or inside a burrow. There is calling in the first 2–3 h of darkness, then quietness till about 3 h before dawn, when the greatest volume of calling occurs till birds leave at dawn. The single white egg is laid between early March and late April in 1- to 3-m-long burrows in dry terrain, particularly slopes covered with tussock grasses. The egg hatches after about 58 days in May to June, and the fledgling, alone from 3 days of age, departs after 130–163 days, rearing in late September to early December. In the Pacific, most birds move eastwards towards South America after the breeding season. There is some competition for burrows with white-headed petrels or sooty shearwaters on certain islands.

Grey petrels mostly eat cephalopods and fish, which they catch by diving or surface-seizing, solitarily or occasionally in groups. They sometimes associate with smaller toothed whales when feeding, and may follow ships.

White-Chinned Petrel *(Procellaria aequinoctialis)*

Individuals are 55 cm long and weigh approximately 1.3 kg; this is the largest burrowing petrel. It is entirely sooty black, browning variably with wear, and has some white feathers on the chin, which are most abundant in South Atlantic and Indian Ocean populations, whereas in the Pacific they are few or absent and barely visible at sea. Feet are black and the bill mainly straw coloured, appearing whitish at sea. They fly with much gliding, interspersed with brief spells of unhurried wing-beats, and seem more at ease in higher winds.

A very abundant species (conceivably 5–10 million birds, but with poor reliability in population estimates), its distribution is circumpolar with breeding colonies in the South Atlantic (South Georgia, Falkland Islands), Indian (Prince Edward, Crozet, and Kerguelen archipelagos), and Pacific (Auckland, Campbell, and Antipodes archipelagos) oceans. Its size has given it some protection against introduced predators, but cats or rats have reduced colonies on Marion and some of the Îles Crozet, and extirpated those on Cochons, Macquarie, and Campbell Islands. Mortality through bycatch in various longline fisheries in the Southern Ocean has also been threatening some populations in the last 20 years. It reaches the edge of the Antarctic pack ice circumpolarly in summer and its range moves northwards to about 30° S in winter, farther off South America and Africa, with birds tending to concentrate over continental shelves and slopes of southern South America, Africa, and Australasia. In the Pacific, the western populations move towards South America after breeding.

The 1- to 3-m long burrows are typically dug into poorly drained habitat with the entrance tunnel for drainage and the nest elevated on a peaty pedestal in the nest chamber. The breeding season is from September to June, with breeders arriving back first to mate, laying of the single white egg during November to December, and hatching after about 59 days in January to February. The chick, alone from 8 days old or earlier, is fed about every second night, with parents absent foraging about 3.8 days at a time. Fledglings depart at about 97 days old in April to early June. Nonbreeders visit the colonies from November to March, calling from the ground or at burrow entrances, uttering their prolonged rattling call. Birds arrive at the colonies mainly late in afternoons but probably also at night, with most calling in the 3 hours after dusk and before dawn, when they leave. Brown (sub-Antarctic) skuas frequently attack and kill adults and fledglings, with a pair of skuas sometimes collaborating in this.

The diet of white-chinned petrels consists mainly of fish, among which lanternfish and nototheniids are important, and cephalopods and various crustaceans, notably euphausiids. They feed by surface-seizing or diving, and often or mainly at night. Though generally solitary, they congregate at food sources such as fishing vessels, follow ships, and are the seabirds most associated with smaller toothed whales in parts of the Southern Ocean.

PHILATELY

Antarctic mail bearing postage stamps commenced with the earliest exploratory expeditions of the twentieth century. Before official post offices were established on board ship or at the expedition base, mail was carried by ship to the expedition port for the application of postage stamps of that country, and despatch to its destination. For example, the Swedish South Polar Expedition (1901–1904) sent mail from its base on Snow Hill Island, but posted from Port Stanley bearing Falkland Islands stamps. Some expedition mails applied an official cancellation while in the Antarctic but were not stamped until arrival at port, so the cancellation did not officially cover the stamp (e.g., Mawson's Australasian Antarctic Expedition, 1911–1913).

The first official post office established in the Antarctic was for Bruce's Scottish National Antarctic Expedition (1902–1904) on Laurie Island, South Orkney Islands. Mail, bearing either Falkland Islands or Argentine stamps, was posted from Stanley (Falkland Islands) or from Buenos Aires, respectively. In 1904, the station was handed over to the Argentine government, which has manned it ever since, although the post office closed in 1905 (reopening in 1942).

The first stamps issued specifically for use in the Antarctic were for the British National Antarctic Expedition (1907–1909). Lieutenant Shackleton was sworn in as postmaster before a New Zealand magistrate and supplied with a stock of the then-current one-penny New Zealand stamps overprinted with "King Edward VII Land." For the BNAE (1910–1913), Captain Scott was likewise sworn in as a New Zealand postmaster and provided with a stock of 1d and ½d stamps overprinted "Victoria Land." For both expeditions, mail was sent from the base post office via Lyttleton, New Zealand. Admiral Byrd's United States Antarctic Expedition of 1928–1930 had on-board post offices on both the *Eleanor Bolling* and *City of New York*. Mail used current US stamps cancelled with the name of the ship (but not the territory) and date, and was posted from New Zealand. Byrd's second expedition (1933–1935) utilised the rapidly increasing popularity of Antarctic philately to contribute towards the cost of the expedition. Almost 121,000 covers were serviced at the two post offices, Little America and on board the *Jacob Ruppert,* for later sale. A special US stamp, designed by President Roosevelt, was used, together with other US and Canal Zone stamps. Later US expeditions (1939–1941, 1946–1947) also had on-board post offices (*Bear* and *Mount Olympus,* respectively, the latter handling 150,000 philatelic covers), with the ships' cancellation on US stamps.

The first commercial use of a post office was at the Norwegian *Hektoria* whaling station at Deception Island, South Shetland Islands, between 1913 and 1931. Several types of cancellation were used (Port Foster, Deception Island, South Shetlands) on contemporary Falkland Islands stamps.

During World War II, the UK government established several bases in the Antarctic Peninsula region, under the covert "Operation Tabarin," later to become the Falkland Islands Dependencies Survey, and ultimately the British Antarctic Survey. Official post offices were established at each, partly to strengthen the UK's political claim to that region (Falkland Islands Dependencies) at a time when Argentina and Chile were also boosting their claims to the same sector. Stamps of the Falklands overprinted with "South Orkneys Dependency of [Falkland Islands]," "South Shetlands...," and "Graham Land..." were cancelled with the appropriate base postmark and sent via the Falklands. From 1946 the UK, Argentina, and Chile built numerous bases, with post offices, throughout the Antarctic Peninsula sector. Many of these were short-lived, while others were opened specifically for the International Geophysical Year (1957–1958). When the French station Dumont D'Urville, together with post office, opened in 1949, it used a single overprinted ("Terre Adélie Dumont D'Urville") stamp of Madagascar. Following the adoption of the Antarctic Treaty in 1961, many national research stations operated post offices for the scientific personnel that also serviced a much greater philatelic clientele. However, of the seven territorial claimants of sectors of Antarctica, only Australia (Australian Antarctic Territory), France (Terre Adélie, but including all of Terres Australes et Antarctiques Françaises [TAAF]), New Zealand (Ross Dependency), and the UK (British Antarctic Territory) issue specific territorial stamps, with several new issues every year. All other nations operating in Antarctica use their current national stamps, some of which depict Antarctic scenes or historical events.

Every few years Australia, New Zealand, and Britain issue new definitive issues with 10–15 stamps of various denominations. Each of these is based on a theme, such as birds, marine creatures, fossils, ships that have served their national stations, explorers, research stations, etc. These nations, and France also, issue short sets of stamps commemorating some regionally relevant historical (e.g., Scott, Shackleton, Mawson, British Graham Land Expedition) or scientific (e.g., Antarctic Treaty, Scientific Committee on Antarctic Research, International Geophysical Year) event or anniversary, or some simply featuring some aspect of scientific research (e.g., dinosaurs, minerals, lichens, seals, petrels, whales, atmospheric phenomena, clothing, modes of transport, etc.). Nonclaimant countries periodically issue stamps of their country with similar themes that are also valid both in the homeland and at their Antarctic station post offices. In the case of the British Antarctic Territory, UK royal family anniversaries are also depicted.

Most of the sub-Antarctic islands operate post offices, but only South Georgia (formerly one of the Falkland Islands Dependencies) and the French Indian Ocean islands (Îles Kerguelen, Crozet, Amsterdam, and St. Paul, which, together with Terre Adélie, constitute TAAF) issue their own stamps. Between 1910 and 1947 South Georgia used stamps of the Falkland Islands with various cancellations marked "South Georgia." From 1944, the island had its own stamps (both definitives and special issues) but, for political reasons, the island's name changed periodically on the stamps. From 1944 until 1963, the stamps bore the name "Falkland Islands Dependencies" (with South Georgia included in the cancellation). Between 1963 and 1980 they became "South Georgia," reverting to "Falkland Islands

Dependencies" from 1980 until 1985 when the island (together with the uninhabited South Sandwich Islands) achieved its own government based in the Falkland Islands. From 1986, stamps then bore the bulky name "South Georgia and the South Sandwich Islands." Of the French territories, the whaling and sheep farming settlement on Îles Kerguelen operated an unofficial post office from 1909, using French stamps. From 1924 to 1929 the islands were an administrative dependency of Madagascar, and mail used a combination of French and, for registration, South African stamps. No post office operated between 1925 and the 1950s, when scientific stations opened on all four islands and the use of TAAF stamp issues commenced. Since 1947–1948, research station post offices on Macquarie and Heard Islands have used Australian stamps, while Marion Island and Gough Island (since the 1960s) have used South African stamps. The sheep settlement on Campbell Island used New Zealand stamps. As with the Antarctic issues, sub-Antarctic territory stamps illustrate thematic and commemorative topics, but only South Georgia has produced multidenominational definitive sets.

All post offices cancel their stamps with an official station postmark, which is changed every few years. Additional official and unofficial cachets are applied for philatelic enthusiasts. The British Operation Tabarin base at Port Lockroy, Goudier Island, abandoned in 1962, was restored and designated an Antarctic Historic Site and, since 1996, when the post office reopened, has been a popular tourist attraction. The island's population of 2–3 probably makes it the smallest post office in the world, yet for 3 months each year it sends out 15–20 sacks of mail.

PHOTOGRAPHY, HISTORY OF IN THE ANTARCTIC

In 1839–1843, James Clark Ross, in command of HMS *Erebus,* and Francis Rawdon Crozier, commanding HMS *Terror,* brought an end to an era of early Antarctic exploration. In those same years, Louis Jacques Mandé Daguerre in France and William Henry Fox Talbot in England introduced the world to the new invention of photography. It was impossible to practise those early systems in an inhospitable climate, but by the end of the century, techniques had advanced sufficiently to make photography in Antarctica feasible even if necessitating strong muscles to carry the equipment and steadfastness and application to process the plates. The *Belgica* expedition of 1897–1899 had a surgeon who also acted as a photographer. Photographs were taken during the British National Antarctic Expedition in 1901–1904 (with engineer Reginald Skelton acting as official photographer) and during Ernest Shackleton's British Antarctic Expedition of 1907–1909 (during which Eric Marshall was officially in charge of the photography, but Sir Philip Brocklehurst and Douglas Mawson did more darkroom work than anybody else), but most of the illustrative work was still undertaken by artists. In 1908–1910, Jean Charcot, leading his second Antarctic expedition in the *Pourquoi Pas?,* organised a photographic laboratory that was described as being "huge," but it did not have a specialist photographer, the scientist responsible being in charge of magnetic studies as well as photography. Inevitably, the results of such part-time activities were indifferent in quality.

When Scott was planning his second expedition, he decided to change this unsatisfactory situation and to appoint a specialist photographer who would thus become the first professional photographer to work in the Antarctic. His choice for the role was Herbert Ponting, a fellow Englishman who had emigrated to the USA in the 1890s and who had subsequently travelled the world with his cameras for the fast-developing photo agencies. Just a few years prior to accepting the invitation to join the Antarctic expedition, he had been covering the Russo-Japanese War.

Ponting could have no complaints about the resources that were put at his disposal. Scott's second-in-command, Teddy Evans, called it "a colossal photographic outfit," and Ponting used it with a single-mindedness that took no account of personal dangers or sometimes the feelings of other expedition members. Thus he braved an attack from killer whales and came close to losing equipment and his own life when leaving until the last moment a leap for safety from ice that was fast breaking up. On arriving in Antarctica, Scott told him to concentrate on his photography during the hours of daylight that were available and to leave unloading *Terra Nova* to the others. Ponting took him at his word despite the evident, if muted, grumbles of his colleagues. It is possible that Ponting extended this concentration to the exclusion of all else somewhat further than Scott originally intended, but whether that was so or not, the others exacted a revenge when, on his various expeditions, Ponting had to haul his sledge heavily laden with photographic equipment by himself without any of the assistance that could have made the task much easier.

But that would not have overly concerned him. He was dedicated to the work at hand and to obtaining the finest record possible of the expedition's work—and of the surrounding landscape complete with its fauna. He was primarily a supreme pictorialist. He typically looked into a scene and calculated the best camera viewpoint, using the most suitable lens with a particular filter if one was required. Since elements within a composition could change with conditions, he was prepared to return time and time again until all of the elements were perfect. Only then would he take a series of photographs, which he would later process with consummate care back in his darkroom at the hut, where his dedication to the task was underlined by the presence of his bed. Although relatively inexperienced in movie photography, he had practised hard before leaving England, and the footage that can still be seen to this day shows his skill at recording *Terra Nova* smashing through the ice (from a temporary and flimsy-looking platform slung out over the ship's side), and his patience later in recording the behaviour of birds, seals, and penguins at Cape Evans. The latter in particular was to point the way for the movie and TV cameramen who were to follow him south decades later. While Ponting's pictorial images are superlative, this should not be interpreted to mean he was not talented in other photographic genres. His relatively limited number of portraits of expedition members are of high quality and his searching treatment when, for example, Oates, Cherry-Garrard, and Meares sat for him makes one wish that he had taken more portraits, especially of expedition members newly returned from exhausting and dangerous sledging trips.

Ponting was undoubtedly a loner and was not an expedition member in the fullest sense of the term. But if his colleagues thought him a little odd—and blanched at the thought of posing for him since this always seemed to result in a mishap of some kind if not injury—they respected his dedication to his task and his hard work. Thus a new verb was introduced: "to pont," which meant to pose until nearly frozen in all sorts of uncomfortable positions. In addition, since the arrangement was that Ponting would spend only one year in Antarctica, he was concerned to pass on as much of his photographic knowledge as possible to other members of expedition—the young geologist Frank Debenham being the main beneficiary. All withstood the first long Antarctic winter reasonably well (catching up with developing and printing provided a valuable outlet for Ponting) and the regard and affection that Ponting came to have for Scott and for his colleagues was shown by the single-minded determination with which, subsequently, he used the still and movie record in an endeavour to safeguard their memory until his death in 1935. Ponting expressed some disappointment with what he achieved in Antarctica, particularly stressing how the rapidly changing weather affected a programme of work even if the outcome could be mitigated by "persistent effort." Despite these misgivings, Antarctica was undoubtedly the acme of Ponting's photographic achievement. Thereafter, he achieved very little professionally that was of merit, and it was almost as though he knew he could never better his performance in the far south and had determined not to try.

Frank Hurley was also a professional photographer; although younger than Ponting, he was a contemporary who went to Antarctica first with Douglas Mawson as a member of the Australasian Antarctic Expedition (1911–1914) and then with Shackleton on his Imperial Trans-Antarctic Expedition (1914–1917). An Australian, Hurley, in many ways, both as a person and as a photographer, could not have been more different from Ponting. He was lively, gregarious, and highly resourceful such that far from concentrating exclusively on his photography he became a fully fledged member of the expeditions in which he participated. This limited the time available for his photography, but this was scarcely a disadvantage because, whereas Ponting was a pictorialist who would wait endlessly for a supreme moment, Hurley was more of an opportunist who photographed events and scenes as they occurred, with less preparation. His ability to do this—and to do it well—made his coverage more complete than Ponting's, particularly as he was more fully involved with the activities of the expeditions that he accompanied, whereas Ponting, for example, never went on any of the sledging journeys from Cape Evans. Faced first with the need to rescue photographic plates and film from the stricken *Endurance* and then to destroy many of those plates as the dangerous events of Shackleton's expedition unfolded, it was typical of Hurley's resourcefulness that, in 1917, within a short time of his return to civilisation and upon being told that additional material was needed to give the record the maximum possible impact, he should agree to return to South Georgia to shoot new material. As a result, the film *In the Grip of the Polar Pack-Ice* was a success and helped to clear all of the expedition's financial liabilities.

Hurley and Ponting met in London in 1916 and obviously had high regard for each other's photography, Hurley talking about Ponting's "beautiful work" and Ponting later describing Hurley as a "crackerjack" with the camera. Significantly, Hurley, unlike Ponting, went on to lead a full photographic life that embraced six trips to Antarctica, military service in two world wars, and various commercial activities before he died in 1962.

The work of Ponting and Hurley may be interpreted to be the "heroic" period of Antarctic photography. For some decades thereafter there were few significant developments other than the use of an aerial survey camera on Byrd's successful flight over the South Pole in November 1929. However, with the passage of some 40 years and by the beginning of the International Geophysical Year in 1957–1958, the practice of photography had changed significantly. The two pioneers had exposed colour plates—the Autochrome system developed in France and Paget plates, a British derivative—but while these constituted the first basically practical colour system, they were far from perfect. By the time of the IGY, convenient roll colour film was firmly established and 35-mm cameras had greatly reduced the weight and inconvenience of the plate cameras of earlier decades—a factor of great significance to the practice of photography in a hostile environment. One of the most significant collections of photographs of this period was produced by the Swiss professional Emil Schulthess, who was accredited to the US Deep Freeze IV operation. His pictorial photographs as a body of work may be regarded as coming the closest to those of Ponting in terms of quality, and it is intriguing that, despite the appeal of colour, which is almost a universal medium in the eyes of today's amateurs and professionals alike, the most compelling images are those shot by Schulthess on black-and-white film. Perhaps this is because, save for the marvellous atmospheric effects seen in Antarctica in the early morning and late evening, it is essentially a monochromatic world that can be rendered in black and white, with its full range of tones and textures, as well as or better than it can in colour.

Expeditions are still organised to go to Antarctica, but the main emphasis is on the work of the scientific stations. Broadcast and other media organisations have brought the continent onto the world's television screens, and tourist trips are now an accepted fact. Professional photographers visit with a view to adding an Antarctic portfolio to their stock libraries. For those working professionally in Antarctica, photography is a medium for technical recording, a means of promoting the interests of their host organisations, or a matter of personal interest. For the tourist, it is the system by which the trip can be recorded and revisited in the years that follow.

Cameras, whether still or movie, film or digital, and video are compact and of high quality. Modern equipment makes photography as reliable and convenient as possible, but Antarctica is still unforgiving. Cameras need to be handled almost all of the time with gloved hands. The batteries powering cameras have traditionally been susceptible to cold temperatures, but lithium batteries are less vulnerable to draining than earlier types—and digital cameras are typically powered by batteries that can be recharged. Most cameras have auto-exposure systems incorporated, and these have to be interpreted skillfully since a typical Antarctic landscape leads to underexposure; there is thus a need to "open up" the aperture and to bracket exposures to be sure of a satisfactory result. Here again the growing popularity of professional-quality digital cameras is an advantage since they tend to display good exposure latitude, whereas the transparency film normally used by professionals—because of its inherent quality—has very limited latitude.

More than a century has elapsed since the first cameras were taken to the continent, and, perhaps because quality is sometimes directly related to the difficulty with which something is obtained, it can be argued that the work of the early pioneers such as Ponting and Hurley has never been surpassed. Quite apart from considerations of inherent quality, perhaps that evaluation stems to a degree from awareness of the difficulties and dangers that were overcome by the pioneers to secure their images and of the heroic and sometimes tragic events that were portrayed.

PHYTOPLANKTON

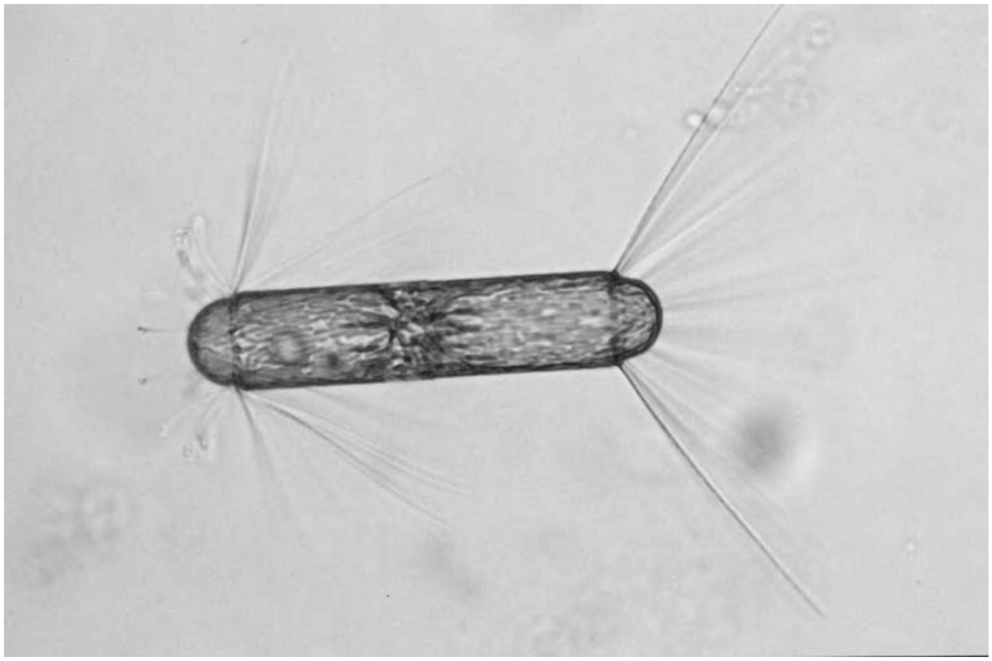
The phytoplankton are the community of free-floating single-celled plants, or algae, that live in illuminated, surface waters of Antarctic marine and freshwater habitats. The name is derived from the Greek "phyton" (plant) and "planktos" (wanderer). The cells are in most cases microscopic and, like larger multicellular plants, derive their energy from sunlight; they are therefore the main primary producers in the Southern Ocean providing the energy and nutrients that support the Antarctic marine food web. Marine phytoplankton communities are composed of a diverse range of algae but are often dominated by a small number of species that, if present in large numbers, form phytoplankton "blooms." These blooms may discolour the water and can be visible to the naked eye. Phytoplankton cells were first recorded in the Southern Ocean by J. D. Hooker, botanist on the *Erebus* and *Terror* Expedition of 1839–1843, with pioneering studies undertaken on subsequent expeditions in the late nineteenth and early twentieth centuries. They remain an important subject of Antarctic scientific research.

There are approximately 400 species of phytoplankton in the Southern Ocean belonging to several taxonomic groups of algae including the cyanobacteria, diatoms (Bacillariophyceae), dinoflagellates (Dinophyceae), silicoflagellates (Dictyochophyceae), coccolithophores (Prymnesiophyceae), cryptomonads (Cryptophyceae), and green algae (Chlorophyceae). Phytoplankton cells are usually distinguished by their size, shape, or plant pigments; however, some species can only be identified using genetic information. Many species are endemic to the Antarctic and relatively uniform in their geographic distribution due to the circumpolar circulation of the Southern Ocean.

Phytoplankton cells usually exhibit vegetative (asexual) growth but also have a sexual reproductive stage. Some cells remain attached to each other after cell division by forming chains or gelatinous colonies of up to several hundred cells. The cell walls of some phytoplankton have specialised outer layers, particularly the diatoms, which are enclosed within a siliceous frustule. As do plants, phytoplankton require light for growth but are capable of surviving the long, dark austral winter by forming resting spores or by deriving energy from extracellular organic compounds. During sea-ice formation, phytoplankton cells can become enclosed within brine channels in the ice lattice and exposed to low temperatures and high salinities. Some cells can survive and grow in such extreme conditions, and those that do may be released back into the water column when the ice melts and may "seed" a new phytoplankton population.

Phytoplankton cells are often classified into three size categories based on the linear dimensions: the picophytoplankton (0.2–2 μm); the nanophytoplankton (2–20 μm); and the microphytoplankton (20–200 μm). These size categories in part reflect the traditional method used by scientists to collect phytoplankton: the larger microphytoplankton (also known as "net" phytoplankton) are retained on plankton nets that are not able to collect the smaller phytoplankton. They also reflect differences in physiology and ecological role.

The picophytoplankton include prokaryotic cyanobacteria and tiny eukaryotic flagellates, whereas the nanophytoplankton are composed of only eukaryotic cells including small diatoms (e.g., *Chaetoceros neglectus*), coccolithophores (e.g., *Emiliania huxleyi*), crytomonads, and other green flagellates. These small cells are well adapted to grow in nutrient-poor waters due to their large surface-area-to-volume ratios; however, they are vulnerable to grazing by fast-growing single-celled zooplankton, which can exert tight control over their numbers. They therefore tend to



The diatom *Corethron criophilum,* a common species of Antarctic phytoplankton. (Photo c/o Christine Campbell, Culture Collection of Algae and Protozoa, Dunstaffnage Marine Laboratory, Oban, UK.)

exhibit small temporal and spatial variations in abundance compared to the larger phytoplankton. Picophytoplankton abundance is relatively low in the Southern Ocean in comparison with warmer tropical and subtropical seas, where they dominate the phytoplankton. By contrast, the nanophytoplankton can often dominate phytoplankton abundance, biomass, and production in the Southern Ocean, especially in offshore waters.

The microphytoplankton include large diatoms (e.g., *Corethron criophilum* and *Eucampia antarctica*), dinoflagellates (e.g., *Protoperidinium antarcticum*), silicoflagellates (e.g., *Dictyocha speculum*) and, on occasions, gelatinous colonies of smaller flagellates and diatoms (e.g., *Phaeocystis antarctica* and *Thalassiosira* spp.). These larger algae tend to dominate the phytoplankton of nutrient-rich inshore waters where they form the main food of multicellular zooplankton, including krill *(Euphausia superba)*. Microphytoplankton characteristically exhibit large temporal and spatial variations in abundance because these slow-growing zooplankton cannot respond quickly to rapid increases in phytoplankton cell numbers.

Phytoplankton production in the Southern Ocean is generally lower than in lower-latitude oceans; however, the abundance and biomass of phytoplankton are patchy, and production, which is a function of biomass and growth rate, can be locally very high. The highest production tends to be associated with coastal waters or hydrographic features, such as oceanographic fronts and eddies. This reflects the higher concentration of nutrients encountered in such areas. High phytoplankton production is also associated with the receding edge of the sea ice, where lower-salinity surface water promotes water-column stability, leading to favourable light conditions for plant growth. Light conditions in the Antarctic, and thus phytoplankton growth, exhibit strong seasonal variation, and the period of maximum phytoplankton production changes from early spring to late summer or early autumn with increasing latitude. Many animals within the Antarctic have adapted their life cycles to exploit these predictable, highly seasonal periods of marine primary production.

Antarctic marine phytoplankton communities have received considerable attention from the scientific community due to their role as primary producers and their influence on the oceanic carbon cycle. Much of this research has focused on the environmental and biological factors controlling their growth rates and biomass. Phytoplankton cells, like larger multicellular plants, require water, light, carbon dioxide, and nutrients in order to grow. The latter include nitrogen, phosphorus, silicon (required by diatoms), and trace metals such as iron. In addition, phytoplankton cells need to avoid being grazed by zooplankton or infected by viruses. In most marine environments the supply of nitrogen limits phytoplankton growth in summer months, but in the Southern Ocean the nitrogen supply is usually sufficient to meet the needs of phytoplankton. Instead, recent studies have shown that phytoplankton growth can be limited by the availability of iron, which is in short supply in offshore regions. This discovery has led to speculation that the Southern Ocean could be fertilized with iron in order to promote phytoplankton growth, thereby removing more carbon dioxide from the atmosphere and helping to slow climate change. Other factors, such as light availability, temperature, and grazing pressure, are also known to affect phytoplankton production, so the situation is complex. This therefore remains a subject of current debate.

PLACE NAMES

Place names form an essential part of cartography. Those used on early Antarctic maps and charts reveal the history of exploration by the different exploring and scientific expeditions, in that features seen by them for the first time were named in each one's native language. The eighteenth-, nineteenth-, and early twentieth-century expeditions originated from Australasia, Belgium, France, Germany, Japan, Norway, Sweden, Russia, the United Kingdom, and the United States. By the 1940s, other nations, such as Argentina and Chile, had undertaken exploratory surveys in the Antarctic, and Spanish was added to the mix of languages used for place names. After the International Geophysical Year (1957–1958), many more countries participated in Antarctic research, and place names have been approved now by Bulgaria, Canada, China, India, Italy, Poland, and Spain.

Because early visits to Antarctica were by sea, prominent land features of value to mariners for navigation purposes, such as islands, headlands, and significant peaks, were amongst the first to be named. Many place names commemorated heads of state or members of royal families, a benefactor of the relevant expedition, or a member of the ship's company; some were descriptive of the feature being named.

A place name usually consists of two parts (generic and specific) and, with its geographic coordinates and official description, should be unambiguously identifiable. The generic part of the name indicates the type of feature, such as island, peninsula, mountain, etc., and the specific part provides a unique identifier for that feature, such as a descriptive or personal name. For example, there are hundreds of islands in the Antarctic but only one Dundee Island, named after Dundee, Scotland, the home port of the Dundee Whaling Expedition, 1892–1893. The range of specific names applied to Antarctic features is summarized in the following table.

The term "Antarctic Continent" was first used on charts published by the United States Exploring Expedition (1838–1842) under Charles Wilkes, and the name Antarctica, proposed in 1886, has been in common usage since the early twentieth century. Antarctica is now defined as the landmass lying almost entirely south of the Antarctic Circle and the offshore islands on its continental shelf. The Antarctic, however, is widely defined as the region lying south of the Antarctic Convergence, including Antarctica and the off-lying and oceanic islands, ice shelves, sea ice, and ocean.

During the early exploration period, some named features were located imprecisely on the rough maps and charts available at the time, and several were misspelled when being transcribed from one chart to another. Furthermore, features in an accessible and oft-visited location gained different names in several languages, whilst others acquired different versions of the same name when expedition volumes in which they were mentioned were translated into another language.

The duplication, translation, and misapplication of place names were already well established when increased activity on the continent in the 1920s and 1930s led to a proliferation of new place names. By then, seven nations had made territorial claims in Antarctica, and those and other nations developed

Types of Specific Names Used for Antarctic Place Names

Type of Name	Example
Descriptive name relating to size, shape, colour, number, accessibility, aspect, or similarity	Small Rock, Islotes Chatos, Blue Lake, Trio Nunataks, Inaccessible Coast, Rugged Island, Cone Nunatak, respectively
Names denoting position (relative to other features or the compass)	Mount Faraway, South Beach, West Cape
Names in association with prominent features	Lachman Crags, from nearby Cape Lachman
Names reflecting occupational use, scientific activity, or historical events	Factory Cove, Pendulum Cove, Coronation Island
Names recalling incidents during travel	Terra Firma Islands, Lost Seal Stream
Names connected with navigation	Anchorage Island, Foul Point
Mythological names and biblical names	Romulus Glacier, Mount Christi
Names of expedition leaders or ship masters	Filchnerschelfeis, Biscoe Islands
Names of royalty	Louis-Philippe Plateau, Prinsesse Astrid Kyst
Supporters of expeditions, including patrons, politicians, and donors of equipment	Beardmore Glacier, Pitt Islands, Cape Calmette, respectively
Names associated with sealers and whalers	Byers Peninsula, Foyn Coast
Names of members of expeditions	Oates Coast, Crary Ice Rise
Names of peoples and of places elsewhere	Argentine Islands, Stonington Island
Names of organizations associated with Antarctic exploration	Royal Society Range, Foundation Ice Stream
Anagrams of names already applied	Dimaryp Peak, after The Pyramid
Acronyms formed from initial letters of other words	Fidase Peak, Scar Inlet
Names founded on error	False Bay, Mistake Peak, Mount Quandary
Names derived from Greek or Latin words	Alpha Island, Mount Solus
Names emphasizing emotions	Deception Island, Cape Disappointment
Whimsical names	Phantom Point, Three Brothers Hill
Names associated with date or season	Mount Christmas, Port Circumcision, Winter Island
Names of ships that have worked in the region	Hero Bay, Jason Peninsula, Mirnyy Peak
Names derived from local geology	Coalseam Cliffs, Mount Glossopteris
Names of plants, mammals, birds, fish, and invertebrates	Cryptogam Ridge, Seal Bay, Albatross Island, Salmon Island, and Midge Lake, respectively
Groups of associated names (e.g., pioneers of medicine and aviation, composers, constellations)	Pasteur Peninsula, Wright Ice Piedmont, Beethoven Peninsula, Pegasus Mountains, respectively

Table after Hattersley-Smith (1991), with additional examples selected from Alberts (1995) and the Composite Gazetteer of Antarctica.

independent policies and procedures for naming new features. Britain established a subcommittee on Antarctic names in 1932, followed by an Antarctic Place Names Committee in 1945; it published its first list of names and their geographic coordinates as an official gazetteer in 1955. The US Special Committee on Antarctic Names was created in 1943, became the Advisory Committee on Antarctic Names in 1947, and published its first list the same year. Australia, Belgium, France, New Zealand, and Russia published lists of names or gazetteers in the late 1950s and 1960s, followed by Argentina, Chile, and Japan in the 1970s, Germany and Poland in the 1980s, and China, India, Norway, and Spain in the 1990s.

In general, Antarctic features are only named if reference to them is needed, so many Antarctic geographic features remain unnamed. Scientific stations, although man-made, have a geographic significance through their location. Whereas some national gazetteers name the stations, others do not. National gazetteers include in-shore submarine features such as bays, inlets, and straits, but names for oceanic features (e.g., seas, seamounts, abyssal plains) are the responsibility of a General Bathymetric Chart of the Oceans (GEBCO) subcommittee.

By the early 1990s, some gazetteers were available digitally and, in 1992, the Scientific Committee on Antarctic Research (SCAR), through its Working Group on Geodesy and Geographic Information, undertook to prepare both a composite gazetteer of Antarctic place names and an internationally agreed-upon set of guidelines for naming new features in Antarctica. The Composite Gazetteer of Antarctica (CGA), coordinated by Italy, was to include all named features on land and under the sea in the region south of 60° S, in the original language of the source gazetteer. The objective of the guidelines, prepared by Germany, was to avoid future translation of all or part of the name and name duplication, thus achieving one name, in its original language, per feature.

After 6 years of data collection, the CGA database held 32,955 names, representing 16,563 geographic features, contributed by 20 countries and 1 international organization (GEBCO). The CGA was published as hard copy in 1998 and released on the internet the same year; its website has been updated by Italy on a quarterly basis ever since, providing countries with the opportunity to have new Antarctic names incorporated in the CGA soon after approval by their national naming authorities. Supplements to the hard copy were published in 2000 and 2004.

Analysis of the CGA carried out by Italy in 2000 showed that there is still potential for confusion in identifying Antarctic features: more than 470 features had 2 or more completely different names, and 3377 names differed due to translation (e.g., Coronation Island and Isla Coronación) or transliteration and translation (e.g., Tizire Hyôga [Japan] and Chijire Glacier [US]). The CGA uses the Roman alphabet, and the transliteration of entries from non-Roman alphabets is as provided by the naming authority; diacritical marks (accents) are identical to those in the source gazetteers.

Responsibility for approving Antarctic names remains with the national naming authorities. Although no single legal authority coordinates the naming of features, the CGA website provides access to a truly international and up-to-date gazetteer of Antarctica.

PLASMASPHERE

The plasmasphere is the relatively dense doughnut-shaped region of plasma (fully ionised gas consisting of ions and electrons) that surrounds the Earth and forms the innermost region of the magnetosphere—the space around the Earth where physical processes are controlled by the extension of the geomagnetic field into space. The plasmasphere floats on top of the partially ionised ionosphere, its lower boundary usually being considered as 1000 km altitude. Above this the dominant ion is hydrogen rather than oxygen, though varying proportions of oxygen and helium ions are also present, with the total number of positively charged ions equal to the number of negatively charged electrons, thus constituting an electrically neutral gas. At night, plasma descending into the ionosphere maintains it in the absence of solar ionisation. The upper boundary of the plasmasphere is the plasmapause, which lies parallel to geomagnetic field lines; as if produced by a bar magnet at the Earth's centre, these lines link the Arctic and Antarctic polar regions and extend tens of thousands of kilometres into space. The existence of the plasmasphere was first inferred by Owen Storey in 1953 from observations of whistlers at Cambridge. Whistlers are natural radio waves with frequencies in the ELF and VLF ranges (typically a few kHz) that are generated in lightning discharges in thunderstorms and travel through the magnetosphere to the opposite hemisphere. Analysis of the whistling sound produced when a whistler is converted from radio to sound waves enables the density of electrons along its path to be determined.

Much of the early exploration of the plasmasphere was done using whistler observations from Antarctica during and immediately following the International Geophysical Year, 1957–1958. Several factors, including low levels of local interference and high thunderstorm activity in the Northern Hemisphere, make the Weddell Sea sector of Antarctica arguably the best region in the world for whistler research. The plasmapause was discovered by Don Carpenter during the early 1960s from whistlers recorded at Eights station, and independently by Konstantin Gringauz from *in situ* measurements on board early Soviet satellites.

Just inside the plasmapause the electron densities are typically 400 million per cubic meter, and energies are about 1 electron-volt, corresponding to a temperature of around 10,000°C. The plasmasphere approximately corotates with Earth. This is in contrast with the plasma outside the plasmasphere, which is an order of magnitude hotter and less dense, and does not corotate. The plasmapause is a relatively thin (about 500 km) boundary layer, typically 20,000 km from Earth, though there is a "bulge" on the dusk side. It is a highly dynamic boundary, particularly near the bulge, exhibiting plasma plumes, "bite-outs," and detached plasma regions in response to changes in the solar wind impinging on the magnetosphere. Because the plasmapause has a "footprint" in the polar regions, Antarctica remains an excellent location for studying it.

In more recent times, Antarctic measurements using fixed-frequency VLF transmissions and ULF magnetic pulsations have been used to study the plasmasphere. Now two new remote-sensing techniques—imaging of EUV radiation from plasmaspheric helium ions, and high-altitude radio echo sounding made by instruments on the IMAGE satellite situated outside the plasmasphere—are enhancing the knowledge and understanding of this key region of Earth's space environment.

PLATE TECTONICS

Principles of Plate Tectonics

The concept of plate tectonics was proposed almost simultaneously in 1968 by Dan McKenzie at the University of Cambridge and Jason Morgan at Princeton University. They recognized that the Earth's solid outer zone, the lithosphere, consisted of a relatively small number of segments or plates, along whose borders most of the Earth's volcanic and seismic (tectonic) activity took place. It was originally thought that there were about ten plates in number, but they are now known to be more numerous. These plates include the continents and the lithosphere beneath the oceans. The plates move across the Earth driven by forces that are still unresolved. Because the carapace of plates is complete, the movement of each plate is constrained by the movements of all the others, and a major change in the direction or rate of motion usually causes the pattern of motion to be globally rearranged. The plates themselves were originally regarded as rigid, with all major deformation taking place at plate boundaries. Although this is mainly the case, it is now known that internal deformation can also occur.

There are three fundamental ways in which a plate may move relative to another, forming three types of plate boundaries.

1. Divergent or constructive plate boundary. Two plates may separate across a divergent or spreading boundary almost always represented by a midocean ridge such as the Mid-Atlantic Ridge. The gap is continuously filled by newly created basaltic crust, which forms the floor of our oceans by a process known as sea-floor spreading. As a result of this process, the age of oceanic crust increases away from the mid-ocean ridge. Furthermore, as new ocean floor forms, it inherits the polarity of the earth's magnetic field, forming a zebra pattern of positive and negative magnetic anomalies on the ocean floor.
2. Convergent or destructive plate boundary. Two plates may converge instead of diverge. In this case, one of the plates, usually that containing the oldest lithosphere, returns to the mantle in a zone known as a subduction zone. Subduction zones are characterized by deep trenches with an abundance of compressive earthquakes aligned along an inclined plane, the Benioff zone, which descends away from the trench at an angle of up to 60 degrees. This may occur between two oceanic plates forming a volcanic arc-trench system common in the western Pacific, or between a continental and an oceanic plate, with the volcanically active South American Andes as an example. Convergence between two plates with continental crust takes quite a different form. Subduction does not occur; instead the boundary is marked by major compressional mountain building, such as is seen in the Himalayan Mountain chain as a consequence of continent–continent collision. Compared to other convergent plate boundaries there is a marked lack of volcanic activity.
3. Transform plate boundaries. The movement of two plates need not be perpendicular; they may converge or diverge at angles of less than 90 degrees. In an extreme case, the plates may move past each other without any convergence or divergence, forming what is known as a transform plate boundary. Midocean ridges are cut by numerous transform faults ranging in size from small offsets of a few tens of metres to large offsets of a few hundred kilometers and fracture scarp lengths of several hundred kilometers.

The major tectonic events of the earth take place at the boundaries between plates: new crust is generated at divergent boundaries, and it is there also that continents break apart and new ocean basins are created. In subduction zones, old crust is recycled into the mantle beneath the lithosphere or accreted against continental margins, thereby increasing the size of the continent. The process is accompanied by mountain-building (orogeny), often involving volcanic activity. Major orogeny also occurs when two continental plates collide. Old zones of convergence and collision, called sutures, contain key records of Earth's history.

Antarctic Plate

The Antarctic plate is situated centrally about the South Pole and is one of the seven major plates present on the earth's surface. It contains the Antarctic continent and a surrounding segment of oceanic crust. The plate is separated from the neighbouring Pacific, Indian, and African plates by constructive plate boundaries that are actively spreading. On this basis, the Antarctic Plate is continuously growing, albeit at a very low rate. The boundary between the Antarctic Plate and the South American plate is complicated, as the South American plate is moving slowly to the left relative to the Antarctic Plate in an east–west direction at about 20 to 24 millimetres per year. Complications along this boundary over the past 40 million years have resulted in formation of a number of smaller plates, the Drake, Scotia, Shetland, and Sandwich plates, along the boundary zone. Starting from the triple junction between the African, South American, and Antarctic plates, the boundary between the South American and Antarctic plates is a divergent spreading ridge with long transform offsets. The boundary between the Scotia and Antarctic plates is for the most part a sinistral transform boundary, which means that the Scotia plate is moving to the left relative to the Antarctic plate across a transform fault. On the western side of southern South America, the Antarctic plate and South American plate are converging, with the Antarctic plate sinking beneath the South American plate forming a subduction zone.

As the Antarctic continent is sitting within the Antarctic plate and away from plate boundaries, the continent is noted for its low levels of volcanic and seismic activity. There are currently only two active volcanoes—Deception Island in the Bransfield Strait off the northern tip of the Antarctic Peninsula, which is related to active sea-floor spreading in a marginal (back-arc) basin due to the subduction of the Drake Plate beneath the Antarctic Plate, and Mount Erebus in the Ross Sea region, which is active and was part of a larger now mostly extinct volcanic province related to the development of an extensional rift system that formed 30–40 Ma. Seismic activity within the continent is related mainly to ice movements.

The ocean floor surrounding the Antarctic continent formed by sea-floor spreading due to the separation of the southern continents and India from Antarctica following the breakup of Gondwana 180 Ma. This has resulted in a number of large fracture zones formed as transform faults to accommodate movement between different landmasses. These include the Tasman and Balleny fracture zones, which were linked to the separation of Australia from Antarctica, which started approximately 100 Ma. In some cases, extensive volcanism related to unusually hot spots in the earth's mantle have resulted in submarine plateaus on the ocean floor. The Agulhas Plateau is an example of one of these submarine plateaus.

Scotia Plate

The Scotia Plate is a medium-sized plate located at the boundary between the South American and Antarctic plates, separating the northern tip of the Antarctic Peninsula from the southern tip of South America. The plate started to form about 30 Ma, probably due to a change in relative plate motions between the two major plates. Sea-floor spreading resulted in the opening of Drake Passage and the development of a circumpolar current, which ultimately had a profound effect on global climate systems, resulting in the cooling of Antarctica and the onset of glaciation. The plate is bounded on its northern and southern sides by the North and South Scotia Ridge, which are sinistral (left-moving) transform faults. In simple terms, the Scotia plate can be seen as an accommodation zone related to the overall westward movement of the South American plate relative to the eastward movement of the Antarctic plate. The Scotia plate has grown by a series of short-lived spreading episodes overlapping in time.

Sandwich Plate

The Sandwich plate is a small plate to the east of the Scotia plate. The plate is moving eastwards away from the Scotia plate but overriding the South American plate. Consequently it is bounded on its western side by a spreading ridge and on its eastern side by a seismically active trench, the South Sandwich Trench, where the South American plate is subducting beneath the Sandwich plate, forming the volcanically active South Sandwich Islands. The plate probably formed about 20 Ma due to a relative change of direction of the larger South American and Antarctic plates.

Drake Plate

The Drake plate is a small plate at the northwest tip of the Antarctic Peninsula off the South Shetland Islands. It is currently converging towards the peninsula margin and being subducted beneath the South Shetland Islands. This process has resulted in the development of a marginal basin, Bransfield Strait, between the South Shetland Islands and the Antarctic Peninsula. In fact, the islands moved away from the peninsula because of the formation of a new spreading system, by a process known as back arc spreading, over the past 1–2 million years. Eventually the spreading ridge between the Drake and Antarctic plates that bounds the northwest edge of the Drake Plate will collide with the trench and the Drake plate will be consumed and disappear. This is exactly what happened over the past 50 million years, as the Drake plate is the remnant of a much larger Phoenix plate, which has been consumed beneath the western margin of the Antarctic Peninsula by the subduction process. Subduction ceased over the past 50 million years due to sequential collision of transform-bounded segments of the spreading ridge with the trench.

The northeast margin of the Drake plate is bounded and separated from the Scotia plate by a fracture zone, a large transform fault called the Shackleton Fracture Zone. Movement across this boundary is sinistral, with the Scotia plate moving to the left relative to the Drake plate.

POLAND: ANTARCTIC PROGRAM

In 1895, Henryk Arctowski contacted Adrien de Gerlache de Gomery, organiser of the Belgian Antarctic Expedition aboard *Belgica,* and was appointed the scientific vice leader of that expedition. Another Pole, Antoni Dobrowolski, also participated in the expedition, which lasted from 1897 to 1899 and was the first to winter in the Antarctic. That was the beginning of Poland's tradition of research in the Antarctic. In the 1960s and 1970s, several Polish scientists participated in Soviet and American Antarctic expeditions, as the country became more active in its scientific exploration.

In order to investigate living resources and fishing possibilities, Poland sent two ships to Western Antarctica in January–February 1976, as part of a research programme directed by Dr. Stan Rakusa-Suszczewski. In December 1976, two more vessels set out from Gdynia, bound for Antarctica. The plan was to establish Henryk Arctowski station. The effort was lead by Rakusa-Suszczewski, and after a short reconnaissance, Admiralty Bay on King George Island was found to be a suitable site for the base. Since its opening in 1977 the station has operated continuously. Its principal role is to serve as an ecological and earth sciences observatory. There has been continuous research in oceanography, geology, geomorphology, meteorology, seismology, magnetism, and, particularly, ecology. Furthermore, research at the Polish station is closely related to international research programmes coordinated by the Scientific Committee on Antarctic Research. Poland also organised seven Antarctic marine and oceanobiological expeditions within the Biomass programme, as well as four Antarctic geodynamic expeditions.

The present Polish national integrated programme is called "Changes and Variability of the Antarctic Coastal Ecosystems." The Department of Antarctic Biology, Polish Academy of Sciences, is responsible for the activities at Arctowski Station and for the organisation of expeditions financed by a special governmental fund (SPUB, about a million dollars yearly) of the Ministry of Scientific Research and Information Technology. The main areas within which research is conducted by the Department of Antarctic Biology are studied in cooperation with many Polish universities and institutes from which researchers join the national program as contractors. The Polish programme takes into consideration financial, logistic, and research abilities of the state. The main areas of scientific interest are as follows:

- Interaction in the near-shore zone of Admiralty Bay, King George Island.
- Monitoring of selected groups of flora and fauna and trophic relations in the near-shore ecosystems.
- Colonisation and succession in coastal and shelf ecosystems.
- Trophochemoreception in invertebrates and fish.
- Management of protected areas.

Arctowski station is visited by more than 2000 tourists every year, which is encouraged since environmental education and promotion of nature conservation have been considered among its missions from the very beginning. It is an attractive, modern, and comfortable place for scientific work, permanently hosting between ten and twenty expedition members, usually including several researchers from other countries. Poland has been undertaking initiatives relating to the protection of the natural environment in the area, facilitated by research in cooperation with Brazil, Peru, and the USA. Due to a Polish initiative, the region of Admiralty Bay has been approved by the Antarctic Treaty as an Antarctic Specially Managed Area and the west side of the Bay as Antarctic Specially Protected Area no. 128. Another ASPA (no.151) was established as a reference point in King George Bay.

POLAR DESERT

A widely accepted definition of a desert is a large tract of land, waterless and virtually devoid of vegetation, with negligible precipitation and usually with extremes of temperature. In this sense, almost the entire continent of Antarctica qualifies as a desert since most of its liquid water is bound in the frozen state and therefore unavailable to any form of life. Here, "polar desert" refers to those extensive ice-free areas that fit the definition above. In effect, they are the areas in which biological or ecological oases occur. Away from the immediate influence of an oasis or water source, life in polar deserts is absolutely minimal and often absent.

Antarctic deserts comprise a system of ice-free terrain ranging from valleys and mountain ranges to various smaller topographical features, and including screes or talus and boulder fields to fine mineral soils, sand, and dunes, often patterned by freeze–thaw activity within them. Melt streams are rare and temporary, while permanent lakes vary from freshwater to highly saline, often with distinctly thermal and/or salt layers. Many of these are permanently frozen, but some have a temporary moat of open water around their margins during the brief summer.

The McMurdo Dry Valleys of southern Victoria Land comprise the largest ice-free expanse (c. 4000 km^2) in Antarctica. Much smaller deserts include Bunger Hills, Vestfold Hills, and Larsemann Hills. Many smaller ice-free, almost waterless areas occur throughout the continent, especially in mountain ranges, notably the Transantarctic Mountains, Prince Charles Mountains, Sør Rondane, Pensacola Mountains, and Ellsworth Mountains.

Because of its proximity to the research stations of McMurdo (US), Scott (New Zealand), and Mario Zuchelli (Italy), the Dry Valleys have received by far the greatest scrutiny by scientists, beginning with the British expeditions of the early 1900s. This is the coldest and driest desert on the planet. Because the average annual temperature is c. –20°C, and precipitation is virtually nonexistent, liquid water is exceptionally scarce, often existing for a very short period during summer, and then often in inconspicuous places. The biota comprises a virtually invisible assemblage of phototrophic (requiring light as an energy source) and heterotrophic (obtaining nourishment from organic substances) microorganisms (notably bacteria, cyanobacteria, algae, and fungi). These, and various microinvertebrates, exist as an assemblage intimately linked with the presence of liquid water and nutrients. Mosses and lichens are absent, except occasionally in seepage areas below glaciers. In places at higher altitudes where cloud banks occasionally develop, a few lichens exist by absorbing moisture from the atmosphere and from the very rare snow that falls there. Research has revealed that this infrequent supply of water produces a closely interconnected series of events that ultimately leads to the biological production and cycling of organic carbon and related elements. Scientists are investigating the interrelationship of the biological, chemical, and physical factors to understand the biogeochemical dynamics within this cold desert ecosystem.

The microinvertebrates are essentially aquatic organisms existing in the film of water beneath stones and at the margin of temporary streams and ponds. When these habitats enter a drought phase, the organisms have remarkable survival strategies that allow them to survive for extended periods without water. Besides being exceptionally cold-hardy, at any stage of their life cycle under conditions of environmental stress, they change their morphology, lose 99% of their free water, and enter an ametabolic state known as anhydrobiosis. In this dehydrated state, the organisms are capable of being transported long distances by the wind, thus dispersing them over large distances. They resume a normal existence when liquid water becomes available again. The dominant invertebrates are nematodes, almost all microbial feeders (e.g., species of *Monhystera, Panagrolaimus, Plectus, Scottnema*), although one *(Eudorylaimus antarcticus)* is a predator. Of particular interest in these deserts, especially the Dry Valleys, is the existence of communities of bacteria, cyanobacteria, algae, fungi, and lichens within the upper 5–10 mm of coarse-grained sandstone rock. This is the most extreme terrestrial habitat on Earth, and this cryptic ecosystem is being used as an analogue in the search for former life on planet Mars.

POLAR FRONT

The Polar Front is the best known of several circumpolar oceanic fronts that surround Antarctica. It separates the cold and relatively fresh Antarctic Surface Water from the warmer and saltier surface waters to the north. W. Meinardus was probably the first to report this front, based on meteorological data collected during the German South Pacific Expedition of 1901–1902. However, there is little doubt that it was known to whalers and sealers who had worked in the Southern Ocean since the early nineteenth century. The Polar Front was originally referred to as the Meinardus line, then the oceanic polar front, and then the Antarctic Convergence, the latter correctly suggesting that surface currents converge there.

The Polar Front can usually be recognized during a seaborne southward transit to Antarctica by a sharp drop in sea surface temperature and salinity, often accompanied by fog and other changes. A more reliable method of locating the front utilizes vertical meridional sections of temperature and salinity. On summer temperature sections, the front can be easily recognized as the northernmost terminus of a characteristic subsurface temperature minimum layer sandwiched between warmer layers of Antarctic and North Atlantic origin. The subsurface temperature minimum is typically defined by the 2°C isotherm at 100- to 300-m depths, but that value has to be adjusted locally from 2.5°C north of Kerguelen to 1°C in the Bellingshausen and Amundsen seas. The corresponding salinity sections usually reveal a subtle salinity minimum immediately south of the front, deepening northward. Available winter data suggest similar definitions at that time of year.

A variety of other criteria have been used to define the Polar Front position, including the salinity minimum at 200 m, the strength of thermal gradients, the position where the temperature minimum layer begins its rapid descent, and the location of sharp changes in surface silicate concentration. The 2°C isotherm limit is often preferred, in part because it also extends vertically to the sea surface in winter, and conforms with the locus of rapid temperature minimum descent. The Polar Front can range over 14° of latitude around Antarctica (48°–62° S, on average), but surface gradients of $\sim$2.7°C are almost independent of latitude, with the minimum (1.6°C–2.5°C) in September–October, and the maximum (4.8°C–5.2°C) in February. While the along-front variability of the surface temperature is small, surface signatures are shifted southward in summer.

The Polar Front is associated with a strong jet-like current that carries 1/5 to 1/3 of the 130-Sv (1 Sv = 1 million cubic meters sec^{-1}) eastward flow of the Antarctic Circumpolar Current. Transports vary with season and year; the time-averaged surface speed of the frontal jet is near 30 cm s^{-1}, but it reaches 50–70 cm s^{-1}, especially in the Drake Passage. Currents associated with this jet have been detected throughout the entire water column (i.e., down to the ocean bottom at 4- to 5-km depths). Accordingly, the front responds to bottom topography and closely follows the sea-floor relief.

The polar front separates two distinct ecosystems, with different species of phytoplankton, zooplankton, fish, seabirds, and mammals. It may also harbor species that are endemic to the frontal zone ecosystem. Satellite remote sensing ocean color data reveal a band of elevated chlorophyll concentration along the front, clear evidence of locally enhanced primary production. Penguins, fish, seabirds, and marine mammals use the front as feeding and spawning grounds. Albatrosses can complete a circumpolar journey around Antarctica in as little as 3 months along the front, thanks in part to its high productivity. Of course they also rely on the winds, which attain maximum speeds near the Polar Front.

Islands located south of the Polar Front have a typical Antarctic climate, with well-developed glaciers and snow fields. Examples are South Georgia and Bouvetøya in the Atlantic sector, Heard Island in the Indian sector, and Peter I Øy in the Pacific sector. Islands located north of the front enjoy a sub-Antarctic climate (e.g., the Falkland Islands in the Atlantic, Prince Edward Islands and Îles Crozet in the Indian sector, and the Campbell Islands in the Pacific sector). Îles Kerguelen are an exception, with a sub-Antarctic climate despite their apparent location south of the front.

At present the Antarctic sea-ice cover extends northward as the winter season progresses, but it does not reach the Polar Front. Since the frontal zone is associated with a surface convergence and enhanced biological activity, it is marked by a high sedimentation rate that has proven useful in paleoceanographic studies. This is because at times when the Antarctic Ice Sheet was larger than today, the polar front shifted north by up to 5° of latitude. The circumpolar distribution of icebergs can also be correlated with the front location, the great majority of them being observed to its south. Most icebergs disintegrate within a few days or weeks after crossing the polar front into warmer near-surface waters.

POLAR FRONT, MARINE BIOLOGY OF

The Polar Frontal Zone (PFZ) separates two high-speed cores of the Antarctic Circumpolar Current (ACC), namely the Sub-Antarctic Front (SAF) to the north and the Antarctic Polar Front (APF) to the south, and represents a transition zone between the less productive, warmer sub-Antarctic waters and the cooler, more productive Antarctic surface waters. The geographic boundaries of the PFZ are difficult to identify, as the positions of the SAF and APF demonstrate a high degree of variability, both spatially and temporally. The variability in the position of the fronts is the result of several factors, including the interaction of the ACC with prominent bottom topography (so-called topographic steering) and seasonal wind patterns. The position of the fronts largely determines the geographic extent of the PFZ. For example, topographic steering in the region of the Crozet and Kerguelen Plateaux and in the vicinity of the South-West Indian Ridge may result in the SAF and APF converging into a single prominent feature, which reduces the PFZ into a narrow band. Nonetheless, the PFZ can broadly be defined as the region between 48° and 50° S.

Both the SAF and the APF have been shown to represent important biogeographic barriers to the distribution of phytoplankton and zooplankton. However, mesoscale features such as the warm- and cold-core eddies generated by flow instabilities of the SAF and APF may regionally (in the Indian sector of the Southern Ocean) assist the transfer of plankton species across the fronts. The waters in the frontal regions are usually characterised by increased biological (phytoplankton and zooplankton) activity. The elevated phytoplankton biomass in the region of the fronts is thought to be associated with localised water-column stability that promotes the growth of the larger nanophytoplankton (2–20 μm) and microphytoplankton (>20 μm). Just as the elevated phytoplankton biomass in the region of the fronts is due to an increased contribution of larger phytoplankton cells to total phytoplankton abundance and biomass, the elevated zooplankton biomass in the region of the two fronts is linked to a high contribution of larger macrozooplankton (>2 cm), mainly euphausiids, chaetognaths, and tunicates, to total zooplankton biomass. The elevated zooplankton biomass in the region of the fronts is thought to be a response to the increased phytoplankton availability. Due to increased zooplankton biomass, the frontal regions represent important foraging grounds for top predators, including flying seabirds, penguins, and seals.

The phytoplankton biomass and production in the open waters of the PFZ are generally low (<1 mg chl-a m^{-3} and <250 mg C m^{-3} d^{-2}) and usually dominated by small picophytoplankton (<2 μm). The low values recorded in the open waters can be ascribed to persistent wind patterns that generate deep-water mixing, which favours the growth of the smaller phytoplankton. Exceptions are recorded in the waters surrounding the numerous oceanic islands (Prince Edward, Crozet, and Kerguelen Islands) within the PFZ, which demonstrate the so-called "island mass effect" of increased phytoplankton biomass and production. In these regions, total chl-a concentration and production may be >2 mg chl-a m^{-3} and >300 mg C m^{-3} d^{-1}, respectively. The microphytoplankton (>20 μm) comprising mainly diatoms contribute most to phytoplankton biomass and production in these regions. The elevated phytoplankton biomass and production values recorded in the waters surrounding the oceanic islands can be attributed to localised water-column stability and increased macronutrient and trace metal (Fe) concentrations generated from freshwater runoff from the islands.

A key feature of the zooplankton community within the open waters of PFZ is the extreme spatial and temporal variability in the community structure, species composition, and biomass. Because the PFZ represents a transition zone between sub-Antarctic and Antarctic surface waters, coupled with the fact that the region is characterised by the presence of both warm- and cold-core eddies, the plankton are represented by species that are Antarctic, sub-Antarctic, and sub-Tropical in origin. Although variable, total zooplankton abundance and biomass in the open waters of the PFZ is typically $<10^4$ ind m^{-2} and biomass <100 mg Dwt m^{-2} with the highest values recorded in summer. Winter values are typically 25–50% lower than the summer values.

The zooplankton species composition in the PFZ demonstrates little or no seasonality. The total zooplankton community is numerically and by biomass dominated by mesozooplankton (200–2000 μm) comprising mainly small copepods (*Oithona, Clausocalanus, Ctenocalanus* spp.), pteropods *(Limacina retroversa),* amphipods *(Themisto gaudichaudii),* and chaetognaths (*Sagitta gazellae* and *Eukrohnia hamata*). The contribution of the different groups to the total zooplankton abundance and biomass demonstrates a high degree of unevenness reflecting the complex oceanographic environment. Although the total zooplankton biomass may at times be dominated by euphausiids (*Euphausia vallentini* and *Thysanoessa vicina*) and tunicates (mainly *Salpa thompsoni*), the contribution of the larger zooplankton to total zooplankton biomass is generally <20% of the total.

A number of studies have investigated the ecological role of the zooplankton within the PFZ. While the larger macrozooplankton may locally represent important consumers of phytoplankton production, seasonal grazing studies indicate that the most important consumers of phytoplankton production in the open waters of the PFZ are small copepods and pteropods. The low grazing impact of the macrozooplankton can be attributed to their low abundances and the predominance of small picophytoplankton within the region, which are too small to be grazed efficiently by the larger zooplankton. The copepods in turn represent the dominant component in the diets of the large numbers of predators (amphipods, chaetognaths, and euphausiids) that characterise the zooplankton assemblages of the PFZ. The large numbers of predators within the area are thought to play an important role in increasing the biologically mediated carbon flux to depth through diel vertical migrations and the production of large faecal pellets with fast sinking rates. These factors combined would serve to increase the localised efficiency of the biological pump.

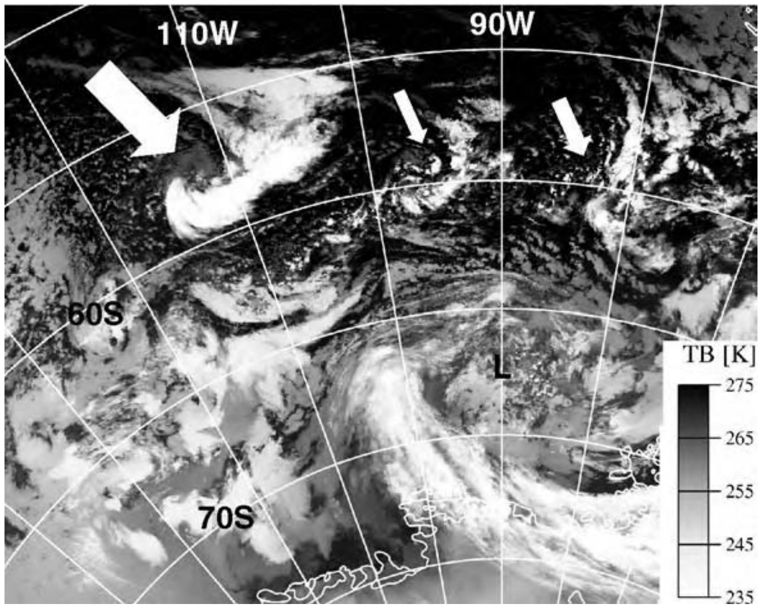
POLAR LOWS AND MESOSCALE WEATHER SYSTEMS

Types of Vortex and Formation Areas

Polar lows and mesoscale cyclones in the Antarctic were not detected until the advent of high-resolution satellite imagery from polar orbiting satellites. Unlike their counterparts in the Arctic, no historical reports about hazards associated with these systems are known, because of the fact that the Antarctic represents a huge area almost free of observational data from ships and surface stations. As a consequence, most of our knowledge about the structure of these systems relies on satellite remote sensing, but invaluable information about the governing processes has also been provided by the improvement of mesoscale numerical models during the last decade.

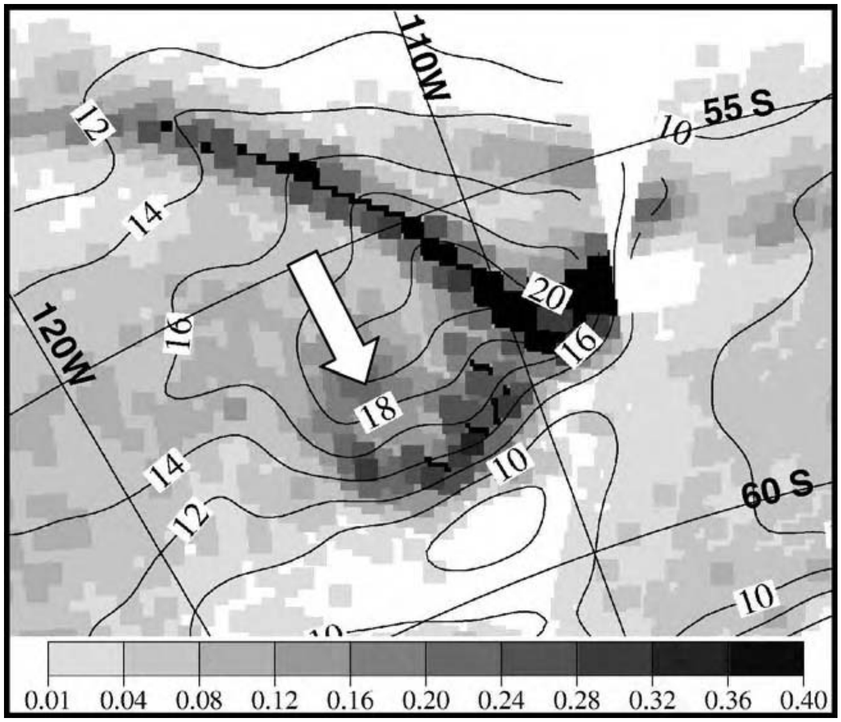
The term "mesoscale cyclone" (MC) is generally used for cyclonic vortices poleward of the Polar Front up to a horizontal scale of 2000 km. The term "polar low" represents a subgroup of intense maritime MCs with scales smaller than about 1000 km and a



AVHRR channel 4 image (mosaic) from AVHRR data (brightness temperature scale in K) for 14 UTC January 11, 1995. The main MC is marked with a large arrow; two minor MCs are marked with small arrows. The centre of the synoptic cyclone is marked "L."

near-surface wind speed exceeding 15 m s^{-1}. Antarctic MCs have been observed in different regions of the Antarctic by means of satellite imagery, geophysical parameters retrieved from satellite data, and—in the few cases where a MC was close to a research station, a ship, or automatic weather stations—by direct observational data. Climatologies of Antarctic MCs are mainly based on satellite imagery and show that MCs at the meso-α (200–2000 km) and the meso-β scale (20–200 km) occur frequently over the Southern Ocean and in the coastal regions of Antarctica. The typical diameter is less than 500 km, and they typically last less than 24 hours. Although these systems are generally not as intense as the sometimes destructive polar lows of the Northern Hemisphere, they can still complicate logistical operations (e.g., aviation) in the Antarctic and could be important in a climatological sense (e.g., by increasing the exchange of momentum and heat between polar and subpolar regions).

The detection of Antarctic MCs using satellite imagery and hence the identification of preferred formation areas depends on the spatial and temporal resolution of the satellite data. For example, most of the MC developments over the large ice shelves could be detected only by satellite imagery with high resolution, such as directly received AVHRR (Advanced Very-High-Resolution Radiometer) data. Since these data are not stored aboard the satellite, an AVHRR receiving station is needed in the area of interest in the Antarctic. Although the number of operational AVHRR stations has increased in recent years, a long-term whole-year climatology for the whole Antarctic using these data is still not available. Satellite-based MC climatologies are therefore limited to a few studies for the full hemisphere with a coarse resolution as well as a couple of regional MC climatologies using high-resolution satellite data. Because of the laborious effort associated with these studies, the maximum time period is less than 10 years. However, the results available so far indicate two different types of preferred formation areas of Antarctic MCs. The first type is represented by the transition zone of the continental ice sheet and the ocean or ice-shelf areas. Many MCs with a lifetime of often less than 12 hours develop over ice-shelf areas and close to the coast. The preferred formation areas are associated with coastal polynyas and confluence zones of the katabatic wind, in particular in the Ross Sea and Weddell Sea regions. During wintertime, the sea-ice front extending far to the north represents another preferred formation area for MCs. The interannual variability of MC frequencies is large. Since the triggering of mesocyclogenesis by large-scale cyclones is important, the general circulation patterns of the higher southern latitudes and their teleconnections to the midlatitudes and the tropics are important factors for the observed MC variability. In particular, the El Niño–Southern Oscillation (ENSO) teleconnection is considered to influence MC formation in the Antarctic.

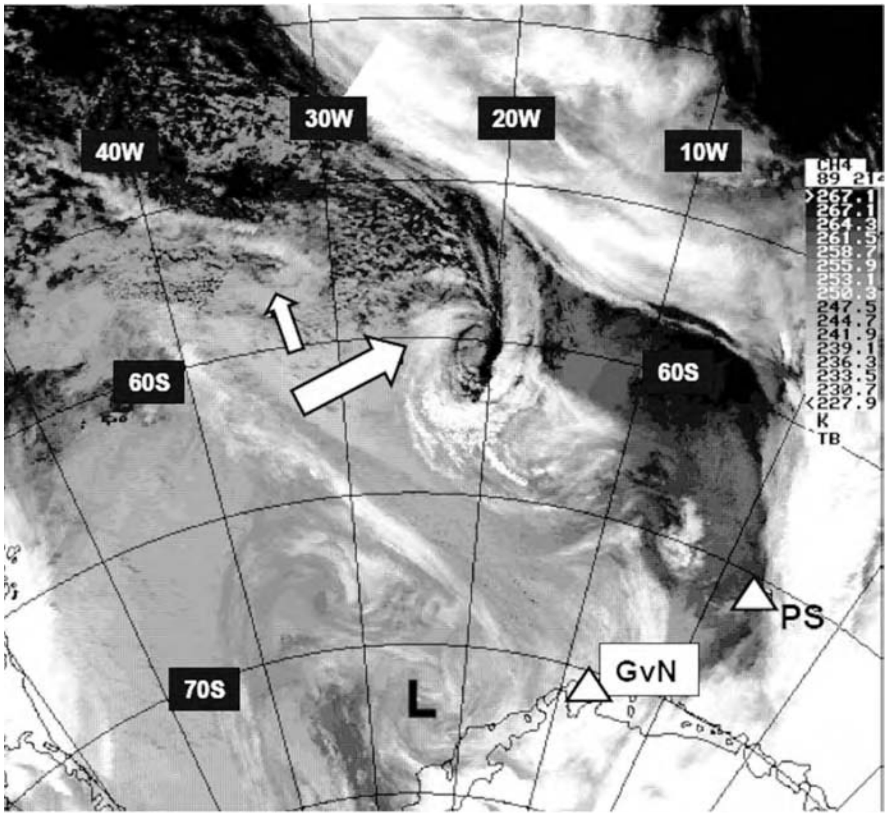


SSM/I-derived cloud liquid water (grey shaded, scale in kg m^{-2}) and near-surface wind speed (contour interval 2 m s^{-1}) for 1126 UTC January 11, 1995.

Structures of the Systems: *In Situ* and Satellite Observations

An example of a satellite-based structure analysis of a polar low developing over an Antarctic ocean is shown in the satellite image of a family of three mesocyclones developing on January 11, 1995 over the northern Bellingshausen and Amundsen Sea. This was observed by means of AVHRR, European Remote Sensing Satellite Scatterometer (ERS-SCAT), and Special Sensor Microwave/Imager (SSM/I) data. The most pronounced MC at 112° W, 58° S had a diameter of about 800 km and a lifetime of more than 24 hours, and it reached the intensity of a polar low. Low-level clouds near the centre and midlevel clouds south of the centre clearly indicated the circulation associated with the MC, and the appearance of the MC on the satellite images resembled a short baroclinic wave with shallow convection west and north of the centre. The centre of a large-scale cyclone (marked "L") remained almost stationary at 90° W, 67° S. The MC is present as a distinct mesoscale signal in SSM/I retrievals of cloud liquid water, near-surface wind speed, and integrated water vapour (not shown). In contrast to AVHRR images, where only the highest cloud layers contribute to the radiance signal, the SSM/I-derived cloud liquid water represents the whole atmospheric column. Compared to the infrared imagery, the baroclinic cloud structure of the MC is much clearer in the cloud liquid water field, because the high cirrus clouds are almost transparent at microwave frequencies. ERS-SCAT data are available for this period, but ERS-derived wind vectors give no insight into the structure of this MC, because of the narrowness of the ERS swaths. Nevertheless, these data have been used to validate numerical simulations for this case study.

The very rare case that an MC developing over the ocean passes directly over an observation station occurred for a MC event during the Winter Weddell Sea Program (WWSP) field phase 1986, when observational data were available from the German R/V *Polarstern,* situated close to a MC on July 31, 1986. The MC developed close to the sea-ice front over the northern Weddell Sea and moved over the sea ice towards the Antarctic coast during its further development. On August 1, 1986 the centre of the MC lay close to the research station Georg von Neumayer (GvN, 8.4° W, 70.6° S) at a distance of about 300 km. The satellite image on 31 July 1986 shows a synoptic-scale cyclone (L) with its main centre close to the Antarctic coast at 24° W, 71° S and the well-developed MC at 20° W, 60° S. The diameter of the MC is about 700 km, and the cloud structure reveals similarities to a short baroclinic wave, and cloud top

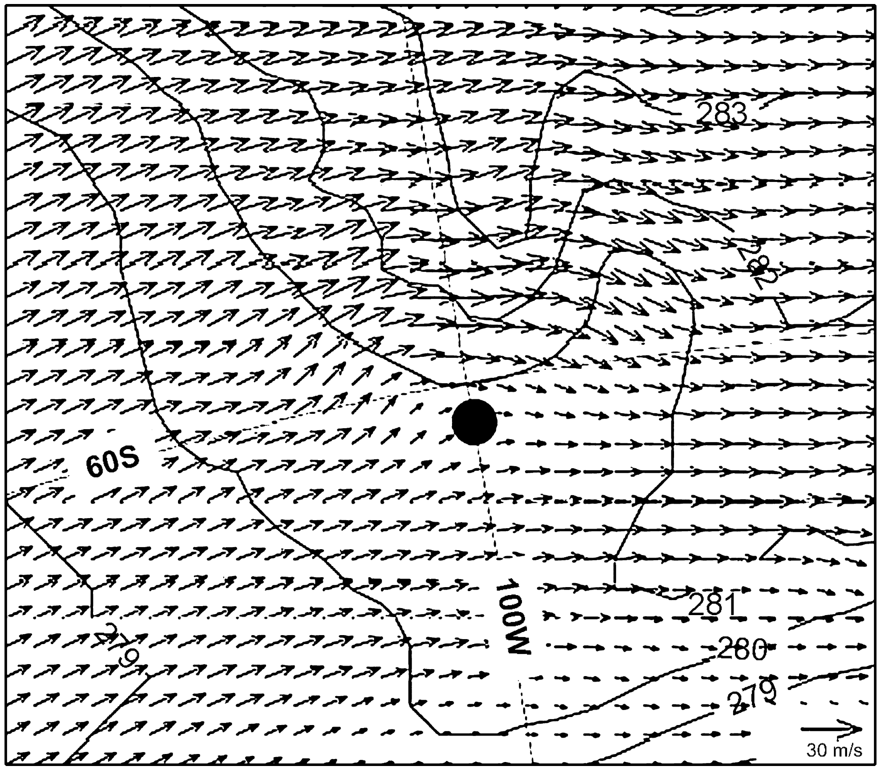


AVHRR infrared image from AVHRR data (brightness temperature scale in Kelvin) for 02-04 UTC on July 31, 1986. The main MC is marked with a large arrow; a minor MC is marked with a small arrow. L marks the centre of a synoptic-scale cyclone. Positions of the R/V Polarstern (PS) and the German research station GvN are indicated.

temperatures of the cloud band east of the centre were about –40°C. This cloud band is associated with the cold front passing over the position of the R/V *Polarstern* (PS) later on. During the approach of the MC to both stations on 31 July, the wind at GvN turned from north to east, and wind speeds increased to values of around 25 m s^{-1} for about 12 hours. The main cloud band of the MC passed over PS around 00 UTC on 1 August, which was associated with a strong temperature fall during the second half of 31 July and a wind peak of 16 m s^{-1} during the frontal passage at 1 August 00 UTC. Series radiosonde profiles obtained at GvN with a resolution of 3 hours showed the cold front as a strong inversion at 930 hPa capping a shallow layer of cold air of about 50-hPa thickness.

Structures and Dynamics: Numerical Simulations

In recent years, mesoscale numerical models have proven to be capable of successfully simulating Antarctic MCs. Simulations for realistic case studies and idealized numerical simulations using full-physics mesoscale models have contributed significantly to the current understanding of mesocyclogenesis in the Antarctic. Three mechanisms are found to be important for the formation and development of Antarctic MCs: baroclinic, barotropic, and convective dynamics. The mechanism of baroclinic instability is well known for cyclones of the midlatitudes and represents the conversion of potential energy (given by horizontal temperature gradients) to kinetic energy. In midlatitudes the preferred cyclone scale by this mechanism is several thousands of kilometers, and the cyclone extends vertically throughout the troposphere. In contrast, the vertical temperature stratification during conditions of MC formation at polar latitudes reduces the vertical scale of the baroclinic cyclones, which results also in a much smaller horizontal scale. A good framework for the understanding of classical baroclinic developments is the so-called isentropic potential vorticity (PV)-thinking, which explains the baroclinic cyclone intensification by a mutual interaction between a low-level PV anomaly and an upper-level PV anomaly upstream of the surface low. Barotropic dynamics in the form of



Mesoscale model simulation with 25 km resolution after 12 h simulation time (valid at 18 UTC January 11, 1995) for the potential temperature (full lines, isolines every 1 K) and wind vectors (every grid point) at 850 hPa. A scaling vector is shown in the lower right corner. The solid dot marks the MC centre.

orographic forcing are important for MC developments near the continental slopes. Downslope winds in and above the atmospheric boundary layer over the slopes of the Antarctic ice sheet cause a vertical stretching of the air, which leads to a barotropic vortex generation, since the conservation of PV requires the production of cyclonic relative vorticity. Among the convective dynamics theories being proposed for polar low formation, the wind-induced surface heat exchange (WISHE) mechanism seems to be present for many MC developments in the Antarctic. This mechanism represents a positive feedback between the surface heat fluxes related to the surface winds and the moist convection associated with latent heat release at upper levels. However, observational as well as modelling studies show that a combination of instability mechanisms is always present during the formation of Antarctic MCs.

For coastal mesocyclone developments the role of the katabatic wind in the formation process was investigated using high-resolution mesoscale models. A generally stable stratification in the boundary layer over the ice slopes of Antarctica leads to the development of a katabatic wind system with downslope wind speeds of 20 m/s and more. Without additional synoptic forcing, the katabatic flow is generally confined to a shallow layer over ice slopes and dissipates relatively soon after crossing the coastline or over the ice shelves. Studies of near-coast developments have revealed the interaction between the synoptic-scale environment, the katabatic wind over the ice slope, and the mesocyclogenesis. Under favourite synoptic flow, a barotropic spin-up of cyclonic vorticity corresponding to an initial mesocyclone at the coast occurs, which may be further intensified by other processes like WISHE or upper-level forcing. For MCs occurring over the Antarctic oceans or near the sea ice front, upper-level forcing was found to be present in most of the cases (i.e., these MCs can be regarded as short baroclinic waves). Convective dynamics are less important than for polar lows in the Arctic, but the intensification process of Antarctic MCs was found to depend on diabatic processes like latent heat release, particularly for wintertime cases near the sea ice front. Forcing by surface energy fluxes and intensification via the

WISHE mechanism plays an important role for the initial phase of wintertime MCs developing over open-water areas.

The simulation of observed Antarctic MCs using limited-area mesoscale numerical models is limited by the quality of the analyses (being used as initial and boundary fields), which are poor compared to the Northern Hemisphere because of the sparse observational network in the Antarctic. However, the increased amount of satellite remote-sensing data being assimilated in the operational global analyses (e.g., analyses of the European Centre for Medium-Range Weather Forecasts [ECMWF]) has led to an improvement of the initial and boundary fields for mesoscale numerical models in the Antarctic and allows more frequent successful simulations of Antarctic MCs. For example, a comparison of images from AVHRR data obtained January 11, 1995 shows both the main MC and a simulation result using a mesoscale model with 25-km resolution for that MC. The wind vector field and potential temperature at 850 hPa reflect the mesoscale circulation of the MC (superimposed on the strong zonal wind) with the circulation centre at about 100° W, 60° S. The temperature field reveals moderate baroclinicity and a wavelike structure. The result is an advection pattern resembling that of a short baroclinic wave. The intensification of the low-level circulation is triggered by a shortwave 500-hPa trough. The maximum upward vertical velocity at 700 hPa lies downstream of the 500- hPa trough axis and over the low-level circulation centre. The numerical model results show the MC as a shortwave baroclinic development triggered by an upper-level trough.

Numerical simulations of topographically forced MCs in coastal regions of the Antarctic continent show that the topography of the coastal regions plays an important role in mesocyclogenesis. One key factor is the katabatic wind system, which is able to initiate low-level MCs in areas of a suitable orography structure. In particular, the area of the southern Ross Sea exhibits a bay-like structure, where many MC developments are observed and also numerically simulated. The second key factor is the support by the synoptic environment, leading to vorticity production by vertical stretching of the synoptically supported katabatic winds. Besides this stretching mechanism, katabatic winds can have a second impact on the generation of MCs by transporting cold air into the coastal areas and thereby enhancing the low-level baroclinicity. A large fraction of short-lived coastal MCs seem to be generated by these mechanisms. For larger-scale and long-lived MCs, the amplification of a near-surface perturbation is found to occur in association with the approach of an upper-level potential vorticity anomaly. The initial low-level perturbations, however, seem to be strongly connected to specific topographical features. Since satellite-based climatologies only include MCs associated with cloud formation, a considerable fraction of topographically forced MCs will remain undetected in areas without a mesoscale observational network.

Contemporary Problems and Future Research

Compared to the Arctic, where the forecast of polar lows belongs to the routine tasks of the weather services, the number of investigated cases for the Antarctic is relatively small. In addition, the tools for validating the numerical forecasts (or even the initial analyses) are much more restricted in the Antarctic due to the sparse observational network. As a consequence, retrievals from satellites have to be used for validation purposes in most cases, which has attained increasing importance with the advent of microwave imagers and scatterometers. These sensors allow the determination of the near-surface wind and integrated water parameters for almost all weather conditions, with a resolution corresponding to that of coarse mesoscale numerical models. Future mesocyclone research in the Antarctic will increasingly use a combination of satellite data, direct observations, and numerical model data. Assimilation of satellite-retrieved geophysical parameters in a numerical model in the form of a mesoscale objective analysis is needed. A high resolution of the model is also essential. Horizontal grid resolutions on the order of 10 km (and nonhydrostatic models) are needed, but so is a high vertical resolution describing the stable boundary layer over the Antarctic ice sheet as well as low-level mesoscale fronts. Special observational programs like the First Regional Observing Study of the Troposphere (FROST) and the planned Antarctic Regional Interactions Meteorology Experiment (RIME) are the only way of getting an improved observational network as well as databases of conventional and satellite data that are easily accessible for the research community.

POLAR MESOSPHERE

The mesosphere is that part of the earth's atmosphere that extends from approximately 50 to 95 km altitude. It is the coldest of the atmospheric regions and lies above the stratosphere and below the thermosphere. Its defining characteristic is that the ambient temperature drops with increasing altitude throughout. At the upper limit, the mesopause, a temperature minimum is reached. Above that, the thermosphere begins and temperatures rise sharply due to the absorption of the sun's extreme ultraviolet radiation by oxygen. Similarly, below the mesosphere, in the stratosphere, heating is primarily caused by the absorption of solar radiation at ultraviolet wavelengths by ozone. In the mesosphere itself, however, absorption of solar radiation is less dominant and other processes become equally important. Temperature changes in the mesosphere can be driven by the indirect action of atmospheric waves propagating up from the troposphere, by exothermic chemical processes, and by radiation of energy into space via carbon dioxide.

Many books and internet sites perpetuate the idea that the upper limit of the mesosphere occurs at around 80 km. However, it is now known that the height of the mesopause varies considerably with season and is always higher than 80 km. In the winter hemisphere, and extending across the equator to about 40° latitude in the summer hemisphere, the mesopause occurs at approximately 100 km altitude; in the summer hemisphere above 40° latitude it drops to around 88 km. At the equinoxes the mesopause occurs near 100 km throughout both hemispheres.

The cold air of the mesosphere overlies the warmer air of the stratosphere. This, together with its negative vertical temperature gradient (lapse rate), makes the mesosphere relatively unstable and turbulent compared to the stably stratified stratosphere. It is a dynamic region where winds regularly exceed 100 km per hour, where large atmospheric tides occur, and where a wide spectrum of atmospheric waves exists with oscillation periods from a few minutes to many days. Wave breaking and turbulence are commonplace. The air at the mesopause is some 3 million times less dense than air at the earth's surface. There is five thousand times more atmosphere (by mass) below the bottom of the mesosphere than above it. That the mesosphere contains less than one five-thousandth of the total atmosphere by mass might appear to make its presence inconsequential, but it has gained importance over recent years because it is the region where ice clouds form on the edge of space; it can be a sensitive indicator of global change; and it is a region where atmospheric waves, propagating up from the troposphere, break and drive middle atmosphere circulation on a global scale.

The polar mesosphere is of special interest because the mesopause at latitudes poleward of about 50° can have the coldest temperature anywhere in the earth's natural environment. Somewhat paradoxically, these extreme low temperatures occur during summer (i.e., November through February in the Antarctic and May through August in the Arctic). Then the temperature drops to around –140°C, several tens of degrees centigrade below the lowest-ever-recorded temperature on Antarctica's surface. This cold summer polar mesopause, some 70°C below the temperature expected under simple radiative equilibrium, is created due to the action of atmospheric waves on middle atmosphere circulation. Gravity waves, which can be generated by the impact of weather on mountains or by shear in the lower atmosphere, have to grow in size in order to conserve energy as they travel upwards into the increasingly rarefied air. When they reach the mesosphere these amplified waves can break, like waves approaching a beach, and transfer their momentum to the horizontal winds. This indirectly drives a summer-to-winter pole-to-pole circulation, which, in order to conserve mass, requires air to move upwards at the summer pole and downwards at the winter pole. When this air is driven upwards it adiabatically expands and thus cools down, markedly reducing the summer mesospheric temperature.

These cold temperatures lead to three important polar phenomena—noctilucent clouds (NLC), polar mesospheric clouds (PMC), and polar mesosphere summer echoes (PMSE). These are all closely related because each is a consequence of minute ice particles, a few tens of nanometers in size, growing near the very cold mesopause. It is these phenomena, primarily occurring in the Antarctic and Arctic, that can be sensitive indicators of global change. The mesosphere is extremely dry and so it is difficult for ice particles to form at all. There is less than 10 parts per million by volume of water at this altitude and the ice will only form when the temperatures are low enough to produce supersaturation. Thus, if the overall temperature in the mesosphere drops by only a few degrees there will be more occasions when conditions favour ice-particle formation and so the occurrence probability of NLC, PMC, and PMSE will increase markedly. Atmospheric models have shown that while an increase in the concentration of "greenhouse gases" such as carbon dioxide and methane in the atmosphere will increase temperatures near the earth's surface, it will decrease temperatures in the mesosphere and above due to increased infrared radiation out into space. Not only will the temperature decrease but the magnitude of that temperature change will be five times larger in the mesosphere than near the ground. Consequently, the mesosphere is inherently more sensitive to greenhouse gases and, advantageously, NLC, PMC, and PMSE provide us with a sensitive means of detecting that change. It is also possible that increased greenhouse gases can lead to increased occurrence of ice in the mesosphere through an increase in mesospheric water vapour content brought about through a higher methane concentration.

Noctilucent clouds (NLC) are visible to the naked eye, but only in twilight conditions. These clouds are the highest on earth and exist on the edge of space some 85 km above the ground—when you peer out of an aircraft window and look down onto weather clouds, these noctilucent clouds are still 50 miles above you. Their great altitude means that when the sun is just below the horizon, its light can still shine onto the underside of the ice particles making up the clouds and be scattered back down to the observer, who is standing in relative darkness. NLC are so optically thin that they scatter less than 1 part in 1000 of light incident upon them. This faint reflection appears brightly against the darkened sky as a silvery-blue veil that frequently exhibits fixed wave patterns as brighter streaks and bands. These patterns, reminiscent of ripple patterns on the bottom of a swimming pool, are caused by atmospheric gravity waves with wavelengths of several tens of kilometers that compress and rarefy the air containing the ice particles to create denser and thinner clouds respectively. As a consequence of the geometry between sun, cloud, and observer required to see these clouds and also the fact that they only occur in summer near the poles, they are generally only observable between latitudes of 50° and 65° near sunrise and sunset for about 3 months per year in each hemisphere. The presence of NLC was first recorded in the summer of 1884 after the eruption of Krakatoa that occurred in 1883. There have been suggestions that NLC occurrence has doubled over the past 40 years and this has been attributed to increasing anthropogenic greenhouse-gas pollution. Others now argue that this increase is only a consequence of observation statistics. While NLC are frequently seen in the Arctic, they are reported less often in the Antarctic because the distribution of land mass and the extremely low number of inhabitants makes observation far less probable.

Powerful laser beam pulses can be fired up to the mesosphere with lidars (laser radars). Below about 80 km altitude the light intensity scattered back to the ground by the molecules in the air is closely related to atmospheric density and temperature. Above 80 km the atmosphere is so tenuous that the scattered return is too weak to detect and so the laser beam frequency is carefully selected to resonate with metal atoms naturally present in the atmosphere at those heights. These are usually sodium, potassium, or iron and are a consequence of meteors burning up on entry to the earth's atmosphere. The resonating metal atoms reradiate light back to the ground and from these returns the temperature profile above 80 km can be determined. Lidars can also be used to reflect off noctilucent clouds to determine their height and denseness. Lidar measurements suggest that noctilucent clouds occur at slightly higher altitudes in Antarctica because the orbit of the earth brings it closer to the sun in January than in July and thus produces greater upwelling of the Antarctic summer atmosphere.

Polar mesospheric clouds (PMC) are essentially the same phenomenon as noctilucent clouds but are observed from above by spacecraft. One small difference lies in which particle size provides the strongest response from space compared to ground-based observations. Comparisons by polar orbiting satellites suggest that the brightness of Antarctic PMC is less than that of Arctic PMC. This lends weight to the notion that the temperature in the Antarctic summer mesosphere is a few degrees warmer than that in the Arctic. There is recent evidence that the brightness of PMC is increasing with time as a consequence of global change.

Ground-based radar, which uses the time delay of radio wave pulses to measure the distance of atmospheric targets, can observe an extra layer of echoes coming from mesospheric heights during the summer in the polar regions. These are polar mesosphere summer echoes or PMSE. These anomalously intense echoes come from a thin layer a few kilometers below the mesopause and are thought to be generated as a result of electrically charged ions accumulating on the ice particles and reducing the diffusivity of electrons so that very small-scale structure in electron concentration can exist. There has been some evidence that PMSE, like PMC, may be weaker in the Antarctic than the Arctic, but further observations are required to confirm or deny this.

Making direct measurements in the mesosphere is challenging. It lies above the altitude of the highest balloons and below the altitude of satellite orbits. *In situ* measurements can only be made using rockets and are therefore very transitory and expensive. The first *in situ* temperature profiles of the Antarctic mesosphere were not measured until 1998 using falling spheres. These 1-m-diameter inflatable mylar spheres are ejected above the mesosphere from meteorological rockets at approximately 115 km altitude. From there they initially plummet towards the ground because the air is so tenuous, but the drag of the air gradually slows them down until, at around 30 km, the atmospheric pressure destroys them. By tracking the descent of the spheres with a high-power radar and applying drag equations to the derived trajectory, it is possible to calculate the atmospheric density and temperature with 100-m-altitude resolution. These falling sphere measurements indicated that January mesopause temperatures in Antarctica (after solstice) were just as cold as those in July in the Arctic, but measurements at summer solstice itself were unable to be made because of the seasonal limitations of shipping the rockets through the Antarctic sea ice.

There is scientific debate about whether mesospheric temperatures in the Antarctic summer are warmer than those in the Arctic summer. The evidence for weaker PMC and PMSE in Antarctica has been used to support the argument that the Antarctic summer mesosphere is warmer. Conversely, however, the falling sphere measurements support the alternative argument, that Arctic and Antarctic summer mesopause temperatures are equal.

Why do contrasts between the Antarctic and Arctic mesosphere matter? General atmospheric circulation models rely on mathematical simplifications of gravity waves because the latitudinal and longitudinal grid size of the models is too large to include the individual gravity waves themselves. These models are used to estimate movement of greenhouse gases and anthropogenic pollutants, to provide climate-change scenarios, and to make ozone hole forecasts. Whether they produce differences between the Antarctic and Arctic middle atmospheres and whether those differences compare favourably to observational measurements is a stringent test of whether the gravity wave simulations are reliable. Their reliability is crucial for predicting climate change.

Maybe more important is that whatever processes can make the temperature in the Antarctic and Arctic differ may also affect the formation of NLC, PMC, and PMSE, which could be our most sensitive "litmus test" for global change. Antarctic measurements, by the difficult logistical constraints imposed, tend to be several years behind similar measurements in the Arctic but are an essential piece in the jigsaw to understand the Earth's atmosphere and how humans are altering planet Earth.

POLLUTION

Pollution is the undesirable change in physical, chemical, or biological characteristics of the environment as a consequence of human activities. It is caused by pollutants, which may be physical processes (such as light and heat), nonliving substances (such as oil and exhaust fumes), or living organisms (such as animals, plants, bacteria, and viruses). It may affect the health, survival, or activities of humans or other living organisms.

Antarctica is undoubtedly the least polluted of all the continents. This is because it has only a small and transient human population and has never been the site of industry, agriculture, or mining. Tourism and science are the main reasons for people's being in Antarctica and, with a few exceptions, the only buildings and infrastructure are there to support scientific research undertaken by the national Antarctic programs. Despite this, it is no longer a pristine environment. Many common pollutants of the modern world are now present in Antarctica. Some have been carried there by large-scale natural processes that move substances around the planet; others have been taken by people and discarded, spilt accidentally, or unavoidably released to the environment during normal use (such as exhaust fumes).

Worldwide, most research and regulatory attention has been directed towards pollution by substances (chemical pollution); however, pollution by physical processes and by living organisms is also of concern. In Antarctica, light pollution caused by station lighting can be detrimental to scientific studies, such as astronomical observations, that require dark conditions, and can cause bird deaths; similarly, broadcast radio waves can obscure the detection of radio signals from space. In general, physical pollution is transient. When the physical process, such as discharge of waste heat or light, is stopped, the problem goes away; for this reason these problems are generally managed within a station to avoid conflict by allocating areas or times for particular purposes. However, there are exceptions where physical pollution can cause lasting effects. If cooling water were pumped into an Antarctic lake it would disturb layering within the water that might have been established over millennia and disrupt the entire ecology of the lake. Similar harm can be caused by physical stirring created by rising air bubbles released by SCUBA divers in lakes.

Biological pollution (the introduction of nonnative species) has been recognised as a serious problem for many years and is the reason for quarantine regulations designed to limit the movement of undesirable living organisms around the world. Unlike physical or chemical pollution, which are generally limited in their extent and duration, biological pollution has the ability to spread and perpetuate itself by replication and for this reason has potentially the most damaging impact. Once a living organism has become established in a new environment it is very difficult to eradicate. Compared with other regions, the Antarctic continent is relatively free of introduced plants and animals, probably because climatic conditions there are so different. In contrast, the sub-Antarctic islands of the Southern Ocean have almost all been significantly changed by introduced species, including cattle, deer, rabbits, cats, and rats, as well as by many species of plants. Introduced species create a cascading series of impacts because of the interconnections in biological systems, for example, the introduction of grazing rabbits causes major changes to vegetation, which then has consequences for the rest of the ecosystem. Introduced species can also displace and out-compete native species. Heard Island is the only large sub-Antarctic island that has not been significantly polluted by introduced species.

Microorganisms such as bacteria, fungi, and viruses have inevitably been introduced to the Antarctic continent and, in localised areas around centres of human activity such as research stations, have become established. At the very least these have changed the microbial community structure of these locations; at the worst, introduced microbial pathogens could cause disease in the native flora and fauna of Antarctica. Introduced microorganisms could very seriously reduce the scientific value of some unique Antarctic environments. Subglacial lakes, such as Lake Vostok, have been isolated from the rest of the world under kilometres of ice for many millions of years and may contain remarkable information about the development of life on this planet. Very great care is necessary to ensure that the act of investigating these lakes does not irreversibly change them by the introduction of chemical or biological pollutants.

The chemical byproducts of modern living have now reached all corners of the world. Global distillation, the cycle of evaporation of pollutants in the warm parts of the planet and condensation in cooler places, is a natural process that selectively moves certain pollutants to polar regions. Transport by evaporation depends on three characteristics of the chemical: persistence—how long it survives in the environment without breaking down; volatility—how easily it evaporates; and water solubility—how easily it dissolves in water. Those most likely to reach the Antarctic by this mechanism are the persistent chemicals with intermediate volatility and intermediate water solubility. They can move great distances by a series of evaporation and condensation cycles or "hops." When they eventually reach a place where low temperatures are not sufficient for further evaporation, they remain and can accumulate. In Antarctica natural rates of breakdown are slower than elsewhere because the environment is not conducive to chemical degradation, which is accelerated by intense sun light, high microbial activity, and warm temperatures—conditions not found in Antarctica.

As a consequence of global distillation, manmade organic chemicals that would not be used in Antarctica, such as the pesticides lindane, toxaphene, and DDT and its derivatives (breakdown products) are found there and can accumulate in the Antarctic food chain. DDT was among the first persistent organic pollutant to be found in Antarctica. It is a synthetic chemical that does not occur naturally, so even very low concentrations are evidence that environmental contamination has occurred. In the 1960s it was found in some Antarctic marine species and since then it has been detected in seawater, sea ice, snow, and land ice. Levels of DDT in snow from increasing depths, representing different times in the past, are consistent with the period of high worldwide use of DDT in the 1970s and the subsequent reduction in use as the environmental problems it causes became apparent and controls on use were implemented. The data from the Antarctic are important as they provide a measure of the global "background" of contamination, uninfluenced by local sources. Overall the Antarctic data indicate that the global background for DDT has reduced one thousand–fold or more since the peak in the 1970s.

DDT has been detected in Antarctic plants and animals from both the land and sea. The highest concentrations are found in the fatty tissues of top predators such as seals and birds, particularly those that scavenge on the carcasses of other predators. There has been little reduction in tissue concentrations in seabirds since the 1970s peak, despite the reduction in worldwide use of DDT and the reduction in the physical environment, indicating that these chemicals are persistent within the food chain, especially in cold climates.

Other chemicals, such as PCBs (polychlorinated biphenyls, used for many industrial applications) and PAHs (polycyclic aromatic hydrocarbons, formed during incomplete combustion of fuel) can also be transported by global distillation and have been detected in Antarctica. However, these chemicals were also taken to Antarctica for particular purposes; for example, PCBs were commonly used as cooling oil in electrical transformers and as additives in paints to maintain flexibility. Because they were used locally, levels of these chemicals in Antarctica are less useful as indicators of global backgrounds than chemicals, such as insecticides, that were never used in Antarctica in large quantities.

In the Arctic, global distillation of chemicals such as PCBs contributes to pollution levels that threaten the health of indigenous human populations, particularly those that rely on local wildlife as an important component of their diet. Chemicals transported by this process are not a concern to human health in Antarctica because, with the exception of fishing, killing of native animals for food is not permitted below 60° S. However, these pollutants may have detrimental effects on Antarctic fauna and flora, although no direct evidence of harm has yet been reported.

The other major sources of pollution in Antarctica are the materials taken there to help people live and work. In the early days of expeditions to Antarctica there was no concept that people could harm the environment. Antarctica was seen as a vast and threatening place in which people needed to be protected from the environment rather than the other way round. Domestic waste was either burnt or disposed of in open rubbish tips just as at home, and support facilities were abandoned when expeditions left. The modern era of Antarctic science really began in 1957 during the International Geophysical Year, which stimulated a significant increase of scientific activity in Antarctica; many new stations were established but attitudes toward the environment continued as before. As a consequence many of the now-abandoned work facilities and waste-disposal sites originate from this period. Gradually, from the 1960s onwards, the world began to realise the consequences of environmental pollution, attitudes started to change, and this began to influence how things were done in Antarctica. During the 1980s, several nations stopped using open rubbish tips and began taking their waste away with them. The growing concern for environmental protection eventually led to agreement by Antarctic Treaty nations that Antarctica should be given comprehensive environmental protection.

The Protocol on Environmental Protection to the Antarctic Treaty was adopted in 1991 and has done much to reduce pollution from activities in Antarctica. This international agreement prohibits some potential pollutants' being taken to Antarctica and, for substances that are essential and cannot be banned, it has guidance on impact assessment, waste management, and emergency response in case of spills. Most wastes generated in Antarctica must now be returned to the country of origin, and disposal of waste to landfill and open burning are not permitted. The protocol requires that abandoned waste disposal sites be cleaned up so long as their removal does not create greater environmental impacts than leaving them where they are. Sewage from research stations must be treated before disposal and can be discharged to the sea only where it will disperse rapidly. The other major sources of pollution in Antarctica are accidental spills, routine operational discharges, such as exhaust emissions, and planned releases for scientific purposes. Recognising that major oil spills have the potential to cause widespread environmental damage, the protocol requires that countries have contingency plans for such environmental emergencies. In addition, the nations working in Antarctica have now agreed on an annex to the Protocol that will establish a financial liability for remediation of environmental damage arising from activities in Antarctica. Overall, the protocol has very successfully reversed the trend from rapid accumulation of pollution in Antarctica to slow removal and remediation.

The quantity of abandoned waste and contaminated soil in Antarctica has been estimated at 1–10 million m^3. This is not a lot compared to the quantity of pollution on the other continents, but it is significant in a place considered by many to be the last great wilderness. Importantly, the pollution is not spread equally over the entire area of Antarctica because most research stations and most human activity is concentrated on the small ice-free areas within 5 km of open coast, which represent only about 0.05% of the land area of Antarctica, or about 6,000 km^2. This narrow coastal strip is also the main habitat for many Antarctic animals and plants. To put the scale of cleanup in perspective, a recent operation using an ice-breaker with a large cargo capacity removed about 1000 m^3 from Australia's Casey Station during the 2003–2004 Antarctic summer season. Using the most optimistic estimate of the quantity of contaminated material in Antarctica, this represents only 1/1000th of the total.

Abandoned waste disposal sites in Antarctica typically contain a wide range of material similar to that in the municipal tip of any small country town. Food waste from kitchens, discarded clothes, and wood from packing crates contribute to the organic material. Organic material is not normally considered a pollutant because in other parts of the world it is plentiful in soils; however, most Antarctic soils and lakes have very low levels of organics and the addition of organic material can significantly change their ecology.

Many of the tips were burnt periodically to reduce their volume. Fuel was used to promote burning and as a result these tips contain residues of petroleum hydrocarbons and PAHs formed by incomplete combustion. The tips also contain waste oil, such as cooking oil and lubricants from vehicles and workshops. Together these form a complex mixture of hydrocarbons. Oily sheens are sometimes seen on water draining from tips during summer, indicating that contamination can spread. Hydrocarbons are known to cause a variety of harmful ecological effects, including smothering and oiling of feathers in extreme cases, direct toxicity to plants and animals, and subtle changes to soil microbial and physical processes.

Waste tips always contain a variety of metal objects, including tin cans, discarded machinery, batteries, copper wire and pipes, and much else. Chemicals discarded from photographic dark rooms and scientific laboratories may also contain metals. Together these become the source for a broad range of trace metals that could have harmful effects. Iron, lead, copper, tin, and zinc are the most common and others, such as arsenic, cadmium, chromium, silver, nickel, and mercury, are sometimes present in lower concentrations. Many metals are common components of natural minerals occurring in Antarctica and elsewhere. In their naturally occurring forms they are generally highly stable and tightly bound within the mineral matrix. In this form they are not readily available for uptake by plants and animals and do not cause ecological problems. The metals in the tip waste are in forms not normally found in the Antarctic environment and may be biologically available. High levels of anthropogenic (derived from human activity) metals are known to have a range of toxic effects.

Many of the waste tips are located in convenient gullies near the sea edge. This was because in the past, when the tips became too large or untidy, a common form of waste management was to push the rubbish on to the sea ice in early spring so that when the sea ice broke up in summer the waste would fall to the sea bed or would float away on pieces of sea ice. Although this was an acceptable solution in the past, it has now created further problems because rubbish and associated pollution is now spread widely on the sea bed rather than being contained at discrete sites.

A further problem with many of the sites used for waste disposal is that large quantities of water flow through them during the brief period in summer when temperatures are above freezing point and the snow melts. As a consequence, contaminants in the tips are not locked away, frozen in one location, but can be mobilised and transported to other places where they can have detrimental environmental effects. Because many of the tips are on the sea shore, the contaminants are carried by melt-streams into the marine environment, where they accumulate in sea-bed sediments, normally over a limited area. Research shows that they have a range of harmful effects on sea-bed animal and plant communities. The overall impact is similar to that caused by contaminants in other parts of the world; sea-bed communities impacted by pollution typically have lower species diversity than other comparable but unpolluted locations. They are often dominated by a few opportunist species able to thrive when competition is reduced because pollution-sensitive species have been eliminated.

Major accidental spills, such as fuel leaking from a damaged ship, are the most dramatic and possibly the most serious cause of pollution in Antarctica; fortunately this has occurred only rarely. Typically Antarctic activities depend on petroleum-based fuel for transport, power, and heating. The national Antarctic research programs together use about 100 million litres of fuel each year. This fuel has to be brought to Antarctica by ship and pumped from the ship to storage tanks, sometimes across several kilometres of open water, sea ice, and land. The harsh conditions of Antarctica undoubtedly add to the risks of spills during shipment, transfer, and storage.

Whenever fuel is carried in large quantities there is the risk of an oil spill, and ships in Antarctica face the additional hazards of navigating through sea ice. Vessels can become trapped by ice and in the past have been crushed and sunk to become a source of pollution as fuel and other substances leak. In recent times there has been only one major ship grounding in Antarctica resulting in the loss of large quantities of oil. In January 1989 *Bahia Paraiso* ran aground close to Palmer Station on the Antarctic Peninsula, releasing about 600,000 litres of diesel fuel. About 300 seabirds were killed by the direct effects of oil fouling and the spill may have contributed to reproductive failure of other birds. Oil also reached the sea bed, where many bottom-living plants and animals were affected. Because of their potential to create widespread pollution, many national Antarctic programs now have contingency plans for responding to oil spills.

Oil spills also occur on land. On several occasions storage tanks have leaked tens of thousands of litres of oil to the environment. If a tank develops a slow leak during winter when everything is covered in snow and ice, it may easily go unnoticed until the summer thaw. There are also many opportunities for smaller spills to occur. The soil around older vehicle workshops is characteristically contaminated with fuel and oil and, without special care, it is easy for small spills to occur during refuelling of vehicles and while transporting fuel to field parties at remote camps.

Pollution from fuel and oil is recognised as a problem in all parts of the world; however, in warmer regions natural processes such as evaporation, photodegradation (breakdown caused by exposure to light), and consumption by microbial organisms eventually degrade the complex molecules of oil, leaving simple and harmless components such as carbon dioxide and water. These processes require heat, light, available water, and nutrients, all of which may be limited in Antarctic soils. For this reason the natural breakdown of oil pollution takes considerably longer in Antarctica and as a consequence the environmental impacts of oil spills on land may last longer than elsewhere. Even in low temperatures light diesel fuels will evaporate quickly from the sea surface, especially under stormy conditions, so the use of dispersants is rarely recommended.

Some emissions, such as sewage effluent and exhaust, are accepted as unavoidable consequences of the human presence in Antarctica. However, measures are in place to reduce their environmental impacts. The protocol prohibits discharge of sewage to ice-free ground or to lakes because the addition of the large quantities of nutrients contained in sewage would significantly change the ecology of these nutrient-deficient biological systems. Discharge of treated effluent to the sea is allowed only where natural currents will permit rapid dispersal. The incineration of waste and the use of fuel in vehicles and generators both release combustion products to the atmosphere. Burning of waste is only permitted in incinerators designed to reduce harmful gases, and there are some attempts to use sustainable wind and solar power to reduce fuel consumption; however, in the foreseeable future, activities in Antarctica will continue to be dependent on burning fossil fuels.

Exhausts from incinerators and engines are complex mixtures of particles and gases; their nature depends on the temperature of incineration and type of material burnt, or the type of fuel, the efficiency of the engine, and how it is being used. Soot particles, sulphur, lead, and organic compounds are all present in exhaust and are detectable in snow at low concentrations around most Antarctic stations; however, no direct ecological effects have yet been reported. The most likely detrimental impact is to reduce the value of Antarctica as a "clean laboratory" for monitoring changes in background levels of some important indicators of global environmental quality, such as atmospheric lead.

Certain scientific activities also have the potential to create pollution, for example, radioisotopes are widely used by scientists as labels to trace natural processes and if handled carelessly could cause contamination. In Antarctica their use is very carefully controlled by the impact assessment process. Isotopes that decay to harmless elements quickly because of their short half-lives are preferable. Organic chemicals such as butyl acetate, kerosene, perchloroethylene, and trichloroethylene are used by scientists to assist with deep ice drilling. There are about 10 deep core holes in the ice of the Antarctic plateau with an average depth of about 2000 m and a diameter of 20 cm; together they contain about 600 m^3 of drilling fluid. Although present in large quantities, most are not an immediate environmental concern because they are locked in the ice and will remain there for many tens of thousands of years. However, they will eventually reach the coast and discharge into the sea. In contrast, the ice drilling to penetrate Lake Vostok is of very immediate concern. The drill hole contains about 60 tonnes of kerosene and freon drilling fluid, some of which could enter and contaminate the lake. The drilling fluid contains several species of bacteria, which could also contaminate the lake and reduce its value as a scientific resource.

The Antarctic Treaty has been very successful at keeping large quantities of radioactive material out of Antarctica. Nuclear testing and the disposal of nuclear waste are both banned in Antarctica. The US Antarctic program had a nuclear reactor at McMurdo Station during 1962–1972 that caused some radioactive contamination of soils before the reactor and the contaminated soils were removed. More recently, the protocol explicitly prohibits some other substances from being taken to Antarctica because they also pose a significant environmental risk; these include polychlorinated biphenyls (PCBs) and pesticides (unless required for scientific, medical, or hygiene purposes).

Despite the requirements of the protocol, high environmental standards are not always achieved and at many Antarctic research stations the standards reached would not satisfy domestic legislation. There are a number of reasons for this. Inefficient and outmoded technologies, such as for sewage treatment and incineration, continue to be used because of the cost and practical difficulties of replacement. In addition, the remoteness of Antarctica contributes to a sense of "out of sight, out of mind" and the difficult climatic conditions force compromise in the search for solutions to environmental problems. The root cause is the system of self-regulation that exists within many national Antarctic programs. In most countries, domestic environmental standards are enforced by legislation and litigation and the roles of proponent and regulator are kept very separate. This is not the case for most national Antarctic programs. The advantage of collocating responsibility for Antarctic operations and environmental management is that first-hand Antarctic experience is readily available; however, this comes at the cost of transparency of process and creates opportunities for conflict of interest.

In the populated parts of the world it is accepted that some contamination of the environment will occur, and guidelines are established to ensure that contaminants do not reach levels that become a threat to human health or to some valued component of the ecosystem. These levels vary depending on the setting; for example, land used for a children's playground would have more stringent standards than land used for heavy industry. Commonly, guidelines are based on toxicology—the study of the toxic effects of chemicals. Environmental standards have not yet been agreed on for Antarctica, but they will be required as targets for environmental remediation now that an effective liability annex to the protocol has been agreed on. It is often assumed that Antarctic animals and plants are more sensitive because they live in what we perceive as a harsh environment or because they have not previously been exposed to pollutants and so have not developed protective measures. In reality there is very little information available to assess the relative susceptibility of polar species (either Arctic or Antarctic) to pollutants. Very few have been used in toxicity tests and the few available results do not yet show a clear picture. However, some patterns are beginning to emerge; for example, the slow development time for some Antarctic species means they are in the sensitive early life stages for longer than similar species found elsewhere and for this reason may be affected by lower concentrations of pollutants. Ultimately people may decide that environmental guidelines based on toxicology are not stringent enough for Antarctica and that higher standards are required consistent with the Antarctic's role as a "clean laboratory" for monitoring the global background of pollution.

POLLUTION LEVEL DETECTION FROM ANTARCTIC SNOW AND ICE

The large Antarctic ice cap has preserved accurately dated archives of global atmospheric pollution for heavy metals. Indeed, the snow layers deposited year after year contain heavy metals that have been emitted in midlatitude areas by human activities, and which were transported in the form of tiny particles to the Antarctic continent by winds. These particles are incorporated into the snow either during or after snow falls, and will be kept there virtually unaltered over long time periods. The snow layer deposited during a given year will be buried by the layer deposited during the following years and will ultimately become ice when it reaches a depth deeper than about 100 m. These accumulated layers will then constitute extremely interesting archives of atmospheric heavy metal pollution since they can be dated using a variety of techniques. To give an example, the snow that is presently at a depth of 10 meters at Dome C on the high East Antarctic plateau was deposited about 2 centuries ago. Its analysis will then give very precious information on the pollution of the atmosphere by heavy metals at that time. It should however be emphasized that these Antarctic archives mainly reflect the pollution emitted in the Southern Hemisphere, especially in South America and southern Africa. This is because pollution emitted in the Northern Hemisphere has difficulty penetrating into the Southern Hemisphere and reaching Antarctica.

Deciphering these frozen archives for heavy metals is unfortunately very difficult. This is because sampling has to be done in very inhospitable places with very low temperatures at high altitudes. Also, Antarctic snow is so clean that the utmost precaution must be taken by the researchers to collect the samples without contaminating them. One thousand tonnes of Antarctic snow typically contains no more than a few milligrams of lead. The analysis of such samples is also a real challenge. First of all the samples must be handled inside special laboratories similar to the clean rooms used in microelectronics to prevent any contamination. Also, incredibly sensitive analytical techniques are necessary to detect these very small amounts of metals. One of these techniques is inductively coupled plasma sector field mass spectrometry. Such a process can detect 10^{-13} g of cadmium in a 1-g sample in a few minutes.

Amongst the most spectacular results obtained so far is the reconstruction of past changes in lead pollution since the middle of the nineteeth century, which was achieved by analyzing a series of snow samples collected in Coats Land, on the Atlantic Ocean side of Antarctica (Planchon et al. 2003). They show that lead pollution of Antarctica started as early as the 1880s (i.e., before the conquest of the South Pole by Roald Amundsen). This early pollution was at least partially linked with nonferrous metal production activities in South America, southern Africa, and Australia. Another important contribution was from coal-powered ships that rounded Cape Horn between the Atlantic and Pacific oceans as well as whaling ships and shore-based stations along the Antarctic coast. This lead pollution then declined in the 1920s, especially because of the opening of the Panama Canal in 1914, which resulted in a pronounced decrease in ship traffic around the southern tip of South America. Lead pollution then increased again after World War II because of the very large rise in the use of leaded gasoline in various countries in the Southern Hemisphere, combined with the continuous increase in nonferrous metal production in South America, southern Africa, and Australia. Finally, lead concentrations strongly declined from the mid-1980s onwards, because of the fall in the use of leaded gasoline in modern cars.

Various other metals have also been determined in the Antarctic snow archives. The time series obtained show a clear increase in the concentrations of chromium, copper, zinc, silver, bismuth, and uranium during the twentieth century (Planchon et al. 2002). They are mainly linked with the emissions of these metals into the atmosphere from nonferrous metal mining and smelting in Chile, Peru, Zaire, Zambia, and Australia.

The general picture that is emerging from these studies is that the pollution of the atmosphere for heavy metals can be detected for many metals in Antarctica, that is, the most remote area of our planet. It means that atmospheric pollution for heavy metals is indeed global.

Scientists also analyze for heavy metals in very ancient Antarctic ice, whose age can reach more than 700,000 years. The goal is no longer to look at pollution, but rather to understand what the past natural concentrations of these metals in the atmosphere before any pollution were. Such information is necessary to put recent changes in a proper perspective (Hong et al. 2003).

Highly interesting data have also been obtained by analyzing heavy metals in the dated snow and ice layers deposited in Greenland, the Northern Hemisphere's counterpart to Antarctica. Greenland provides us with a good view of the history of heavy-metal pollution in the Northern Hemisphere. Amongst the most interesting results obtained in Greenland is the evidence of early pollution of the atmosphere of the Northern Hemisphere for lead and copper two millennia ago at the height of the Roman Empire (Hong et al. 1994, 1996). The determination of platinum, palladium, and rhodium in Greenland snow dated from the last few decades also showed evidence of large-scale pollution of the Northern Hemisphere for these metals linked with the ever-increasing use of automobile catalytic converters (Barbante et al. 2001).

Various studies are currently ongoing, especially for metals such as mercury.

POLYNYAS AND LEADS IN THE SOUTHERN OCEAN

The sea ice surrounding Antarctica and covering much of the Southern Ocean is far from homogeneous; instead it is littered with patches of open water and cracks. Larger, persistent areas of open water within the sea ice pack are called polynyas (a word of Russian origin), while linear cracks in the sea ice are called leads. These areas of open water have an important impact on both the ocean and the atmosphere, as they enhance energy and moisture exchange between the two. The elevated heat and moisture fluxes within polynyas and leads are signalled by what Apsley Cherry-Gerrard called "frost smoke"—a condensation fog that occurs a few metres above the surface as the air becomes saturated and water vapour condenses out. The impression one gets is of the ocean boiling like a kettle; given the enormous air–sea temperature differences (perhaps 30°C–40°C), the physics is not that different. Another signal of polynyas and leads is the dark "water sky" reflections that they cast upwards onto any low-level cloud. In the featureless, often all-white seascape of the sea ice pack, these water skies stand out. To the present day they provide a navigational beacon for ships crossing the sea ice pack, indicating where the easy passages of open-water areas are situated.

Polynyas are typically rectangular or elliptical in shape and occur regularly in the same location. They can be classified by location as either coastal (or shelf-water) polynyas if they are over the continental shelves, or as open-ocean (or deep-water) polynyas if they are located farther offshore. Polynyas are typically tens to hundreds of kilometres in scale. Leads are typically much narrower across, from tens of metres to a few kilometres, but can be up to hundreds of kilometres long.

The topological distinction between polynyas and leads is reinforced by a causal distinction. Polynyas are formed by a coherent external forcing mechanism that either moves or melts the sea ice, for example, advection by strong winds and ocean currents or melting by warm water. In contrast, leads are formed by an internal deformation of the sea-ice pack, where cracks develop somewhat at random as a result of sea ice dynamics. This means polynyas tend to occur in fixed and predictable locations, for example, tied to particular parts of the coastline or to seamounts, whereas leads occur seemingly at random as the sea ice cover is shattered by internal stresses. Of course, the sea ice is also externally forced by wind stress, ocean currents, and tides.

Coastal polynyas generally form when strong persistent winds blow the sea ice offshore. Hence they tend to be located on coastlines prone to persistent offshore winds, often topographically driven, such as katabatic winds or barrier winds. For example, there are recurrent coastal polynyas off the Ronne Ice Shelf, the Ross Ice Shelf, and the Mertz Glacier, and in Terra Nova Bay. As sea ice is advected offshore, an area of near-freezing water opens up and fluxes of heat from the relatively warm water into the cold atmosphere result in the formation of new sea ice. The latent heat that is released during this freezing means these polynyas are traditionally known as "latent heat" polynyas, although in this case "wind-driven" would be a better description, as this is what drives their life cycle.

During an episode of relatively strong offshore winds, a coastal polynya will act as a site of enhanced ice production. In particular, millimetre-scale frazil ice crystals are formed throughout the water column. The frazil ice rises and is collected into slurries, often organised into a downwind-oriented band by circulations in the surface waters called Langmuir circulations. These slurries, also known as "grease ice," are on the order of 10 cm deep, and damp the surface waves. The frazil and grease ice are advected downwind, with this mixture eventually piling up against the downwind consolidated ice pack. During this advection, the ice will coalesce and freeze into a more solid ice covering, but also be broken into metre-sized discs, or "pancake ice," through swell and wave action. Coastal polynyas have been dubbed "ice factories," producing ten times more than the average sea ice thickness around Antarctica. Once the winds drop, offshore ice advection slows, and the new ice that is being formed will gradually seal over the polynya. The balance between ice advection and ice production determines the width of coastal polynyas. For the same wind speed, lower air temperatures lead to higher ice production and so narrower polynyas, while higher air temperatures lead to lower ice production and so wider polynyas.

Open-ocean polynyas form over deeper waters, that is, off the continental shelves, although they are often associated with submarine mountains. The most intriguing example was the "Weddell Sea Polynya" of 1974–1976, when an area the size of France remained largely ice free for three consecutive winters, yet this has not occurred to the same extent since. It was only observed by the very new (at that time) satellite-borne passive microwave remote sensors. It originally formed over the Maud Rise seamount (65° S, 6° E), but moved westwards during the 3-year period. There are also recurrent open-ocean polynyas over Maud Rise and in the Cosmonaut Sea. Open-ocean polynyas are generally formed by an upwelling of warmer waters from depth, triggered by submarine topography, weak vertical stratification, eddy formation, tidal motion, or some combination of factors—indeed, their formation is still a matter of debate. The warm waters melt existing sea ice and prevent new ice from forming, thus keeping the polynya open and giving rise to the term "sensible heat" polynyas. They are to some degree self-sustaining, as the surface waters of the polynya are cooled by the atmosphere, leading to sinking and turbulent convection. The convection will cease as the cooling decreases in spring, or it can be shut off earlier by a fresh-water cap formed by lateral advection or melting and precipitation.

Most coastal polynyas tend to be wind-driven, or current-driven, while most open-ocean polynyas tend to be thermally driven. However, some polynyas have combinations of these mechanisms; for example, the Ross Ice Shelf polynya is primarily controlled by synoptic-scale weather systems forcing ice divergence in front of the ice shelf, but an upwelling of warm water also contributes to this region's being prone to thin ice and open-water areas.

Radiation is also important in controlling the surface energy balance of polynyas and leads. During winter, the relatively warm surface means a relatively large upward longwave (infrared) radiative flux, contributing to a cooling of the ocean. During spring and summer, polynyas and leads absorb more shortwave (solar) radiation due to their lower albedos, and so contribute to an enhanced warming of the ocean, compared to the surrounding ice-covered areas.

Polynyas and leads are significant for the ocean, the atmosphere, human activities, and biology. For the ocean, their importance lies in their ability to change water properties. The role of coastal polynyas as zones of enhanced sea ice production means they are sources of salt (as some salt is rejected as sea water freezes) and so act to make the surface waters more saline and dense. Over continental shelves such as in the southern Weddell Sea, this creates High Salinity Shelf Water, which sinks and then predominantly circulates underneath, and interacts with, the Ronne-Filchner Ice Shelf, eventually leaving this cavity as Ice Shelf Water. This then mixes with other water masses, ending up leaving the continental shelf to form Antarctic Bottom Water—the deepest water mass of the world's oceans. The rate of ice formation within coastal polynyas is a key component in this chain of events and so plays a role in forcing the ocean's thermohaline circulation. Open-ocean polynyas also create dense water masses through a cooling throughout the depth of the ocean by open-ocean convection (i.e., a cooling into the atmosphere). Water mass transformations will also be enhanced by elevated cooling and brine rejection under leads; however, due to their more random location, such transformations are not as concentrated into particular locations and so perhaps less directly relevant for ocean circulation.

During winter, exposing areas of relatively warm open water also has a dramatic impact on the atmosphere, acting as a source of heat and moisture at the surface. Polynyas and leads act to warm and moisten the atmosphere and induce a convective well-mixed boundary layer. The convective circulation will be of a similar horizontal scale to the heating source (i.e., the polynya or lead). So polynya-induced atmospheric modifications can be tens to hundreds of kilometres in scale, and reach thousands of metres in height. Polynyas act through warming and, in general, accelerating the atmospheric boundary layer to develop mesoscale cyclones, enhance synoptic-scale cyclones, and accelerate katabatic flows through an "ice-breeze" mechanism. In contrast, lead-induced atmospheric circulations will tend to be much smaller, only hundreds to thousands of metres across and generally limited to tens to hundreds of metres vertically.

In addition to local changes to the atmospheric circulation, the integrated affect of polynyas and leads is to enhance the transfer of heat and moisture from the ocean to the atmosphere. For much of the year, a great deal of the Southern Ocean is insulated from the atmosphere by sea ice. Any areas of open water break through this insulation. So within polynyas and leads the air-sea turbulent heat exchange can be up to two orders of magnitude higher than over the surrounding sea ice. Therefore, although the areal coverage of polynyas and leads is small, only a small percent of the total area covered by sea ice, their contribution to warming the atmosphere and cooling the ocean is large.

As mentioned earlier, polynyas and leads provide natural routes for ships crossing the ice-covered seas. In addition to aiding immediate navigational choices, the larger predictable areas of open water or thin ice have for years been used as preferred shipping lanes for the resupply of Antarctic bases. For example, during the resupply of the British Antarctic Survey's Halley Research Station, on the Brunt Ice Shelf, in the southeastern Weddell Sea, the ships always curve well to the east of a straight line from the Falkland Islands, or South Georgia, to pass through the recurrent polynyas and thin ice in the vicinity of Maud Rise around 0°–5° E.

Polynyas and leads are havens of biological and wildlife activity. Sea mammals need breathing holes in the sea ice, so they tend to concentrate in polynyas, while during summer, polynyas' lower ice concentration means an earlier melt back, a larger annual absorption of solar radiation (due to a lower albedo), and so higher primary productivity. This attracts krill and therefore penguins, birdlife, and sea mammals to these areas.

Numerous mathematical models of individual polynyas and leads have been developed, to examine polynya dynamics, sea ice dynamics, and the impact of polynyas and leads on the circulation of the atmosphere and the ocean. It is now realised that some representation of polynyas and leads is also required in large-scale climate models, but due to their relatively small size their primary effects—heating the atmosphere and cooling the ocean—have to be represented in a simplified manner. Given the limited observations and developing understanding of the physics of polynyas and leads, their representation in climate models is presently crude and very much an area of active research.

PONIES AND MULES

Shackleton's British Antarctic Expedition

With hindsight it is easy to say that the use of ponies as draught animals in the Antarctic was a poor choice. However, at the time Ernest Shackleton first took ponies to the continent on his British Antarctic Expedition (1907–1909), there were plausible reasons for the decision. Shackleton believed that the dogs that had gone south across the Ross Ice Shelf with Robert Falcon Scott, Edward Wilson, and him on the British National Antarctic Expedition in 1902–1903 had failed. That the three men had no previous experiences working with or driving dogs, and had therefore not truly known how to do so, did not seem to enter into his assessment.

Shackleton was told of the advantages of ponies by Albert Armitage, second-in-command of Scott's expedition, who had also been a member of the Jackson-Harmsworth Expedition to Franz Josef Land in 1894–1897. So when he considered modes of transport for his own expedition, Shackleton consulted Frederick Jackson, the leader of that earlier expedition. Jackson felt the ponies he had used had been an unqualified success, and he pointed out that ponies had been used extensively in other cold northern lands, as indeed they had recently in the Russo-Japanese War. There was also a feeling that ponies would withstand the cold better than dogs, drag heavier loads on less food, and provide good meat for humans.

Shackleton arranged for the purchase of fifteen Manchurian ponies from northern China. They were each approximately 14 hands in height and estimated to be 14–17 years old. From China they were taken by ship to Lyttelton, New Zealand, where they were quarantined on Quail Island. W. H. Tubman, a local horse trainer, and Dr. Alistair Mackey of the expedition looked after the ponies, which had the reputation of being wild and difficult to manage. They broke them in to the practice of hauling sledges. However, *Nimrod,* the expedition ship, was so small that only ten could be taken south. Their food consisted of 20 tons of maize, 1000 pounds of Maujee ration, known as "Equine pemmican" (dried beef, carrots, milk, currants, and sugar), and 10 tons of compressed fodder of oats, bran, and chaff obtained in Australia.

Before Shackleton's party was able to land, two of the ponies had been destroyed. The others became the first to be landed in the Antarctic on February 5, 1908, and were soon being used to help haul materials as the ship was unloaded. A special shelter for the ponies was built against the hut using maize bales and canvas tarpaulin for the roof. The snow that piled up around it gave further insulation. Within the first month of being at Cape Royds, four more of the ponies died from eating either large quantities of salt-covered sand or corrosive materials that had been stored nearby.

Only four ponies—Quan, Socks, Grisi, and Chinaman—were left to face the winter. Quan was a trouble-maker, biting and kicking and making a din at night, but he nevertheless became a favourite. Grisi was aggressive toward the other ponies. There was a night light in the "stable," and a nightwatchman inspected it every 2 hours. The shelter was shared with the dogs.

With only four ponies left, Shackleton reduced his southern party from six to four men, and they left Cape Royds on October 29 to try to reach the South Pole. From the start, the ponies proved to be problematic. Within an hour of their departure Socks went lame, and then at lunch Grisi kicked out, catching

Jameson Adams 3 inches below the knee and exposing the bone. It was soon shown that the poor creatures simply were not appropriate for travel in a glacial environment. They constantly broke through the crust of snow that dogs would have lightly run across. They were not designed for the cold weather, as they sweated throughout their bodies and had hides that helped dissipate heat rather than retain it, which meant that when they had to bivouac outside each night, exposed to the bitter cold and wind, the men had to build snow walls to protect them from the wind, to rub them down, and to cover them with blankets. Then in the morning they had to scrape the snow off their hooves. Moreover, the ponies' food was excessively bulky.

The ponies soon began to wear down, and on November 21 Chinaman was put down. A week later it was Grisi's turn, and on December 1 Quan was killed after breaking down in harness. Only Socks was left, and on December 7, while the party was slowly making its way up the Beardmore Glacier, he went down a deep crevasse, almost pulling Frank Wild in with him, and depriving the men of what would have been an important supply of meat. So ended the first use of ponies in the Antarctic, but Shackleton's subsequent success in reaching a point only 97 miles from the Pole left open the question of whether, had Socks not been lost as both a puller and a food supply, Shackleton and his party might have been the first to reach the South Pole.

Scott's Last Expedition

When Scott planned his second Antarctic expedition, he included the use of several modes of transport, including ponies, dogs, and motor sledges. Although he has been criticized for bringing ponies, it must be remembered that Shackleton had made a remarkable journey with them, so it was logical for Scott to use them as well.

Scott sent his brother-in-law, Wilfred Bruce, to obtain ponies from Harbin in northern China. He was assisted by the Russian jockey Anton Omelchenko, who was hired to look after them on the journey. Money donated by schools, clubs, and individuals paid for the 20 animals selected, 18 Manchurian and 2 Siberian ponies 14–15 hands high. At Vladivostok, Bruce and Omelchenko met up with Cecil Meares, Dmitri Gerof, and their Siberian huskies. The party traveled to Lyttleton via Kobe, Japan, and Australia, spending 52 days aboard ship before reaching Quail Island.

Captain L. E. G. Oates, who was in charge of the ponies, had had extensive experience with horses in England, during the Boer war, and in India. He purchased extra fodder himself for the ponies and had it put aboard *Terra Nova*. The ponies were reported to be rather old and not in tip-top condition. A storm on the way south accounted for the loss of two of the ponies. However, once on land the ponies were staked on snow away from the volcanic ash and sand that had proven fatal for Shackleton's animals.

Much else had been learnt from Shackleton's experiences, and the ponies' legs were protected from the ice with puttees, thick rugs were worn, and snow shelters were built at each stop. However, they still suffered from thinning coats, which might have been due to their transfer from the Northern Hemisphere and subsequent lack of time for winter coats to grow.

The first autumn depot-laying journeys were disastrous. Six of eight ponies were lost, three due to poor condition, others on an unfortunate incident on the sea ice near Hut Point, and Hackenschmidt died on a separate journey.

Despite some medical problems, the ponies flourished under Oates' care, and there were thirteen ready for the main sledging journey in the spring, the start of which, unfortunately, was delayed to allow for better conditions for the ponies. As on Shackleton's expedition, the ponies worked well at the beginning of the journey, pulling loads in excess of 500 lbs. Soft, deep snow, blizzards, and cold took their toll, however, and Jehu was shot on November 24 and three more in the first days of December. The long blizzard, starting on December 5, was as hard on the ponies as on the men. The relationship between the men and ponies was shown when Edward Wilson fed Noddy his precious biscuits, despite knowing his equine friend was due to be shot the next day. On December 9, the five remaining ponies—Snippits, Jimmy Pigg, Nobby, Bones, and Snatcher—were destroyed as their fodder had run out and the men had reached the edge of the Beardmore Glacier.

Mules

Before Scott left New Zealand in 1910, he and Oates had decided to obtain mules for their second season in the Antarctic. They wanted trained Indian mules, which were donated by the Indian government. A small group of 7-year-olds standing about 13 hands were chosen. Much thought was given to their preparation for the Antarctic. They were trained at high altitude and a special "rocking box" was used to simulate the movement of the ship. The idea was to strengthen their muscles so that the journey to New Zealand and then on to the Antarctic would be less of an ordeal than it had been for the ponies.

The mules arrived in New Zealand in September 1911, equipped with rugs and leg coverings lined with thick felt and laced with canvas. These were manufactured at the Elgin Mills, Cawnpore. Eye shades, head pieces, and tethering chains covered with thick felt and leather showed the care taken in their preparation.

James Robert Dennistoun, a New Zealand farmer and mountaineer, looked after them on Quail Island. Good horse boxes were provided for *Terra Nova* and placed facing inwards. Eyebolts were fixed to these temporary stables so that a fallen mule could be winched up. On the voyage south, the mules received three feeds a day and plenty of water.

Apsley Cherry-Garrard and Tom Lashly took charge of the mules in the Antarctic, but each was assigned to a leader for field work: Khan Sahib to Edward Nelson, Lal Khan to Tryggve Gran, Pyaree to Lashly, Rani to Tom Crean, Gulab to Thomas Williamson, Begum to Patrick Keohane, and Abdullah to F. J. Hooper.

The mules were part of the search party that found the bodies of Scott, Wilson, and Birdie Bowers on the Ross Ice Shelf on November 11. The next day, Lal Khan and Khan Sahib were shot due to poor condition. Bad weather conditions on the return contributed to the deterioration of Begum and Abdullah, and they were destroyed. Finally, the remaining three mules were shot at Cape Evans just prior to the party's final departure from the Antarctic in January 1913.

PRECIPITATION

The Antarctic is generally regarded as the "White Desert," which implies a significant aridity over the continent as a whole, where it averages 20 cm per annum water equivalent (w.e.) or 50 cm snow. However, it is clear that there are considerable spatial and temporal variations in precipitation over a continent some 13 million km^2 in size and ranging in altitude from low-lying coasts to above 4000 m above sea mean level. It should be noted that *in situ* measurements of Antarctic precipitation are extremely limited, due to the imprecise nature of snow-gauge data. More reliable precipitation trends are associated with snow stake surveys and related pit excavations, where snow densities and water equivalent values can be determined. Also, the analysis of annual accumulation layers in ice cores has provided useful data, and satellite observations are used to determine ice-thickness changes at a variety of scales.

The measuring stations are only sparsely distributed over the continent and are concentrated along the coast, where local orographic controls are influential (e.g., at Law Dome, Wilkes Land). Furthermore, their observation record is relatively short and has been interrupted by station closures and transfers. Climate models (e.g., the Regional Atmospheric Climate Model [RACMO]) are used to reveal precipitation trends but need verification by additional measurements and/or ice core data.

Precipitation occurs when saturated air is forced to rise by free or mechanical convection, which cools adiabatically and condenses. The resultant hydrometeors eventually exceed their terminal velocity through a number of growth mechanisms, especially the Bergeron-Findeisen process associated with the coexistence of supercooled droplets and ice crystals. This results in precipitation that in Antarctica is mostly in a solid form, although on the coast, up to 1 cm rain per annum is recorded, whereas the northern parts of the Antarctic Peninsula receive up to 10 cm rain per annum. Mechanical or forced convection dominates vertical air movement in Antarctica, since the lapse-rate steepening requirement for free convection is negated by the persistent temperature inversion. It is mainly associated with orographic uplift and frontal displacement combined with the mass convergence of air in low-pressure systems. These convective controls dominate the distribution of precipitation in Antarctica. For example, the flat inland ice domes of East Antarctica are arid since precipitation is less than 10 cm w.e. per annum. This true polar desert is remote from coastal depressions/cyclones and orographic enhancement and is influenced more by the persistent glacial anticyclone and associated air subsidence and katabatic air flow.

Consequently, some 90% of the precipitation that occurs above 3 km on the Antarctic plateau is associated with an unusually strong advection of maritime air above the stable surface inversion. This invading airstream cools adiabatically and becomes supersaturated with ice crystals, which are precipitated on to the plateau surface from clear skies. Conversely, coastal Antarctica is directly influenced by migratory depressions and fronts. On the advancing edge of the low, the northerly Southern Maritime airstream has a high moisture content, which, coupled with dynamic and frontal uplift, accentuates precipitation along the coasts (exceeding 40 cm w.e. per annum) and Antarctic Peninsula. Here, precipitation exceeds 60 cm w.e. per annum and approaches 150 cm in some sources. Orographic enhancement is evident along the windward slopes of the peninsula, Marie Byrd Land, and the Transantarctic Mountains, where precipitation is concentrated. However, the ice-free Dry Valleys (so called oases), such as the Wright Valley in Victoria Land, are maintained by a strong snow-shadow effect, excessive deflation, and sublimation in this windy and dry environment.

The strong orographic control on Antarctic precipitation is confirmed by climate/atmospheric modelling. Over the Antarctic Peninsula, maximum precipitation exceeds 200 cm w.e. per annum on the northwest slopes, compared with less than 50 cm in the snow shadow of the eastern slopes. The modelling also confirmed very strong windward and snow-shadow effects on a local scale in coastal East Antarctica, where topographic promontories block the circumpolar easterlies. For example, Law Dome in Wilkes Land had strong east-to-west precipitation gradients with distinctive snow-shadow effects on the leeward slopes.

Temporal precipitation trends in Antarctica appear to be related to the strengthening of the circumpolar vortex in the Southern Hemisphere Annual Mode (SAM) or Antarctic Oscillation (AAO) in the summer and autumn/fall seasons in recent decades. The resultant zonal/westerly air flow advects warm moist maritime airstreams over the Antarctic Peninsula. A strong circumpolar vortex (i.e., high AAO index) is responsible for significant changes in precipitation (reaching 99% confidence levels). For example, increases up to 30% are found over the warming western Antarctic Peninsula, while the cooling western Marie Byrd Land and East Antarctic show decreases of a similar magnitude. However, in the snow shadow zone of the eastern side of the Antarctic Peninsula, precipitation patterns remain constant.

PRIESTLEY, RAYMOND

Raymond Edward Priestley, Kt, MC, DSc, MA, was born on July 20, 1886, at Tewkesbury in the west of England, the second son of the headmaster of the local grammar school.

It was through a chance encounter in 1907 at University College, Bristol, where he was completing the second year of a geological degree, that he was recommended for Ernest Shackleton's British Antarctic Expedition. A scientist who had been south with the *Challenger* Expedition (1872–1876), and was then working at Bristol Museum, had just declined an invitation to join Shackleton when Priestley's older brother walked in. It was suggested to him that the younger Priestley might be interested in going as the expedition's geologist. He was. A casual interview in London followed, and soon thereafter he was set to work sorting out equipment.

He was curious to know why he had been chosen instead of any of the dozen well-qualified applicants, and was told later by Jameson Boyd ("Bill") Adams that the other recruits were "real hard nuts" and that Shackleton had commented "Well! Anyhow I can manage that fellow!" Thus it was that Priestley got his first chance in scientific life. But Shackleton was a shrewd judge of character and the youthful, quiet, conscientious, hard-working Priestley proved to be one of the most useful and best-liked of the expedition members.

On arrival at McMurdo Sound in January 1908, he was incapacitated by an old knee injury and was temporarily relegated to caring for the eight ponies, but was soon working with Professor T. W. Edgeworth David of Sydney University, a world-renowned geologist who became his mentor and life-long friend. It was typical of Priestley that when David officially joined the expedition after it had sailed—thereby replacing Priestley as head geologist—rather than being upset by an effective demotion, he was enormously excited and positive because it would mean better scientific results for the expedition.

In between transport rehearsals, with ponies, man-hauling, and an Arrol-Johnston car, David, Priestley, and Douglas Mawson—another Australian geologist who had actually been appointed as the expedition physicist—collected as many geological specimens as far afield as possible. In March 1908, David led the first ascent of the active volcano Mount Erebus (12,450 feet/3795 m), conducting observations and collecting samples at the craters. (Priestley led a second ascent in 1912, during Robert Falcon Scott's *Terra Nova* expedition.) That winter, Priestley also took over the biological dredging while the biologist James Murray was unwell.

Shackleton's main summer journey was a bid to reach the South Pole while a second party, led by David, located the South Magnetic Pole. Having helped lay depots for both polar parties, Priestley, Sir Philip Brocklehurst, and Bertram Armytage began geological work at "Dry Valley" and later the Ferrar Glacier. Very few fossils and no valuable minerals were found, but their work was nevertheless of great interest, and they corrected the maps made on Scott's first expedition.

The expedition returned to New Zealand in March 1909, and Priestley eventually joined David in Australia to work on their rock collections. A monograph, published jointly, was the first attempt to elucidate the structural geology of South Victoria Land and was part of Priestley's work for a research degree. Another important result came by chance when on the way home he just managed to rescue a piece of limestone that Frank Wild had collected from the Beardmore Glacier and was about to give away. Thin sections revealed that it was full of fragments of *Archaeocyathus,* a common ancestor of sponges and corals, the only recognisable fossil collected on the expedition. It was eventually the subject of a memoir by Professor Griffith Taylor.

In December 1910, one of Scott's recruits for the *Terra Nova* expedition became ill and Priestley was asked to replace him. Once more he left university without a degree and, according to his diary, "So began the second chapter of adventure, twice as long, twice as exciting and twice as profitable...."

Back in the Antarctic in January 1911, Priestley was assigned to Victor Campbell's Northern Party, which wintered at Cape Adare and was later stranded at Evans Cove when *Terra Nova* failed to relieve them. The six men spent an appalling winter in a small ice cave on Inexpressible Island, with only 6 weeks' planned provisions and a small quantity of seal and penguin meat, using blubber for light and heat. It is a measure of the esteem in which the ever-cheerful and competent Priestley was held that he was put in charge of the rations. In the spring, half-starved, with worn clothes and tents torn to ribbons, they struggled back to base at Cape Evans, where they learnt of the loss of Scott's Pole party. Some of their own notes and specimens survived and were later worked on. Samples from Priestley Glacier contained pieces of a fossil tree, later named *Antarcticoxylon Priestleyi,* evidence of a subequatorial past.

Priestley received a Polar Medal and Clasp for his Antarctic service. After distinguished service in France during World War I, for which he was awarded the Military Cross, he was seconded to the War Office to write official histories. He returned to Cambridge in 1920, where he at last gained his degree and was elected Fellow of Clare College. Frank Debenham, Griffith Taylor, and Charles Wright were also in Cambridge working on expedition reports, and Priestley became involved with Debenham in the founding of the Scott Polar Research Institute.

In 1934, Priestley was appointed Registrar General of the Faculties, the first of his many academic posts, and a year later became Vice-Chancellor of Melbourne University. 1n 1938, he was appointed Principal and Vice-Chancellor of Birmingham University, where he remained until his retirement in 1952, serving on numerous committees and being made a member of the Asquith Commission on Higher Education in the Colonies. He was knighted in 1948 for his services to education.

He was appointed chairman of the Royal Commission on the Civil Service (1953–1955), president of the British Association for the Advancement of Science (1956), a member of the Royal Society's Antarctic Committee (1955–1958), president of the Royal Geographical Society (1961–1963), and acting director of the Falkland Islands Dependencies Survey, later renamed British Antarctic Survey (1955–1958). To all of these he bought wisdom, experience, and energy.

In 1957, Priestley accompanied H. R. H. the Duke of Edinburgh on a tour of the British Antarctic bases, and he was a guest of Operation Deep Freeze IV in 1958–1959. The latter enabled him to revisit the scenes of his early labors.

In 1915, Priestley married Phyllis Mary Boyd, a New Zealander, by whom he had two daughters. Lady Priestley died in 1961 and Sir Raymond on June 24, 1974.

PRINCE EDWARD ISLANDS

The Prince Edward Islands are an archipelago of two small islands located at 46°54′ S, 37°45′ E. Marion Island rises to 1230 m and has a surface area of approximately 290 km^2, whilst the smaller Prince Edward Island (45 km^2) lies 22 km northeast of Marion Island and rises to 672 m. The islands represent the peaks of two coalescing shield volcanoes, with an oldest recorded date of 450 ka for rocks on Marion Island. The islands are entirely oceanic in origin and their lavas (Aa, pahoehoe, and block lavas) are basaltic, with pyroxene, olivine, and feldspar predominating. The last eruptions were small, nonpyroclastic outflows in 2004 and 1980, although scoria cones across the islands testify to earlier more explosive events. Typically, the lavas are divided into older "grey" (276–100 ka) and younger "black" (15 ka to 400 years) lavas, although the distinction is often not clear. Volcanism is thought to have been initiated by isostatic adjustment, especially following deglaciation at the end of the last glacial maximum.

Marion Island shows signs of five to eight glaciations during the Quaternary. Landforms such as erratics, striae, and moraines all testify to substantial glacial activity. By contrast, there is little evidence for glaciation on Prince Edward Island. Temperatures during the last glacial maximum were 2°C–4°C lower than at present and the whole of Marion Island may have been covered by ice, with the exception of some areas such as Feldmark Plateau and parts of Long Ridge. The young landscape of the islands is highly dynamic. Important features include stone stripes that are a consequence of interactions between wind and surface cooling, solifluction terraces, especially those associated with the cushion-plant *Azorella selago,* surficial creep by needle ice, frost heave, and lens formation. Permafrost occurs at altitudes above 1000 m, but is rapidly degrading as a consequence of current warming. The small stationary glacier between the peaks is likewise rapidly declining in extent.

The islands have a cool oceanic climate with little seasonal or diurnal variation. Mean annual temperature is 6.2°C, and total precipitation is c. 2000 mm. The winds are typically westerly or northwesterly, often reaching gale force. Cloud cover is high and snow may fall at any time of the year, although it is more common in winter with the snow line descending to c. 500 m. During summer the peaks may be almost entirely free of snow. The weather is a consequence of periodic cyclones that bring warm, northwesterly winds and rain to the islands. As these cold fronts pass, the winds switches to the southwest, bringing cold, clear-sky conditions associated with snow and graupel showers. Microclimates are typically warmer, with the western sides of the island also warmer and moister than the eastern. During the past 50 years, conditions have changed substantially at the islands. Mean annual temperature has increased by slightly more than 1°C, annual rainfall has declined by 600 mm, and the frequency of easterly winds and sunny days has increased. There has also been a southward shift in the sub-Antarctic front, associated with warmer sea temperatures and a planktonic biota more typical of warm water bodies.

Biogeographically, both the marine and terrestrial components of the biota have their strongest relationships with other South Indian Ocean Province islands, such as Îles Crozet and Îles Kerguelen.

However, weaker relationships with the Antarctic, southern continents, and Africa are also evident. The islands are home to many species of algae, bryophytes, and lichens, twenty-seven species of vascular plants, many marine invertebrates, about one hundred terrestrial free-living invertebrates, twenty-nine seabird species, three seal species, and a resident population of killer whales. Globally significant populations of several pelagic seabird species breed on the islands, including the wandering albatross, Crozet shag, and Indian yellow-nosed albatross. The fish fauna are comparatively poorly known, although *Dissostichus eleginoides* (patagonian toothfish) was commercially exploited in the 1990s.

The vegetation can be split into two major biomes: polar desert and sub-Antarctic tundra. Polar desert occurs at elevations above 500 m. Here, there are no closed plant communities, and the cushion-plant *Azorella selago* is the only vascular plant species found in the biome, although it also disappears above c. 800 m. Polar desert is dominated by bryophytes and lichens, which are more common on less mobile substrates such as welded scoria or grey lava outcrops. The sub-Antarctic tundra biome can be divided into six major complexes, which are a consequence of differences in water availability and movement, and nutrient availability. These are the coastal salt-spray complex, fellfield complex, slope complex, biotic grassland complex, biotic herbfield complex, and mire complex. Invertebrate assemblages can be classified in a similar way, largely reflecting their response to the abiotic environment and the plant communities, although they also show much finer-scale spatial structuring.

The islands were discovered in 1663 by Barent Barentzoon Ham, and the first recorded landing was by a party of sealers in 1803/1804. Subsequently there was considerable sealing activity, and the islands were visited by several scientific expeditions, including *Challenger,* which was the first to put scientific personnel ashore. Owing to their strategic position, the islands were annexed for the colonial government of South Africa in 1947 by Lieutenant-Commander John Fairbairn of HMSAS *Transvaal*. Since then, South Africa has maintained a station at the islands. At first it was used solely for meteorological observations. The first biological and geological expedition took place in the 1965/1966 season, and both marine and terrestrial scientific research have been ongoing at the islands since that time. The dynamics of these systems and their interactions are now especially well studied and form the basis for ongoing investigations of system responses to environmental change.

Major conservation threats to the islands' biota and ecosystems include invasive alien species, global climate change, and exploitation of marine resources, which has both direct and indirect effects on pelagic seabirds and seals. The islands have been declared Special Nature Reserves under the South African National Environmental Management: Protected Areas Act, the highest level of protection any area can enjoy. They may be used for conservation and science only and are managed by the Prince Edward Islands Management Committee. Recently, the South African government announced its intention to declare the surrounding seas a Marine Protected Area.

PRODUCTIVITY AND BIOMASS

Biomass is defined as the total weight (total numbers × average weight) of organisms in a given area or volume. *Productivity* is the amount of biomass produced in an area or volume over a period of time. It can be divided into *primary productivity,* which refers to the production of biomass by plants through photosynthesis, and *secondary productivity,* which is the rate of production of biomass by heterotrophs (organisms that consume other organisms).

Patterns of primary productivity dictate the structure of biological communities. Antarctica does not support many land-living plants and virtually all primary production takes place in the sea by small, single-celled algae called phytoplankton. Most are found either suspended close to the sea surface or attached to surface-dwelling ice so that they can obtain sufficient amounts of light. Phytoplankton have relatively short life cycles, lasting days to weeks, which results in a high rate of turnover. This can be described in terms of the ratio of annual production to biomass, (P:B y^{-1}), which is >10 y^{-1} for Southern Ocean phytoplankton compared with ~ 0.3 y^{-1} for terrestrial systems in other parts of the world, where biomass persists for years in trees.

Since the 1980s, satellites have mapped the colour of the surface of the ocean in order to determine the distribution of phytoplankton biomass. They found the Southern Ocean to be highly heterogeneous, with phytoplankton biomass tending to be low in open ocean regions and very high around island systems, oceanic fronts, and retreating ice edges. The availability of the trace element iron, which is required for photosynthesis, may be a cause of these differences.

Secondary productivity depends on primary productivity and there is frequently a positive relationship between the two. As a general rule, secondary productivity in herbivores is ten times less than the primary production on which it is based. This is because a lot of phytoplankton goes ungrazed, especially in Antarctica, where superblooms of diatoms and dinoflagellates saturate herbivore consumption. Further energy is lost through incomplete assimilation and respiration before consumed matter is converted to body mass. Planktonic heterotrophs have longer life cycles and slower turnover rates than phytoplankton: salps *(Salpa thompsoni)* live for about a year; krill *(Euphausia superba)* and copepods (e.g., *Calanoides acutus* and *Rhincalanus gigas*) live for 2 or more years. Correspondingly, their P:B ratios are lower (normally between 1 and 3 y^{-1}) than those of phytoplankton. The persistence of these animals over time means that their biomass levels can exceed those of phytoplankton, despite their smaller productivities. Around South Georgia, for instance, the combined biomass of krill and *C. acutus* (in grams carbon per m^2) is ~ 2.5, while that of phytoplankton is ~ 1.

The P:B ratios of benthic organisms (0.1 to 0.8 y^{-1}) are even smaller than those of zooplankton, reflecting the fact that most of these organisms have a long lifespan (>3 y) and generally grow slowly. Very few other benthic communities in the world reach the high levels of biomass observed on Antarctic shelf environments. In shallow waters the biomass (like biodiversity) is typically 10–1000 $g.m^2$ and can be very patchy. Sheltered areas may accumulate biomass >5000 $g.m^2$ whilst recently ice scoured areas can be ~ 1 $g.m^2$ or even less. Being large increases food-capturing area, which helps these creatures to make the most of the oscillating seasonal food supply as it falls from the productive layers above. The low ambient temperatures in this environment increase the availability of oxygen dissolved in water and reduce the maintenance costs that would otherwise prevent these animals from achieving such sizes.

PROTECTED AREAS WITHIN THE ANTARCTIC TREATY AREA

The Antarctic Treaty Area is a protected area. The Antarctic Treaty itself contains measures to protect the region from damage by nuclear explosions and radioactive wastes, and in Article IX the intent was made clear that measures should be taken for the preservation and conservation of living resources. However, the treaty itself was not designed primarily for environmental protection, and soon after the treaty entered into force the parties introduced the Agreed Measures for the Conservation of Antarctic Fauna and Flora (1964), in which Antarctica was designated a "Special Conservation Area." From the outset, there was a recognition that despite the special conservation status accorded the region as a whole, there would be a need for more specific and stringent protection at particularly special or vulnerable sites. Thus, Article VIII of the Agreed Measures provided for designation of Specially Protected Areas (SPAs). The principal aim of SPAs was to preserve ecological systems that were unique or of outstanding scientific importance. All entry to SPAs was prohibited except in accordance with a permit, which could only be granted for a compelling scientific purpose that could not be served elsewhere.

There was also recognition of the need to afford protection to Historic Sites and Monuments (HSMs) at the first meeting of the treaty parties in 1961, and a formal list of sites was first adopted in 1972. In the same year, the Site of Special Scientific Interest (SSSI) category was introduced. In 1975, the category of Areas of Special Tourist Interest was agreed on, although none were ever designated. The category of Marine SSSI was introduced in 1987, while in 1989 two further categories, Specially Reserved Areas (SRAs) and Multiple-Use Planning Areas (MPAs) were agreed on. A special category, "Tomb," was assigned to the site of the 1979 aircraft crash on Mount Erebus, Ross Island, in order to ensure that it was left in peace. The purpose of these additional categories was to encompass a broader set of values for special protection than was possible under the provisions of the SPA. Although these categories did allow for inclusion of wider values, there remained lacking an overall strategic vision for development of the system.

At the time of agreement of the Protocol on Environmental Protection to the Antarctic Treaty in 1991, nineteen SPAs (fifteen of which were designated in 1966 soon after the category was introduced), thirty-five SSSIs (five of which were Marine), one Tomb, and fifty-nine HSMs had been designated. One SRA and one MPA were agreed on for voluntary observance, although these were never formally designated.

The Protocol on Environmental Protection to the Antarctic Treaty, in Article 2 (Objective and Designation), declares Antarctica "a natural reserve, devoted to peace and science," reaffirming the special conservation status accorded the area under the Agreed Measures. Moreover, the Protocol took steps to rationalize the rather unwieldy Antarctic protected area system that had evolved by replacing all of the previous categories, with the exception of HSMs, by two designations under Annex V on Area Protection and Management: Antarctic Specially Protected Areas (ASPAs) and Antarctic Specially Managed Areas (ASMAs). When Annex V came into force on 24 May 2002, all SPAs and SSSIs previously designated were incorporated as ASPAs, and renumbered by a three-digit schema (ASPA No. 101, ASPA No. 102, etc.) to avoid confusion with the old system. Functions previously covered by the other categories are included under the provisions for ASPAs and ASMAs. HSMs continue much as before, although they may also be designated as ASPAs or ASMAs if required.

Article 3 of Annex V stipulates that any area, including any marine area, may be designated as an Antarctic Specially Protected Area (ASPA) to protect outstanding environmental, scientific, historic, aesthetic, or wilderness values, any combination of those values, or ongoing or planned scientific research. Designation of a marine area requires the prior approval of the CCAMLR Commission. Areas designated should be of "sufficient size" to protect the identified values. The purpose of the ASMA is to improve the coordination of activities and to help minimise environmental impacts or risks of mutual interference within a specified area. Management plans are required for both ASPAs and ASMAs, and include an identification of site values, management objectives, a site description, and policies for the conduct of activities within the area. Entry into an ASPA is prohibited except by a permit issued according to the conditions prescribed by the management plan. Entry into an ASMA does not require a permit, but activities within are guided by the management plan and a Code of Conduct.

As of June 2006 there were sixty-seven ASPAs and four ASMAs formally designated, as well as seventy-six HSMs.

An important advance in Annex V is that it provides a stronger strategic vision for the development of the Antarctic protected areas network, and aims specifically to establish it on a more systematic basis by including the following:

1. Areas kept inviolate so that they may be available for future comparisons with localities that may have been affected by human activities.
2. Representative examples of major terrestrial and marine ecosystems.
3. Important or unusual assemblages of species.
4. Type localities or the only known habitats of particular species.

Antarctic Specially Protected Areas (ASPAs) and Antarctic Specially Managed Areas (ASMAs) in the Antarctic Treaty Area as of June 2006

No.	Antarctic Specially Protected Areas	Former Site No.	Current Plan Adopted
101	Taylor Rookery, Mac.Robertson Land	SPA No. 1	1992
102	Rookery Islands, Holme Bay, Mac.Robertson Land	SPA No. 2	1992
103	Ardery Island and Odbert Island, Budd Coast	SPA No. 3	1992
104	Sabrina Island, Balleny Islands	SPA No. 4	N/A
105	Beaufort Island, Ross Sea	SPA No. 5	2003
	Cape Crozier, Ross Island—Redesignated SSSI No. 4 in 1975	SPA No. 6	2002
106	Cape Hallett, Victoria Land	SPA No. 7	2002
107	Emperor Island, Dion Islands, Marguerite Bay, Antarctic Peninsula	SPA No. 8	2002
108	Green Island, Berthelot Islands, Antarctic Peninsula	SPA No. 9	2002
	Byers Peninsula—Redesignated SSSI No. 6 in 1975	SPA No. 10	2002
	Cape Shirreff—Redesignated SSSI No. 32 in 1989	SPA No. 11	1989
	Fildes Peninsula—Redesignated SSSI No. 5 in 1975	SPA No. 12	1975
109	Moe Island, South Orkney Islands	SPA No. 13	1995
110	Lynch Island, South Orkney Islands	SPA No. 14	2000
111	Southern Powell Island and adjacent islands, South Orkney Islands	SPA No. 15	1995
112	Coppermine Peninsula, Robert Island, South Shetland Islands	SPA No. 16	1970
113	Litchfield Island, Arthur Harbour, Anvers Island, Palmer Archipelago	SPA No. 17	2004
114	Northern Coronation Island, South Orkney Islands	SPA No. 18	2003
115	Lagotellerie Island, Marguerite Bay, Antarctic Peninsula	SPA No. 19	2000
116	"New College Valley," Caughley Beach, Cape Bird, Ross Island	SPA No. 20	2000
117	Avian Island, off Adelaide Island, Antarctic Peninsula	SPA No. 21	2002
118	Summit of Mount Melbourne, Victoria Land (includes "Cryptogam Ridge")	SPA No. 22	2003
119	Forlidas Pond and Davis Valley ponds, Dufek Massif	SPA No. 23	1991
120	"Pointe-Géologie Archipelego," Terre Adélie	SPA No. 24	1995
121	Cape Royds, Ross Island	SSSI No. 1	2002
122	Arrival Heights, Hut Point Peninsula, Ross Island	SSSI No. 2	2004
123	Barwick and Balham Valleys, Victoria Land	SSSI No. 3	2002
124	Cape Crozier, Ross Island	SSSI No. 4	2002
125	Fildes Peninsula, King George Island, South Shetland Islands	SSSI No. 5	1975
126	Byers Peninsula, Livingston Island, South Shetland Islands	SSSI No. 6	2002
127	Haswell Island	SSSI No. 7	1975
128	Western shore of Admiralty Bay, King George Island	SSSI No. 8	2000
129	Rothera Point, Adelaide Island	SSSI No. 9	1996
	Caughley Beach—Incorporated into SPA No. 20 in 2000	SSSI No. 10	2000
130	"Tramway Ridge," Mount Erebus, Ross Island	SSSI No. 11	2002
131	Canada Glacier, Lake Fryxell, Taylor Valley, Victoria Land	SSSI No. 12	1997
132	Potter Peninsula, "25 de Mayo" (King George) Island, South Shetland Islands	SSSI No. 13	1997
133	Harmony Point, west coast of Nelson Island, South Shetland Islands	SSSI No. 14	1997
134	Cierva Point and offshore islands, Danco Coast, Antarctic Peninsula	SSSI No. 15	1997
135	Northeastern Bailey Peninsula, Budd Coast, Wilkes Land	SSSI No. 16	2003
136	Clark Peninsula, Budd Coast, Wilkes Land	SSSI No. 17	2000
137	Northwest White Island, McMurdo Sound	SSSI No. 18	2002
138	Linnaeus Terrace, Asgard Range, Victoria Land	SSSI No. 19	1996
139	Biscoe Point, Anvers Island	SSSI No. 20	2004
140	Parts of Deception Island, South Shetland Islands	SSSI No. 21	1985
141	"Yukidori Valley," Langhovde, Lützow-Holmbukta	SSSI No. 22	2000
142	Svarthamaren, Mühlig-Hofmannfjella, Dronning Maud Land	SSSI No. 23	2004
	Summit of Mount Melbourne—Incorporated into ASPA No. 118 in 2003	SSSI No. 24	2003
143	Marine Plain, Mule Peninsula, Vestfold Hills, Princess Elizabeth Land	SSSI No. 25	2003
144	"Chile Bay" (Discovery Bay), Greenwich Island, South Shetland Islands	SSSI No. 26	1987
145	Port Foster, Deception Island, South Shetland Islands	SSSI No. 27	1987
146	South Bay, Doumer Island, Palmer Archipelago	SSSI No. 28	1987
147	Ablation Valley–Ganymede Heights, Alexander Island	SSSI No. 29	2002
	Avian Island—Redesignated SPA No. 21 in 1991	SSSI No. 30	2002

Historic Sites and Monuments (HSMs) in the Antarctic Treaty Area as of June 2006

No.	Description	Proposer	Latitude	Longitude
1	Flag mast erected in December 1965 at the South Geographical Pole by the First Argentine Overland Polar Expedition.	Argentina	90° S	
2	Rock cairn and plaques at Syowa Station in memory of Shin Fukushima, a member of the 4th Japanese Antarctic Research Expedition, who died in October 1960 while performing official duties. The cairn was erected on 11 January 1961, by his colleagues. Some of his ashes repose in the cairn.	Japan	69°00′ S	39°35′ E
3	Rock cairn and plaque on Proclamation Island, Enderby Land, erected in January 1930 by Sir Douglas Mawson. The cairn and plaque commemorate the landing on Proclamation Island of Sir Douglas Mawson with a party from the British, Australian, and New Zealand Antarctic Research Expedition of 1929–1931.	Australia	65°51′ S	53°41′ E
4	Station building to which a bust of V. I. Lenin is fixed, together with a plaque in memory of the conquest of the Pole of Inaccessibility by Soviet Antarctic explorers in 1958.	Russia	83°06′ S	54°58′ E

Historic Sites and Monuments (HSMs) in the Antarctic Treaty Area as of June 2006 (Continued)

No.	Description	Proposer	Latitude	Longitude
5	Rock cairn and plaque at Cape Bruce, Mac.Robertson Land, erected in February 1931 by Sir Douglas Mawson. The cairn and plaque commemorate the landing on Cape Bruce of Sir Douglas Mawson with a party from the British, Australian, and New Zealand Antarctic Research Expedition of 1929–1931.	Australia	67°25′ S	60°47′ E
6	Rock cairn at Walkabout Rocks, Vestfold Hills, Princess Elizabeth Land, erected in 1939 by Sir Hubert Wilkins. The cairn houses a canister containing a record of his visit.	Australia	68°22′ S	78°33′ E
7	Stone with inscribed plaque, erected at Mirny Observatory, Mabus Point, in memory of driver–mechanic Ivan Kharma, who perished on fast ice in the performance of official duties in 1956.	Russia	66°33′ S	93°01′ E
8	Metal monument-sledge at Mirny Observatory, Mabus Point, with plaque in memory of driver–mechanic Anatoly Shcheglov, who perished in the performance of official duties.	Russia	66°33′ S	93°01′ E
9	Cemetery on Buromskiy Island, near Mirny Observatory, in which are buried Soviet, Czechoslovakian, and GDR citizens, members of Soviet Antarctic Expeditions, who perished in the performance of official duties on 3 August 1960.	Russia	66°32′ S	93°01′ E
10	Building (magnetic observatory) at Dobrowolsky Station, Bunger Hills, with plaque in memory of the opening of Oasis Station in 1956.	Russia	66°16′ S	100°45 ′E
11	Heavy tractor at Vostok Station with plaque in memory of the opening of the Station in 1957.	Russia	78°28′ S	106°48′ E
12	Delisted.			
13	Delisted.			
14	Site of ice cave at Inexpressible Island, Terra Nova Bay, constructed in March 1912 by Victor Campbell's Northern Party, British Antarctic Expedition, 1910–1913. The party spent the winter of 1912 in this ice cave. A wooden sign, plaque, and seal bones remain at the site.	New Zealand	74°54′ S	163°43′ E
15	Hut at Cape Royds, Ross Island, built in February 1908 by the British Antarctic Expedition of 1907–1909, led by Sir Ernest Shackleton. Restored in January 1961 by the Antarctic Division of New Zealand Department of Scientific and Industrial Research. Site incorporated within ASPA 157.	New Zealand/ UK	77°33′ S	166°10′ E
16	Hut at Cape Evans, Ross Island, built in January 1911 by the British Antarctic Expedition of 1910–1913, led by Captain Robert F. Scott. Restored in January 1961 by the Antarctic Division of New Zealand Department of Scientific and Industrial Research. Site incorporated within ASPA 155.	New Zealand/ UK	77°38′ S	166°24′ E
17	Cross on Wind Vane Hill, Cape Evans, Ross Island, erected by the Ross Sea Party, led by Captain Aeneas Mackintosh, of Sir Ernest Shackleton's Imperial Trans-Antarctic Expedition of 1914–1916, in memory of three members of the party who died in the vicinity in 1916. Site incorporated within ASPA 155.	New Zealand/ UK	77°38′ S	166°24′ E

No.	Description	Proposer	Latitude	Longitude
18	Hut at Hut Point, Ross Island, built in February 1902 by the British Antarctic Expedition of 1901–1904, led by Captain Robert F. Scott. Partially restored in January 1964 by the New Zealand Antarctic Society, with assistance from the United States Government. Site incorporated within ASPA 158.	New Zealand/ UK	77°50′ S	166°37′ E
19	Cross at Hut Point, Ross Island, erected in February 1904 by the British Antarctic Expedition of 1901–1904, in memory of George Vince, a member of the expedition, who died in the vicinity.	New Zealand/ UK	77°50′ S	166°37′ E
20	Cross on Observation Hill, Ross Island, erected in January 1913 by the British Antarctic Expedition of 1910–1913, in memory of Captain Robert F. Scott's party, which perished on the return journey from the South Pole in March 1912.	New Zealand/ UK	77°51′ S	166°41′ E
21	Remains of stone hut at Cape Crozier, Ross Island, constructed in July 1911 by Edward Wilson's party of the British Antarctic Expedition (1910–1913) during the winter journey to collect Emperor penguin eggs.	New Zealand	77°31′ S	169°22′ E
22	Three huts and associated historic relics at Cape Adare. Two were built in February 1899 during the British Antarctic *(Southern Cross)* Expedition, 1898–1900, led by Carsten E. Borchgrevink. The third was built in February 1911 by Robert F. Scott's Northern Party, led by Victor L. A.Campbell. Scott's Northern Party hut has largely collapsed, with only the porch standing in 2002. Site incorporated within ASPA 159.	New Zealand/ UK	71°18′ S	170°12′ E
23	Grave at Cape Adare of Norwegian biologist Nicolai Hanson, a member of the British Antarctic *(Southern Cross)* Expedition, 1898–1900, led by Carsten E. Borchgrevink. A large boulder marks the head of the grave with the grave itself outlined in white quartz stones. A cross and plaque are attached to the boulder.	New Zealand/ UK	71°17′ S	170°13′ E
24	Rock cairn, known as "Amundsen's cairn," on Mount Betty, Queen Maud Range, erected by Roald Amundsen on 6 January 1912, on his way back to *Framheim* from the South Pole.	Norway	85°11′ S	163°45′ W
25	Delisted.			
26	Abandoned installations of Argentine Station "General San Martin" on Barry Island, Debenham Islands, Marguerite Bay, with cross, flag mast, and monolith built in 1951.	Argentina	68°08′ S	67°08′ W
27	Cairn with a replica of a lead plaque erected on Megalestris Hill, Petermann Island, in 1909 by the second French expedition led by Jean-Baptiste E. A. Charcot. The original plaque is in the reserves of the Museum National d'Histoire Naturelle (Paris).	Argentina/ France/UK	65°10′ S	64°09′ W
28	Rock cairn at Port Charcot, Booth Island, with wooden pillar and plaque inscribed with the names of the first French expedition led by Jean-Baptiste E. A. Charcot, which wintered here in 1904 aboard *Le Français*.	Argentina	65°03′ S	64°01′ W
29	Lighthouse named "Primero de Mayo" erected on Lambda Island, Melchior Islands, by Argentina in 1942. This was the first Argentine lighthouse in the Antarctic.	Argentina	64°18′ S	62°59′ W

No.	Description	Proposer	Latitude	Longitude
30	Shelter at Paradise Harbour erected in 1950 near the Chilean Base "Gabriel Gonzalez Videla" to honour Gabriel Gonzalez Videla, the first head of state to visit the Antarctic. The shelter is a representative example of pre-IGY activity and constitutes an important national commemoration.	Chile	64°49′ S	62°51′ W
31	Delisted.			
32	Concrete monolith erected in 1947, near Capitán Arturo Prat Base on Greenwich Island, South Shetland Islands. Point of reference for Chilean Antarctic hydrographic surveys. The monolith is representative of an important pre-IGY activity and is currently preserved and maintained by personnel from Prat Base.	Chile	62°28′ S	59°40′ W
33	Shelter and cross with plaque near Capitán Arturo Prat Base (Chile), Greenwich Island, South Shetland Islands. Named in memory of Lieutenant-Commander González Pacheco, who died in 1960 while in charge of the station. The monument commemorates events related to a person whose role and the circumstances of whose death have a symbolic value and the potential to educate people about significant human activities in Antarctica.	Chile	62°29′ S	59°40′ W
34	Bust at Capitán Arturo Prat Base (Chile), Greenwich Island, South Shetland Islands, of the Chilean naval hero Arturo Prat, erected in 1947. The monument is representative of pre-IGY activities and has symbolic value in the context of the Chilean presence in Antarctica.	Chile	62°50′ S	59°41′ W
35	Wooden cross and statue of the Virgin of Carmen erected in 1947 near Capitán Arturo Prat Base (Chile), Greenwich Island, South Shetland Islands. The monument is representative of pre-IGY activities and has a particularly symbolic and architectural value.	Chile	62°29′ S	59°40′ W
36	Replica of a metal plaque erected by Eduard Dallmann at Potter Cove, King George Island, to commemorate the visit of his German expedition on 1 March, 1874 on board *Grönland*.	Argentina/ UK	62°14′ S	58°39′ W
37	Statue erected in 1948 at General Bernardo O'Higgins Base (Chile), Trinity Peninsula, of Bernardo O'Higgins, the first ruler of Chile to envisage the importance of Antarctica. This monument is representative of pre-IGY activities in Antarctica and has a symbolic meaning in the history of Antarctic exploration since it was during O'Higgins's government that the vessel *Dragon* landed on the coast of the Antarctic Peninsula in 1820.	Chile	63°19′ S	57°54′ W
38	Wooden hut on Snow Hill Island built in February 1902 by the main party of the Swedish South Polar Expedition led by Otto Nordenskjöld.	Argentina/ UK	64°22′ S	56°59′ W
39	Stone hut at Hope Bay, Trinity Peninsula, built in January 1903 by a party of the Swedish South Polar Expedition.	Argentina/ UK	63°24′ S	56°59′ W
40	Bust of General San Martin, grotto with a statue of the Virgin of Lujan, and a flag mast at Base "Esperanza," Hope Bay, erected by Argentina in 1955, together with a graveyard with stele in memory of members of Argentine expeditions who died in the area.	Argentina	63°24′ S	56°59′ W

41	Stone hut on Paulet Island built in February 1903 by survivors of the wrecked vessel *Antarctic* under Captain Carl A. Larsen, members of the Swedish South Polar Expedition led by Otto Nordenskjöld, together with a grave of a member of the expedition and the rock cairn built by the survivors of the wreck at the highest point of the island to draw the attention of rescue expeditions.	Argentina/ UK	63°34′ S	55°45′ W
42	Area of Scotia Bay, Laurie Island, South Orkney Island, in which are found a stone hut built in 1903 by the Scottish Antarctic Expedition led by William S. Bruce; the Argentine meteorological hut and magnetic observatory, built in 1905 and known as Moneta House; and a graveyard with twelve graves, the earliest of which dates from 1903.	Argentina	60°46′ S	44°40′ W
43	Cross erected in 1955, at a distance of 1300 m northeast of the Argentine General Belgrano I Station (Argentina), subsequently moved to Belgrano II Station (Argentina), Nunatak Bertrab, Confin Coast, Coats Land in 1979.	Argentina	77°52′ S	34°37′ W
44	Plaque erected at the temporary Indian station "Dakshin Gangotri," Princess Astrid Kyst, Dronning Maud Land, listing the names of the First Indian Antarctic Expedition, which landed nearby on 9 January 1982.	India	70°45′ S	11°38′ E
45	Plaque on Brabant Island, on Metchnikoff Point, mounted at a height of 70 m on the crest of the moraine separating this point from the glacier and bearing the following inscription: This monument was built by François de Gerlache and other members of the Joint Services Expedition 1983–1985 to commemorate the first landing on Brabant Island by the Belgian Antarctic Expedition, 1897–1899: Adrien de Gerlache de Gomery (Belgium), leader, Roald Amundsen (Norway), Henryk Arctowski (Poland), Frederick Cook (USA), and Emile Danco (Belgium) camped nearby from 30 January to 6 February 1898.	Belgium	64°02′ S	62°34′ W
46	All the buildings and installations of Port-Martin base, Terre Adélie constructed in 1950 by the 3rd French expedition in Terre Adélie and partly destroyed by fire during the night of 23 to 24 January 1952.	France	66°49′ S	141°24′ E
47	Wooden building called "Base Marret" on the Île des Pétrels, Terre Adélie, where seven men under the command of Mario Marret overwintered in 1952 following the fire at Port Martin Base.	France	66°40′ S	140°01′ E
48	Iron cross on the North-East headland of the Île des Pétrels, Terre Adélie, dedicated as a memorial to André Prudhomme, head meteorologist in the 3rd International Geophysical Year expedition, who disappeared during a blizzard on 7 January 1959.	France	66°40′ S	140°01′ E
49	The concrete pillar erected by the First Polish Antarctic Expedition at Dobrolowski Station on the Bunger Hill to measure acceleration due to gravity $g = 982{,}439.4$ mgal $\pm$ 0.4 mgal in relation to Warsaw, according to the Potsdam system, in January 1959.	Poland	66°16′ S	100°45′ E

50	A brass plaque bearing the Polish Eagle, the national emblem of Poland, the dates 1975 and 1976, and the following text in Polish, English, and Russian: "In memory of the landing of members of the first Polish Antarctic marine research expedition on the vessels 'Profesor Siedlecki' and 'Tazar' in February 1976." This plaque, southwest of the Chilean and Soviet stations, is mounted on a cliff facing Maxwell Bay, Fildes Peninsula, King George Island.	Poland	62°12′ S	59°01′ W
51	The grave of Wlodzimierz Puchalski, surmounted by an iron cross, on a hill to the south of Arctowski station on King George Island. W. Puchalski was an artist and a producer of documentary nature films, who died on 19 January 1979 whilst working at the station.	Poland	62°13′ S	58°28′ W
52	Monolith erected to commemorate the establishment on 20 February 1985 by the People's Republic of China of the "Great Wall Station" on Fildes Peninsula, King George Island, in the South Shetland Islands. Engraved on the monolith is the following inscription in Chinese: "Great Wall Station, First Chinese Antarctic Research Expedition, 20 February 1985."	China	62°13′ S	58°58′ W
53	Bust of Captain Luis Alberto Pardo, monolith and plaques on Point Wild, Elephant Island, South Shetland Islands, celebrating the rescue of the survivors of the British ship *Endurance* by the Chilean Navy cutter *Yelcho,* displaying the following words: "Here on August 30th, 1916, the Chilean Navy cutter *Yelcho* commanded by Pilot Luis Pardo Villalón rescued the 22 men from the Shackleton Expedition who survived the wreck of the 'Endurance' living for four and one half months in this Island." The monolith and the plaques have been placed on Elephant Island and their replicas on the Chilean bases Capitan Arturo Prat (62°30′ S, 59°49′ W) and President Eduardo Frei (62°12′ S, 62°12′ W). Bronze busts of the pilot Luis Pardo Villalon were placed on the three aforementioned monoliths during the XXIVth Chilean Antarctic Scientific Expedition in 1987–1988.	Chile	61°03′ S	54°50′ W
54	Richard E. Byrd Historic Monument, McMurdo Station, Antarctica. Bronze bust on black marble, 5 ft high by 2 ft square, on wood platform, bearing inscriptions describing the polar achievements of Richard Evelyn Byrd. Erected at McMurdo Station in 1965.	USA	77°51′ S	166°40 ′E
55	East Base, Antarctica, Stonington Island. Buildings and artefacts at East Base, Stonington Island, and their immediate environs. These structures were erected and used during two US wintering expeditions: the Antarctic Service Expedition (1939–1941) and the Ronne Antarctic Research Expedition (1947–1948). The size of the historic area is approximately 1000 m in the north–south direction (from the beach to Northeast Glacier adjacent to Back Bay) and approximately 500 m in the east–west direction.	USA	68°11′ S	67°00′ W

56	Waterboat Point, Danco Coast, Antarctic Peninsula. The remains and immediate environs of the Waterboat Point hut. It was occupied by the UK two-man expedition of Thomas W. Bagshawe and Maxime C. Lester in 1921–1922. Only the base of the boat, foundations of doorposts and an outline of the hut and extension still exist. It is situated close to the Chilean station "President Gabriel Gonzáles Videla."	Chile/UK	64°49′ S	62°51′ W
57	Commemorative plaque at "Yankee Bay" (Yankee Harbour), MacFarlane Strait, Greenwich Island, South Shetland Islands. Near a Chilean refuge. Erected to the memory of Captain Andrew MacFarlane, who in 1820 explored the Antarctic Peninsula area in the brigantine *Dragon*.	Chile/UK	62°32′ S	59°45′ W
58	Delisted.			
59	A cairn on Half Moon Beach, Cape Shirreff, Livingston Island, South Shetland Islands, and a plaque on "Cerro Gaviota" opposite San Telmo Islets commemorating the officers, soldiers, and seamen aboard the Spanish vessel *San Telmo,* which sank in September 1819; possibly the first people to live and die in Antarctica. Site incorporated within ASPA 149.	Chile/Spain/ Peru	62°28′ S	60°46′ W
60	Wooden plaque and cairn located at Penguins Bay, southern coast of Seymour Island (Marambio), James Ross Archipelago. This plaque was placed on 10 November 1903 by the crew of a rescue mission of the Argentinian Corvette *Uruguay* in the site where they met the members of the Swedish expedition led by Dr. Otto Nordenskjöld. The text of the wooden plaque reads as follows: "10.XI.1903 Uruguay (Argentine Navy) in its journey to give assistance to the Swedish Antarctic expedition." In January 1990, a rock cairn was erected by Argentina in memory of this event in the place where the plaque is located.	Argentina	64°16′ S	56°39′ W
61	"Base A" at Port Lockroy, Goudier Island, off Wiencke Island, Antarctic Peninsula. Of historic importance as an Operation Tabarin base from 1944 and for scientific research, including the first measurements of the ionosphere, and the first recording of an atmospheric whistler, from Antarctica. Port Lockroy was a key monitoring site during the International Geophysical Year of 1957/1958.	UK	64°49′ S	63°29′ W
62	"Base F (Wordie House)" on Winter Island, Argentine Islands. Of historic importance as an example of an early British scientific base.	UK	65°15′ S	64°16′ W
63	"Base Y" on Horseshoe Island, Marguerite Bay, western Graham Land. Noteworthy as a relatively unaltered and completely equipped British scientific base of the late 1950s. "Blaiklock," the refuge hut nearby, is considered an integral part of the base.	UK	67°48′ S	67°18′ W
64	"Base E" on Stonington Island, Marguerite Bay, western Graham Land. Of historical importance in the early period of exploration and later British Antarctic Survey (BAS) history of the 1960s and 1970s.	UK	68°11′ S	67°00′ W

65	Message post, Svend Foyn Island, Possession Islands. A pole with a box attached was placed on the island on 16 January 1895 during the whaling expedition of Henryk Bull and Captain Leonard Kristensen of the ship *Antarctic*. It was examined and found intact by the British Antarctic Expedition of 1898–1900 and then sighted from the beach by the USS *Edisto* in 1956 and USCGS *Glacier* in 1965.	New Zealand/ Norway/UK	71°56′ S	171°05′ W
66	Prestrud's Cairn, Scott Nunataks, Alexandra Mountains, Edward VII Peninsula. The small rock cairn was erected at the foot of the main bluff on the north side of the nunataks by Lieutenant K. Prestrud on 3 December 1911 during the Norwegian Antarctic Expedition of 1910–1912.	New Zealand/ Norway/UK	77°11′ S	154°32′ W
67	Rock shelter, "Granite House," Cape Geology, Granite Harbour. This shelter was constructed in 1911 for use as a field kitchen by Griffith Taylor's second geological excursion during the British Antarctic Expedition of 1910–1913. It was enclosed on three sides with granite boulder walls and used a sledge to support a seal-skin roof. The stone walls of the shelter have partially collapsed. The shelter contains corroded remnants of tins, a seal skin, and some cord. The sledge is now located 50 m seaward of the shelter and consists of a few scattered pieces of wood, straps, and buckles. Site incorporated within ASPA 154.	New Zealand/ Norway/UK	77°00′ S	162°32′ E
68	Site of depot at Hells Gate Moraine, Inexpressible Island, Terra Nova Bay. This emergency depot consisted of a sledge loaded with supplies and equipment that was placed on 25 January 1913 by the British Antarctic Expedition, 1910–1913. The sledge and supplies were removed in 1994 in order to stabilize their deteriorating condition.	New Zealand/ Norway/UK	74°52′ S	163°50′ E
69	Message post at Cape Crozier, Ross Island, erected on 22 January 1902 by Captain Robert F. Scott's *Discovery* Expedition of 1901–1904. It was to provide information for the expedition's relief ships, and held a metal message cylinder, which has since been removed. Site incorporated within ASPA 124.	New Zealand/ Norway/UK	77°27′ S	169°16′ E
70	Message post at Cape Wadworth, Coulman Island. A metal cylinder nailed to a red pole 8 m above sea level, placed by Captain Robert F. Scott on 15 January 1902. He painted the rocks behind the post red and white to make it more conspicuous.	New Zealand/ Norway/UK	73°19′ S	169°47′ E
71	Whalers Bay, Deception Island, South Shetland Islands. The site comprises all pre-1970 remains on the shore of Whalers Bay, including those from the early whaling period (1906–1912) initiated by Captain Adolfus Andresen of the Sociedad Ballenera de Magallanes, Chile; the remains of the Norwegian Hektor Whaling Station established in 1912 and all artefacts associated with its operation until 1931; the site of a cemetery with 35 burials and a memorial to 10 men lost at sea; and the remains from the period of British scientific and	Chile/Norway	62°59′ S	60°34′ W

5. Areas of particular scientific interest.
6. Examples of outstanding geological, glaciological, or geomorphological features.
7. Areas of outstanding aesthetic and wilderness value.
8. Sites or monuments of recognized historic value.
9. Any other areas that may be appropriate to protect the values set out in Article 3.

This framework allows for the development of a comprehensive system of specially protected areas in Antarctica. However, progress towards that comprehensive, representative system has so far been limited, and current sites are largely those that were designated prior to agreement on the Protocol. For example, most ASPAs are on land concentrated around the coast, are within close proximity of stations, and are found particularly along the Antarctic Peninsula and in the McMurdo Sound region of the Ross Sea. There are few marine ASPAs, and these are of limited size. Biological and scientific values are best represented, whilst relatively few sites have been designated for other purposes. Most sites aim to protect a few specific values or features, rather than represent an ecosystem. None has been designated specifically for aesthetic and wilderness values. In part, the slowness to introduce new areas since agreement on the Protocol has been caused by the practical need to engage much effort in preparing new or revised management plans for the existing protected areas to meet the more demanding requirements of Annex V.

To a large extent, the distribution of ASPAs mirrors the concentration on human activities in Antarctica, and thus also the pressures on the environment that exist or have been perceived. The distribution of activities has also strongly influenced the availability of knowledge from which to discriminate areas with values that may be worthy of designation. Without such knowledge, the scientific basis for selection and design of specific areas to include in the system is constrained. This is particularly the case in the Antarctic marine environment, where data are often relatively sparse. However, it would be unwise to wait until all gaps in knowledge have been filled before taking steps to expand the range of environment types represented in the system. Human activity, and possibly impacts, may expand into these areas more rapidly than detailed databases and knowledge can be acquired. An initial response to this dilemma may be to undertake a systematic and detailed appraisal of the gaps and needs for special protection in Antarctica, with a view to identifying values and areas that deserve priority attention. Focussed effort might then be made to develop the protected area network in Antarctica on a more systematic basis, working towards the more comprehensive and representative system envisaged in the Protocol.

Other protected areas designated under Conventions within the Antarctic Treaty system are the CCAMLR Ecosystem Monitoring Programme (CEMP), sites under the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR), and Seal Reserves under the Convention for the Conservation of Antarctic Seals (CCAS).

PROTOCOL ON ENVIRONMENTAL PROTECTION TO THE ANTARCTIC TREATY

The Development of a Comprehensive Environmental Protocol

Between 1981 and 1988, the Antarctic Treaty Consultative Parties were working on developing a mineral resource convention (Convention on the Regulation of Antarctic Resource Activities, or CRAMRA), a regime that would have provided an environmentally based regulatory framework for future mineral resource development. CRAMRA never entered into force, as Australia and France in 1989, later followed by other nations, decided against ratification. These parties advocated instead that comprehensive environmental protection measures be put in place for Antarctic activities.

Many of the mechanisms of environmental protection that had been included in CRAMRA had actually drawn upon earlier adopted hortatory recommendations, and it was consequently recognized that it would be helpful to collect, codify, and, to the degree necessary, extend the existing system of environmental measures in Antarctica into a harmonized and comprehensive framework.

Thus, acknowledging this need, the consultative parties decided to undertake as a priority objective to further elaborate a comprehensive system for the protection of the Antarctic environment. To contribute to this objective, a Special Antarctic Treaty Consultative Meeting was called for in 1990 to explore and discuss all aspects of such a proposal (Recommendation XV-1 [1989]).

The first session of the eleventh Antarctic Treaty Special Consultative Meeting was held at Viña del Mar (Chile) from November 19 to December 6, 1990. Mr. Oscar Pinochet de la Barra, Head of the Delegation of Chile, acted as Chairman for this session.The second session took place in Madrid (Spain) from April 22 to 30, from June 17 to 22, and from October 3 to 4, 1990 under the chairmanship of Mr. Carlos Blasco Villa, Head of the Delegation of Spain.

At the first session, debate on the form and content of the environmental framework to be developed was discussed, and a number of proposals were put forward. Australia, Belgium, France, and Italy advocated for a separate convention; some countries promoted a framework protocol, supported by drafts submitted by the UK and US; while New Zealand fronted a comprehensive protocol.

After extensive debates and discussions, as well as informal consultations, a compromise text was submitted by the Norwegian diplomat Rolf Trolle Andersen. The work at the following session in Madrid was greatly facilitiated by the Andersen text. Further deliberations followed, including extensive legal drafting work led by Mr. Pieter Verbeek from The Netherlands.

On October 4, 1991, the Representatives of the Consultative Parties adpoted by consensus the Protocol on Environmental Protection to the Antarctic Treaty, of which four Annexes form an integral part, concerning environmental impact assessment (Annex I), conservation of Antarctic fauna and flora (Annex II), waste disposal and management (Annex III), and prevention of marine pollution (Annex IV).

Parties to the Protocol on Environmental Protection to the Antarctic Treaty

Country	Date of Signature	Date of Ratification
Argentina	4 Oct. 1991	28 Oct. 1993
Australia	4 Oct. 1991	6 April 1994
Belgium	4 Oct. 1991	26 April 1996
Brazil	4 Oct. 1991	15 Aug. 1995
Bulgaria		21 April 1998[1]
Canada	4 Oct. 1991	13 Nov. 2003
Czech Republic	1 Jan. 1993	25 Aug. 2004
Chile	4 Oct. 1991	11 Jan. 1995
China	4 Oct. 1991	2 Aug. 1994
Ecuador	4 Oct. 1991	4 Jan. 1993
Finland	4 Oct. 1991	1 Nov. 1996
France	4 Oct. 1991	5 Feb. 1993
Germany	4 Oct. 1991	25 Nov. 1994
Greece	4 Oct. 1991	23 May 1995
India	2 July 1992	26 April 1996
Italy	4 Oct. 1991	31 March 1995
Japan	29 Sept. 1992	15 Dec. 1997
Korea, Republic of	2 July 1992	2 Jan. 1996
Netherlands	4 Oct. 1991	14 April 1994
New Zealand	4 Oct. 1991	22 Dec. 1994
Norway	4 Oct. 1991	16 June 1993
Peru	4 Oct. 1991	8 March 1993
Poland	4 Oct. 1991	1 Nov. 1995
Russian Federation	4 Oct. 1991	6 Aug. 1997
South Africa	4 Oct. 1991	3 Aug. 1995
Spain	4 Oct. 1991	1 July 1992
Sweden	4 Oct. 1991	30 March 1994
Ukraine		25 May 2001[1]
United Kingdom	4 Oct. 1991	25 April 1995
United States of America	4 Oct. 1991	17 April 1997
Uruguay	4 Oct. 1991	11 Jan. 1995

[1]Date deposit of accession. Entry into force 30 days after the deposit of accession.

Thus, within only 2 years of the collapse of CRAMRA, the Protocol on Environmental Protection to the Antarctic Treaty was signed. In the protocol, the Parties commit themselves to the comprehensive protection of the Antarctic environment and dependent and associated ecosystems.

The protocol in short does the following:

- Designates Antarctica a "natural reserve, devoted to peace and science."
- Establishes environmental principles for the conduct of all activities.
- Establishes an indefinite moratorium on mining (which in principle can be renegotiated 50 years after the coming into force of the protocol).
- Subjects all activities to prior assessment of environmental impacts.
- Provides for the establishment of a Committee for Environmental Protection, to advise the Antarctic Treaty Consultative Parties.

The Coming into Force of the Protocol

Article 23 (1) of the protocol established that the protocol should enter into force on the 30th day following the ratification by all states that were Antarctic Treaty Consultative Partes at the date on which the protocol was adopted.

At the conclusion of the negotiations of the Protocol on Environmental Protection it was recorded that it was desirable to ensure the effective implementation at an early date of the provisions of the protocol. Therefore, pending the entry into force of the protocol, it was agreed that all parties should aim to the extent practicable to apply the protocol provisions, as well as Annexes I–IV, in accordance with their legal systems.

In the aftermath of the adoption of the protocol, and before it came into force, the parties elaborated and adopted national implementing legislation for the protocol, and many parties introduced legislation in the following years (e.g., Australia in December 1992, Argentina in May 1993, Sweden in 1994, and Norway in 1995).

In addition to the national initiatives relating to the implementation of the protocol, the Transitional Environmental Working Group (TEWG) met at three consecutive Antarctic Treaty Consultative Meetings after the adoption, but prior to the entry into force of the protocol. The TEWG was established in the anticipation and preparation of the entry into force of the protocol, including in particular the establishment of the Committee on Environmental Protection.

Although a number of countries ratified the protocol shortly following its adoption, it nevertheless took a good 6 years before it entered into force. Thirty days following the ratification of Japan, the last country, the protocol entered into force on January 14, 1998.

Today, no country seeking to become a Consultative Party to the Antarctic Treaty can do so without first having ratified the environmental protocol. This requirement is provided for in Article 22 (4) of the protocol.

Further Annexes

Article 9 (2) of the protocol opens for further annexes to be adopted as part of the protocol. The question of protected areas had become an issue already during the protocol negotiations and the outcome of this debate was Annex V on area protection and management, subsequently adopted at ATCM XVI under Recommendation XVI-10. Annex V did not enter into force until May 24, 2002, following the approval of this recommendation by all consultative parties.

At the adoption of the protocol the commitment of the parties to elaborate rules and procedures relating to liability for damage arising from activities taking place in the Antarctic Treaty area had been expressed (also established in Article 16 of the protocol itself) and that work on elaboration of such a regime should begin at an early stage. The XVII Antarctic Treaty Consultative Meeting in Venice in 1992 convened a group of legal experts, under the leadership of Dr. Rüdiger Wolfrum (Germany), to undertake such elaboration. The group presented its report to the XXII Consultative Meeting in 1998. The first round of negotiations on a liability annex was conducted in 1999.

In 2005, at ATCM XXVIII in Stockholm, the negotiations were finalized under the leadership of Ambassador Don Mackay (New Zealand) and an *Annex on Liability Arising from Environmental Emergencies* (Annex VI to the Protocol) was agreed on under Measure 1 (2005). Once this Annex enters into force, an operator active in Antarctica who fails to take "prompt and effective response action to environmental emergencies arising from its activities" shall be liable for the cost of the response action taken by another party.

During the final discussions at ATCM XXVIII several parties noted, however, that Annex VI does not completely discharge the obligations under Article 16 of the protocol. The parties therefore recorded, through Decision 1 (2005), their intention to resume negotiations to elaborate further rules and procedures as may be necessary relating to liability for damage arising from activities taking place in the Antarctic Treaty Area and covered by the protocol.

State of the Environment Reporting

The protocol's Article 12, 1(j) requires that the Committee for Environmental Protection (CEP) provide advice on "the state of the Antarctic environment." The issue of reporting on the state of the Antarctic environment has been an outstanding issue for the parties since the environmental protocol was signed in 1991. A system for reporting on the state of the environment will underpin the environmental principles of the environmental protocol outlined in Article 3, and will provide a useful mechanism for the CEP to fulfil its wider functions (e.g., under Articles 12 1[a], [b], [e], [f], [i], and [k]). A web-based system, the State of the Antarctic Environment Reporting (SAER), for routinely reporting on key environmental indicators, is under development under the auspices of the CEP. The potential value of the SAER comes from its ability to be updated and to provide a central location for recording changes in the status of key indicators over time. Efforts to identify environmental indicators and associated parameters that indicate the impact of human activities in Antarctica and which can be integrated with the SAER system is also ongoing within the CEP.

The Effect of the Protocol

Although the protocol was to a large degree built upon existing regulations and recommendations, it did introduce several fundamental new elements. The protocol approached the question of environmental protection in a *comprehensive manner;* it collected the existing recommendations into a *legally binding instrument;* and it provided for the establishment of a *Committee for Environmental Protection* (CEP) that would oversee the implementation of the protocol's provisions.

As regards Antarctic environmental management, the protocol has served to minimize environmental impacts of human activities in the region by increasing environmental awareness amongst Antarctic operators, inducing transparency of domestic implementation, and providing for mutual control among states regarding environmental practices.

Although the protocol to a large degree has improved environmental management in Antarctica substantially, there are still key issues that remain to be solved. There are still no common standards regarding environmental impact assessments. The assessment of cumulative impact in a multinational/operational environment has proven to be an enormous challenge. There are still unresolved issues of jurisdiction, control, and enforcement, especially regarding activities by third parties, such as tourism. The continued deliberations over the liability question also indicate that there are some major outstanding important environmental issues to be clarified.

PROTOZOA

The correct approach to the classification of protozoa at higher taxa level is still the subject of ongoing debate; however, all the main classically defined groups of terrestrial protozoa (ciliates, flagellates, and both "naked" and testate amoebae) are represented in Antarctica. Within each group the species richness is usually much smaller than that observed in more temperate or tropical areas. For example, within the ciliates (usually considered to be a monophyletic group) a recent review suggested that approximately 15% of soil living species occurred in the Antarctic and sub-Antarctic islands; this contrasted with around 40% for Australia and Tasmania (Foissner 1998). For testate amoebae (which build a "shell," composed of organic matter or material from the environment, that may not be monophyletic), there is a clear trend of reduced species richness with declining mean January temperature when sub-Antarctic sites are compared with those from the maritime or continental Antarctic (Smith 1996). Similar patterns are probably present in other protozoan groups, but their biogeography within the Antarctic has not been studied in as much detail as the testate amoebae.

The main reason for the low species richness of Antarctic protozoa is probably the severity of the climate; the role of constraints on dispersal in the biogeography of polar protozoa is currently controversial but seems very likely to also be of importance (Wilkinson 2001). Most areas of the Antarctic are likely to have been recolonised by protozoa since the last glaciation, that is, within the last 10,000 years. It is also clear that knowledge of Antarctic protozoa is as yet incomplete; for example, in a study of ninety soil samples from Antarctica, Foissner (1997) estimated that 15% of the ciliate taxa found were undescribed species.

As well as reduced species richness, many of the Antarctic protozoa are usually recorded as having low population densities; one important exception to this generalization is protozoan communities in the guano of marine birds (Smith 1996). In Wilkes Land, Eastern Antarctica, the highest abundances of both ciliates and testate amoebae were recorded from Moss samples (Petz 1997); in general, substrates with higher organic matter content tend to support more protozoa. Studies of the population ecology of soil testate amoebae on South Georgia found that they showed rapid population growth rates (in excess of 5% per day) during the spring (Smith and Headland 1983).

Over the next few decades it is likely that global warming will have a major impact on Antarctic ecology. Because of their short generation times and small size (and hence presumed ease of dispersal), it has been suggested that distribution changes in Antarctic protozoa may provide a sensitive indication of the biological effects of climate change. For example, the soil ciliate *Colpoda* spp. has been suggested as a useful indicator species for the effects of climate change in the Antarctic (Smith 1996; Smith and Crook 1995).

R

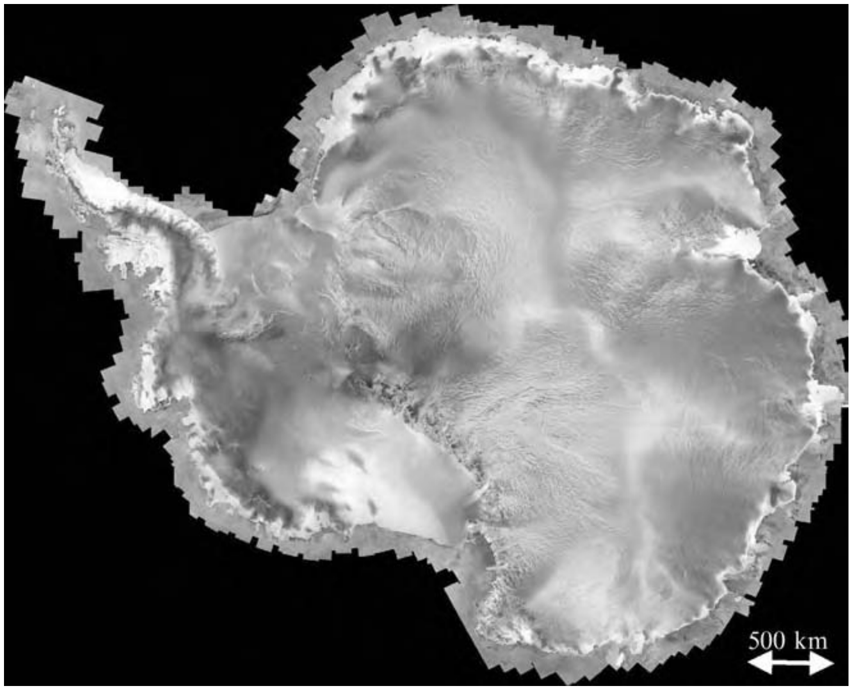
RADARSAT ANTARCTIC MAPPING PROJECT

Shrouded in darkness during the austral winter and often obscured from view by persistent cloud cover, Antarctica remained one of the most poorly mapped parts of our planet. That changed in 1997 when the Antarctic Mapping Mission-1 (AMM-1) project began to scan Antarctica from space. This was made possible by the Canadian RADARSAT-1 satellite, which carries a C-band (5.3 GHz) Synthetic Aperture Radar (SAR) capable of acquiring high resolution (25 m) images of Earth's surface day or night and under all weather conditions. RADARSAT-1 also collects data using a variety of swath widths, incidence angles, and resolutions, and, most importantly for scientists interested in Antarctica, it was maneuvered in orbit to rotate the normally right-looking SAR to a left-looking mode. This "Antarctic Mode" provided the first, nearly instantaneous, high-resolution views of the entirety of Antarctica.

The goal of the RADARSAT Antarctic Mapping Project (RAMP) was to create the first, high-resolution, radar image of the continent. The resulting map now serves as a benchmark for gauging future changes in the polar ice sheet, enables deeper understanding of the behavior of the glacier and its interaction with the polar atmosphere and coastal ocean, and simply expands our ability to explore the vast, remote, and often beautiful, southernmost continent (Jezek 1999; Liu and Jezek 2004).

AMM-1 contingency acquisitions began seven days prior to the start of the nominal acquisition plan. Nominal acquisitions started on schedule shortly after noon Eastern Standard Time on September 26, 1997. The nominal plan was designed to obtain complete mapping coverage within 18 days from the coast to the South Pole and it proceeded nearly flawlessly through completion on October 14. An additional opportunity was realized because of the early start on September 19. Radar data collected after the conclusion of the nominal mission were acquired exactly 24 days after the beginning of the early start data. This schedule repositioned the spacecraft to within a few hundred meters of its position 24 days earlier. Consequently, the data are suitable for interferometric analysis—a demonstrated technique for estimating ice sheet surface displacement. Exact repeat data collections started on October 14 and continued through October 20.

The RAMP mosaic is assembled from about 4500 radar scenes and is truly a new view of Antarctica. Evident in the mosaic are large-scale spatial variations in radar brightness. The bright portion of Marie Byrd Land and the eastern sector of the Ross Ice Shelf represent regions where significant melting and refreezing occurred during an early 1990s melt event. Most of the coastal areas and much of the Antarctic Peninsula also appear bright because of summer melt. But, unlike Greenland, where most of the large-scale brightness patterns are associated with firn melt faces, the remaining strong variations in radar brightness are more likely associated with changing patterns in surface accumulation rate. At a somewhat smaller scale, thousands-of-kilometers-long curvilinear features



RADARSAT-1 SAR mosaic of Antarctica. The map is a polar stereographic projection with standard latitude of 71° S and is referenced to the WGS84 ellipsoid. Light shading indicates strong backscatter. Dark shading indicates weak backscatter.

snake across East Antarctica. These appear to follow ice divides separating the large catchment areas (Liu et al. 1999). The reason that the ice divides appear so prominently in the radar imagery is unknown.

On an intermediate scale, the East Antarctic Ice Sheet appears to be very "rough." The texturing is probably due to the flow of the ice sheet over a rough glacier bed. Textures are particularly strong parallel to the flanks of the Transantarctic Mountains and extending deep into adjacent portions of the East Antarctic Plateau. Long linear patterns are strongly suggestive of subglacial geology and may indicate that the ice sheet in this area is resting on relatively resistant basement rocks. The texture changes abruptly across the northernmost section of the Wilkes Subglacial Basin located in George V Land. There, the imagery shows remarkable, subtle rounded shapes similar in appearance to the signature of subglacial lakes such as Lake Vostok.

Most intriguing are ice stream and ice stream-like features in Queen Maud. Ice streams are made visible by the intense crevassing along the shear margins where chaotic surface roughness results in a strong radar echo. Fast, channeled flow, which are two of the diagnostic characteristics of ice streams, are evident in the surface velocity field computed from repeat pass interferometry (described in the next section). Slessor Glacier is located on the northeastern margin of the Filchner Ice Shelf. The upper reaches of the glacier consist of a network of tributaries that feed a funnel shaped midsection. Patches of crevasses punctuate the interior of the funnel. The ice stream is about 450 km long from the grounding line to the upstream area.

An enormous ice stream, reaching at least 800 km into East Antarctica, feeds Recovery Glacier. It too is fed by a funnel shaped catchment. Down-glacier, crevasses cascade across the ice stream at several locations suggesting that strong variations in basal topography modulate the flow. The confluence of a thin, elongated, 280 km long tributary ice stream with Recovery Glacier is located approximately 250 km from the constriction where Recovery Glacier enters the Filchner Ice Shelf. The central body of the pipe-like tributary is crevasse-free, indicating that shear stresses are concentrated only at the margins. The tributary is an enigma in that there is little evidence for ice flow into the tributary from the adjacent ice sheet and there is little, if any, indication as to the source of ice from the up-glacier catchment region.

During the early 1990s, researchers at the Jet Propulsion Laboratory showed that synthetic aperture radar (SAR) offered a revolutionary new technique for estimating the surface motion of glaciers (Goldstein et al. 1993). Known as radar interferometry, multiple observations of a site are used to obtain very precise estimates of surface displacement. The demonstration of this technique for SARs in general and the demonstration during AMM-1 that the technique worked for RADARSAT-1 in particular (Joughin et al. 1999; Gray et al. 2001; Gray et al. 2002) were the impetus for the Modified Antarctic Mapping Mission (MAMM), which occurred during the fall of 2000.

MAMM had two primary science objectives (Jezek 2002). The first was to remap the perimeter of the continent and the majority of Antarctica's fast moving glaciers. Intuitively, these are the areas that are most likely to have experienced change over the intervening three years. The second MAMM objective was more ambitious—to obtain as much surface velocity data on the ice sheet as possible. Measurements of Antarctic ice sheet surface motion are of keen interest to geoscientists. The rate and direction of motion reveals important information about the forces acting on the glacier, provides knowledge about the rate at which ice is pouring into the coastal seas, and enables scientists to predict how the ice sheet might respond to changing global climate.

MAMM acquisitions were planned in two ways to attain these goals. First, data were acquired so that, where possible, the position of structures on the glacier could be compared between the 1997 and 2000 data sets so as to measure point velocities (Jezek et al. 2003). Second, and the real challenge of MAMM, was to acquire interferometric data to estimate velocity fields. The second approach required the use of RADARSAT-1 fine and standard beams, and unprecedented control of the spacecraft orbit and attitude. The outcomes of this effort are extraordinary observations of glacier motion captured over three 24-day RADARSAT cycles.

Interferometrically derived data acquired over the David Glacier and the Drygalski Ice Tongue located in Northern Victoria Land, Antarctica serve as an example of MAMM surface velocities. The ice tongue is a long, relatively narrow, extension of David Glacier onto the Ross Sea. Near the coast, several small outlet glaciers flank the David Glacier, which itself is fed by a system of tributaries. Surface speeds derived from MAMM interferometric data increase from about 100 m/yr in the upstream portions of David Glacier to about 750 m/yr at the tip of the Drygalski Ice Tongue. The Drygalski Ice Tongue has been studied since the early 1900s. Holdsworth (1985) compared historical, airborne photographic and Landsat data to estimate a velocity of 730 m/yr ± 36 m/y for a point 50 km from the coast. This is similar to the MAMM result of 710 m/yr ± 10 m/y to within the estimated errors. Several other investigators analyzed sequential Landsat scenes by coregistering images with tie points. The MAMM result at the landward end of the velocity profile (578 m/yr) compares favorably with Swithinbank's (1988) estimate of 580 m/yr but less than Lucchitta and others' (1993) estimate of about 640 m/yr. The MAMM maximum value (755 m/yr) is similar to 15-year average-maximum velocities (719 m/yr over 1973–1988) quoted by Frezzotti (Frezzotti 1993; Frezzotti et al. 2000) but less than Lucchitta and others (1993) whose estimated 15-year average velocities (1973–1988) near the tip are approximately 800 m/yr. The MAMM maximum values are also less than Frezzotti's 13-month average-maximum velocity of 912 m/y (1988–1990). Frezzotti and others (1998) compare their Landsat derived velocities with Global Positioning system data collected on the ice tongue. They find that the GPS velocities agree with the Landsat feature retracking data on the landward half of the ice tongue.

RAMP demonstrated the technical capability to acquire nearly instantaneous high-resolution microwave imagery of the entire Antarctic continent. The technical achievement is being followed by an unfolding scientific examination that is revealing the glaciology and geology of Antarctica in unexpected detail. As importantly, the acquisitions provide an important benchmark for gauging and understanding future changes in the Antarctic Ice Sheet.

REMOTE SENSING

Introduction

Over the past 30–40 years, satellite and other remote sensing methods have provided an immense wealth of new data to revolutionise understanding of the Antarctic. While important, field measurements are logistically challenging, expensive, and sparse. Satellites alone can measure and monitor remote and vast areas in a sustained, consistent, systematic, repetitive, and cost-effective fashion and on a variety of scales. Remote-sensing systems used fall into two broad categories: active and passive. Active systems (e.g., radars and lasers) transmit electromagnetic energy towards the surface and record the time interval, intensity, and characteristics of the return echo scattered (reflected) back. Passive systems sense naturally occurring radiation (e.g., reflected solar or emitted thermal). Earth-observing sensors operate at wavelengths/frequencies corresponding to "atmospheric transmission windows" in the electromagnetic spectrum, within which atmospheric contamination effects are minimised. Sensors operating outside such windows provide key information on the vertical structure/characteristics of the atmosphere itself. In all cases, polar-orbiting rather than geostationary satellites are most useful; as the latter sit at points ~37,000 km above the Equator, their coverage of Antarctica is geometrically distorted and limited, although they provide useful information on cloud/weather patterns over peripheral seas.

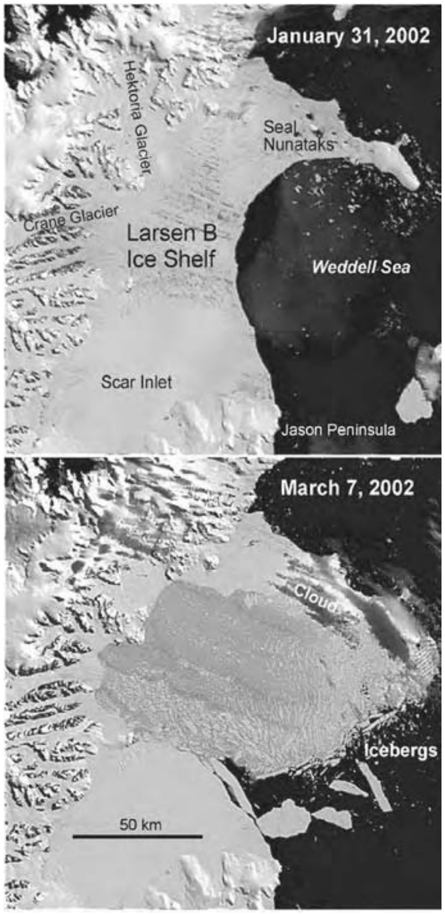
Passive Remote Sensing

Optical to Thermal Infrared (OTIR) Radiometers

Satellite detectors operating at optical wavelengths measure reflected solar radiation in the spectral region 0.4 to 3.0 μm. This comprises the visible (0.4–0.70 μm) and reflected infrared or IR (0.70–3.00 μm), with the near-IR and middle (shortwave) IR occupying the 0.70–1.30 μm and 1.30–3.00 μm bands, respectively. Being reliant on sunlight, these sensors are ineffective during periods of darkness—a major limitation in polar regions. Another limitation is their inability to "see" through clouds, although they yield important information on cloud fraction/type.

Broadly speaking, sea-ice spectral reflectance (ratio of radiant energy reflected by a body to that incident upon it) depends upon its age and thickness, and the presence/absence of a snowcover. Snow reflectance depends on the refractive index of ice, grain-size distribution, density, depth, and liquid-water content. Maps of surface albedo (the ratio of upwelling to downwelling radiative flux at the surface) can be retrieved from satellite radiance data after accurately masking cloud, correcting atmospheric effects, and converting angular measurements to the "full hemisphere" angular distribution of the surface (the bidirectional reflectance distribution function [BRDF]). While the broadband albedo of ice-free ocean is ~0.05–0.1, that of sea ice ranges from ~0.1 to ~0.9, enabling ice-ocean discrimination and ice-type classification. The strong sensitivity of near-IR radiation to snow grain-size growth with melting further enables the detection/monitoring of seasonal melt/refreeze. Ice-sheet surface grain size is itself retrievable from 1.6 μm data (e.g., from the Global Imager [GLI] aboard ADEOS-II [operational from 2002–2003]).

The basis of thermal infrared (TIR) remote sensing is that every object with a physical temperature >0 K



The extraordinary disintegration of the Larsen B Ice Shelf captured in NASA MODIS imagery. (Imagery courtesy Ted Scambos [US National Snow and Ice Data Center], acquired from the NASA Visible Earth website [http://visibleearth.nasa.gov/].)

thermally emits radiation that can be recorded by radiometers operating in the 3–15 μm region, and typically exploiting atmospheric-transmission windows at 3–5 μm and 8–15 μm. Data from the 3–5 μm region contain both solar-reflected and thermally emitted contributions, and are most commonly used to distinguish clouds from snow/ice during daylight hours. Thermal radiation, mainly 8–15 μm, emitted by objects as a function of their physical temperature and emissivity μ (the ratio of the radiation emitted by an object to that emitted by a blackbody [perfect radiator] at the same temperature). It follows that maps of skin-surface temperature can be derived from cloud-free TIR data, with knowledge of μ (which approximates unity at these wavelengths) and atmospheric contributions. The latter are typically minimised by differencing data from spectrally adjacent channels with different absorption responses to water vapour (e.g., band 4 [10.3–11.3 μm] and band 5 [11.5–12.5 μm] of the NOAA Advanced Very High Resolution Radiometer [AVHRR]). Other important applications include the detection/mapping of surface features/ice distributions during polar darkness, and sea-ice classification based upon thermal variation due to ice thickness (for thin ice). Much again depends upon accurate cloud detection and masking—a major challenge given the similarity in reflective and thermal properties of snow/ice and clouds.

Spaceborne OTIR missions can be divided into the following categories:

- *Moderate-resolution sensors,* with a spatial resolution of 0.25–4 km and swath width of ~1500–2800 km, offer virtually complete polar coverage on a daily basis. Primary examples are the NOAA AVHRR (1978–present), the Optical Linescan System (OLS) aboard Defense Meteorological Satellite Program (DMSP) satellites (1979–present), Moderate-resolution Imaging Spectro-radiometers (MODISs) aboard the NASA satellites Terra (1999–present) and Aqua (2002–present), the Medium Resolution Imaging Spectrometer (MERIS) aboard ESA's Envisat (2002–present, lacking TIR channels), and Visible/Infrared Imager Radiometer Suite (VIIRS) sensors aboard National Polar Orbiting Environmental Satellite System (NPOESS) satellites (from 2006). Near real-time availability has led to dramatic discoveries, including the disintegration of the Larsen B Ice Shelf in early 2002 and the calving of immense icebergs from the Ross Ice Shelf. Major products are large-scale maps of surface temperature and albedo. Other applications include sea ice motion from sequential imagery using cross-correlation techniques, mapping of fast ice, ice-sheet morphological features and coastal configuration, and enhanced-resolution ice-sheet digital elevation models (DEMs) using photoclinometric processing (shape-from-shading) techniques. A subgroup are *ocean-colour sensors,* which measure subtle variations in the colour of near-surface, ice-free waters. The magnitude of primary production can be derived from this information, based on the amount of solar radiation absorbed by phytoplankton chlorophyll in the upper-water column. Important current sensors are the OrbView-2 Sea-viewing Wide Field-of-view Sensor (SeaWiFS, 1997–present), MERIS and MODIS, with VIIRS in future. Major discoveries have related to the close association between sea ice distribution and phytoplankton blooms.

- *High-resolution sensors* acquire data over a narrow swath (<200 km) with a nominal repeat cycle of 16–26 days, and a spatial resolution of ~5 to <100 m. Current commercial examples include the Enhanced Thematic Mapper Plus (ETM+) on Landsat-7 (1999–present), and the High-Resolution Geometric (HRG) and High-Resolution Stereoscopic (HRS) sensors aboard SPOT-5 (2002–present). While SPOT sensors offer higher resolution than Landsat and to a higher latitude (~86° versus ~82.5°), Landsat scene coverage is greater (i.e., 185 × 185 km versus 60 × 60 km). Moreover, SPOT sensors (1986–present) lack the nighttime viewing capability of modern Landsat TIR channels. Non-commercial examples include the EOS Terra Advanced Spaceborne Thermal Emission and Reflection radiometer (ASTER) and the Advanced Visible and Near-Infrared Radiometer-2 (AVNIR-2) on the Japanese Advanced Land Observing Satellite (ALOS, launch 2005). This sensor class is best suited to studies requiring localised detailed coverage. While sea-ice applications are largely limited to the validation of coarser-resolution data, Landsat in particular has made a major contribution to ice-sheet research (since 1972) (e.g., in the production of high-density maps of ice velocity by measuring temporal displacement of conspicuous features [e.g., crevasses], and mapping/monitoring of ice-sheet morphology/margins [many subtle morphological features which cannot be identified at ground level are readily apparent from space]).
- *Ultra-high-resolution optical sensors* provide images at a spatial resolution of <1 m to <5 m but over narrow scenes of <20 km (limiting polar applications to very detailed localised studies). Commercial examples include Ikonos-2 (launch 1999), Quickbird-2 (2001), and EROS-A1 (2001). SPOT-5 has a 2.5 m resolution mode with wider coverage (60 km). Declassified Intelligence Satellite Photography (DISP) imagery, in hard-copy format and dating back to 1962, became available in 1995. The limited number of cloud-free scenes available provide tantalising glimpses of past conditions, and have been combined with modern imagery to monitor change (e.g., in glacier and ice-sheet margins).
- *Multi-angle sensors* record near-simultaneous observations of the same point from multiple angles during a single data acquisition. Examples are the Envisat Advanced ATSR (AATSR), the ASTER, and the Multi-angle Imaging Spectro-Radiometer (MISR, 1999–present). The latter operates four bands in the visible to near-IR (360 km swath, spatial resolution 270 m). Information on reflectance change at different view angles affords enhanced surface discrimination and improved surface-albedo retrieval by enabling more complete characterization of the surface BRDF. Both the MODIS and MISR spectro-radiometers also provide more precise measurements of cloud features at higher resolutions than before to greatly benefit climate research.
- *Hyperspectral sensors (imaging spectroscopy)* simultaneously acquire images in many narrow and contiguous spectral bands, to construct a complete reflectance spectrum for each pixel. The first spaceborne hyperspectral sensor, the EO-1 Hyperion Imaging Spectrometer (launch 2000), acquired measurements across 220 calibrated spectral bands in 10 nm bandwidths (from 0.4 to 2.5 μm) with a 10–30 m resolution, but over a narrow (7.5 km wide) swath. While of limited Antarctic applicability, such data show potential for improved though localised estimates of surface optical albedo, snow-grain size, and sea-ice classification.

Passive Microwave Radiometers

With excellent wide-swath coverage uninterrupted by clouds/darkness, satellite passive-microwave (PMW) radiometers are the primary source of information on Antarctic sea-ice concentration and extent. They measure the intensity of naturally emitted thermal radiation from the surface, in a similar fashion to thermal infrared radiometers but at much longer (i.e., centimetre) wavelengths. Their ability to detect sea ice is based upon the strong microwave-emissivity contrast between ice and ocean under freezing conditions (e.g., ~0.94 versus ~0.34 respectively at 37 GHz [horizontal polarization]). Polarization describes the locus of the electric-field vector in the plane perpendicular to the direction of propagation. Current sensors are the DMSP Special Sensor Microwave/Imager (SSM/I, 1987–present) and Aqua Advanced Microwave Scanning Radiometer (AMSR-E, 2002–present). While the spatial resolution of sea-ice products is poor (12.5–25 km), complete daily polar coverage is possible. Dating back to 1973, this unique dataset is widely applied to analyses of sea-ice trends/variability and process studies. The real-time downloading of satellite PMW data by modern icebreakers and research vessels has resulted in safer navigation and immense fuel savings. Other important applications include routine mapping of sea-ice temperature and snow-depth with AMSR-E data, sea-ice motion, and polynyas. Future coverage with the NPOESS Conical-scanning Microwave Imager/Sounder (CMIS, starting in 2009) includes an additional atmospheric-*sounding* capability. By operating at frequencies around spectral bands characteristic of target gases (e.g., 60 GHz and 183 GHz), microwave sounders measure the vertical profiles of atmospheric temperature and moisture.

Over cold dry ice sheets, PMW radiometers provide information on surface and near-surface properties, with microwave emission being determined by snow/firn temperature, layering, density, grain size/shape, and surface roughness. A research-and-development product is ice-sheet accumulation rate, based on its physical relationship with microwave emission as affected by depth-dependent grain-size distributions. As snow/firn emissivity is highly sensitive to liquid water, PMW data also provide key information on interannual variability in the timing/extent of seasonal surface melt and freeze-up (both pack ice and ice sheet).

Active Remote Sensing

Radars transmit a microwave signal then measure the reflection back from the target object as a function of frequency (wavelength), polarization, and incidence angle, again unaffected by cloud and darkness. The strength of the radar return (backscatter) is determined both by surface electrical properties and geometric characteristics. Significant microwave penetration into snow/ice can yield additional information on structural/internal properties.

Synthetic Aperture Radar

First launched on Seasat in 1978, the Earth-observing spaceborne synthetic aperture radar (SAR) is a powerful operational and research tool. SARs differ from spaceborne real-aperture radars (e.g., aboard Russian Kosmos Okean satellites, which are limited to a ground resolution of $\sim$1–2 km), by exploiting the satellite's along-track motion to computationally synthesise a large antenna and increase the resolution to tens of metres. Coverage is over a relatively narrow swath of 75–500 km. Key missions include ERS-1 (1991–2000), ERS-2 (1995–), JERS-1 (1992–1998), Radarsat-1 (1995–) and –2 (launch 2006), Envisat (2002–), the Advanced Land Observing Satellite (ALOS, 2005–), and in the future TerraSAR-X (launch 2006) and –L (launch 2007).

SAR provides all-weather high-resolution imagery of radar backscatter with which to map and interpret surface and near-surface characteristics. Clear feature-delineation is possible over ice sheets due to the radar's sensitivity to subtle variations in grain size, local relief, surface roughness, and moisture content. Major applications include mapping/monitoring of large-scale zones of different snow and ice diagenesis ("facies"), and seasonal/inter-annual patterns of melt/refreeze. An important product is the first high-resolution "snapshot" map of the entire Antarctic Ice Sheet by the Radarsat-1 Antarctic Mapping Mission (AMM-1). Main sea-ice applications are ice-type classification and open water-thin ice discrimination, ice motion/deformation, fast-ice extent, wave-ice interaction, seasonal melt/freeze-up detection, ice-edge characteristics, and wind speed and direction, and iceberg detection and tracking—a powerful combination. Overall limitations include the high data volume and relative complexity of interpretation. Although SARs are generally unsuited to routine large-scale coverage, reduced-resolution data have recently become available in near-real time from the Envisat Advanced SAR operating in Global Monitoring Mode (1 km resolution over a 400 km swath).

Extraordinary discoveries have recently resulted from interferometric processing of SAR imagery. SAR interferometry (InSAR) combines coherent image pairs acquired by antennae at different times and/or slightly different locations to construct interferograms (maps of phase difference). This enables detection of small (centimetre-scale) differences in range to a surface target from two (or more) observation points, from which high-resolution surface change/motion and topographic maps can be constructed. Although the availability of suitable image pairs is limited by temporal surface decorrelation over the period separating image acquisitions (for repeat-pass systems), InSAR has provided a wealth of new information on ice-sheet mass balance and dynamics. Uniquely, it has the capacity to acquire high-density ice-motion data in featureless expanses (where conventional feature-tracking techniques fail). It can also resolve glacier/ice stream surge behaviour and grounding-line location and migration, the latter by virtue of its sensitivity to vertical tidal motion of floating ice shelves/glaciers. Much-improved estimates of net mass budget and ice-shelf basal melt rates have resulted. To date, suitable InSAR data have come mainly from the ERS Tandem Mission (1995–1996), when ERS-1 and -2 flew in identical orbits but one day apart. No dedicated satellite InSAR system has been launched to date, although a tandem Radarsat-2 and -3 mission is planned. An alternative technique, speckle tracking, has been devised to derive ice-velocity data in fast-flowing regions (where InSAR processing fails). This exploits the cross-correlation function of speckle patterns (noise-like characteristics) in pairs of real-valued SAR-amplitude images, and is also suitable where the time interval between images is large (e.g., the 24-day repeat interval of Radarsat-1). Maximum-coherence tracking is similar, but uses phase information.

Another exciting development is the launch of satellite SARs with multipolarization (e.g., Envisat ASAR) and full-polarimetric capability (e.g., ALOS Phased Array L-band SAR [PALSAR] and advanced SARs aboard TerraSAR-X/-L and Radarsat-2). These systems not only receive the transmission polarization and its orthogonal, but can also record phase differences between different polarization combinations. Sensors with full-polarimetric capability can simultaneously acquire backscatter-amplitude data at HH, VV, HV, and VH polarizations, while also measuring relative phase between channels. This provides the potential to significantly improve sea-ice classification (particularly for thin-ice types) and ice-water discrimination under windy conditions, as well as the detection of ice-sheet facies and related boundaries. Another emerging technique is POLInSAR, or the melding of SAR polarimetry and interferometry. This shows potential as a means of enhancing the discrimination of polar surface types, by enabling more complete separation of surface- and volume-scattering effects and contributions.

Radar Scatterometers

Although primarily designed to measure wind velocity over open ocean, radar scatterometers also provide important information over ice-covered surfaces. Their strength lies in their excellent wide-swath coverage, low data rate, near-real time availability, all-weather, day/night operation, near-daily complete polar coverage, and a continuous time series of stable and accurately calibrated data dating back to 1991. Although their nominal spatial resolution is poor (i.e., 25–50 km), it has been improved by recent processing advances. Important missions include the Seasat-A Scatterometer (SASS, 1978), ERS-1 (launch 1991), ERS-2 (launch 1995), the NASA Scatterometer (NSCAT) aboard ADEOS-I (1996–1997), and SeaWinds on QuikSCAT (1999–present) and ADEOS-II/Midori-2 (2002–2003), with the Advanced Scatterometer (ASCAT) on MetOp in 2005. Radar scatterometers are well-suited to the mapping of regional-to-hemispheric patterns of melt/freeze-up, ice-sheet facies and operational monitoring of sea-ice motion and extent and large-iceberg tracking. Other applications include inference of mean surface wind-field direction over the ice-sheet interior (based upon their sensitivity to snow-dune orientation), empirical determination of ice-sheet accumulation patterns, and mapping of different sea ice-type regimes.

Radar Altimeters and LASER Altimeters

Radar altimeters transmit short pulses of electromagnetic radiation towards the surface at nadir, then measure the reflected energy. With precise knowledge of the satellite position, the recorded time-delay between pulse transmission and receipt provides a measure of ice-sheet surface elevation along the satellite ground track. These data have enabled the construction of high-resolution DEMs to revolutionise ice-sheet dynamics modeling, and the measurement of surface-elevation changes over periods of 5–10 years. Recent discoveries include a major thinning trend of -11.7 ± 1.0 cm a^{-1} over the Pine Island-Thwaites Glaciers drainage basin (West Antarctica) from 1992–1996 using ERS-1 and -2 data.

While early altimeters (e.g., Seasat [1978] and Geosat [1985–1990]), were designed for open-ocean operation, modern altimeters (e.g., aboard ERS-1 and -2 and Envisat), include an "ice mode" of operation to provide more precise measurements over ice. These altimeters perform well over relatively smooth ice-sheet interiors, but less so over more variable/steeper terrain (e.g., around ice-sheet margins). This led to the development of two innovative new spaceborne systems, namely ICESat and CryoSat. With coverage to 86° S and launched in January 2003, the Geoscience Laser Altimeter System (GLAS) on NASA's ICESat is a range-measuring device similar to radar but transmitting pulses of light—in this case at 1.064 μm (for altimetry) and 0.532 μm (for measuring cloud and aerosol vertical distributions). Advantages include a smaller surface footprint ($\sim$60 m) and along-track spacing ($\sim$172 m), and minimal signal penetration into the snow/ice mass to enable much-improved measurement of ice-sheet margins (to an unprecedented accuracy of $<$1.5 cm a^{-1}). A major limitation compared to radar is its inability to penetrate cloud cover. Another objective is measurement of sea-ice thickness, surface roughness, and surface reflectivity. CryoSat was designed to exploit sophisticated radar techniques to enhance resolution and observing capabilities, thereby providing improved estimates of ice-sheet thickness changes and sea-ice thickness. Unfortunately, CryoSat failed to enter orbit due to a launch malfunction in early October 2005.

Gravity Missions

Launched in March 2002, the joint US-German Gravity Recovery and Climate Experiment (GRACE) is the first in series of missions devoted to measurement of the Earth's time-variant gravity field, the others being GOCE (the Gravity field and steady-state Ocean Circulation Explorer, launch 2005) and the GRACE-FO (Follow-On, launch 2007). Gravity measurements are sensitive to changes in mass under the satellite, including mass redistribution due to crustal uplift and mantle inflow and changes in the mass of snow/ice contained in the ice sheet. Used in concert with ICESat, GRACE provides an important new constraint on contemporary total mass-imbalance estimates, to enable estimates of ice sheet–related contributions to global sea-level change to an unprecedented accuracy of $\sim$0.2 mm a^{-1}.

Aircraft and Field Measurements

Satellites also play a major role in transmitting information from sensor packages deployed on the surface (e.g., automatic weather stations and ice beacons/buoys), in the ocean (e.g., Argo floats), and attached to birds and mammals. Remote autonomous vehicles (underwater and airborne) gather oceanographic information unattainable by spaceborne sensors (e.g., under-ice ocean conditions/properties, ocean fluorescence, and water chemistry). Ice-draft measurements are acquired by long-term arrays of moored upward-looking sonars (ULSs), for conversion into point ice-thickness estimates. Sea-ice thickness profiles have also been acquired by helicopter- and ship-borne electromagnetic induction (EMI) sounding, which exploits the marked contrast in sea-ice and seawater electrical conductivities to detect the ice-water interface, with surface-elevation measurements provided by laser-altimeter data. Work is underway to develop low-frequency (300–1300 MHz) radar systems for measuring sea-ice thickness from aircraft. Surface and aircraft campaigns remain essential to both validate/calibrate satellite data/products and provide information currently unattainable from space (e.g., ice-sheet vertical flow characteristics and absolute grounded-ice thickness). Measurement of the latter can only be carried out by surface/airborne radio-echo sounding, or ice-penetrating radar, which also provides a means of tracking internal layers related to past ablation/accumulation conditions.

REPRODUCTION

Antarctic seas are usually viewed as being among the harshest environments on Earth: perpetually cold, freezing over and thawing annually, and continually dark for months each year, restricting food production. Such an environment would be expected to generate unusual adaptations in the biology of the animals living there, including their reproduction. On the other hand, being constantly cold is at least a constant; in temperate and even tropical seas wide temperature swings can dominate life. Moreover, the ice cover dampers disruptive storms, making the environment relatively benign (in winter) and especially favorable for life. Both of these views have validity, as seen in different benthic inhabitants of Antarctic waters.

In shallow water, less than 30 m deep, ice forms seasonally on the bottom around the Antarctic continent, and small icebergs occasionally scour the bottom. The biota in these areas is in a constant state of flux. Some of the animals (sea stars, sea urchins, scallops, worms, fishes) are mobile and so can take advantage of the relatively high productivity in the summer while evading ice damage in the winter. In contrast, the environment in deeper water is unusually calm and undisturbed over very long periods, but varies from place to place with respect to food supply from overlying waters. Areas that receive abundant seasonal food are often biologically complex and diverse, comparable with other diverse marine ecosystems in the world, with dense communities of sponges, soft corals, bryozoans, and other sessile animals. More food-limited areas, covered with thick layers of ice that inhibit productivity, are less complex but may still have a high diversity of small animals, perhaps most comparable to that in the equally stable but food-limited deep-sea.

In the shallow, seasonally rich but disturbed habitats, most animals have reproductive modes similar to their counterparts in other parts of the world. They are mainly gonochoric: separate males and females spawn seasonally, releasing large numbers of small gametes that develop into feeding (planktotrophic) larvae. Such larvae are capable of wide dispersal to distant recently disturbed areas where they can settle and grow into adults with limited risk from competition and predation. In contrast to temperate and tropical species, however, Antarctic species display extremely slow gametogenesis, development, and growth, probably a consequence of low temperature and low food supplies during most of the year. Current work is being done on two of these species: the sea star *Odontaster validus* and the sea urchin *Sterechinus neumayeri*. Both are abundant and easy to rear in the laboratory, and they are excellent for the studying metabolism and development at freezing temperatures.

The biologically complex deeper communities, with extensive cover of sessile, suspension-feeding animals, are more challenging for incoming larvae. Just finding a place to settle is a problem, as well as avoiding being eaten or overgrown by competitors. Most animals in deeper Antarctic communities meet these challenges by producing relatively few but large eggs that develop into large pelagic larvae, and after more limited dispersal, settle as large, more competitive juveniles. This mode of development occurs not only in sessile animals such as sponges and soft corals, which produce large nonfeeding larvae around the world, but also in the sea stars that feed mainly on the sponges and soft corals. Two well-studied examples are the sea stars *Acodontaster hodgsoni* and *Porania antarctica.*

In addition to the putative adaptive value of producing relatively few but large nonfeeding larvae that can recruit into biologically complex communities, there may be historic reasons for the high proportion of nonfeeding larvae in Antarctic waters relative to other seas. During glacial maxima, extensive, thick ice sheets probably extended out over the continental shelf, effectively blocking sunlight year round and severely reducing phytoplanktonic food for feeding larvae. One theory is that during such times, selective extinction of species with feeding larvae could have resulted in the disproportionate number of species with nonfeeding larvae that is seen today.

In addition, some groups (clades) of animals in Antarctic waters are unusual because they produce no pelagic larvae at all; instead, the embryos are either retained (brooded) on or in the mother's body or placed in benthic capsules, where they develop directly into juveniles, bypassing the larval stage. Heart urchins (e.g., *Abatus* spp.) and pencil urchins (e.g., *Ctenocidaris* spp. and *Notocidaris* spp.) are good examples of brooding species that are unusually abundant in Antarctic waters. This mode of development is found in a large variety of animals around the world; what is unusual in the Antarctic is the relatively large number of closely related species, all of which brood, especially among echinoderms and molluscs. Nineteenth-century expeditions noted this phenomenon, and in the mid-twentieth century the Danish marine biologist Gunnar Thorson promoted the idea ("Thorson's Rule") that all polar and deep-sea benthic invertebrates had nonpelagic development as an adaptation to conditions thought to be unsuitable for pelagic, feeding larvae.

Though it is now known that Thorson's Rule is incorrect, the species-rich clades of brooding echinoderms and molluscs remain nearly unique to Antarctic and sub-Antarctic habitats and demand to be explained. One plausible explanation is the unusually favorable conditions for speciation that are provided by the Antarctic Circumpolar Current. This current has been flowing through Drake's Passage for ~30 million years. Brooding individuals could be picked up infrequently from the bottom, particularly during volcanic activity and earthquakes, and transported to new habitats. Because they retain their offspring, and produce no larvae to get carried away, they would be immediately isolated reproductively, and could readily evolve into new species in their new habitats. That would not happen if there was a constant input of new larvae from distant habitats. Such events would not have to happen often over the past 30 million years for numerous closely related species to accumulate in the nearly unchanging Antarctic marine environment. This hypothesis, accounting for the unusual species-rich clades of animals with nonpelagic development in Antarctic waters, remains tentative and must be further explored using modern cladistic approaches and a long-term geologic perspective, but it provides the basis for further study.

RESTORATION: SUB-ANTARCTIC ISLANDS

Restoration is a community phenomenon: an attempt to reproduce exactly the entire community that had been present before some disturbance. Such disturbance is provided largely by nonnative mammals that have driven the extinction of insular species. The indigenous species of the sub-Antarctic islands form a unique collection of plants and animals adapted to conditions in the region. This assemblage is the result of dispersal mechanisms, community interactions and environmental conditions unique to these remote parts of the Southern Ocean. The insular indigenous species are vulnerable to the impacts of introduced mammals such as mice, rats, rabbits, feral cats, and larger herbivores such as goats, sheep and reindeer.

The response to such biodiversity threats is to develop and improve techniques to remove introduced populations from islands. With good planning, adequate techniques and sustained effort, it is possible to control or eradicate invasive species from island ecosystems through measures that are appropriate to the species and the ecosystem. Whereas control operations manage the impacts of the invasives by sustained harvesting of the invasive species populations, eradication permanently removes impacts of the invasive alien species by eliminating the entire population(s). Although eradication is preferred, raising opportunities for ecological restoration, ecosystem response to alien species removals may be unexpected and unwanted such as ecological release of invasive plants when an introduced herbivore is removed, or the irruptions of prey species after the removal of a predator. Invasive mammals are some of the easier species to eradicate, which is fortunate as they are among the most ecologically damaging. Established populations of plants and invertebrates with dormant life stages and high intrinsic rates of increase, on the other hand, present more of a challenge for eradication from islands. The feasibility of eradication will also be affected by risks to nontarget species, which may prevent the use of certain techniques and limit the use of others. Moreover, prevention of initial or further invasion is of paramount importance, especially as there is a correlation between the frequency of landfalls or visits made by humans and the number of alien species that become established. Initially such species are limited in their distribution to areas of human occupation, but most spread from the site(s) of first introduction into other areas. It is therefore important to contain and eliminate species while their distribution is limited.

Despite the adverse weather conditions and challenging topography of sub-Antarctic islands, the successful eradication of introduced species, in particular introduced mammals, from these islands is no longer a rare event. The removal of feral cats from 290 km^2 Marion Island in the south Indian ocean, the largest island where cats have been successfully eradicated (in 1991 after a $\sim$15 year campaign), was followed by (unconfirmed) success at Macquarie Island (120 km^2) in 2000. Bolstered by previous eradications of rats from small islands in lower latitudes, Campbell Island at 113 km^2 in the New Zealand sub-Antarctic represents the largest island where rat eradication was ever undertaken. Islands of the sub-Antarctic Auckland Archipelago were variously rid of mice, rabbits, goats, and cattle between 1983 and 1989, as were some small islands at Îles Kerguelen released from the effects of rabbits.

Methods used to eliminate alien invasives vary substantially depending on the target species. Biocontrol using the feline panleucopaenia (cat flu) virus (feral cats), and myxomatosis (rabbits) provided the initial knock down of the target population(s), followed by other appropriate techniques such as hunting with/without trained dogs, trapping (e.g., walk-in or leg-hold) and poisoning (e.g., 1080 and brodifacoum in artificial or natural baits, at bait stations or by bait sowing). Alien vascular plant and invertebrate species, prioritized according to the degree of threat they pose to the natural environment, especially new introductions, should be targeted immediately. Early detection, emphasis on destroying nascent foci of a potential invasion, and continually surveying for the putative eradicated species are essential. Eradication methods and their combinations (mechanical, chemical, biological) for almost all vascular plant species may amount to considerable time spent cutting or digging out mature individuals, treating stumps with biodegradable herbicides, and blanket spraying of dense infestations. Little information for eradication of both plant and invertebrate invasions in the sub-Antarctic exists, perhaps due to the difficulty of doing so once these have become established.

To achieve eradication, a well-accepted set of conditions must be met, such as proper planning, a commitment to completion of the eradiaction, putting the entire population of the target species at risk, removing them faster than they reproduce, and preventing reinvasion. In fact, prevention of reintroduction is as important as eradication itself. Every island has its own plant and animal species, and where there are several animal invasives, it is important to remove them in the correct order. The removal of one may trigger an increase in the second or make the second more difficult to find or remove. Likely changes to the ecosystem following the initial knockdown of numbers of the introduced animals should be taken into consideration. Support from the local community (expeditioners and/or inhabitants) and public at large is highly desirable, and an ability to demonstrate the benefits of the eradication programme (e.g., the recovery of threatened bird populations after elimination of an alien predator), balanced with ethical considerations (e.g., humaneness of techniques used; clearance by ethics committees) is essential. The positive values of rare breeds of feral animals are a consideration, but their continued presence on sub-Antarctic islands are conditional upon lack of impacts on the primary indigenous values, and each case must be judged on its merits.

In the context of restoration of the intrinsic values of the sub-Antarctic islands, it should be appreciated that no modified habitat can be returned to its pristine condition after alien introductions have been eliminated, but that in time it might resemble the original condition. Immediate results may be spectacular, but a long time may be required for the development of a system that resembles the original one. Indeed, the reinstatement of biotic communities in their original pristine state can seldom be seen as an achievable goal. Prevention is infinitely better than cure.

RIISER-LARSEN, HJALMAR

Hjalmar Riiser-Larsen was born June 7, 1890, in Oslo and made his name within pioneer flying. Although he helped to start both a separate Norwegian Air Force and Norwegian civil aviation routes, he is probably best known for his expeditions with Roald Amundsen.

Riiser-Larsen began his career in the navy, but an experience as a passenger on a navy plane in 1913 turned him to flying himself. He was in the first group of naval pilots to be trained in Norway in 1915, and he quickly made a name for himself. In autumn 1919, he was in Germany testing new planes for the navy, and there he had his first experience of dirigibles. In 1921, he received training as a dirigible operator in Britain. He pioneered long-distance flying in Norway, with his friend and fellow pilot Finn Lützow-Holm.

In 1925, he was the pilot of one of the two aircraft, named *N24* and *N25*, that Roald Amundsen intended to fly to the North Pole. Due to mechanical difficulties, the party landed on the ice at 87°43′ N, and it was Riiser-Larsen's flying skills that brought all six men back to Svalbard in *N25* three weeks later. In 1926, he was navigator and pilot on the dirigible *Norge* during the Amundsen-Ellsworth-Nobile transpolar flight from Svalbard to Alaska, over the North Pole. In 1928, he joined in the search for Nobile's crashed dirigible *Italia,* and later for Amundsen's lost plane.

Riiser-Larsen was the leader of Lars Christiansen's third *Norvegia* expedition to the Antarctic in 1929–1930. With two planes, and Lützow-Holm as fellow pilot, Bouvetøya was photographed from the air, as was also the western part of Enderby Land. On December 22, 1929, Riiser-Larsen and Lützow-Holm landed their plane off a small island by Cape Ann and raised the Norwegian flag, a claim not sustained by the Norwegian government. In mid-January they met the RRS *Discovery* with the British, Australian, New Zealand Antarctic Research Expedition, led by Sir Douglas Mawson, and a friendly agreement was made on where the two expeditions should work. Riiser-Larsen went on to the discovery and aerial charting of Kronprins Olav Kyst and Kronprinsesse Märtha Kyst in what is now Dronning Maud Land.

Riiser-Larsen was again leader on the second half of the fourth and final *Norvegia* expedition, when Prinsesse Ragnhild Kyst was mapped from the air and annexed for Norway, becoming part of the Dronning Maud Land claim in 1939.

In 1933, he led his own expedition to the Antarctic, intending, with two companions and fifty-eight dogs, to explore the coastline from Enderby Land to the Weddell Sea. The expedition was unloaded on to the off-shore sea ice, which broke up during the first night. The camp was divided in two and the ice floe with the men and four dogs drifted out to sea, while the other dogs disappeared. Thanks to a shortwave radio, the men could broadcast an emergency call to the whaling fleet and they were picked up after a couple of days before the ice floe disintegrated. This was the last of Riiser-Larsen's polar expeditions, and he devoted himself thereafter to the development of aviation in Norway. He was highly decorated by several nations during his career. He died in Copenhagen on June 3, 1965.

RODINIA

Rodinia is the name for an ancient supercontinent (a continent that includes all of the landmasses of the Earth, surrounded by a superocean) that existed between 1000 and 750 Ma. The name Rodinia was coined by Mark McMenamin and has its origins in a Russian or Bulgarian word for "to originate" or "homeland" referring to the origins of animal life.

The concept that all of the Earth's continents had been amalgamated into a single landmass in the past was first seriously mooted by Suess in the late nineteenth century, and reiterated by Wegener in the early twentieth, finally finding general acceptance with the plate tectonic revolution of the 1960s. The first proposed Gondwana supercontinent overlapped with the age of the dinosaurs and its final amalgamation and eventual fragmentation lay fully within the period of Earth history for which we have a fossil record.

A more ancient supercontinent, existing in the period that predated the fossil record (more than 543 Ma), was first mooted in the 1970s based on palaeomagnetic evidence. However, the idea did not gain scientific acceptance until the early 1990s when a series of geological synthesis papers demonstrated a former physical connection between the continents, predating the formation of Gondwana. The name Rodinia predated the scientific acceptance of the idea by barely a year.

The modern conception of Rodinia was born out of a scientific idea called the SWEAT (Southwest US–East Antarctica) hypothesis, in which Antarctica played a key role. The acronym comes from the fact that the southwestern US and East Antarctica have sufficient geological similarities to suggest that they were linked together more than 750 Ma. This is, in particular, via distinctive fragments of an even older mountain belt, called the Grenville Belt, that had been active from 1300–1000 Ma. Fragments of the Grenville Belt were known from many continents and it quickly became apparent that they were the key to piecing together Rodinia, which had Laurentia at its core and South America on its eastern flank.

Although there are many uncertainties of timing over the exact details of the process, Rodinia appears to have formed by a series of continent–continent collisions, creating orogens (mountain belts) generally referred to as Grenvillian in the northern hemisphere, Kibaran in Africa, Albany-Fraser in Australia, and Uruaçu-Sunsás-Cariris Velhos in South America. Rodinia lasted about 200 million years, surrounded by the Mirovoi Superocean, and began to break up about 800–750 Ma. This was associated with emplacement of mafic dyke swarms (the Franklin dyke swarm is a particularly well-preserved example in Canada), formation of rift basins such as the Reelfoot rift basin which extended from the modern-day Gulf of Mexico to Illinois, and the origin of the Pacific and Iapetus (a precursor to the Atlantic) oceans. It is suggested that another supercontinent called Pannotia (residing in the southern hemisphere) briefly existed during the breakup of Rodinia.

Since its proposal, the configuration of the supercontinent has gone through much revision and, although there is scientific consensus that it existed, there is no universally agreed configuration. Following SWEAT, the AUSWUS (Australia–southwestern US) hypothesis made convincing claims for juxtaposition of the western half of Australia against the southwestern USA and similar suggestions have been made for Australia against Mexico, the AUSMEX hypothesis. Recent palaeomagnetism studies have shown that there is still considerable uncertainty in Rodinia configurations and even go so far as to argue that although Rodinia probably existed, there is no evidence for SWEAT or AUSWUS or AUSMEX.

One consequence of the conception of Rodinia is that it supported a palaeoenvironmental hypothesis called the "Snowball Earth" recently championed by Paul Hofmann. Brian Harland first proposed this as early as 1964 and the hypothesis presented the surprising implication that in the past the Earth was encased in ice from pole to equator to pole. On some Rodinia reconstructions the continents are largely distributed in the Southern Hemisphere and within 60 degrees of the equator. Unexpectedly, if sedimentary rocks from this time are examined, a strange mix of limestones that formed in warm shallow marine conditions, so-called cap carbonates, and glacial sediments are found. The glacial sediments are similar to those seen in Scotland and Canada today, sands and gravels and unsorted mixtures of mud and gravel called diamictons, but the Rodinia deposits have been converted to rock.

The distribution of these rocks supports the unexpected conclusion that there was continental glaciation from high latitudes right to the equator. The warm-water shallow-water marine limestones are found resting on top of the glacial sediment deposits in many cases and this relationship suggests that there was low altitude glaciation as well as low latitude glaciation. An explanation for this touches on one of the major current competing hypotheses for the onset of global glaciation. This invokes declining levels of atmospheric carbon dioxide, a greenhouse gas, as the major cause. Although it relates more to the death than the birth of Rodinia, a keystone of the "Snowball Earth" hypothesis is that the breakup of Rodinia resulted in increased weathering rates and carbon dioxide draw-down that began a downward spiral into global glaciation.

East Antarctica was at the heart of the first evidence for Rodinia, which came from the observation that it and the southwestern US were once side-by-side. Antarctic geological data and discoveries have subsequently been of key importance in the development of the idea, which has been extremely stimulating for geological study of the Precambrian history of the continent. The conception of Rodinia has made geologists look again at East Antarctica, which has been assumed to have been unchanged since Archaean times, and find new evidence for Proterozoic geological subdivisions of the craton and former mobility between these younger component parts.

RONNE ANTARCTIC RESEARCH EXPEDITION (1947–1948)

Led by Norwegian-American Finn Ronne (1899–1980), the Ronne Antarctic Research Expedition (RARE) of 1947–1948 was the last large private expedition to Antarctica. It explored both coasts of the Antarctic Peninsula and the Weddell Sea's southern margin, on the ground and with aircraft, and also marked the first time that women wintered in Antarctica.

Cdr Finn Ronne, USNR, served as ski expert and dog-driver on Richard E. Byrd's second Antarctic expedition and was second-in-command of East Base, at Stonington Island in Marguerite Bay on the west side of the Antarctic Peninsula, during the US Antarctic Service Expedition (USAS) of 1939–1941. His father, Martin Ronne, was a sailmaker on Roald Amundsen's Norwegian Antarctic Expedition (1910–1912) and sailmaker, ski instructor, and dog-driver on Byrd's first Antarctic expedition.

Although a private expedition, the RARE received funding from the American Geographical Society, the Office of Naval Research (which paid for scientific work), and the North American Newspaper Alliance, which bought exclusive news rights. The US government loaned clothing and equipment, including a 1200-ton diesel-powered wooden US Navy tug (renamed *Port of Beaumont*) commanded by Cdr Isaac Schlossbach USN (Ret.); three US Army Air Force ski-equipped aircraft (a Stinson L-5, a single-engine Norseman C-64, and a twin-engine Beechcraft C-45); and two US Army Weasel tracked vehicles.

The expedition sailed from Beaumont, Texas, on January 25, 1947, with forty-three huskies to be used as sledge dogs, but half died of distemper en route to Antarctica. Among the expedition's twenty-three members, nearly all unpaid volunteers, were Edith ("Jackie") Ronne, wife of the expedition leader, and Jennie Darlington, wife of pilot Harry Darlington. The women had not planned to participate in the expedition, but at a late hour Finn Ronne convinced his wife to come to write its newspaper dispatches and other records. Jennie Darlington, asked to join as well, became pregnant during the expedition and nearly gave birth to the first native Antarctican.

The expedition arrived at Stonington Island on March 12; *Port of Beaumont* was frozen into Back

Bay, 500 yards (450 m) from the base, through the winter. Plans to reuse the USAS's former East Base were complicated when Ronne found it damaged and looted. Recriminations flew, with Ronne suggesting that the eleven occupants of the UK's neighboring Falkland Islands Dependencies Survey (FIDS) Base E might have been responsible, while the FIDS members said the destruction was caused by visiting Argentines or Chileans. This led to initial chilliness in relations between the two expeditions, but they soon grew closer and eventually cooperated on field work, building on their respective strengths: dog teams and dog-handling (British) and aircraft (Americans).

The expedition's main objectives were to determine whether the mountain range running along the Antarctic Peninsula connected to either the Queen Maud Mountains or the mountains of Marie Byrd Land; and to determine whether the Weddell and Ross seas were connected, by exploring the Antarctic continent's, and the world's, last major stretch of unexplored coast, along the Weddell Sea from the Antarctic Peninsula to Coats Land. The first 3-hour reconnaissance flight to the south was made on March 18, and the expedition's scientists began collecting data on tides, weather, and seismic activity.

A six-man party set up a weather station on the 6000-foot (1830 m) peninsular plateau on July 15. After being confined to their tents for eight days by harsh weather, two men, physicist Harris-Clichy Peterson and geologist/surveyor Robert Dodson, remained at the camp while the others returned to Stonington Island. Late on July 26, Dodson appeared at the American base with the news that Peterson had fallen into a crevasse nine miles away. A joint American-British team rescued him the next day. He was not seriously harmed despite plunging 110 feet (34 m)—and remaining wedged for 10 hours lying face-down in the crevasse.

During a British-American exploration flight to the east side of the Peninsula on September 15, the two planes became separated. The British plane crash-landed on sea ice in Marguerite Bay, and only after a 9-day search by the Americans was its crew found unhurt.

An advance base for weather observation was established on September 29 at Cape Keeler on the east side of the Antarctic Peninsula plateau, along the Weddell Sea coast 125 miles (200 km) southeast of Stonington Island.

Aviation was restricted by unfavorable weather, but several notable flights—usually involving a shuttle system using two planes to relay fuel—were achieved. On November 21 and December 12, Ronne navigated flights along the southern coast of the Weddell Sea and found that it connects to Coats Land, with no outlet south to the Ross Sea. He named the newfound territory Edith Ronne Land. However, later investigations during the IGY, also by Ronne, determined that most of the area is an ice shelf, so the name Ronne Ice Shelf is applied to the area west of Berkner Island, separating it from the Filchner Ice Shelf. On November 23, a long flight was made to the southwest, over the eastern and southern coasts of Alexander Island, with a landing (the first) at Charcot Island on the return to base.

Meanwhile, surface field parties were active. Dodson and chief scientist Robert Nichols, on a geological survey using a thirteen-dog team, made a 90-day (September 28 to December 26) sledge trip south to George VI Sound, covering 450 miles (725 km). A four-man British-American Weddell Sea coast party, with three sledges and twenty-three dogs, covered 1180 miles (1900 km) in 106 days, from October 9, 1947, to January 22, 1948.

Two icebreakers taking part in the US Operation Windmill, USS *Burton Island* and USS *Edisto,* broke out *Port of Beaumont,* still held by sea ice, on February 20, 1948, and the expedition reached New York on April 15 that year.

The Ronne expedition achieved a great deal with its relatively limited budget of less than $50,000, far smaller than many expeditions of its era. It explored more than 250,000 square miles (650,000 km^2) of Antarctica, and in 346 hours of flight time, including eighty-six landings in the field, took nearly 14,000 photographs covering 450,000 square miles (1,165,000 km^2), crucially, with ground control.

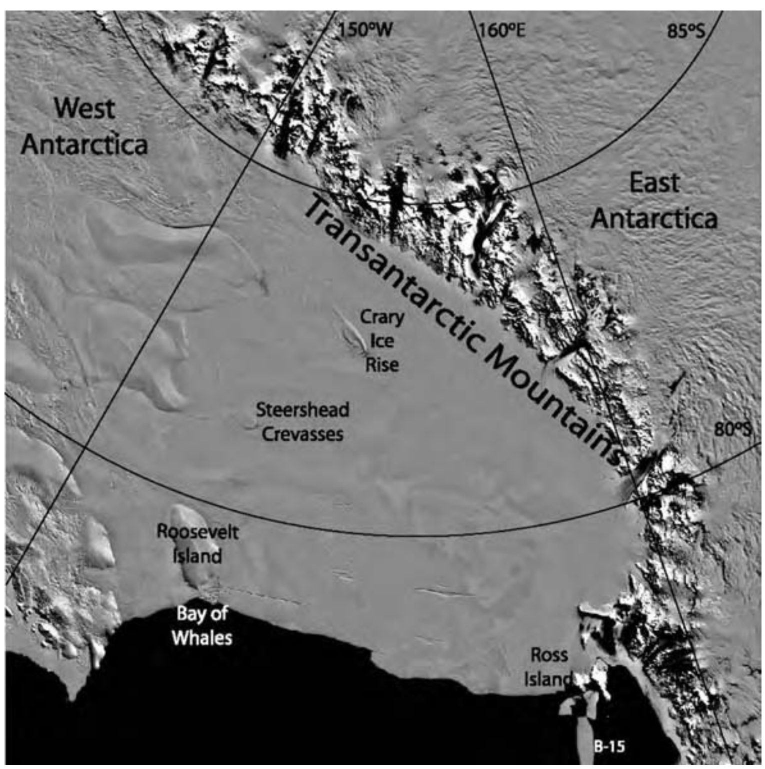
ROSS ICE SHELF

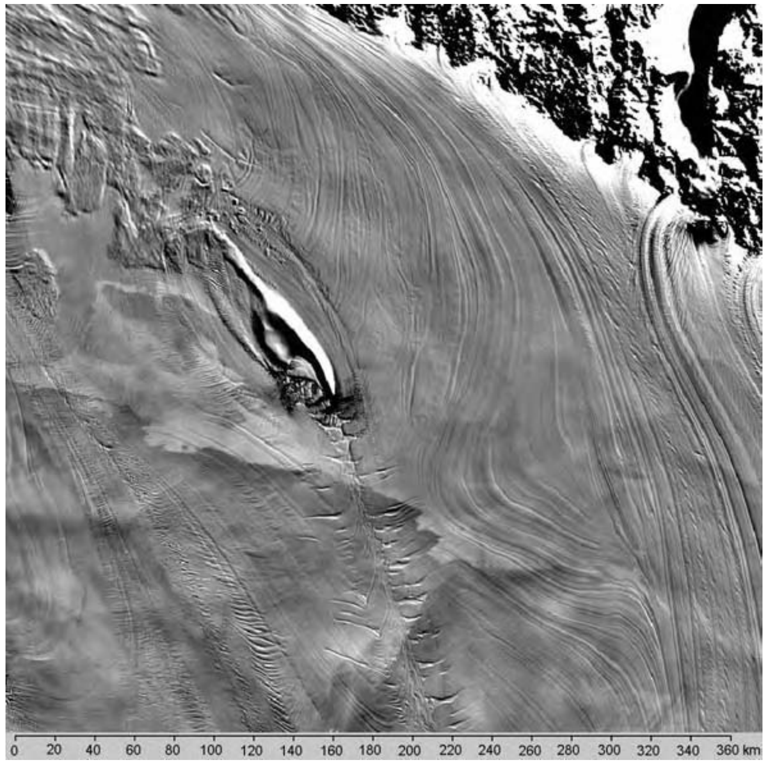
The Ross Ice Shelf is a vast, roughly triangular plate of thick floating ice extending from about 78° S to 85° S and from 150° W to 160° E. It is about 520,000 km^2 in area (roughly equivalent to Texas or Spain), making it the largest single sheet of floating ice in the world. The average depth of the ice is approximately 370 meters. McMurdo Station and Scott Base, both on Ross Island, lie near the ice shelf's northwestern corner. The Bay of Whales and Roosevelt Island, near the former exploration bases sharing the name Little America, lie near its northeastern corner. The southwestern edge is defined by 700 kilometers of the Transantarctic Mountains while the eastern edge is marked by a series of ice streams emerging from West Antarctica. Ice up to 700 meters thick flows into the ice shelf along these edges from West Antarctic ice streams and East Antarctic outlet glaciers, traveling at speeds up to 800 meters per year. These ice flows merge to form the ice shelf, along with snow which accumulates on the surface at an average rate of 15 centimeters per year (in water equivalent units). The northern edge of the shelf constitutes the calving ice front.

The ice is not stagnant, but flows generally horizontally northward driven by gravity, which causes it to thin and spread out, and by the push of the glaciers and ice streams that discharge into it. It also moves downward as additional snow accumulates on the surface. The horizontal motion is resisted by the water in which the ice shelf floats and by areas where the ice comes into contact with stationary rock, principally the Transantarctic Mountains and isolated elevated regions of the seafloor: Roosevelt Island, Crary Ice Rise, and Steershead Crevasses are three primary regions of subshelf resistance. Ice moves over or around these areas of contact, creating fields of crevasses that can fracture the ice through its full thickness. Ice at the calving front is typically 200 meters thick and moves at about 1000 meters per year.

Water circulates in the cavity between the bottom of the ice and the sea floor. The circulation pattern is driven by tidal forces and is generally counterclockwise, taking about 5 years for a full transit beneath the ice. As the circulating water is forced downward



Satellite image of the Ross Ice Shelf using data from NASA's Moderate Resolution Imaging Sensor (MODIS). South Pole is off the top of figure. (Image courtesy of National Snow and Ice Data Center.)



Satellite image detail of flowstripes on the Ross Ice Shelf. Transantarctic Mountains are in the upper right and Crary Ice Rise is the bright and dark feature left of center. Ice flow is from upper left to lower right. In the upper left is a region of grounded ice in the mouth of Whillans Ice Stream. As this ice flows around Crary Ice Rise, crevasses are formed that are carried along in the ice shelf. Evidence of time-variable flow is seen in the large looped flowstripes right of center. (Image courtesy of National Snow and Ice Data Center.)

by the increasing ice thickness, it melts the underside of the ice shelf. Conversely, as the water rises on its journey back out, it freezes to the underside. This causes the water cavity to be deeper on the western side (about 500 meters deep) and shallower (about 200 meters deep) on its eastern side.

In most years, the surface of the ice shelf receives snow and does not melt. This snow builds up, compressed by subsequent snowfalls. Ice is lost primarily by the calving of icebergs at the shelf front. These icebergs can be extremely large, as in the case of the Connecticut-sized B-15 iceberg formed in 2001. Calving is episodic and generally removes only a portion of the ice front, which is then replaced by the continued seaward flow of the shelf.

The ice front has remained at approximately the same position for the past century, with northward flow balancing the calving of icebergs from the front. At the end of the last glacial period the region of the Ross Ice Shelf contained ice so thick that the base of the ice contacted the bed nearly everywhere, and grounded ice extended an average of 200 km farther north, approaching Coulman Island. As the climate began to warm approximately 20,000 years ago, the ice sheet began to thin and retreat. As grounded ice thinned and retreated, a floating ice shelf was formed. Retreat of the shelf front began about 11,400 years ago.

Aside from regions where concentrated stresses create crevasses, the surface of the Ross Ice Shelf is very flat, rising less than 1 meter over a distance of 10 kilometers. This flatness, as well as the great southerly extent of the Ross Ice Shelf (within 550 kilometers of the South Pole), was favored by early explorers. Both Roald Amundsen and Robert Falcon Scott chose to make their treks to the South Pole across the Ross Ice Shelf.

This flatness is deceptive; precise satellite sensors have revealed an extensive set of subtle surface features that record the last millennium of ice flow into the ice shelf. The feeding glaciers and ice streams introduce sets of flowstripes that trace the path of ice flow across the ice shelf. The western third of the ice shelf shows a steady flow from East Antarctica, while the eastern third shows a similar steady pattern of flow from the northern part of West Antarctica. The middle third, however, shows distorted flowstripes indicating time-variable flow of the incoming ice streams.

Sir James Clark Ross is believed to have discovered the ice shelf in 1841. Study of the Ross Ice Shelf began with the explorers of the first decade of the twentieth century who collected the first information on surface elevation, despite the hardships of traversing the shelf's surface by dogsled and skis. Admiral Richard Byrd's expeditions of Antarctica, begun in 1928, introduced airplanes as a means to survey more of the shelf's area. The first circumnavigation of the shelf was conducted from 1957 to 1958 during the International Geophysical Year using snow tractors. This traverse party, led by Albert Crary, made the first extensive measurements of the shelf's thickness and the depth of the water cavity below using seismic techniques, used multiple pressure altimeters to measure the elevation of the ice shelf, dug snow pits to determine snow density, hardness, and average accumulation rates, and measured snow temperatures to determine mean annual air temperatures. More intensive studies using advanced geophysical techniques were employed from 1973 to 1978 during the Ross Ice Shelf Geophysical and Glaciological Survey, which included the first hole drilled through an ice shelf providing direct access to the subshelf water cavity. Field studies have continued to the present, employing ever more sophisticated instruments and methods, including an increased use of satellite data.

ROSS ISLAND

Ross Island is located in the Ross Sea at 77°30′ S, 168°00′ E on the east side of McMurdo Sound. It is roughly triangular in shape, approximately 43 miles from Cape Bird on the north to Cape Armitage on the south and approximately the same distance from Cape Royds on the west to Cape Crozier on the east. Ross Island is volcanic in origin. Mount Erebus, Antarctica's largest and most active volcano, rises 12,450 feet (3795 meters) from the center of the island and Mount Terror, an extinct volcano, rises, 10,600 feet (3230 meters) 20 miles (32 km) to the east of Erebus. Two other peaks are found on Ross Island: Mount Bird, rising 5800 feet (1765 meters) just south of Cape Bird, and Mount Terra Nova, rising 6990 feet (2130 meters) between Mount Erebus and Mount Terror.

Ross Island was discovered by James Clark Ross on an expedition to find the south magnetic pole. Sailing with his two ships, the *Erebus* and the *Terror,* in January 1841, he sighted a high mountain "emitting flame and smoke in great profusion," a mountain he named Erebus. As Ross continued his exploration of the area, he discovered a bay that he named McMurdo Bay (later renamed McMurdo Sound), after the senior lieutenant of the *Terror*.

Geologically, Ross Island is the result of volcanic activity that began approximately 4 Ma with the formation first of Mount Bird, then Mount Terror, and finally, Mount Erebus, which is younger than 1 million years. Mount Erebus produces an unusual volcanic rock popularly called kenyte (technically known as anorthoclase phonlite, a unique type of feldspar). The only other place in the world this igneous rock is found is in Kenya, Africa.

There are several glaciers on Ross Island, the most visited being the Erebus Glacier, which flows from the lower slope of Mount Erebus. The Erebus Glacier flows onto the sea ice to form the Erebus Glacier Tongue. Ice caves form where the Erebus Glacier Tongue extends onto the sea ice.

Recorded temperature extremes have been as low as –50°C and as high +8°C. The monthly mean temperatures ranges from –3°C in January to –28°C in August. Drifting snow can accumulate 1.5 meters per year, although the station becomes snow-free in summer. Average wind is about 5.1 meters per second; a gust of 52 meters per second was recorded in July 1968 (NSF 1997).

The sea around Ross Island is rich with marine life, an important factor for supporting the native birds and mammals. Slow-growing sea sponges feed on the diatom rich waters. Sea anemones and sea stars, brittle stars and brittle worms, all inhabit the waters around Ross Island. Many species of fish also inhabit these waters including ones that have a natural antifreeze in their bodies that allows them to survive in the extremely cold water without freezing. Krill, small shrimplike crustaceans, are also abundant in the waters around Ross Island.

Feeding on the krill and small fish in the waters off Ross Island are two of the best-known bird inhabitants of Antarctica. Ross Island is home to three Adélie penguin colonies, the largest one at Cape Cozier, another at Cape Bird, and the most southerly Adélie rookery in Antarctica at Cape Royds. Emperor penguins, the largest of the Antarctic penguins, breed in the vicinity of Ross Island and can occasionally be seen on the sea ice nearby. Skuas also breed on Ross Island, feeding on the eggs and chicks of the Adélie penguins as well as fish and anything else edible they can find.

Seals are also found around Ross Island. The most common is the Weddell seal. Weddell seals are solitary animals, preferring to lie on the sea ice when they are not hunting for fish. When hunting for food, the Weddell seal dives beneath the sea ice and can stay underwater for more than fifteen minutes, diving to depths of more than 1000 feet (304 meters). Crabeater seals are also found in the vicinity of Ross Island. The crabeater seal is more agile on land and ice than other Antarctic seals. Occasionally leopard seals are seen in the waters around Ross Island, near the fast ice edge or penguin rookeries. The leopard seal is the only seal that regularly preys on warm blooded animals, often hunting for penguins or sea birds.

The Antarctic is home to a number of whales, and the area around Ross Island is frequented by orcas, also know as killer whales, and minke whales. Orcas are often seen during the austral summer patrolling the waters near penguin rookeries as well as the ice edge. Minke whales feed on the krill abundant in these waters during the austral summer.

Human Use and Habitation

The Heroic Era

Though discovered by James Clark Ross in 1841, no humans set foot on Ross Island until 1902 when Robert Falcon Scott, in the ship *Discovery,* made his way into McMurdo Sound. As part of his *Discovery* expedition, Scott planned to explore the Ross Ice Shelf, known at that time as the Barrier. He also hoped to find a sheltered location to set up winter quarters, a location that would also provide him access to the geographic south pole. He explored the area around Cape Bird and Cape Crozier but returned to McMurdo Sound and decided to winter at Hut Point, the southwestern extremity of Ross Island. During February and March the *Discovery* hut was constructed. Because it was too hard to heat efficiently, Scott and his men did not live in the hut but used it primarily for storage.

Discovery expedition named many of the features of Ross Island. Cape Armitage was named for Scott's navigator. Observation Hill, adjacent to present day McMurdo Station was named because, at 750 feet (228 meters), it made an excellent lookout site. The point of land where they were to build their hut was Hut Point and the bay to the south of Hut Point was named Winter Quarters Bay. These names continue in use today.

The next historic expedition to Ross Island was Ernest Shackleton's *Nimrod* expedition, 1907–1909. Shackleton had hoped to base himself near the Bay of Whales, but he found the ice there too dangerous. So he headed north towards Ross Island but was only able to get as far as Cape Royds, a spot about 22 miles (37 km) north of Hut Point and Scott's *Discovery* hut. Here, in February 1908, Shackleton constructed a small hut for himself and fifteen expedition members. From this site, Shackleton and three others made it to within 97 miles (156 km) of the geographic south pole, making use of the *Discovery* hut as a shelter while laying supply depots along the planned route. In addition to reaching the furthest point south yet achieved, Shackleton's *Nimrod* expedition made the first ascent of Mount Erebus and reached the south magnetic pole.

Scott's second (and last) expedition left England in June 1910 on the *Terra Nova.* He reached Ross Island in the first week of January 1911, but was unable to base at Hut Point because of ice conditions. Instead he chose a location about 15 miles (24 km) to the north, which he named Cape Evans in honor of his second in command. Scott constructed a new hut at Cape Evans, 24 feet wide (7.3 meters) and 48 feet long

(14.6 meters) to accommodate twenty-five men. From the hut at Cape Evans, Scott sent out two parties, one to carry out geological exploration and the other to lay a supply depot for the planned journey to the Pole. Both parties used the *Discovery* hut for shelter, and in November 1911, Scott and four companions used it as their starting point for their trek to the South Pole. Today the hut at Cape Evans remains much as it was left, slabs of seal blubber in the outer porch area and provisions and photographic supplies still on the shelves.

The final expedition to Ross Island in this time period (commonly known as the Heroic Era) was part of Shackleton's *Endurance* expedition. With the South Pole having already been reached, Shackleton concluded that the one remaining Antarctic challenge was to cross the continent from sea to sea. The route he chose was from the Weddell Sea to McMurdo Sound. The task of laying supply depots from Ross Island to the foot of the Beardmore Glacier, which Shackleton planned to traverse after reaching the Pole, was given to the captain and crew of the *Aurora*. They frequently used the *Discovery* hut as a base of operations for laying supply depots though the depots were never used. While the *Aurora* handled the McMurdo Sound end of the attempt to cross the continent, Shackleton sailed the *Endurance* to the Weddell Sea. There the *Endurance* became trapped by ice, drifted for ten months, and was eventually crushed.

The Modern Era

McMurdo Station, located on the bare volcanic rock of Hut Point Peninsula, is the largest research station in Antarctica and the logistics hub of the US Antarctic Program (USAP). The station was established in December 1955 to support research for the International Geophysical Year (IGY). Since then it has grown from a few buildings to a complex logistics staging facility of more than 100 structures. It has a helicopter pad and an outlying airport, Williams Field, as well as a landing strip on the Ross Ice Shelf, Pegasus site, and a landing strip closer in to the station on the annual sea ice. McMurdo Station is also the world's most southern seaport, with an ice pier and vessel offloading facilities located at Winter Quarters Bay.

The station has administrative facilities, dormitories, equipment repair facilities, a power plant and associated fuel storage tanks, a firehouse, a reverse osmosis water plant, and a wastewater treatment plant. Buildings are linked by above-ground water, sewer, telephone and power lines. Peak population during the austral summer can exceed 1100, with a winter population of about 250. The winter population is normally isolated from late February, when airfield operations cease, until late August.

The USAP employs Hercules (LC-130 and C-130), Starlifter (C-141), and Galaxy (C-5) aircraft in airlift operations. During the summer months, October to February, these planes fly between Christchurch, New Zealand, and McMurdo, carrying passengers and cargo. The ski-equipped LC-130s are also used for flights to South Pole Station. Twin Otters are used primarily to support more remote field camps.

Scott Base, the New Zealand research station, is situated on Pram Point at the end of Hut Point Peninsula. Scott Base was originally constructed to support New Zealand's contribution to the IGY project and as headquarters for Sir Edmund Hillary's activities in support of the British Commonwealth Trans-Antarctic Expedition, which made the first land crossing of the Antarctic continent.

Today the base has accommodations for up to eighty-six people and comprises eight main interconnected buildings that house administration areas, equipment workshops, a power plant, and a laboratory. The base also has bulk fuel storage tanks, two helicopter pads, a reverse osmosis water treatment plant and a wastewater treatment facility. Scott Base is run by the New Zealand Antarctic Institute, operating as Antarctica New Zealand. New Zealand shares use of the McMurdo airfield facilities with the US Antarctic Program.

Specially Protected Areas

Under the Antarctic Treaty System, the concept of setting aside areas for special protection was introduced by the Agreed Measures for the Conservation of Antarctic Fauna and Flora (1964). Protected areas were designated for scientific reasons. The Protocol on Environmental Protection to the Antarctic Treaty, which entered into force in 1998, provided for modifications to protected area designations, expanding on the reasons for protection to include historic, aesthetic and wilderness values as well as scientific values. A new designation was given for areas to be set aside and entered only under permit, Antarctic Specially Protected Areas (ASPAs).

Because of its unique place in the history of Antarctic exploration as well as its wealth of unusual biota, Ross Island has a number of areas set aside as ASPAs. Five sites have been designated as specially protected for their scientific values:

- ASPA No. 116, "New College Valley," Caughley Beach, Cape Bird, located at 77°13′ S, 166°29′ E, was originally designated as two sites. The two sites were merged under a single designation in 2000. Caughley Beach lies between the Cape Bird northern and middle penguin rookeries, about 1 km north of Cape Bird. The site was designated to protect one of the most extensive stands of moss, algae, and lichens in southern Victoria Land as well as the terrestrial ecosystem within the site that is the subject of continuing long-term research.
- ASPA No. 121, Cape Royds, located at 77°33′ S, 166°08′ E, is an area designated to protect the most southerly Adélie penguin colony known. The area extends 500 m offshore from the high water mark and extends inland to include the entire penguin colony and past Pony Lake (named by Shackleton's British Antarctic Expedition of 1907–1909 because they had their ponies tethered nearby).
- ASPA No. 122, Arrival Heights, Hut Point Peninsula, at 77°49′ S, 166°39′ E, is an area close to McMurdo Station designated as an electromagnetically quiet site for installation of sensitive instruments used to record data associated with upper atmosphere research programs.
- ASPA No. 124, Cape Crozier, is defined by lines joining 77°28′ S, 169°20′ E; 77°28′ S, 169°28′ E; 77°31′ S, 169°28′ E; and 77°31′ S, 169°20′ E. It was designated to protect the long-term research value of the emperor and Adélie penguin colonies found in the site that have been the subject of study for over 30 years.
- ASPA No. 130, Tramway Ridge, Mount Erebus, at 77°31′ S, 167°07′ E, encompasses the entire warm ground area of lower Tramway Ridge. It is designated to protect one of only three known high-altitude areas in the Antarctic of fumarolic activity (a volcanic area from which hot smoke and gases escape) and associated vegetation.

Historic Sites and Monuments on Ross Island

Site Number and Name	Description
HSM 15 Hut at Cape Royds	Hut built in February 1908 by the British Antarctic Expedition, 1907–1909, led by Sir Ernest Shackleton. Located within ASPA No. 157.
HSM 16 Hut at Cape Evans	Hut built in January 1911 by the British Antarctic Expedition, 1910–1913, led by Captain Robert F. Scott. Located within ASPA No. 155.
HSM 17 Cross at Cape Evans	Cross on Windvane Hill erected by Ross Sea party of the Imperial Trans-Antarctic Expedition, 1914–1916, led by Sir Ernest Shackleton, in memory of three members of the party who died. Located within ASPA No. 155.
HSM 18 Hut at Hut Point	Hut built in February 1902 by the British Antarctic Expedition, 1901–1904, led by Captain Robert F. Scott. Designated as ASPA No. 158.
HSM 19 Cross at Hut Point	Cross erected in February 1904 by the British Antarctic Expedition, 1901–1904, in memory of George Vince, a member of the expedition, who died in the vicinity.
HSM 20 Cross on Observation Hill	Cross erected in January 1913 by the British Antarctic Expedition of 1910–1913 in memory of Captain Robert F. Scott's party which perished on the return journey from the South Pole in March 1912.
HSM 21 Hut at Cape Crozier	Remains of a stone hut constructed in July 1911 by Dr. Edward Wilson's party of the British Antarctic Expedition, 1910–1913, during the winter journey to collect emperor penguin eggs. Located within ASPA No. 124.
HSM 54 Bust on Ross Island	Bronze bust on black marble erected in 1965 at McMurdo Station to commemorate the polar achievements of Admiral Richard E. Byrd.
HSM 69 Message post at Cape Crozier	Erected on January 22, 1902 by Captain Robert F. Scott's Discovery Expedition of 1901–1904. It was to provide information for the expedition's relief ships, and held a metal message cylinder which has since been removed. Located within ASPA No. 124.
HSM 73 Memorial Cross, Lewis Bay	Stainless-steel cross erected in January 1987 on a rocky promontory 3 km SE from the crash site, in memory of the people who lost their lives when their aircraft crashed into the lower slopes of Mount Erebus.
HSM 75 "A Hut," Pram Point	The "A Hut" of Scott Base, erected in 1956, is the only existing 1956–1957 Trans-Antarctic Expedition building in Antarctica. It was also the first New Zealand building erected in Antarctica.

Four ASPAs have been designated for their historic values and to provide further protection of the artifacts on site.

- ASPA No. 155, Cape Evans, at 77°38′ S, 166°24′ E, is centered on Scott's *Terra Nova* hut. Designated to protect historic structures and relics pertaining to the Heroic Age of Antarctic exploration, the site has considerable historical, cultural, and scientific significance.
- ASPA No. 156, Lewis Bay, Mount Erebus, comprises an area of approximately 15.2 km^2 at 167°28′ E, 77°25′ S. Originally designated a tomb in 1981, the site encompasses the crash zone of an Air New Zealand DC-10 aircraft that crashed into the northern slope of Mount Erebus on November 28, 1979. All 257 people on board the aircraft lost their lives in the tragedy.
- ASPA No. 157, Backdoor Bay, Cape Royds, is located at 77°33′ 10.7″ S, 166°10′ 6.5″ E. It is centered on the hut built in 1908 by Shackleton's *Nimrod* Expedition. The site was designated to provide protection for the hut and associated historic artifacts.
- ASPA No. 158, Hut Point, at 77°50′ 50″ S, 166°38′ E, consists solely of the hut built by Scott's *Discovery* expedition in 1902.

Historic Sites and Monuments

The Antarctic Treaty also provides for designating specific Historic Sites and Monuments (HSMs), a designation intended to preserve and protect individual historic sites and monuments in Antarctica. Because of its historical significance, Ross Island has eleven sites that are designated as HSMs.

ROSS, JAMES CLARK

James Clark Ross participated in a total of nine polar expeditions, more than any other nineteenth-century naval officer, and wintered in the Arctic for a total of nine winters. Third son of George and Christian Ross, he was born at Finsbury Park, London, on April 15, 1800. Entering the Royal Navy as a first-class volunteer on April 5, 1812, he joined HMS *Briseis,* commanded by his uncle, John Ross. For seven years thereafter he served exclusively on his uncle's ships in the Baltic Sea, the White Sea, and the English Channel. In 1818, he sailed to the Arctic for the first time, as midshipman on board HMS *Isabella* on John Ross's expedition to Baffin Bay, in search of the Northwest Passage. On this voyage James Clark Ross was assigned to assist Colonel Edward Sabine with his studies of terrestrial magnetism, recording his observations. This would determine the direction of his future career.

In 1819, Captain William Edward Parry selected Ross, in part due to his expertise in magnetism and scientific investigations, to serve as midshipman on board his ship HMS *Hecla* on Parry's first Arctic expedition. Thus James Clark Ross experienced his first Arctic wintering at Winter Harbour, Melville Island, 1819–1820. In 1821–1823, he again joined Parry, as midshipman on board HMS *Fury,* wintering first at Winter Island, then at Igloolik in Foxe Basin. Ross acted as the expedition's naturalist, collecting birds, mammals, and plants. On December 26, 1822, Ross was made lieutenant and soon after his return to England was elected a Fellow of the Linnaean Society. In the following year he was bound for the Arctic once again, as second lieutenant on board HMS *Fury* on Parry's third expedition. Blocked by ice in Prince Regent Inlet, the expedition wintered at Port Bowen on the Baffin Island shore. In 1825, *Fury* was driven ashore by the ice at Fury Beach on the east coast of Somerset Island and had to be abandoned. This was a clear demonstration to Ross of the power of sea ice.

Ross's fifth expedition took him to Svalbard in 1827, second-in-command of Parry's expedition on board HMS *Hecla,* the aim of which was to reach the North Pole. Parry found a safe anchorage in Treurenburg Bay (now Sorgfjorden) in northeastern Spitsbergen, and a party led by Parry and Ross started north across the ice with boats mounted on runners. Realizing that the southerly drift of the pack ice was exceeding their northerly rate of progress, Parry finally turned back after more than a month on this "Arctic treadmill." After their return home Ross was promoted commander on November 8, 1827.

Two years later James Clark's uncle, John, invited him to be second-in-command of his private expedition, on board *Victory,* still in search of the Northwest Passage, via Prince Regent Inlet. The younger Ross made the most important sledging trips of the expedition from the ship's winter quarters at the east end of the Isthmus of Boothia. In the spring of 1831, he located the North Magnetic Pole near Cape Adelaide on the west coast of Boothia Peninsula. Later (in 1832 and 1833), he played a crucial role in the retreat north to Fury Beach and beyond, after *Victory* had been abandoned when the ice did not break up. Thus, along with the rest of *Victory*'s complement he survived four consecutive unsupported winters in the Arctic.

Ross was promoted post captain on October 28, 1834. Then, in 1836, he mounted a rescue expedition for eleven whaling ships beset in the ice of Davis Strait. In HMS *Cove* he searched Davis Strait and the Labrador Sea from mid-April until early August; the whalers (except one that was crushed by the ice) managed to get free on their own.

In September 1839, the Lords of the Admiralty chose Ross, as the Royal Navy's most experienced ice-navigator and an expert on magnetism, to lead an expedition to the Antarctic to explore that continent and to locate the South Magnetic Pole. The expedition sailed from the Thames in HMS *Erebus* and *Terror* on September 25, 1839. In the summer of 1840–1841, Ross pushed through the pack ice into the open waters of the Ross Sea and was the first to see the ice cliffs of the Great Ice Barrier or Ross Ice Shelf. Ross determined that the South Magnetic Pole lay some distance inland in Victoria Land, west of the Ross Sea. In the following summer, he returned to the Ross Sea again, and mapped more of the Barrier. In March 1842, his two ships collided in a gale and came within an ace of being driven against an iceberg. And finally in the summer of 1842–1843, he penetrated into the northwest corner of the Weddell Sea and discovered and mapped Erebus and Terror Gulf and many of the surrounding islands.

On the expedition's return to England in September 1843, Ross was knighted and was awarded an honorary degree by Oxford Univesity. On October 18 of that year, he married his fiancée, Anne Coulman, and they settled on their estate near Aylesbury.

After Sir John Franklin's expedition disappeared into the Arctic in 1845 and had not been heard of by the spring of 1847, Lady Franklin asked Ross to lead a search expedition. He sailed for the Arctic in HMS *Enterprise* and *Investigator* in May 1848. The expedition entered Lancaster Sound but, unable to penetrate further due to ice, was forced to winter at Port Leopold at the northeastern tip of Somerset Island. In the spring of 1849, sledging parties searched most of the coasts of Somerset Island. The ships were released on August 29, 1849, but again became beset in the pack and drifted helplessly eastwards down Lancaster Sound for more than 250 miles before finally being freed.

Ross's health, already affected by his long years in the polar regions, was undermined further by this, his ninth wintering, and he now retired to his estate, although he continued to be consulted by the Admiralty concerning the search for Franklin. He was made rear admiral in 1856 and died at his home on April 3, 1862.

ROSS SEA, OCEANOGRAPHY OF

The Ross Sea is typically taken to comprise the large southward embayment lying between Cape Adare on the west and Cape Colbeck on the east, discovered by

James Clark Ross in 1841. Most of that embayment is a broad continental shelf, with average depths in excess of 500 m, half of it covered by the ~500,000 km^2 Ross Ice Shelf. For many authors, however, the Ross Sea includes similarly large portions of the adjacent deeper ocean, extending eastward with the Ross Gyre and northward to at least the winter ice edge. Between the continental shelf break, near 600 m, and the northern edge of the Ross Ice Shelf, the sea floor is characterized by a series of banks and troughs that run generally north–south in the eastern sector and more northeast–southwest in the west, where several islands and seamounts appear. The largest island, also named for Ross, separates the northwest end of the ice shelf from McMurdo Sound. Roosevelt Island, directly south of the Bay of Whales, is submerged beneath the northeast extremity of the ice shelf. The bottom troughs deepen southward, with depths >1500 m north of and beneath the ice shelf, providing reservoirs for the salty, dense waters that result from sea ice formation.

While the Ross Sea continental shelf is ice covered for most of the year, the region between the shelf break and ice shelf front is usually accessible by ship during summer. This has historically facilitated expeditionary work toward the continental interior in this sector. Reduced ice concentrations first appear along the western front of the Ross Ice Shelf in late spring, becoming a large open area characterized by high biological productivity by December. By late January, this northward ice removal often meets southward ice decay from the north, opening a passage west of the dateline. After a February minimum extent, the sea ice starts to increase again from south to the north, covering the shelf region by late March or early April and reaching a winter maximum in September. As in other areas around Antarctica, sea ice extent variability reflects forcing over a larger region. Both summer minima and winter maxima in ice extent display a periodicity of several years, with a tendency for increased (decreased) sea-ice extent to be associated with a higher (lower) frequency of ENSO-scale events. Insufficient information is available to know whether ice extent and thickness have varied significantly over the last several decades.

In some areas, particularly in and north of McMurdo Sound, the sea ice is anchored fast to the shore, even during summer. Elsewhere the pack ice is free to move, and is typically advected, often at great speed, under the influence of winds, tides, and ocean currents. Studies based on GPS buoys deployed on the ice, and beset ships, have displayed rapid north-northwestward drifts up to 15 km per day. Ice can increase in thickness both dynamically and thermodynamically, with its growth and areal expansion initially dominated by frazil ice and pancake development. The rate of congelation ice growth at the base of ice floes is dependent on the difference between ocean and air temperature. More ice is produced in the southern Ross Sea where that thermal gradient is larger and prevailing winds move young ice away from the coastline.

Large and persistent areas of open water and thin ice (polynyas) are a common feature of the Ross Sea, and play an important role in many physical and biogeochemical processes, including heat transfer between ocean and atmosphere, and in phytoplankton production. The large Ross Sea Polynya results mainly from southerly winds flowing off the Ross Ice Shelf east of Ross Island, in turn fed by katabatic (gravity drainage) flows down valleys along the Transantarctic Mountains. It is also influenced by cyclogenesis events in the eastern Ross Sea. The smaller Terra Nova Bay Polynya occupies a coastal area of ~6000 km^2 on the western side of the Ross Sea, and is maintained by katabatic winds from interior East Antarctica that flow down the Reeves Glacier. These winds push newly formed ice away from shore, while the Drygalski Ice Tongue prevents pack ice from drifting northward and filling the Polynya, which plays a key role in the thermohaline circulation of the Ross Sea.

Summer waters on the Ross Sea continental shelf are among the best sampled around Antarctica due to the generally ice-free conditions and presence of ship-supported research stations. However, winter data are scarce, as are measurements from underneath the Ross Ice Shelf. Physical features of the water column, particularly in the western Ross, are strongly influenced by the persistent polynyas, beneath which High Salinity Shelf Water (HSSW) is generated by near-continuous freezing during autumn and winter. The densest water mass in the Southern Ocean, HSSW has temperatures close to the sea surface freezing point, ~–1.9°C, and salinities above 34.75 ‰, increasing with depth. Stronger surface forcing on the western shelf produces positive east–west salinity and density gradients, with the saltiest water near-bottom spreading both north and south. HSSW that reaches the continental shelf break can mix with Circumpolar Deep Water (CDW) to form new Antarctic Bottom Water. HSSW that moves southward can flow beneath the ice shelf, where it interacts with the ice, becoming colder, but also fresher and lighter in the process, emerging as Ice Shelf Water (ISW). Colder than the sea surface freezing point, ISW flows northward at intermediate depths (300–600 m), also mixing with CDW near the shelf break and contributing to bottom water formation.

Low Salinity Shelf Water (LSSW) is found at intermediate depths and below in the central-eastern

Ross Sea, and probably forms mainly at the sea surface during winter. Antarctic Surface Water (AASW) occurs throughout the continental shelf region in summer and over the deep ocean year round. It derives in part from the upwelled and modified CDW, and is characterized by higher temperatures, lower salinities, and a shallow mixed layer during summer. The surface mixed layer is relatively stable and contains meteoric and other material released by melting ice, favoring the onset of intense phytoplankton blooms. Recent freshening of Ross Sea waters may result from increased precipitation, reduced sea-ice production, and increased melting of glacial ice, but much of the observed change is believed to be imported from coastal regions to the east.

Surface circulation in the Ross Sea is dominated by the winds, while at greater depths the flows are strongly influenced by the submarine ridges and troughs. Time series current measurements have now been made at numerous locations over the shelf and slope. In combination with mathematical models, these measurements show the circulation to be highly variable in space and time. The circulation has a small vertical shear below the mixed layer and is strongly affected by bottom topography due to the weak stratification. Our understanding of the circulation and transformation of waters in the cavity beneath the Ross Ice Shelf also relies largely on modeling efforts. A relatively sluggish circulation under the ice shelf contrasts with stronger flows close to the ice front. Chlorofluorocarbon (CFC) measurements in water masses that have circulated beneath the ice shelf indicate that HSSW can evolve to ISW can in as little as 3–4 years.

A strong frontal region, the Antarctic Slope Front, separates shelf waters from the deeper ocean along the continental shelf break. This feature is topographically controlled and constitutes an important area for the vertical and lateral exchange of heat, salt, freshwater, nutrients, particulates, and atmospheric gases. While largely subsurface, the Antarctic Slope Front has also been related to high biological productivity. Temperature is the best indicator of this front, often showing horizontal gradients of 2–3°C in $<$20 km. Tides in the Ross Sea are predominantly diurnal (i.e., one maximum and minimum occur daily), with velocities on the central continental shelf typically about 10–20 cm s^{-1}. Tidal heights can exceed 0.8 m under the eastern Ross Ice Shelf, less than beneath the Filchner and Ronne Ice Shelves in the southern Weddell Sea. Under the ice shelves, tides are expected to provide most of the kinetic energy for ocean mixing and ablation of the basal ice. Tidal currents are largest along the shelf break, again with the diurnal constituents being dominant, with measured current speeds sometimes exceeding 100 cm s^{-1} during spring tide. These currents can strongly modify the location of the Antarctic Slope Front and play a major role in the mixing of the various water masses that come together there, and in the on cross-slope drainage of dense waters into the deep ocean.

The fauna of the Ross Sea ecosystem are typical of other Antarctic regions and depend on phytoplankton—a primary food source for shrimplike krill, which in turn are consumed by fish, seals, whales, and penguins. Some studies suggest that the amount of phytoplankton in the Ross Sea can be twenty times that in the ocean off Bermuda during the summer. The production of zooplankton (secondary producers), however, is like that found in other coastal regions of the Southern Ocean, and is dominated by two similar and probably competing krill species: *Euphausia superba* and *Euphausia crystallorophias*. Winds and mesoscale cyclones influence the spatial and temporal distribution of sea ice, as well as the upper ocean mixed-layer depth, thereby controlling primary production in the ice and open water systems. The Ross Sea area is particularly fertile because winds clear away the sea ice, creating a large spring polynya in the southwest sector in November and December. Exposure of surface waters to sunlight allows phytoplankton to flourish, to the extent that chlorophyll concentrations typically exceed 5 mg m^{-3} over an area of about 100,000 km^2, vs. < 0.05 mg m^{-3} in low productivity central ocean gyres. In the cold, dark, and diverse benthic (close to the sea floor) environments, many animals grow slowly, but are long-lived and sometimes reach giant size.

The Ross Sea fishery is the southernmost in the world, with Antarctic toothfish currently constituting more than 95% of the catch, which has steadily increased from about 40 tons in 1998 to over 1800 tons in 2003. In early 2003, New Zealand fishermen working this sector captured the first live specimen of *Mesonychoteuthis hamiltoni,* a deep-sea squid. Almost 20 feet (6 meters) long, half the apparent full-grown size, with spiked tentacles and huge, protruding eyes, the monster was feeding on Patagonian toothfish caught on a longline. About eighty species of local fish include four families and fifty-three species of the endemic perciform suborder Notothenioidei. Mainly a benthic group, notothenioids have adaptively radiated to pelagic and semipelagic realms, dominating the fish fauna of the southern Ross and playing a key role in the food web. Of the four notothenioid families, nototheniids show the most ecological and dietary diversification, with pelagic, cryopelagic, epibenthic, and benthic species. *Pleuragramma antarcticum* constitutes $>$90% of both the abundance and biomass of the midwater fish fauna. Antarctic petrels, south polar skuas, emperor and Adélie penguins, Weddell seals, and minke and killer whales are the higher vertebrate components of the food web, and all prey on notothenioids in some measure.

The Ross Sea supports large populations of upper-trophic level organisms, with 25% and 30% of the world populations of the circumpolar emperor *(Aptenodytes Forsteri)* and Adélie penguins *(Pygoscelis Adeliae)* nesting along its coastline, which represents less than 10% of the Antarctic continental margin. There are thirty-eight Adélie penguin rookeries in the Ross Sea, with more than 1 million breeding pairs. The distribution of Adélie colonies is controlled by the location of polynyas, which allow access to breeding sites and also provide food early in the spring when the sea is still frozen. Adélie penguin colonies in the Ross Sea region have displayed significant variation in size from year to year, changes that are believed to be closely related to sea-ice extent. Because Adélie populations were smaller during the late 1950s to early 1970s, ice extent in the Ross Sea could have been greater at that time.

ROSS SEA PARTY, IMPERIAL TRANS-ANTARCTIC EXPEDITION (1914–1917)

On September 18, 1914, Sir Ernest Shackleton said farewell to eleven members of the Ross Sea Party led by Lieutenant Æneas Mackintosh, their task to depot supplies on the Great Ice Barrier (now known as the Ross Ice Shelf) between Ross Island and the Beardmore Glacier, for Shackleton's proposed crossing of Antarctica from the Weddell Sea to McMurdo Sound.

Shackleton's Imperial Trans-Antarctic Expedition was supported by government and private funding amounting to approximately £60,000, although the Ross Sea part of the plan was considerably undercapitalized. Its members included three Antarctic veterans, Mackintosh, Ernest Joyce, and James Paton, and the expedition had 80 tons of stores, nearly thirty dogs, and a Girling motor sledge. In Sydney, Australia, the ship *Aurora,* last used for Douglas Mawson's Australasian Antarctic Expedition, was refitted, and late appointments were made, including of scientists and crew. Mackintosh was still endeavoring to raise funds right up until the expedition finally left Hobart on December 24. After visiting Macquarie Island, *Aurora* reached Cape Evans in McMurdo Sound on January 16, 1915.

Four sledging parties of three men each planned to depot supplies at 80°S before the onset of winter. However, the motor sledge broke down, and, with loads exceeding 1000 pounds (450 kg), the men were forced to relay on difficult surfaces with low temperatures. It was tough on the men but most affected the dogs, many of which had started unfit and subsequently died. On February 11, 1915, the Bluff depot was placed at 79°52′ S, and the same day, on the far side of the continent, Shackleton's ship *Endurance* reached its southernmost point in the Weddell Sea.

The return journey from 80°S began on February 24, and on March 6, six men who had returned to Hut Point were collected by *Aurora*. The others arrived at Hut Point a month later, and then had to wait until the reforming of the ice permitted their 15-mile (24 km) journey to Cape Evans, where the party had settled into the hut built for Scott last expedition.

There were now ten men ashore; Mackintosh, Joyce, Ernest Wild, Alexander Stevens (chief scientist), Dick Richards, Keith Jack, Rev. Arnold Spencer-Smith, John Cope, Victor Hayward, and Irvine Gaze. Meanwhile, while Mackintosh, the ship's captain as well as leading the party on land, was ashore with the sledging party, First Officer Joseph Stenhouse was responsible for the task of locating a suitable winter mooring. Cape Evans was selected.

The ship was thought to be secure for the winter, but on May 6 a blizzard broke up the ice in McMurdo Sound. Leaving two anchors on the beach, *Aurora,* still loaded with stores, drifted helplessly into the Ross Sea. Frequent attempts were made with wireless to contact Cape Evans, but, in late July, ice pressure put such a strain on the ship that the rudder was smashed, the vessel threatened to disintegrate, and preparations were made to abandon ship. In a blizzard the mizzen mast and aerials were damaged; further problems included petty thieving and the near death of Stenhouse from carbon monoxide poisoning.

Those at Cape Evans assumed the ship was lost, and there was also concern for those sledging, but eventually the shore party was reunited on June 2. Plans were then made for the next season, stores were tallied, equipment was serviced, and clothing and footwear were made by Joyce. Sledging began on September 1, before spring was properly started, when stores were taken to Hut Point. The motor sledge was returned to Cape Evans but not used agaom. There were now only four fit dogs and, leaving geologist Stevens behind, the others set out on October 1. The intention was to move further supplies to the Bluff depot and from there to the Beardmore Glacier, a distance of 330 miles (530 km). Meanwhile, in the next month, *Endurance,* her hull crushed, sank in the Weddell Sea.

After a few weeks sledging, a second Primus stove failed and it was decided to send Cope (the supposed medic, although he had little true training), Gaze, and Jack back to base. The others in two parties led by Mackintosh and Joyce, reached 82° S on January 16, 1916. By then Mackintosh and Spencer-Smith were ill and on January 22 Spencer-Smith was left in a tent while Mackintosh, Joyce, Wild, Richards, and Hayward continued south. On the evening of January 26, Joyce, Wild, and Hayward placed the final depot in "The Gap" near Mount Hope. Spencer-Smith was then collected and placed on a sledge, and the party continued homeward until February 17, when a blizzard set in for five days. With the party low in food and fuel, Wild was left to care for Mackintosh and Spencer-Smith, while Joyce, Richards, and Hayward made a dash for the Bluff depot. They collected supplies and returned six days later.

Winter was approaching and all of the men were suffering from scurvy, particularly Spencer-Smith, Mackintosh, and Hayward. On March 7, after leaving Mackintosh with a week's provisions, the others headed for Hut Point to try to get Spencer-Smith back to safety; the next day, however, Spencer-Smith died. Leaving Hayward at Hut Point, Joyce, Wild, and Richards returned for Mackintosh who had been alone for five days. Shackleton's needs had been met, but at a high price.

As the five men recovered, Mackintosh decided on May 8 to cross with Hayward to Cape Evans against the advice of the others. The two men left on their own and were never seen again. Within hours a blizzard broke up the new ice, and it was not until July 15 that Joyce, Wild, Richards, and the four dogs made the crossing. With the party of seven reunited at Cape Evans, the men concentrated on sealing and on making scientific observations. In September, however, Richards took ill with heart trouble, although Cope, who had previously spent days in his bunk, nursed him back to health. In the spring, trips were made to Cape Royds for penguin eggs, and in December a visit was made to Spencer-Smith's grave, where a cross was erected. Later a further cross was placed on Wind Vane Hill.

Meanwhile, *Aurora* broke free on February 12, 1916, and on March 15 they left the pack ice. Two weeks later, using a jury rudder constructed by carpenter Clarence Mauger, and receiving a tow from the tug *Dunedin, Aurora* arrived at Port Chalmers. By late April the expedition was in effect bankrupt, and, within a month, the British, Australian, and New Zealand governments were planning the relief of the men on Ross Island and repairs were begun on the ship. In October Captain John King Davis was appointed to lead the relief expedition, and Stenhouse and three of his crew were dismissed. Shackleton, having arrived at South Georgia and subsequently rescued the men of *Endurance,* had turned his attention to the Ross Sea Party. He immediately sailed for New Zealand, reaching Wellington on December 2, and on December 20 he sailed as a passenger on the relief expedition, the governments having refused to let him have any official position of authority.

On January 10, 1917, Richards slowly regaining his health, was looking for seals when he saw *Aurora*. The men quickly packed a sledge and headed towards the ship, where, to their astonishment, they were met by Shackleton. Further searches were made for Mackintosh and Hayward before *Aurora* again headed north. On the evening of February 9, they reached Wellington, where a civic reception was given. *Aurora* was returned to Shackleton and sold, and the expedition paid off. Later, with Paton again aboard serving as bosun, Aurora was lost with all hands while making a passage between Australia and South America.

ROSS SEAL

The Ross seal, *Ommatophoca rossii,* is a member of the carnivore family Phocidae (true or earless seals) and one of four distinct Antarctic phocid seals. It has a circumpolar distribution around Antarctica. The Antarctic seals colonized then temperate Antarctic seas about 15 Ma, and subsequent cooling and eventual glaciation of the Antarctic led to speciation among the ancestral phocid seals. The oldest evidence of the Ross seal is a fossil mandible from New Zealand, which dates from the late Pliocene.

The name "Ross seal" derives from James Clark Ross, who collected two of these seals in 1840 during his voyage of exploration into the Ross Sea on the HMS *Erebus*. The genus name is from the Greek *omma* meaning eye, highlighting its obviously large eyes. This is possibly an adaptation for pursuing prey under the ice and at depth.

Ross seals grow from 2 m to 2.6 m long and up to 225 kg. Females are slightly larger than males. The pelage is the shortest of any pinniped. It is dark brown dorsally and cream or tan coloured ventrally, with several dark stripes radiating down the throat from the mouth and some spotting along the boundary between the countershaded dorsal-ventral pattern. Compared with other Antarctc phocids, Ross seals have relatively small but robust bodies with short, broad heads that can be withdrawn into rolls of fat about the neck. The short snout gives a blunt pointed profile. The eyes are noticeably large and forward pointing and the ear openings are very small. The front teeth are all small, with the canines being very sharply conical and recurved, which are possibly adaptations for securing squid prey. The molars are reduced, barely extending above the gum. The fore flippers have reduced claws and the terminal joints are elongated. The hind flippers have very long cartilaginous extensions: they may reach 22% of the body length, the greatest for any phocid, and appear to drag behind. Pups are dark brown above, paler underneath, and weigh approximately 17–27 kg at birth. They show the striped pattern on the throat characteristic of the adult.

Ross seals make unique "trilling, cooing, and chugging" sounds both in air and underwater. On ice, frequently in response to a disturbance, a Ross seal will raise its head near vertically, arch its back, and inflate the trachea and soft palate with air. Three types of vocalizations are typical: an unvoiced exhalative sound with the mouth open, and, with the mouth and nostrils closed, chugging pulses and siren calls of rising and lowering frequency. These sounds emanate from an expanded throat and chest, evidently owing to the inflation of the laryngeal air sacs. In air the frequencies range from 100 to 1000 Hz, but underwater they may reach as much as 4.5 kHz. The calls stand out well against background noise and are therefore possibly used to indicate location.

Many aspects of the species' behaviour and biology remain unknown because of its relatively low abundance and distribution in pack ice areas, which has limited access. Ross seals breed in the early spring to early summer months. Of nine adult females examined in August and September, 88% were pregnant. Pups each with an accompanying adult female can be seen between 2 October and 15 December with a peak in the period 6–15 November. Since they are generally solitary when encountered, a mating system of serial monogamy rather than polygyny is suggested.

Little is known of the reproductive biology of Ross Seals. The estimated age of sexual maturity is 3–4 years for females and 2–7 years for males. Lactation is thought to last four to six weeks, and is followed by mating and an inferred period of delayed implantation of about 2 months. Although usually solitary during the nonbreeding season, up to five Ross seals have been seen together on the same ice floe. During the spring breeding season they principally occur in regions of heavy, consolidated pack ice. During midsummer they seem to prefer the denser ice types more prevalent in the inner ice pack, but they are also present in open pack ice within the inner reaches, and occasionally on fast ice. Although absent from the outer pack at this time, it has recently been found that they also make prolonged and repeated foraging trips far to the north into the open water. If these trips are typical of Ross seal behaviour they may account for occasional sightings in lower latitudes, such as at Heard Island and southern Australia.

Ross seals hunt within the pack ice, eating mostly midwater squid, but also fish (including Antarctic silverfish) and invertebrates (including euphausids, amphipods, and isopods). The high proportion of empty or nearly empty stomachs of Ross seals during January conforms with the knowledge that the species moults (in January and February) and consequently generally fasts at this time. One study of a female during January showed that she hauled out during the day and dived continually when in the water at night. Dives averaged 110 m deep and 6.4 min long, the deepest and longest dive being 212 m and 9.8 min respectively. Dives were deepest during twilight and shallowest at night as the seals presumably followed the vertical movement of their prey in the water column. However, while out in the open sea through March to September a male Ross seal dived virtually continuously with diving activity fairly evenly distributed throughout 24-hour periods, never exceeding 30 min or 492 m, with dive depths widely and fairly evenly distributed between 12 m and 400 m.

Although the densest concentrations of Ross seals had previously been observed in the southeast Atlantic sector in the King Haakon VII Sea off Dronning Maud Land, data from the early 1990s suggest that Ross seal abundance in that sector declined over the previous 20 years. The population of Ross seals has been estimated to be about 131,000 making it the least abundant Antarctic pinniped.

ROTIFERS

Rotifers are microscopically small inhabitants of freshwater that are characterised by a muscular pharynx, and one or two circles of vibrating cilia (small hairs) on their heads whose synchronized beating gives the appearance of a rotating disc(s) from which their common name—the wheel animalicules—is derived.

Rotifers are found wherever there is freshwater in lakes and pools, in gutters and birdbaths, even in tiny cryosonite holes in glaciers, as well as in the soil and on vegetation, indeed wherever there is a thin film of water. More than 150 different species have been recorded from the Antarctic region out of world total of some 2000.

The first rotifer survey in the Antarctic was carried out by James Murray, the biologist with Ernest Shackleton's British Antarctic Expedition 1907–1909. Since then rotifers have been found throughout the Antarctic region but Murray's pioneering work remains the most interesting. He recorded fifteen species of freshwater rotifer from the McMurdo Sound Area—a mixture of cosmopolitan and endemic species including a number that were new to science.

Of particular interest were *Epiphanes senta* (O. F. Müller) and *Philodina gregaria* Murray. *Epiphanes* *senta* is a cosmopolitan species that is normally found in shallow bodies of water enriched by farmyard animals so that its presence in pools adjacent to penguin and seal wallows in the Antarctic is not really surprising. As a member of the Monogononta it possesses a single gonad and reproduces by cyclical parthenogenesis. Normally the amictic females lay diploid eggs that develop into more amictic females. However, under certain conditions, such as when their habitat is drying up or freezing, mictic females are produced. Mictic females lay haploid eggs that either hatch into males or if fertilized by a male produce resting eggs. Males are very rare and often unlike their females. They are very small, about one half the size of the females, and the digestive system is rudimentary or lacking. The testis and penis are large and during their short lives (they are often only around for one or two days in any year) they endeavour to impregnate as many females as possible. The resulting resting eggs may remain dormant for years, but under the right conditions they hatch into amictic females and thus the cycle begins again.

Philodina gregaria has a pair of gonads and is classified as a Digononta (or bdelloid) rotifer. It is bright red in colour with a pair of conspicuous orange eyespots and is only found on the Antarctic continent and some off-lying islands. It does not occur on South Georgia or any of the other subantarctic islands. Bdelloid rotifers only reproduce by parthenogenesis, and most importantly males do not occur in this group. Most produce eggs that can survive harsh environmental conditions, but *Philodina gregaria* is unusual in that it produces live young. It is an extremely long-lived rotifer—laboratory reared specimens lived for more than three months. During their first month they grow. Thereafter a single offspring is produced every three days so that mothers typically produced up to twenty offspring. Mature adults survive the winter frozen in the pond ice. When the spring thaw occurs they rehydrate and immediately begin reproducing. Enormous populations with densities of many millions of individuals per square metre commonly occur so that they colour the bottom of the pools bright red.

Fast breeding rates, the production of resting eggs and the ability to withstand freezing mean that some species of rotifer are ideally suited to life in the Antarctic. As a result of its ability to respond to changing conditions to survive freezing and thawing *Philodina gregaria* is the archetypal Antarctic invertebrate.

ROYAL ALBATROSS

Royal Albatross (*Diomedea epomophora,* of the Diomedeidae family within the order Procellariiformes). Two separate taxa, southern *(D. e. epomophora),* and northern *(D. e. sanfordi)*. A large, white-bodied albatross with upper wing black (northern), or mixed black and dusted with white, or white from leading edge with black wingtips (southern), black eyelids, and black cutting edge to bill. Bill coloured horn, but pink when rearing chicks. Main dimensions: wingspan 270–312 cm; body mass 6.25–10 kg. The southern royal albatross competes with the wandering albatross *(D. exulans)* for the title of the world's largest seabird.

The northern royal albatross, breeds at the Sisters and Forty Fours islets at the Chatham islands (99.5% of population) and at mainland Taiaroa Head (0.5%) on New Zealand's South Island, with an estimated total breeding population of 7700 pairs. Nests are built of soil, rock chips, and woody plants on the exposed tops of the islets and headland. Individuals spend over 80% of their life at sea, with regular circumpolar migrations to winter at the southern Chilean and Patagonian continental shelves. The feeding range is primarily over the continental shelf, shelf edge and shelf break to 2000 m depth. The diet consists of cephalopoda (75%–85%) principally *Moroteuthopsis ingens* and *Histioteuthis atlantica,* fish (15%–20%), crustacea, pyrosoma and salps (3%–5%). Migration over deeper waters is very rapid. Classified as Endangered due to its restricted breeding range, and the degradation of their island habitat from storms during the 1980s. Facing a possible population decrease of 50% over three generations unless the habitat improves.

Southern royal albatrosses breed at the Campbell Islands (99%) and Adams, Enderby, and Auckland islands in the Auckland Islands group (1%), with an estimated total breeding population of 8300 pairs. Birds breed on sheltered flattish ground close to ridges, plateaus, and occasionally among scrubby woodlands, with nests of peaty soil and tussock grasses. Similar migratory and feeding zones as the northern royal albatross. Classified as Vulnerable due to its restricted breeding range. The total population is probably stable, but increasing on Enderby Island after extirpation there in the nineteenth century.

Both forms of royal albatrosses lay one egg (380–520 g) in November or December, with incubation lasting 79 days, and fledging taking 225 to 280 days after hatching. This timing ensures that breeders can only breed successfully every 2 years. First return to the natal colony is at 3 or 4 years, with breeding commencing at 6 to 8 years. Some 50%–60% of fledglings survive to breed, with a 5% annual adult mortality. The oldest marked individual reached 62+ years (northern species). "Adolescent" courtship displays occur in groups or "gams" of up to twenty birds for 1 to 2 years before pairing. At least one prebreeding season is spent more quietly "keeping company" with the mate at potential nest sites.

Both taxa have a minor reported interaction with fisheries (trawling and longline). Satellite tracking has demonstrated their ability to travel up to 1800 km in 24 hours during migration, but probably flying for 14 hours daily maximum. Public viewing of the mainland colony at Taiaroa Head attracts more than 300,000 tourists annually.

ROYAL GEOGRAPHICAL SOCIETY AND ANTARCTIC EXPLORATION

One senses that the Royal Geographical Society (RGS) has suffered throughout its existence from a sense of inferiority regarding its more prestigious cousin, the Royal Society, and that this attitude is neither inappropriate nor inaccurate. Without the resources or expected role in the cultural and intellectual life of Great Britain that the Royal Society enjoys, the RGS justly stands in a lesser position. Yet greatness can be defined as narrowing the gap between what one is and what could be, and in this respect the achievements of the RGS regarding exploration in general in the nineteenth and early twentieth centuries, and the exploration of the Antarctic in particular, mark it out for praise and demonstrate even a touch of greatness.

The RGS had been a sponsor and backer of exploration virtually since its founding in 1830. Sir John Barrow, the chairman of the Council of the Society, had used his position as Second Secretary of the Admiralty to become the force behind many Arctic expeditions, and had been a key figure in pushing James Clark Ross's Antarctic expedition of 1839–1843, on which Ross navigated through the ice surrounding the Ross Sea and proceeded to establish a farthest south of 78°10′ S, while discovering the Victoria Land coast, Ross Island, and the Great Ice Barrier (now known as the Ross Ice Shelf).

In the mid-nineteenth century, Sir Roderick Murchison served 16 years as president of the RGS. Under his leadership, the RGS sponsored and helped fund expeditions in many parts of the world, including the Franklin searches in the Arctic and virtually every British expedition to enter Africa during that period. For many of the expeditions sponsored by the RGS—regardless of destination—limited resources were overcome by tenacity.

Apart from Barrow's connections with Ross's expedition, the Society took little part in the exploration of the far south in first two-thirds of the nineteenth century. However, in the "Heroic Era" of Antarctic exploration, the RGS was a crucial leader in developing, sponsoring, and promoting exploration to the Antarctic. Here, a third great leader of the RGS must be singled out as critical to the process: Sir Clements R. Markham (1830–1916), who became president of the Society in 1893 and whose single-minded determination overcame considerable odds during a long struggle to get Britain again involved in Antarctic exploration, leading ultimately to the launch of his dreamed-of expedition.

Markham chose Robert Falcon Scott (1868–1912) to command the British National Antarctic Expedition, and it was Markham who insisted on a purpose built vessel—*Discovery*—which survives to this day in Dundee, Scotland. Markham enlisted every individual and every society that could be of any use in meeting his goal. Early on, he involved a leading academic, John Murray (1841–1914), in the project and eventually persuaded the Royal Society to participate as joint sponsors. Markham was a prime mover in the Sixth International Geographical Congress held in London in 1895, which passed the famous resolution declaring that the exploration of Antarctica was the most important geographical work remaining to be done in the world.

The political influence of the Royal Society was critical in getting H. M. Government to make the grant of £45,000 that allowed Markham's dream to become a reality. For all his efforts and enthusiasm, one is hard-pressed to believe that, without the help of the Royal Society, Markham would ever have seen his great adventure off to explore the far south.

Before the expedition sailed, the RGS and the Royal Society fell out over the issue of science versus adventure. The latter felt that they had lost when Scott was given overall command and the chosen scientific leader, John W. Gregory (1864–1932), resigned from the expedition owing to what he perceived as unfavorable terms for science.

The RGS deserves much of the credit for the successes of the *Discovery* expedition, while its flaws may easily and accurately laid at the feet of Markham, whose devotion to a romanticized memory of the Royal Navy's involvement in the Arctic led him to impose bad advice on Scott.

Following Scott's return to Great Britain, the Society's involvement in further Antarctic exploration and research was severely limited both by the departure of Markham from the presidency and the degree to which his extravagant use of the RGS's funds for the British National Antarctic Expedition impoverished the Society's coffers. The Society provided limited support in terms of finance, equipment, and expertise to later British explorers in the Heroic Era, but several people associated with the RGS remained major players in exploration by their advice and support, notably H. R. Mill (1861–1951) (once the RGS librarian) and J. Scott Keltie, the Society's secretary.

Markham, and therefore somewhat the RGS, was not overly helpful prior to or positive after Ernest Shackleton's British Antarctic Expedition of 1907–1909, and the Society's treatment of Roald Amundsen (1872–1928) upon his return from his successful attainment of the South Pole remains a blot on its history. George Curzon, the Society's president in 1912, made an unfortunate remark about the Norwegian's success and his use of dogs, which justifiably rankled Amundsen.

Yet such incidents cannot diminish the contributions of the RGS to Antarctic exploration. The Society did give support—although modest due to its limited resources—to Scott's second expedition, Douglas Mawson's Australasian Antarctic Expedition, and other exploring efforts throughout the end of the Heroic Era and since.

ROYAL SOCIETY AND ANTARCTIC EXPLORATION AND SCIENCE

The Royal Society of London for Improving Natural Knowledge (RS), founded in 1660, still continues as an independent organization. It has some 1200 Fellows, including both men and women, covering a wide range of disciplines and coming from Commonwealth countries and the Irish Republic, with, additionally, a limited number of Foreign Members of distinction. In the course of time, some twenty Fellows have been directly involved in Antarctica, and the Society itself has played intermittent but considerable roles in supporting investigations in the southern polar regions.

The RS was the first to send professional scientists south of the Equator, Edmund Halley going almost as far as South Georgia in a geomagnetic survey in 1699–1700 at the request of the Society and the expense of the government. This impressed on governments that voyages carried out specifically for scientific purposes might be well worth the cost. Halley's influence on Antarctic research was unintended and indirect, but effective. He had predicted the transit of Venus would occur in 1769, so the RS petitioned King George III for support to observe it from a good position in the South Pacific, and HMS *Endeavour* sailed there under Captain James Cook. With him were the astronomer Charles Green, Joseph Banks, FRS, and Daniel Solander, FRS. Banks was a botanist, a gifted scientist who worked well with Cook. Apart from his astronomical task, Cook had been given secret instructions to look for the hypothetical "Terra Incognita." He found no evidence of it but on his return precipitated a circumnavigation farther south. This penetrated to 71°10′ S in HMS *Resolution,* and obtained the rough outline of the Antarctic continent, although not actually seeing it. On return in 1776, Cook was elected FRS. He had not taken Banks with him because the retinue and paraphernalia that Banks wanted were too much for the ship. Instead Johann Forster, FRS, and his son went and did good work, especially in ornithology. Banks never did reach the Antarctic, but being elected to the highly influential position of President of the RS, which he held for 42 years, he was able to promote future work in the south, including giving help to the Russian Fabian von Bellingshausen, who made an Antarctic circumnavigation in 1819–1821.

However, in general in the first part of the nineteenth century, there was little interest in Antarctica except from sealers. The Royal Navy was most concerned with the Arctic, and among naval officers elected to the RS—26 in 1816–1845—only Captain Henry Forster went to the far south (1828), extending gravimetric observations for the Admiralty but going as far as Deception Island at the Society's request. Then came a burst of activity, centred on terrestrial magnetism and called by William Whewell "by far the greatest scientific undertaking the world has ever seen." Both the British Association for the Advancement of Science and the RS—the latter recalling that the idea dated back to "our illustrious countryman Halley in AD 1701"—resolved that observations should be made in the far south. Edward Sabine, FRS, became the main driving force, and the government agreed to the dispatch of HMS *Erebus* and HMS *Terror* under the command of Captain James Clark Ross, FRS, a veteran Arctic explorer. For use by the expedition, the RS compiled a useful booklet on various topics, notably physics and meteorology. The two ships successfully penetrated the pack ice into what is now the Ross Sea, making spectacular geographical discoveries (1839–1843). The highest mountain seen was named in honour of Ross's friend, Sabine, at that time Foreign Secretary of the RS. Later it was he who worked up the magnetic data and published it in lengthy papers between 1842 and 1868 in the *Transactions of the Royal Society*. A major scientific advance was made by Joseph Hooker, assistant surgeon (later FRS), who in compiling the standard work *Flora Antarctica* rather casually pointed out that phytoplankton is the source of food in the oceans.

Following this there was an "age of averted interest" of nearly 50 years, interrupted only by the voyage of HMS *Challenger* (1872–1876), instigated by the RS and financed by the government. It included only a short incursion through the Antarctic Circle, but its dredging produced important findings about the geology of the continent and the biology of the surrounding seas.

The great revival of interest came with the Sixth International Geographical Congress (1895) proposing an expedition and the RS setting up an Antarctic committee and arranging an international discussion on Antarctic Research (1898). Cooperation with the Royal Geographical Society (RGS) resulted in an unpleasant squabble between Sir Clements Markham, the President of the RGS, who wanted an expedition in naval tradition, and the RS, which backed a scientifically directed venture with exploration in second place. Markham eventually overcame opposition and appointed a naval officer, Robert Falcon Scott, as commander of the 1901–1904 British National Antarctic Expedition. Fortunately Scott was not only an excellent sailor but had scientific insight and empathy with his scientists. He named as the Royal Society Range the high mountains to the west of McMurdo Sound. The scientific output was outstanding, and Scott's second expedition received advice and financial support from the Society.

However, the RS showed no great interest in other expeditions for the next 50 years, although T. W. Edgeworth David, FRS, scaled Mount Erebus and also reached the South Magnetic Pole during Ernest Shackleton's British Antarctic Expedition, on which Douglas Mawson, later to be FRS and leader of Australian expeditions, received his polar initiation. The RS had no formal connection with the marine *Discovery* Investigations (1925–1939), although five of its staff became FRSs, or with the Norwegian–British–Swedish Expedition of 1949–1952.

However, the Society became deeply involved in the International Geophysical Year of 1957–1958 (IGY). As the adhering organisation for the International Council of Scientific Unions (ICSU), it became responsible for the British contribution. Apart from being involved in organisation—managed supremely well by its executive secretary, Sir David Martin—and giving the Falkland Islands Dependencies Survey (becoming the British Antarctic Survey (BAS) in 1961) great assistance, the RS, with government help, set up its own base, one of the first auroral stations, Halley Bay, at 75°31′ S, 26°36′ W, accommodating twenty scientific and technical staff to make upper atmosphere and geomagnetic observations. In 1958, the station was transferred to what was to be BAS.

The RS was involved in setting up the Antarctic Treaty (1961), playing an important role in advising on scientific matters. Its Committee ceased to give advice to BAS when management of that was transferred to the Natural Environment Research Council. The RS continued to arrange exchange of Antarctic scientists between the UK and the USSR (1968), to organise discussion meetings, and to have several Fellows involved in research and international relations. Two directors of BAS, Sir Vivian Fuchs (1974) and Dr. Richard Laws (1980) were elected Fellows. In 2004, the Society had Antarctic representation in the Natural Environment Research Council, Scott Polar Research Institute, Trans-Antarctic Association, and the UK representatives to the Scientific Committee for Antarctic Research.

RUSSIA: ANTARCTIC PROGRAM

The Russian (Soviet) Antarctic Program was created in July 1955 for the USSR participation in the International Geophysical Year (IGY). From the beginning, the Program had two independent sections: (1) expedition, aiming at organizing and conducting monitoring of environmental state parameters, special full-scale scientific experiments, and logistics operations in the Antarctic, and (2) scientific, with the purpose of analyzing and generalizing scientific data collected during the expedition period. Different state executive agencies were charged with supervision of these sections. Prior to the end of the IGY, the leadership in both was entrusted to the USSR Academy of Science, whereas the Main Administration of the Northern Sea Route (Glavsevmorput') of the USSR Ministry of Marine Fleet was responsible for logistics operations. From 1959, Glavsevmorput' was in charge of all expedition objectives of the Soviet Antarctic Expedition (SAE) and the USSR State Committee for Science and Technology (GKNT) for research in the Antarctic. The latter distributed topical research tasks among different Soviet ministries that had research institutions with interests in Antarctic studies. They included USSR Academy of Science, Ministry of Biology, Main Administration of the Hydrometeorological Service under the USSR Council of Ministers (GUGMS), Main Administration for Geodesy and Cartography, and Ministry of Fishery. In the structure of Glavsevmorput', the Arctic and Antarctic Research Institute (AARI) was made responsible for SAE activities.

After the abolishment of Glavsevmorput', AARI was transferred to the GUGMS, preserving its earlier functions concerning the Antarctic, whereas GUGMS and its successors (Goskomhydromet, Roshydromet) were responsible in the executive structure of the country for undertaking all expedition operations in the Southern Polar area.

On August 9, 1992, functions of supervision and control of the Russian Antarctic Expedition (RAE) activity were assigned to Roshydromet by the Decree of the President of the Russian Federation.

In 1992, GKNT was replaced by the Ministry of Science of Russia, which remained in charge of Antarctic studies but with a changed order of financing. Funds were allocated directly to institutes-executors rather than to their agencies. In 1998, in accordance with the Decision of the RF Government, Federal Program "World Ocean" was adopted, with one of its subprograms called "Study and Research of the Antarctic." The subprogram was under the management of the Federal Service of Russia for Hydrometeorology and Environmental Monitoring (Roshydromet), which is currently in charge of the expedition and research activities in the Antarctic.
