families to their corresponding binding sites in the *Mmp13* promoter also appears to regulate *Mmp13* gene expression during osteoblast differentiation (Winchester et al., 2000). As discussed earlier, MMP-13 expression is regulated by a variety of growth factors, hormones, and cytokines, but the effects of these compounds appear to be cell-type specific. Data obtained in breast cancer and other cell lines suggest that the differential expression of and regulation of MMP-13 in osteoblastic compared with nonosteoblastic cells may depend on the expression of AP-1 factors and posttranslational modifications of Runx2 (Selvamurugan and Partridge, 2000; Selvamurugan et al., 2000a). The close proximity of the AP-1 and RD sites and their cooperative involvement in the activation of the *Mmp13* promoter suggest that the proteins binding to these sites physically interact; Runx2 was found to directly bind c-Fos and c-Jun in both in vitro and in vivo experiments (D'Alonzo et al., 2002). To determine the importance of these regulatory sites in the expression of *Mmp13* in vivo, transgenic mice containing the *Escherichia coli* lacZ reporter fused to either the wild-type *Mmp13* promoter or that with mutated AP-1 and RD sites were generated (Selvamurugan et al., 2006). The wild-type transgenic lines expressed higher levels of bacterial β-galactosidase in bone, teeth, and skin compared with the mutant and transgenic lines. Thus, the AP-1 and RD sites of the promoter most likely regulate and are necessary for gene expression in vivo in bone, as well as teeth and skin.

We have shown that the RD and AP-1 sites in the proximal promoter region are essential for PTH stimulation of *Mmp13* promoter activity (Selvamurugan et al., 1998; Winchester et al., 2000; D'Alonzo et al., 2002). At the *Mmp13* promoter in UMR 106-01 cells, Runx2 binds histone deacetylase 4 (HDAC4) at the RD binding site, resulting in a repression of transcription under basal conditions (Shimizu et al., 2010). After PTH treatment, PKA-dependent phosphorylated HDAC4 dissociates from Runx2, which is then free to recruit histone acetyltransferases, especially p300 and p300/CBP-associated factor, to activate transcription (Boumah et al., 2009, Lee and Partridge, 2010). We also demonstrated that HDAC4 associates with myocyte enhancer factor 2C (MEF2C) and MEF2C participates in PTH-stimulated *Mmp13* gene expression by increased binding to c-Fos at the AP-1 site in the *Mmp13* promoter. As with Runx2, PTH causes release of HDAC4 from MEF2C and p300 is recruited to bind MEF2C (Nakatani and Partridge, 2017).

In vivo, we have found that global $Hdac4^{-/-}$ mice have increased MMP-13 mRNA and protein expression in hypertrophic chondrocytes and trabecular osteoblasts (Shimizu et al., 2010). Global $Hdac4^{-/-}$ mice are runted in size and do not survive to weaning. This phenotype is primarily due to the acceleration of onset of chondrocyte hypertrophy and, as a consequence, inappropriate endochondral mineralization. MMP-13 is thought to be involved in endochondral ossification and bone remodeling. To identify whether the phenotype of $Hdac4^{-/-}$ mice was due to upregulation of MMP-13, we generated *Hdac4/Mmp13* double-knockout mice and determined the ability of deletion of MMP-13 to rescue the $Hdac4^{-/-}$ mouse phenotype (Nakatani et al., 2016). $Mmp13^{-/-}$ mice have normal body size. The double-knockout mice were significantly heavier and larger than $Hdac4^{-/-}$ mice, survived longer, and recovered the thickness of their growth plate zones. Micro-computed tomographic analysis revealed that $Hdac4^{-/-}$ mice had significantly decreased cortical bone area compared with the wild-type mice. In addition, bone porosity was significantly decreased. The double-knockout mice recovered these cortical parameters. Likewise, their trabecular bone recovered toward normal for this age. Taken together, our findings indicate that the phenotype seen in the $Hdac4^{-/-}$ mice is partially derived from elevation of MMP-13 and may be due to a bone remodeling disorder caused by overexpression of this enzyme.

Plasminogen activators

The PA/plasmin pathway is involved in several processes, including tissue inflammation, fibrinolysis, ovulation, tumor invasion, malignant transformation, tissue remodeling, and cell migration. The PA/plasmin pathway is also thought to be involved in bone remodeling by osteoblasts and osteoclasts. The pathway results in the formation of plasmin, another neutral serine proteinase, which degrades fibrin and the ECM proteins fibronectin, laminin, and proteoglycans. In addition, plasmin can convert MMPs, procollagenase, and prostromelysin to their active forms (Eeckhout and Vaes, 1977). Plasminogen has been localized to the cell surface of the human osteosarcoma line MG63, where its activity was enhanced by endogenous cell-bound uPA (Campbell et al., 1994).

The PA/plasmin pathway is regulated by members of the serpin family in addition to various hormones and cytokines. The primary function of this family of inhibitors is to neutralize serine proteinases by specific binding to the target enzyme. Serpins are involved in the regulation of several processes, including fibrinolysis, cell migration, tumor suppression, blood coagulation, and ECM remodeling (Potempa et al., 1994). Members of this pathway involved in the regulation of the PA/plasmin pathway are PAI-1 and PAI-2, which regulate uPA and tPA; protease nexin-1, which regulates thrombin, plasmin, and uPA; and α_2-antiplasmin, which regulates plasmin. Active PAI-1 combines with uPA and tPA, forming an equimolar complex, exerting its inhibition through interactions with the active-site serine. PAI-1 has been detected in media of cultured human fibrosarcoma cells (Andreasen et al., 1986) and primary cultures of rat hepatocytes and hepatoma cells.

PAI-1 was also detected in conditioned medium of rat osteoblast-like cells and rat osteosarcoma cells (Allan et al., 1990). The expression of uPA, tPA, type I receptor for uPA, PAI-1, PAI-2, and the broad-spectrum serine proteinase inhibitor protease nexin-1 is induced by PTH treatment in primary mouse osteoblasts. The regulation of these various enzymes within bone tissue may determine the sites where bone resorption will be initiated (Tumber et al., 2003).

Urokinase-type plasminogen activator

The uPA is secreted as a precursor form of ~55 kDa (Nielsen et al., 1988; Wun et al., 1982). It is activated by cleavage into a 30-kDa heavy chain and a 24-kDa light chain, joined by a disulfide bond, with the active site residing in the 30-kDa fragment. Urokinase has a Kringle domain, a serine proteinase-like active site, and a growth factor domain (GFD). The noncatalytic NH_2-terminal fragment contains the GFD and the Kringle domain and is referred to as the amino-terminal fragment (ATF). The uPA and PAI-1 are involved in regulation of the first steps of angiogenesis (Pepper, 1997). Rabbani et al. (1990) demonstrated that ATF stimulated proliferation and was involved in mitogenic activity in primary rat osteoblasts and the human osteosarcoma cell line SaOS-2. The GFD of the ATF is necessary for the binding of uPA to its specific receptor.

Tissue-type plasminogen activator

The tPA is secreted as a single-chain glycosylated 72-kDa polypeptide. This enzyme has been found in human plasma and various tissue extracts, as well as in normal and malignant cells. The cleavage of tPA forms a 39-kDa heavy chain and a 33-kDa light chain linked by a disulfide bond. The heavy chain has no proteinase activity, but contains two Kringle domains that assist in binding fibrin to plasminogen (Banyai et al., 1983; Pennica et al., 1983). Furthermore, the heavy chain contains a finger domain involved in fibrin binding (van Zonneveld et al., 1986) and a GFD with homology to human and murine EGF. tPA has been shown to be expressed in osteoblastic cells after nicotine or PTH treatment (Katano et al., 2006; Tumber et al., 2003).

Plasminogen activators in bone

PA activity is increased in normal and malignant osteoblasts as well as calvariae by many agents, including PTH, $1,25(OH)_2D_3$, PGE_2, IL-1α, fibroblast growth factor, and EGF (Hamilton et al., 1984, 1985; Thomson et al., 1989; Pfeilschifter et al., 1990; Cheng et al., 1991; Leloup et al., 1991; De Bart et al., 1995). It should be noted that other work suggests that PAs are not necessary for PTH- and $1,25(OH)_2D_3$-induced bone resorption (Leloup et al., 1994). Expression of tPA, uPA, PAI-1 and -2, protease nexin, and urokinase receptor isoform 1 was detected in microdissected mouse osteoclasts (Yang et al., 1997). Deletion of tPA, uPA, PAI-1, and plasminogen genes in mice can lead to fibrin deposition, some growth retardation, and inhibition of the osteoclast's ability to remove noncollagenous proteins in vitro (Carmeliet et al., 1993, 1994; Bugge et al., 1995; Daci et al., 1999). Moreover, lack of both PAs leads to elongation of neonatal bones and increased bone mass. Osteoblast differentiation and formation of a mineralized bone matrix are enhanced in osteoblast cultures derived from $tPA^{-/-}/uPA^{-/-}$ neonatal mice (Daci et al., 2003). In a more recent paper (Kawao et al., 2014) the authors showed that bone repair after a femoral bone defect was significantly delayed in global $tPA^{-/-}$ mice but not in global $uPA^{-/-}$ mice and concluded that this was due to reduced proliferation of osteoblasts. In another study of global $uPA^{-/-}$ mice (Popa et al., 2014), fracture healing was slightly delayed with increased cartilage area and decreased tartrate-resistant acid phosphatase staining, suggesting a role for osteoclastic uPA expression.

There are conflicting data as to whether the increase in osteoblastic PA activity in vitro is due to an increase in the total amount of one or both of the PAs or is due to a decline in the amount of PAI-1. All possible results have been observed, depending on which osteoblastic cell culture system is used or the method of identification of the enzymes. The latter have been difficult to assay categorically because there have not been abundant amounts of specific antibodies available for each of the rat PAs. Similarly, different groups have found the predominant osteoblastic PA to be uPA, whereas others have obtained results indicating it to be tPA.

A range of agents have also been found to inhibit the amount of osteoblastic PA activity. These include glucocorticoids, TGFβ, bFGF, leukemia inhibitory factor, and IGF-1 (Allan et al., 1990, 1991; Cheng et al., 1991; Forbes et al., 2003; Lalou et al., 1994; Pfeilschifter et al., 1990). Where it has been examined, in many of these cases the decline is due to a substantial increase in PAI-1 mRNA and protein. Nevertheless, some of these agents also markedly enhance the abundance of mRNA for the PAs (Allan et al., 1991), although the net effect is a decline in PA activity.

Cysteine proteinases

The major organic constituent of the ECM of bone is fibrillar type I collagen, which is deposited in intimate association with an inorganic calcium/phosphate mineral phase. The presence of the mineral phase protects the collagen not only from thermal denaturation but also from attack by proteolytic enzymes (Glimcher, 1998). The mature osteoclast, the bone-resorbing cell, has the capacity to degrade bone collagen through the production of a unique acid environment adjacent to the ruffled border through the concerted action of a vacuolar proton pump ([V]-type H^+-ATPase) (Chakraborty et al., 1994; Bartkowicz et al., 1995; Teitelbaum, 2000) and a chloride channel of the Cl-7 type (Kornak et al., 2001). Loss-of-function mutations in the genes that encode either this proton pump (Li et al., 1999; Frattini et al., 2000; Kornak et al., 2000) or the chloride channel (Kornak et al., 2001) lead to osteopetrosis. At the low pH in this extracellular space adjacent to the ruffled border, it is possible to leach the mineral phase from the collagen and permit proteinases that act at acid pH to cleave the collagen (Blair et al., 1993). Candidate acid-acting proteinases are cysteine proteinases such as cathepsin K. Cathepsin K is highly expressed in osteoclasts (Drake et al., 1996; Bossard et al., 1996). Cysteine proteinases contain an essential cysteine residue at their active site that is involved in forming a covalent intermediate complex with their substrates (Bond and Butler, 1987). The enzymes are either cytosolic or lysosomal. The latter have an acidic pH optimum and make up the majority of the cathepsins. These enzymes are regulated by a variety of protein inhibitors, including the cystatin superfamily (Turk and Bode, 1991) and α_2-macroglobulin (Barrett, 1986). Their extracellular abundance must consequently be regulated by cell surface receptors for α_2-macroglobulin as well as the lysosomal enzyme targeting mannose-6-phosphate/IGF-2 receptors.

The involvement of lysosomal cysteine proteinases in bone resorption has been indicated by many studies showing that inhibition of these enzymes prevents bone resorption in vitro as well as lowering serum calcium in vivo (Delaissé et al., 1984; Montenez et al., 1994). In particular, cathepsin K (Tezuka et al., 1994b) was found to have substantial effects on bone. Mice containing a targeted disruption of cathepsin K were developed and found to exhibit an osteopetrotic phenotype characterized by excessive trabeculation of the bone marrow space (Saftig et al., 1998, 2000). Cathepsin K−deficient osteoclasts are capable of demineralizing the ECM, but are unable to fully remove the demineralized bone (Gowen et al., 1999). In addition, cathepsin K mutations have been linked to pycnodysostosis, a hereditary bone disorder characterized by osteosclerosis, short stature, and defective osteoclast function (Gelb et al., 1996). Further studies show that the expression of MMP-9, TRACP (tartrate-specific acid phosphatase) for osteoclastic enzymes and osteoblastic proteases (MMP-13, MMP-14), and RANKL is increased in cathepsin K−deficient mice (Kiviranta et al., 2005). Moreover, cathepsin K−deficient osteoclasts compensate for the lack of this enzyme by using MMPs in the resorption of bone matrix (Everts et al., 2006). It has been shown that cathepsin K is responsible for the activation of pro-MMP-9 in acidic environments such as are seen in tumors and during bone resorption (Christensen et al., 2015). Importantly, cathepsin K not only degrades type I collagen, it also degrades periostin, bradykinin, TGFβ1, and IGF-1, among other proteins (Bonnet et al., 2017; Godat et al., 2008; Fuller et al., 2004; Panwar et al., 2016). Cathepsin K inhibition increases periostin levels and bone formation in vivo (Bonnet et al., 2017). Its inhibition also leads to increases in serum TGFβ and evident fibrosis in a number of tissues (Runger et al., 2012).

Cathepsin inhibitors may be therapeutically beneficial in the treatment of osteoporosis and rheumatoid arthritis to stimulate cortical bone formation and inhibit bone resorption (Xiang et al., 2007). However, cathepsin K deficiency reduces atherosclerotic plaque and induces plaque fibrosis (Lutgens et al., 2006a). Use of a cathepsin K inhibitor as a possible therapeutic target for atherosclerosis should have been evaluated with care because cathepsin K inhibition probably leads to a profibrotic, but also to a more lipogenic, plaque phenotype (Lutgens et al., 2006b). In fact, this may have been the reason the cathepsin K active-site inhibitor odanacatinib failed in osteoporosis treatment clinical trials due to strokes and other cardiovascular adverse events (Mullard, 2016). However, other non-active-site inhibitors, ectosteric inhibitors, may be promising alternatives (Panwar et al., 2016) that do not have the off-target effects of odanacatinib, since they appear to inhibit only the cathepsin K−mediated degradation of type I collagen.

Immunohistochemistry revealed that the majority of the cysteine proteinases (cathepsins B, K, and L) and the aminopeptidases (cathepsins C and H) are products of osteoclasts (Ohsawa et al., 1993; Yamaza et al., 1998; Littlewood-Evans et al., 1997), although immunoreactive staining for cathepsins B, C, and H was also seen in osteoblasts and osteocytes. It is notable that the most potent collagenolytic cathepsin at acid pH, cathepsin L, was strongly expressed in osteoclasts and very weakly in osteoblasts. Mathieu et al. (1994), however, have detected both cathepsins B and L as proteins secreted by their immortalized osteogenic stromal cell line MN7. Everts et al. (2006) have shown that cathepsin L is involved in modulating MMP-mediated resorption by calvarial osteoclasts.

There has been work demonstrating that osteocytes produce cathepsin K (Qing et al.,2012), and this may have an important physiological role in osteocytic osteolysis, particularly in the lactating mouse, when serum PTH-related protein

levels are high and demand for calcium for milk production is very high. Presumably, osteocytic cathepsin K also degrades growth factors, or perhaps activates them, and thus, could have an added role in bone turnover. The knowledge that the osteocyte expresses cathepsin K is also a cautionary note in the use of the cathepsin K−Cre mouse, since this is unlikely to be specific for osteoclasts.

Oursler et al. (1993) have also demonstrated that normal human osteoblast-like cells produce cathepsin B and that dexamethasone can increase expression and secretion of this lysosomal enzyme by these cells. Interestingly, they also showed that dexamethasone treatment causes activation of TGFβ and, by the use of lysosomal proteinase inhibitors, ascribed a role for cathepsins B and D in the activation of this growth factor.

Aspartic proteinases

These lysosomal proteinases contain an aspartic acid residue at their active site and act at acid pH. Very little investigation has been conducted on these enzymes in bone cells, except for the observations that cathepsin D, a member of this family, can be found by immunohistochemical staining in osteoblasts and osteocytes (Ohsawa et al., 1993), and expression of this enzyme is increased markedly by dexamethasone treatment of human osteoblasts in culture (Oursler et al., 1993). Cathepsin D is secreted into the resorbing area of human odontoclasts in order to participate in degradation of mineralized tooth matrix (Gotz et al., 2000).

Conclusions

The osteoblast lineage has the ability to produce proteinases of all four classes, but far more is known about their production of collagenase and PAs, at least in vitro. We still do not know the absolute role of any of these osteoblastic enzymes in vivo. Further work with global and conditional knockouts of the respective enzymes is likely to be the only way we will determine their required functions. These roles may not be restricted to assisting in the resorption process but may include functions to regulate bone development. In addition, the osteoclast produces MMP-9 and cathepsin K, which appear to have similar roles in the two diverse processes.

Chapter outline

Introduction

Cell adhesion molecules play important roles in bone cell functions and fate. Integrins are a family of cell surface adhesion transmembrane molecules composed of α chains and β chains that assemble noncovalently as heterodimers (Campbell and Humphries, 2011), allowing the attachment of osteoclasts and osteoblasts to the extracellular matrix (ECM). Binding of integrins to ECM proteins is essential for the function of bone cells (Bennett et al., 2001; Horton, 2001), and contributes to activating a number of intracellular signals that govern bone cell fate and activity (Marie et al., 2014a). Cadherins are other attachment molecules that control the functions of bone cells through cell−cell adhesion, interactions with other cell surface molecules, and modulation of intracellular pathways (Marie et al., 2014b). During recent years, progress in cell biology and mouse genetics has led to significant advances in our understanding of the roles of integrins, cadherins, and other cell attachment molecules in the control of bone cell activity in vitro and in vivo, and the mechanisms involved in these functions are now better understood. This chapter updates our knowledge of the role of these molecules in bone cell functions and discusses potential therapeutic strategies that emerged from these findings.

Role of integrins in bone cells

Osteoblasts and osteocytes

Osteoblasts and osteocytes express several integrins, although the pattern of expression varies with the stage of cell differentiation (Clover et al., 1992; Hughes et al., 1993; Hultenby et al., 1993; Grzesik and Robey, 1994). Integrin binds to the Arg−Gly−Asp (RGD) sequence present in bone matrix proteins such as fibronectin, type I collagen, bone sialoprotein, and osteopontin (Gronthos et al., 2001; Grzesik, 1997; Puleo and Bizios, 1991; Schaffner and Dard, 2003). Integrins control cell adherence to the ECM through the assembly of intracellular proteins linked to the cytoskeleton. In addition to allowing

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00017-8

cell−matrix adherence, integrins play a key role in osteoblast differentiation (Moursi et al., 1997; Jikko et al., 1999; Mizuno et al., 2000), an effect that is mediated by intracellular signals generated by ECM−osteoblast interactions. Integrin−ECM interaction leads to the phosphorylation of focal adhesion kinase (FAK) and subsequent activation of mitogen-activated protein kinase (MAPK) extracellular signal-regulated kinase 1/2 (ERK1/2), phosphatidylinositol 3-kinase (PI3K), or GTPases of the Rho family (Lai et al., 2001; Salasznyk et al., 2007; Khatiwala et al., 2009). These signals converge to promote specific gene expression and osteoblast differentiation. In mesenchymal skeletal cells (MSCs), ERK1/2 phosphorylation induced by ECM−integrin binding leads to RUNX2 activation and osteoblast differentiation (Ge et al., 2012). FAK also activates Wnt/β-catenin signaling (Sun et al., 2016), making the activation of FAK an essential step for osteogenic differentiation (Tamura et al., 2001). In vivo, deletion of FAK in type I collagen-expressing osteoblasts reduced reparative bone formation in mice (Rajshankar et al., 2017). However, the lack of FAK in osteoblasts may be in part compensated for by proline-rich tyrosine kinase 2 (PYK2), a tyrosine kinase highly homologous to FAK, in the focal adhesion sites (Kim et al., 2007). One important regulator of integrin-mediated signaling is integrin-linked kinase (ILK), a linker between integrins and the cytoskeleton. In osteoblasts, ILK-dependent phosphorylation of α-nascent polypeptide−associated complex, a c-JUN transcriptional coactivator, potentiates c-JUN-dependent transcription and osteoblast maturation (Meury et al., 2010). ILK also interacts with Wnt signaling by phosphorylating glycogen synthase kinase-3β, leading to β-catenin− lymphoid enhancer factor transcriptional activity and expression of Wnt target genes (Dejaeger et al., 2017). Data indicate that conditional inactivation of ILK in osteoprogenitors impaired bone formation associated with reduced bone morphogenetic protein (BMP)/Smad and Wnt/β-catenin signaling, showing the important role of this linker between integrins and the cytoskeleton in bone formation (Dejaeger et al., 2017). In addition to control of cell differentiation, osteoblast attachment to the ECM is essential for cell survival (Grigoriou et al., 2005; Triplett and Pavalko, 2006). Disruption of RGD−integrin binding leads to altered osteoblast adhesion in vitro (Gronthos et al., 2001), and conversely integrin−ECM interaction suppresses cell apoptosis through PI3K activation (Frisch and Ruoslahti, 1997). Thus, integrins play an important role in the control of bone formation through activation of signaling mechanisms regulating both osteoblast differentiation and survival (Fig. 17.1).

The specific role of integrins in osteoblast function and fate is now better understood. The β1 integrin is the main adhesion receptor required for adhesion to fibronectin and type I collagen in vitro. In vivo, impairment of β1 integrin in mature osteoblasts led to decreased osteoblast activity, bone formation, and bone mass in growing mice (Zimmerman et al., 2000). Disruption of β1 integrin signaling by overexpression of its cytoplasmic tail resulted in skeletal defects, showing the important role of β1 integrin in osteogenesis (Globus et al., 2005). In support of the role of β1 integrin in bone formation, ablation of the specific β1 integrin regulator ICAP-1 in osteoblasts resulted in defective osteoblast proliferation, differentiation, and function; decreased type I collagen deposition; and delayed bone formation in mice (Bouvard et al., 2007; Brunner et al., 2011). Data showed that conditional β1 integrin deletion in early osteogenic mesenchymal cells or in preosteoblasts caused abnormal skeletal ossification or affected intramembranous and

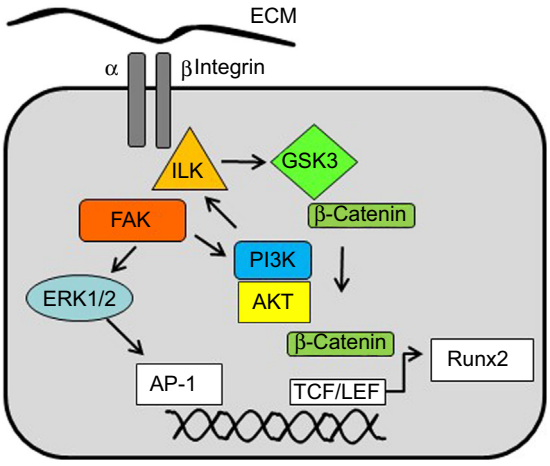

FIGURE 17.1 Role of integrins in osteoblasts. Simplified scheme showing how integrin-mediated signals regulate osteoblast function. Extracellular matrix (*ECM*)−integrin interaction via RGD interacts with integrin-linked kinase (ILK) and activates focal adhesion kinase (FAK), extracellular signal-regulated kinase 1/2 (ERK1/2), and Wnt/β-catenin signaling, leading to Runx2 expression and osteogenic differentiation, and with phosphatidylinositol 3-kinase/protein kinase B (PI3K/AKT) to trigger osteoblast survival (see text for more details). *AP-1*, activator protein 1; *GSK3*, glycogen synthase kinase-3; *TCF/LEF*, T cell factor/lymphoid enhancer factor.

endochondral bone formation in young mice. In contrast, osteocalcin-specific β1 integrin deletion had only minor effects on the skeletal phenotype, indicating that the β1 integrin is essential for early stages of osteogenesis in vivo (Shekaran et al., 2014). In addition to β1, other integrins were shown to control osteoblast function and fate. Early in vitro studies showed that the αVβ3 integrin is involved in dexamethasone- and BMP-2-induced osteoblast differentiation (Cheng et al., 2000, 2001). More recent data indicate that the αVβ3 integrin mediates BMP-2-induced osteoblast differentiation in vitro through activation of the ILK/ERK1/2 signaling pathway (Su et al., 2010). Another integrin, αVβ5, was found to mediate osteoblast attachment to vitronectin in vitro (Lai et al., 2000). The αVβ1 integrin was reported to promote osteoblast differentiation and to inhibit adipocyte differentiation in MSCs through its interaction with RGD present in osteopontin (Chen et al., 2014). Another integrin, α2β1, a major receptor for collagen type 1, is involved in osteoblast differentiation (Takeuchi et al., 1997) by activating ERK signaling and RUNX2 expression in vitro (Xiao et al., 1998). In vivo, α2 integrin deficiency resulted in altered bone properties in mice (Stange et al., 2013). This integrin was found to play a key role in MSC osteogenic differentiation and survival through activation of Rho-associated protein kinase (ROCK) and FAK signaling (Popov et al., 2011; Sens et al., 2017). The α4β1 integrin, which binds to fibronectin, was also found to be involved in MSC homing and osteoblast differentiation in vivo (Kumar and Ponnazhagan, 2007). Both MSCs and osteoblasts express α5β1 integrin, which interacts with fibronectin and is involved in the differentiation of osteoblast precursor cells (Hamidouche et al., 2009). The downregulation of α5 integrin subunit blunts osteoblast differentiation, while its overexpression promotes osteoblast differentiation in MSCs, an effect that is mediated by FAK and ERK1/2 signaling leading to RUNX2 activation (Hamidouche et al., 2009). α5β1 integrin activation also promotes insulin-like growth factor 2 (IGF-2) expression and signaling in MSCs, which contributes to osteogenic differentiation (Hamidouche et al., 2010). In addition, α5β1 integrin activation cross talks with Wnt signaling. α5β1 integrin priming by a monoclonal antibody, or a high-affinity peptide ligand, leads to increased osteogenic differentiation (Hamidouche et al., 2009) in part through activation of PI3K/protein kinase B (AKT) and Wnt/β-catenin signaling, indicating that Wnt/β-catenin signaling is involved in osteoblast differentiation mediated by α5β1 integrin (Saidak et al., 2015). In pluripotent cells, other integrins may be involved in osteogenic differentiation. In vitro data indicate that fibrinogen binds to the α9β1 integrin in human embryonic stem cells to induce pluripotent stem cell osteogenic differentiation mediated by SMAD1/5/8 signaling and *Runx2* expression (Kidwai et al., 2016).

There is ample evidence that integrins are critically involved in the response of osteoblasts and osteocytes to mechanical loading via cytoskeleton−integrin interactions at focal adhesion sites (Katsumi et al., 2004; Bonewald and Johnson, 2008; Turner et al., 2009) and induction of intracellular signaling mechanisms, including FAK, ERK, ROCK, PI3K/AKT, and Wnt signaling (Pommerenke et al., 2002; Wu et al., 2013; Du et al., 2016; Plotkin et al., 2005; Wang et al., 2007; Lee et al., 2010; Chen and Jacobs, 2013; Uda et al., 2017). Several integrins may be involved in the mechanisms mediating mechanotransduction, depending on the context. As expected from the aforementioned important role of β1 integrin in osteoblast differentiation, β1 integrin expressed by osteogenic cells was found to play a major role in mechanotransduction (Iwaniec et al., 2005; Phillips et al., 2008; Litzenberger et al., 2010). In osteocytes, in addition to the β1 integrin, the αVβ3 integrin is required for mechanotransduction (Thi et al., 2013), which involves calcium influx (Miyauchi et al., 2006), IGF-1 expression (Dai et al., 2014), and inhibition of the Wnt inhibitor sclerostin by periostin (Bonnet et al., 2012). In vivo, skeletal unloading in mice decreased αVβ3 integrin expression in osteoblasts, resulting in altered activation of IGF-1 signaling (Bikle, 2008). Skeletal unloading also reduced α5β1 integrin expression in osteoblasts and osteocytes, resulting in decreased PI3K signaling and altered bone formation (Dufour et al., 2007). Conversely, mechanical strain activates α5β1 integrin (Yan et al., 2012) and PI3K/AKT signaling in osteoblasts (Watabe et al., 2011). The activation of α5β1 integrin by mechanical stress in osteoblasts also causes opening of connexin 43 hemichannels and the subsequent release of anabolic factors (Batra et al., 2012). Other integrins were found to be involved in mechanotransduction. In vitro, the α2 integrin subunit is upregulated during induction on stiffer matrices and mediates the osteogenic differentiation of MSCs (Shih et al., 2011). However, mechanosensitivity appears to depend on the ligation between α2 or α5 subunit and ECM proteins to induce FAK activation (Seong et al., 2013), suggesting that specific integrin subunits may mediate mechanosensitivity in osteoblasts. Thus, several mechanisms generated by integrin−ECM interactions in osteoblasts and osteocytes are involved in the bone cell response to mechanotransduction.

The essential role of integrins in both bone formation and mechanotransduction suggests that targeting specific integrins may be an efficient way to promote osteogenic differentiation and bone regeneration. Several strategies were used to target integrins. One example is the ectopic expression of the α4 integrin in MSCs (Kumar and Ponnazhagan, 2007). While the injection of modified MSCs into mice led to increased cell homing in bone and their subsequent differentiation into osteoblasts (Guan et al., 2012), the systemic injection of a peptidomimetic ligand (LLP2A) that binds the α4β1 integrin, conjugated to a bisphosphonate to allow bone binding, led to increased osteoblast differentiation and bone formation in mice with established osteopenia (Guan et al., 2012; Yao et al., 2013). Another strategy is to target the α5β1

integrin (Marie, 2013). Lentiviral-mediated expression of the α5 integrin subunit in human MSCs promoted osteogenic differentiation, bone formation (Hamidouche et al., 2009), and bone repair in critical-size bone defects in mice (Srouji et al., 2012). Moreover, α5 integrin activation by a synthetic cyclic peptide, which activates FAK and ERK1/2−MAPK signaling in osteoprogenitor cells, led to increased osteoblast differentiation and to reduced cell apoptosis in vitro (Fromigué et al., 2012). In vivo, the local injection of an α5 integrin agonist peptide into adult mice increased parietal bone formation, indicating that pharmacological activation of α5 integrin in osteoprogenitor cells is effective in promoting de novo bone formation (Fromigué et al., 2012). An alternative strategy to target integrins may be the use of recombinant NELL-1, a secreted osteoinductive protein that binds to β1 integrin. In vitro, this strategy leads to activation of Wnt/β-catenin signaling and increased osteoblast differentiation. In vivo, delivery of NELL-1 to ovariectomized mice or osteopenic sheep improved bone mineral density (James et al., 2015). These studies showed that targeting integrins may be a promising approach for promoting bone formation and repair in skeletal disorders.

Osteoclasts

Osteoclasts are the multinucleated cells that resorb the bone matrix to promote skeletal modeling and renewal (Soysa and Alles, 2016; Cappariello et al., 2014). They rely on a tight and dynamic mechanism of adhesion to the mineralized matrix, which ensures cell changes indispensable for bone resorption. These are (1) the polarization of the osteoclast and (2) the sealing of the extracellular space between the cell and the bone matrix to be removed, called resorption lacuna (Soysa and Alles, 2016; Cappariello et al., 2014) (Fig. 17.2). The principal integrin involved in the adhesion of osteoclasts to the substrate is the αVβ3 receptor. While αV-deleted mice are embryonically lethal, β3-deleted mice showed a phenotype mimicking Glanzmann thrombasthenia (Morgan et al., 2010) and osteopetrosis (Zou and Teitelbaum, 2015; McHugh et al., 2000). Osteopetrosis is caused by osteoclast dysfunction, and these observations revealed the relevance of the αVβ3 integrin in osteoclast biology. Specifically, β3-null osteoclasts form normally but are prevented from resorbing bone. Their cytoskeletal array is disrupted, adhesion to substrate is reduced, and cell spreading is impeded (McHugh et al., 2000). These results suggest that the αVβ3 integrin is not involved in the molecular mechanisms of osteoclastogenesis, but it rather affects the morphological and molecular changes that make osteoclasts capable of resorbing bone. αVβ3 heterodimers are clustered in specific adhesion areas, called podosomes (Marchisio et al., 1984), that are typical of osteoclasts and other highly motile cells, such as monocytes, macrophages (Calle et al., 2006), and invasive cancer cells, in which they are called invadopodia (Eddy et al., 2017). Compared with classical focal adhesions, podosomes and invadopodia are much more dynamic, with a turnover of a few minutes rather than the hours observed in focal adhesions (Georgess et al., 2014). A typical feature of osteoclast podosomes is their clustering in a continuous peripheral annulus, called actin ring

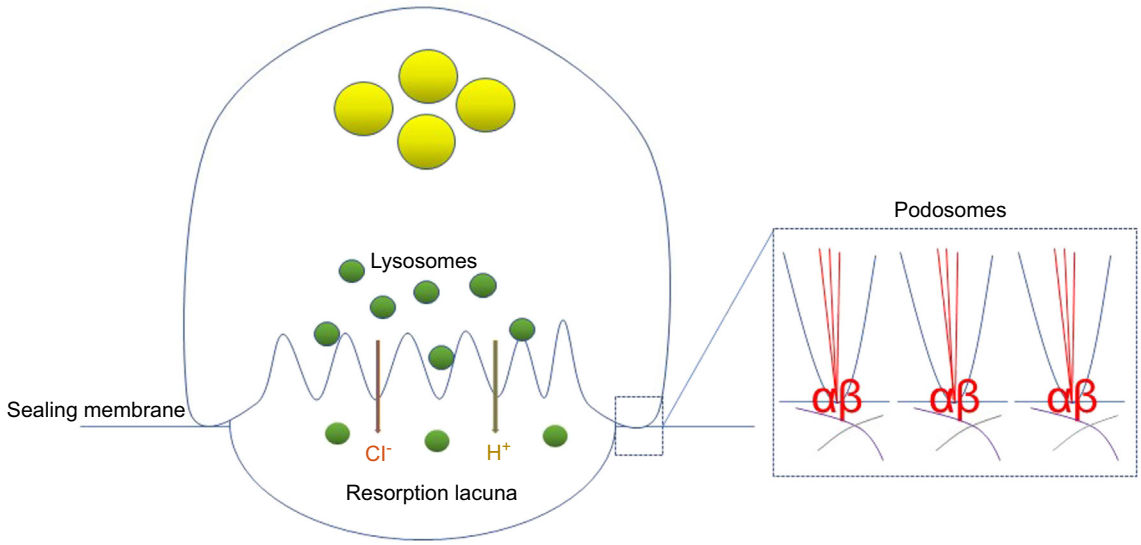

FIGURE 17.2 Role of integrins in osteoclasts. Cartoon showing a polarized osteoclast sitting on the resorption lacuna. Release of protons and chlorides acidifies the lacuna microenvironment, solubilizing the hydroxyapatite and allowing the degradation of the organic matrix by lysosomal enzymes therein secreted. Adhesion to the mineralized matrix occurs through podosomes located in the sealing membrane, which establish contacts with the extracellular molecules through integrin receptors (see text for more details).

(Cappariello et al., 2014), representing the sealing zone of the apical membrane. Here, the number of podosomes and the extension of the acting ring are proportional to the activity of the osteoclasts, reaching the maximum development during bone resorption, when multiple actin rings/osteoclast can be observed (Cappariello et al., 2014). For their high dynamism, podosomes and their associated αVβ3 integrins change rapidly in terms of number and distribution, contributing not only to the sealing of the resorption lacuna and the subsequent organization of the inner irregular domain of the apical membrane lodging the molecular mechanisms of bone resorption, called the ruffled border, but also to the osteoclast motility on the mineralized matrix during and between the bone resorption cycles (Cappariello et al., 2014; Rucci and Teti, 2016). In osteoclast podosomes, the αVβ3 integrin is largely represented and concentrated in a circular podosomal area of membrane adhesion to substrate, whose cytosolic center lodges a core of microfilaments; actin-binding proteins, including α-actinin; and actin-branching proteins, including cortactin, the ARP2/3 complex, and WASP and WASP-interacting protein (Georgess et al., 2014; Rucci and Teti, 2016). The αVβ3 integrin circular "rosette" that surrounds this microfilament core is associated with several intracellular adhesion proteins, such as vinculin, talin, paxillin and tensin, that link the integrins to the microfilaments (Saltel et al., 2008; Correia et al., 1999; Evans and Matsudaira, 2006; Marchisio et al., 1988; Akisaka et al., 2001). Importantly, this complex structure includes microfilament-severing proteins (gelsolin and cofilin) (Ory et al., 2008), as well as the small GTP-binding protein RHO (Teitelbaum, 2011) and the guanine exchange factors DOCK5 and VAV3, which provide rapid podosome remodeling indispensable for their dynamism (Purev et al., 2009). This is also ensured by the localization in podosomes of the large GTP-binding protein dynamin, which regulates E3 ubiquitin ligase c-CBL-dependent degradation or receptors and signaling factors (Bruzzaniti et al., 2005). GTPase activity of dynamin is enhanced by GRB2, which also increases WASP-mediated ARP2/3-dependent actin nucleation (Spinardi and Marchisio, 2006). Along with the microfilament-severing function of gelsolin and cofilin, this molecular cascade ensures rapid microfilament turnover and podosome disassembly and reassembly (Luxenburg et al., 2012). Moreover, ubiquitin ligases, including c-CBL and CBL-b (Horne et al., 2005), phosphoinositide kinases such as PI3K (Chellaiah et al., 2001), nonreceptor tyrosine kinases such as c-SRC and PYK2 (Duong et al., 1998; Destaing et al., 2008), ABL and FAK (Ray et al., 2012), and phosphatases, including PTPα, PTPε, and SHP2 (Granot-Attas and Elson, 2008), associate with the αVβ3 integrin complex to further regulate osteoclast adhesion and podosome dynamics.

Genetic studies have been instrumental in demonstrating the relevance of the αVβ3 receptor signaling in osteoclast activity. The analysis of *c-Src* deletion in mice showed that osteoclasts were not able to polarize and became immotile (Lowe et al., 1993). They exhibited a severe osteopetrotic phenotype, which was observed, in milder form, also in *Pyk2*- and *c-Cbl*-null mice (Gil-Henn et al., 2007; Tanaka et al., 1996). c-SRC coprecipitates with the αVβ3 integrin and through its c-CBL tyrosine phosphorylation activity, promotes substrate ubiquitination and prolonged cell survival (Horne et al., 2005). Furthermore, c-SRC contributes to the metabolism of PYK2 and p130CAS, involved in the organization of the sealing membrane (Nakamura et al., 1998). Therefore, given that c-SRC is upstream of the tyrosine phosphorylation cascade involving PYK2, c-CBL and p130CAS, it is likely that these intracellular signaling molecules act synergistically to determine correct cytoskeletal arrangement, podosome formation, and osteoclast polarization and survival.

On the extracellular side, the osteoclast αVβ3 integrin binds the RGD sequence of a number of matrix proteins that contribute to osteoclast adhesion and outside-in signaling (Rucci and Teti, 2016). Many proteins are recognized by the αVβ3 integrin, including osteopontin, bone sialoprotein 2, vitronectin, fibronectin, and von Willebrand factor (Zou and Teitelbaum, 2010). αVβ3 integrin recognizes also collagen type I but only upon molecular remodeling, the collagen type I RGD sequence being lodged in a cryptic domain. In osteoclasts, osteopontin, bone sialoprotein II, synthetic RGD peptides, echistatin (an RGD-disintegrin peptide extracted from the poison of viper venom), and the αvβ3 integrin activating LM609 monoclonal antibody mobilize intracellular calcium through the αVβ3 receptor, albeit with some species specificity. In fact, in rat osteoclasts, αVβ3 integrin activation triggers intracellular calcium transients and cell retraction (Shankar et al., 1993), while in chicken osteoclasts it induces a calmodulin/Ca^{2+}-ATPase-dependent calcium efflux and intracellular reduction (Miyauchi et al., 1991). The molecular mechanisms underlying these opposite events have not been investigated, leaving this question still open. Finally, in mouse osteoclasts, osteopontin induces RGD-dependent nuclear translocation of nuclear factor of activated T cells 1 (NFATc1), a transcription factor essential for osteoclastogenesis (Tanabe et al., 2011), whose activation is triggered by calcium oscillations (Negishi-Koga and Takayanagi, 2009). The αVβ3 integrin is relatively infrequent in the organism, and osteoclasts are among the cells mostly enriched in these receptors. The αVβ3 integrin has been considered a pharmacological target to combat cancer-induced osteolytic lesions, osteoporosis, and rheumatoid arthritis (Desgrosellier and Cheresh, 2010; Schneider et al., 2011; Tian et al., 2015). αVβ3 integrin targeting molecules include cyclic peptides carrying the αVβ3 integrin binding site (Auzzas et al., 2010), neutralizing antibodies (Hsu et al., 2007) and nonpeptide antagonists (Hsu et al., 2007; Sheldrake and Patterson, 2014). Several of them have been tested in preclinical studies, and one has been tested in clinical trials to treat cancer (Danhier et al., 2012).

Other integrin members are also expressed by osteoclasts. αVβ1, αMβ2, and αVβ5 receptors are expressed by osteoclast mononuclear precursors and switch to αVβ3 during preosteoclast maturation in polykarya (Inoue et al., 1998). The α2β1 integrin is engaged in the binding to collagen type I. It does not recognize vitronectin, fibronectin, or fibrinogen and promotes migration and fusion of precursors into mature cells (Townsend et al., 1999). However, these integrins have not been investigated any further and their relevance in osteoclast biology is probably underestimated.

Chondrocytes

Chondrocytes express a panel of at least seven integrin heterodimers recognizing molecules of the basal lamina and the territorial cartilage matrix. α5β1, αNβ3, and αNβ5 are fibronectin receptors expressed by chondrocytes, which, along with the α6β1 receptor recognizing laminin, and the α1β1, α2β1 and α10β1 integrins binding collagen, ensure tight chondrocyte interaction with the substrate (Loeser, 2002; Aszodi et al., 2003). The dominant integrin subunit in chondrocytes is the β1 chain (Woods et al., 2007a). Consequently, conditional chondrocyte knockout (KO) of *β1 integrin* resulted in a severe cartilage phenotype (Woods et al., 2007a). Typical chondrodysplasia malformations were noticed in these mice, with shorter long bones and reduced growth plate hypertrophic zone. No vascularization of the primary ossification centers was observed, with vessel present only in the periosteum. The growth plate appeared broadened, the chondrocyte columnar array was disrupted, and the hypertrophic zone mineralization was reduced and patchy (Woods et al., 2007a). Given the broad presence of the β1 chain in at least five chondrocyte integrin receptors, such a severe cartilage phenotype is not surprising. Furthermore, a similar outcome was observed in conditional *Il1*-null chondrocytes in mice (Grashoff et al., 2003; Terpstra et al., 2003).

The expression of chondrocyte β1 integrins is regulated by mechanical forces. Tension forces stimulate their expression with a mechanism that appears to be mediated by FAK, and this effect leads to inhibition of chondrogenesis, especially through α2β1 and α5β1 receptors (Takahashi et al., 2003; Onodera et al., 2005). This result is rather surprising and while it is confirmed by the observation that plating mesenchymal stem cells on integrin-activating RGD peptides results in their reduced commitment to chondrogenesis (Connelly et al., 2007), it is contradicted by the discovery that inhibition of β1 integrin activity reduces chondrogenesis and cartilage production (Shakibaei, 1998). These results suggest that integrins have dual roles in cartilage development, inhibiting or inducing chondrogenesis in unlike contexts and in response to different environmental regulations. Functionally, Wang and Kirsch (Wang and Kirsch, 2006) showed that β1 and β5 integrins promote cell survival, while their deletion or blockage by neutralizing antibodies reduces hypertrophic differentiation (Hirsch et al., 1997). Proliferative and hypertrophic chondrocytes of the growth plate express the highest levels of α5β1 receptors, and neutralization of this integrin results in impairment of chondrocyte proliferation (Enomoto-Iwamoto et al., 1997). The α5β1 integrin is also important for the development of the appendicular skeleton and joints. For instance, premature formation of prehypertrophic chondrocyte and joint fusion were observed when *α5β1 integrin* was misexpressed (Garciadiego-Cázares et al., 2004). Finally, deletion of *α10β1 integrin* caused dysfunctions of the growth plate, inducing growth retardation (Bengtsson et al., 2005), with increased apoptosis and altered chondrocyte morphology. Instead deletion of the α1 chain caused osteoarthritis but not growth defects (Zemmyo et al., 2003).

In addition to integrins, the adhesion of chondrocytes to the cartilage matrix is ensured by other types of molecules. The discoidin domain receptor, *Ddr2*, is highly expressed by articular chondrocytes in osteoarthritis, and its conditional deficiency in growth plate chondrocytes was associated with decreased chondrocyte proliferation and subsequent dwarfism (Labrador et al., 2001). Annexin V instead mediates adhesion to the N telopeptide of collagen II in articular cartilage and growth plate, where it appears to regulate apoptosis and matrix mineralization (Wang and Kirsch, 2006; Jennings et al., 2001; Kirsch, 2005). Finally, CD44, an important membrane glycoprotein receptor recognizing collagens and hyaluronic acid, increases during chondrogenesis and contributes to the organization of the territorial matrix and the regulation of chondrocyte survival (Nicoll et al., 2002; Knudson, 2003).

Role of cadherins in bone cells

Osteoblasts and osteocytes

Cadherins are transmembrane glycoproteins that mediate calcium-dependent cell−cell adhesion through homophilic interactions of their extracellular domains (Gumbiner, 2005). The intracellular domain of cadherins interacts with cytoskeletal proteins at adherens junction sites and with signaling molecules such as vinculin, α- and β-catenin, and other molecules involved in cellular signaling processes (Nelson and Nusse, 2004). Osteoblasts express Cadh1 (E-cadherin), Cadh2 (N-cadherin), Cadh3 (P-cadherin), and Cadh11 (“osteoblast cadherin”) (Cheng et al., 1998; Goomer et al., 1998;

Ferrari et al., 2000; Lemonnier et al., 2000; Kawaguchi et al., 2001a), although the expression of these cadherins changes with the stage of osteoblast differentiation. Cadh2 expression initially increases during osteogenic differentiation in vitro but declines thereafter (Ferrari et al., 2000; Greenbaum et al., 2012), whereas Cadh11 is upregulated throughout the osteoblast differentiation program (Kawaguchi et al., 2001b; Shin et al., 2000). In vivo, *Cadh2* is expressed in lining cells but not in osteocytes (Shin et al., 2000). In vitro and in vivo studies suggest that cadherins may control precursor cell lineage determination (Marie et al., 2014a). Both *Cadh2* and *Cadh11* are downregulated with commitment of mesenchymal progenitors to adipogenesis in vitro (Kawaguchi et al., 2001b; Shin et al., 2000). Adult *Cadh11*-KO mice showed increased number of adipogenic precursors and adipogenic differentiation in vitro, suggesting that Cadh11 blocks adipogenesis (Di Benedetto et al., 2010). However, deletion of *Cadh11* does not result in a major skeletal defect in adult mice (Di Benedetto et al., 2010) and causes only modest osteopenia in young mice (Castro et al., 2004), presumably due to compensation by Cadh2. Indeed, ablation of one *Cadh2* allele in *Cadh11*-null mice resulted in severe osteopenia associated with reduced bone strength (Di Benedetto et al., 2010). Consistent with a role for Cadh2 in osteogenesis, overexpression of a dominant-negative *Cadh2* mutant in mature osteoblasts using the osteocalcin promoter resulted in reduced osteoblast differentiation, bone formation, and bone mass (Castro et al., 2004). However, *Cadh2* haploinsufficiency, or conditional deletion of *Cadh2*, in osteoblasts led to increased differentiation of bone marrow stromal cells in vitro, suggesting that Cadh2 may inhibit terminal osteoblast differentiation. Thus, although Cadh2 and Cadh11 contribute to early stages of osteoblast differentiation, Cadh2, but not Cadh11, downregulation is required for terminal differentiation.

How do cadherins control osteoblast differentiation and fate? As they behave as adhesive molecules, cadherins can control osteoblast precursor cell fate in part through cell−cell adhesion (Haÿ et al., 2000). Blocking Cadh2-mediated cell−cell adhesion using specific peptides or antibody reduces osteoblast differentiation in vitro (Ferrari et al., 2000; Haÿ et al., 2000). However, overexpression of *Cadh2* in osteoblasts driven by the Col1A1 promoter reduced osteoblast activity and peak bone mass, indicating that Cadh2 controls bone formation through other mechanisms than cell−cell adhesion (Haÿ et al., 2009a). Cadherins are known modulators of intracellular signaling related to Wnt signaling (Heuberger and Birchmeier, 2010). Cadherins can bind to β-catenin, which leads to increased stabilization of the adhesion structure. Conversely, the release of β-catenin from cadherins destabilizes the adhesion complex and allows cell mobility (Gottardi and Gumbiner, 2001). In addition, cell−cell adhesion mediated by cadherins promotes β-catenin phosphorylation and inactivation of Wnt/β-catenin signaling (Lilien and Balsamo, 2005). Furthermore, cadherins can sequestrate β-catenin at the cell membrane, resulting in decreased β-catenin pool availability for nuclear translocation (Gottardi and Gumbiner, 2001). In osteoblasts, several interactions between cadherins and Wnt signaling molecules were shown to control osteogenic differentiation (Lilien and Balsamo, 2005). The decreased β-catenin abundance at cell−cell contacts induced by deletion of *Cadh2* or *Cadh11* led to decreased cell−cell adhesion with a negative effect on osteoblastogenesis (Di Benedetto et al., 2010). In addition to this mechanism, Cadh2 can bind to low-density lipoprotein receptor−related protein (LRP) 5 or LRP6 via Axin, leading to LRP5/6 sequestration at the cell membrane, reduced LRP5/6 availability, and decreased Wnt/β-catenin signaling (Haÿ et al., 2009a). Cadh2/Axin/LRP5/6 interaction in osteoblasts also reduces ERK1/2 and PI3K/AKT signaling, resulting in decreased osteoblast proliferation, differentiation, and survival (Marie et al., 2014a). Furthermore, Cadh2/LRP5/6 interaction in osteogenic cells causes decreased endogenous Wnt3a expression, which contributes to reduced Wnt signaling and osteoblastogenesis (Marie et al., 2014a). The resulting effect of the negative interaction of Cadh2 overexpression on Wnt signaling in osteogenic cells is to decrease bone formation and delay peak bone mass in young mice (Haÿ et al., 2009a). Consistent with the finding that Cadh2 negatively regulates Wnt/β-catenin signaling in osteoblasts (Marie et al., 2014a; Haÿ et al., 2009a), Cadh2 was found to restrain the bone anabolic action of intermittent parathyroid hormone (iPTH). In vitro, the ablation of *Cadh2* in osteogenic cells results in increased LRP6/PTHR1 interaction and enhanced iPTH-induced protein kinase-dependent Wnt/β-catenin signaling. In mice, conditional *Cadh2* deletion in osteoprogenitor cells led to a greater than normal osteoblast activity and bone mass in response to iPTH, indicating that Cadh2−LRP6 interaction restrains PTH-induced β-catenin signaling (Haÿ et al., 2009b). Consistently, overexpression of *Cadh2* blunted the suppressive effect of PTH on sclerostin/SOST expression in vitro and in vivo, further indicating that Cadh2 expression influences the anabolic effect of iPTH in mice (Revollo et al., 2015). However, the influence of Cadh2 on Wnt signaling and osteogenic cell commitment and differentiation varies with aging. While Cadh2 overexpression in osteoblasts decreased osteoblast differentiation and increased bone marrow adipocyte differentiation in young mice, this phenotype was fully reversed with aging (Yang et al., 2016), which is consistent with the downregulation of Cadh2 during osteoblast maturation. This phenotype was linked to reversal with age of endogenous Wnt5a and Wnt10b signals that are key factors controlling osteogenic cell lineage commitment (Yang et al., 2016). In addition to aging, the negative effect of Cadh2 on Wnt/β-catenin signaling depends on the osteogenic cell differentiation stage. Conditional deletion of *Cadh2* in osteoprogenitors at embryonic and perinatal age was detrimental to bone accrual, whereas loss of *Cadh2* in osteolineage cells in adult mice favored bone formation (Haÿ et al., 2014), indicating that Wnt/β-catenin

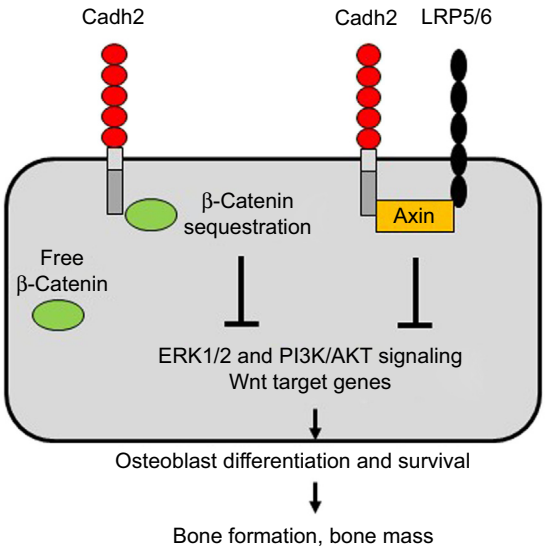

FIGURE 17.3 Role of cadherins in osteoblasts. Cadherin 2 (*Cadh2*) can interact with β-catenin at the cell surface, resulting in β-catenin sequestration, decreased free β-catenin, and reduced Wnt signaling. Cadh2 can also interact with the Wnt coreceptors low-density lipoprotein receptor–related protein 5 (*LRP5*) and *LRP6*, resulting in reduction of Wnt/β-catenin signaling and other signaling pathways that control osteoblast function and survival, bone formation, and bone mass (see text for more details). *ERK1/2*, extracellular signal-regulated kinase 1/2; *PI3K/AKT*, phosphatidylinositol 3-kinase/protein kinase B.

signaling, bone formation, and bone mass are directly influenced by the level of expression of Cadh2 at all stages of the osteoblast lineage. Cadherins also modulate Wnt/β-catenin signaling induced in response to mechanotransduction in bone cells. Mechanical stimulation induced by oscillatory fluid flow in osteoblastic cells leads to reduced Cadh2/β-catenin binding at the cell membrane, resulting in β-catenin nuclear translocation and osteogenic differentiation (Fontana et al., 2017). In addition to the impact on Wnt signaling, Cadh2 interacts with PI3K signaling in osteoblastic cells. Cadh2-mediated adherens junctions activate the PI3K signaling cascade in osteoblasts, which contributes to osteoblast differentiation and osteogenesis in the perichondrium (Arnsdorf et al., 2009). Conversely, *Cadh2* overexpression in osteoblasts reduced Wnt-dependent PI3K/AKT signaling, resulting in decreased osteoblast survival in mice (Marie et al., 2014a; Haÿ et al., 2009a). Thus, cadherins control bone formation through multiple mechanisms that are directly or indirectly linked to Wnt/β-catenin signaling (Fig. 17.3).

Based on the finding that Cadh2 interacts with LRP5/6 to reduce β-catenin/Wnt signaling and osteoblast function (Haÿ et al., 2009a), therapeutic approaches targeting Cadh2/LRP5/6 interaction were developed for promoting bone formation (Guntur et al., 2012). In vitro, deletion of the Cadh2 domain interacting with Axin and LRP5/6 leads to promotion of Wnt/β-catenin signaling and osteoblast differentiation (Fiorino and Harrison, 2016). Moreover, disruption of the Cadh2/LRP5/6 interaction using a competitor peptide that binds to the Cadh2/Axin-interacting domain of LRP5/6 results in enhanced Wnt/β-catenin signaling and osteoblast function in vitro, and increased calvaria bone formation in mice (Marie and Haÿ, 2013). In senescent osteopenic mice, blocking the Cadh2/LRP5/6 interaction led to increased endogenous Wnt5a and Wnt10b expression, osteogenic differentiation, bone formation, and bone mass (Haÿ et al., 2012), suggesting a therapeutic approach targeting the Cadh2/LRP5/6 interaction for promoting bone formation in the aging skeleton.

Osteoclasts

Osteoclasts have been investigated for cadherin expression, especially to understand the mechanisms underlying the fusion process of mononuclear precursors into polykarya (Mbalaviele et al., 1995). Osteoclasts express Cadh1, while they are negative for Cadh2 and Cadh3. Interestingly, Cadh1 expression peaks at the time of preosteoclast fusion, a process that is largely inhibited by Cadh1-neutralizing antibodies. Cadh1 inhibition blocks migration of osteoclast precursors, which is essential for mononuclear cell clustering and fusion of their plasma membranes (Fiorino and Harrison, 2016). In contrast, neutralization of Cadh1 fails to affect proliferation of precursors or adhesion to substrate, confirming a specific role of this cell adhesion molecule in the maturation of polykarya (Mbalaviele et al., 1995). In osteoclast precursors, Cadh1 is localized in areas of membrane protrusions (Fiorino and Harrison, 2016) that are distributed throughout the entire cell surface, but its

expression dramatically declines in mature multinucleated osteoclasts. Cadh1 engagement in osteoclast precursors activates gene expression, and several osteoclast genes are under the control of the Cadh1 pathway. Blocking Cadh1 function, before the preosteoclasts fuse into polykarya, retards the expression of the osteoclast transcription factor NFATc1, the fusion protein dendritic cell-specific transmembrane protein, and the osteoclast enzymes cathepsin K and tartrate-resistant acid phosphatase. Since these genes are essential for osteoclast multinucleation and maturation, these observations highlight the important role of Cadh1 in the late stage of osteoclastogenesis. Conversely, overexpression of *Cadh1* in osteoclast precursors brought forward the activation of NFATc1, which translocates to the nucleus earlier than in control cells (Fiorino and Harrison, 2016). Given that the studies on osteoclast cadherins are scanty, we have no specific clues on the signals induced by these molecules during osteoclastogenesis. However, Cadh1 is implicated in the maturation of a number of other macrophage subtypes. For instance, it is involved in the differentiation and motility of Langerhans cells and regulates the activity of dendritic cells via cooperation of the Wnt/β-catenin signaling (Van den Bossche et al., 2012). Because of the tight interaction of Cadh1 with β-catenin and the role of Wnt/β-catenin signaling in osteoclast formation (Kobayashi et al., 2015), it is likely that these two pathways cooperate for the regulation of osteoclastogenesis as well. Another cadherin isoform identified in osteoclasts is Cadh6/2 (Mbalaviele et al., 1998). Dominant negative or antisense *Cadh6/2* prevents osteoclast precursors from interacting with ST2 cells, known to support osteoclastogenesis, suggesting this cell adhesion molecule is involved in heterotypic interaction between these two cell types, leading to full maturation of the osteoclasts (Mbalaviele et al., 1998). Unfortunately, there are no other data supporting this observation; therefore the underlying molecular mechanisms remain elusive.

Chondrocytes

The most prominent cadherin in chondrocytes is Cadh2. It is strongly expressed during mesenchymal condensation, which allows the formation of the primordial tissue from which limb cartilage originates (Oberlender and Tuan, 1994). This process can be impaired using Cadh2 blocking antibody, which prevents mesenchymal condensation and subsequent chondrogenesis. Cadh2 was upregulated in an in vitro model of chondrocyte differentiation. It was detected in prechondrogenic cells and transiently increased during cell aggregation, disappearing in hypertrophic chondrocytes (Tavella et al., 1994). Cadh2 appears to be essential for cellular condensation (Woodward and Tuan, 1999). Using high-density micromass cultures, Woodward and Tuan (Woodward and Tuan, 1999) induced chick limb mesenchymal cell condensation by ion cross-links promoted by poly-L-lysine. This condition unveiled a time-dependent increase in Cadh2, while its neutralization by a specific antibody inhibited the effect of poly-L-lysine on chondrogenesis. Forced overexpression of *Cadh2* induced precartilage cellular condensation and enhanced chondrogenesis in vitro, with a mechanism that required both extracellular and intracellular domains of Cadh2 (Delise and Tuan, 2002). Cadh2 also appears to be a target for the antichondrogenic effect of retinoic acid. Retinoic acid inhibits the progression of condensed precartilage tissue to cartilage nodules. This progression occurs upon suppression of Cadh2 expression, which is prevented by retinoic acid along with the downregulation of the associated α- and β-catenins. This effect of retinoic acid is blocked by cytochalasin D, a molecule that disrupts the microfilaments implicated in the Cadh2 adhesion function (Cho et al., 2003).

Another important regulator of chondrogenesis that requires Cadh2 is transforming growth factor β (TGFβ). TGFβ induces chondrogenesis through activation of MAPKs, especially p38 and ERK1. These signaling kinases transiently upregulate Cadh2 to allow cellular condensation, followed by its downregulation to induce progression toward chondrogenesis (Tuli et al., 2003). Cellular condensation is also regulated by the small GTP-binding protein RAC1, which triggers upregulation of Cadh2 as well (Woods et al., 2007b). TGFβ also induces the expression of Wnt7. Chondrogenesis is regulated by the Wnt pathway and Wnt7a is a lead chondrogenic signaling t that acts in concert with Cadh2. Using the chick limb mesenchymal cell micromass cultures, Tufan et al. (Tufan et al., 2002) investigated the role of *Chfz-1* and *Chfz-7*, which are members of the Wnt pathway encoded by the Frizzled genes. While CHFZ-1 surrounded the nascent cartilage rudiment, CHFZ-7 was expressed in the area of cell condensation, with progressive downregulation toward the peripheral area. This pattern of expression was similar to the expression of Cadh2, and misexpression of *Chfz-7* impaired chondrogenesis at the early stage of formation of the precartilage aggregates. Notably, *Cadh2* expression was downregulated by *Chfz-7* misexpression, suggesting a functional link between Cadh2 and the Wnt pathway during mesenchymal condensation and subsequent chondrogenesis (Tufan et al., 2002).

To induce chondrogenesis, Cadh2 must be cleaved by ADAM10. Cadh2 cleavage mutants failed to induce cartilage formation, impeding the organization of cartilage aggregates as well as the synthesis of proteoglycans. Furthermore, overexpression of these mutants downregulated type II collagen, aggrecan, and type X collagen (Nakazora et al., 2010), confirming a pivotal role for enzymatic cleavage in the activation of cartilage matrix production. Another factor involved in chondrogenesis that affects Cadh2 is the C-type natriuretic peptide. Treatment of micromass cultures of chick limb

mesenchymal cells with this factor upregulated *Cadh2* along with collagen type X and glycosaminoglycans, ending up with enhanced chondrogenesis (Alan and Tufan, 2008). Despite these striking observations, *Cadh2*-null mice have no skeletal alterations. Given the redundant functions of cadherins, it was hypothesized that, in this mouse model, *Cadh2* deficiency is compensated for by the activity of Cadh11 in cartilage development. *Cadh11* is strongly upregulated in response to chondrogenic conditions and is expressed in normal and osteoarthritic articular cartilage (Stokes et al., 2002). In the growth plate, *Cadh11* is expressed in the late hypertrophic zone. Knockdown of *Cadh11* inhibited the formation of calcified nodules in a growth plate–derived chondrocyte cell line (Matsusaki et al., 2006). The function of Cadh11 has been investigated during the differentiation of mesenchymal stem cells. Kii et al. (Kii et al., 2004) observed that teratomas derived from embryonic stem cells transfected with *Cadh11* formed preferentially bone and cartilage. Using tridimensional hanging drop cultures, it was noticed that *Cadh11*-transfected cells formed sheetlike aggregates, as opposed to *Cadh2*-overexpressing cells, which formed spherical structures, suggesting independent and nonoverlapping functions of Cadh11 and Cadh2 in this context (Kii et al., 2004).

Roles of other attachment molecules in bone cells

Syndecans

Cell surface proteoglycans are composed of a membrane-associated core protein to which glycosaminoglycan (heparan sulfate [HS] or chondroitin sulfate) chains are covalently attached. HS chains can bind several proteins, including growth factors, signaling proteins, membrane receptors, and ECM proteins (Bishop et al., 2007; Bernfield et al., 1999), thus allowing regulation of the availability and function of signaling proteins (Mitsou et al., 2017; Billings and Pacifici, 2015). Notably, binding of extracellular ligands on HS chains increases the probability for ligands to interact with their high-affinity receptors (Billings and Pacifici, 2015). In the growth plate, HS proteoglycans (HSPGs) bind members of the hedgehog, BMP, fibroblast growth factor (FGF), and Wnt protein families (Huegel et al., 2013). Syndecans are an HSPG family composed of four members (syndecan-1 to -4) (Dews and Mackenzie, 2007). In bone, syndecan-1 is expressed transiently during mesenchymal condensation, syndecan-2 is expressed by mesenchymal cells and persists during bone development and osteoblast differentiation, syndecan-3 is mainly expressed in cartilage, whereas syndecan-4 expression is more ubiquitous (David et al., 1993). In osteoblasts, syndecan-2 is strongly associated with FGF/FGFRs (Molténi et al., 1999a; Song et al., 2007) and granulocyte/macrophage colony-stimulating factor (Modrowski et al., 2000), and contributes to the activity of these ligands. Syndecan-2 expression is regulated by Runx2, Wnts, FGF, and TGFβ in osteoblastic cells (Teplyuk et al., 2009; Worapamorn et al., 2002; Dieudonné et al., 2010). BMP-2 increases the synthesis of syndecans (Gutierrez et al., 2006) and interacts with HS complexes to regulate osteoblast differentiation in mesenchymal stromal cells (Manton et al., 2007). In osteogenic cells, syndecan-2 acts as a coreceptor for FGFRs, which is essential for the response to FGF2 (Molténi et al., 1999b; Steinfeld et al., 1996). FGF binding to HS chains results in growth factor dimerization and formation of a tertiary complex with FGFR (Matsuo and Kimura-Yoshida, 2013). Syndecans also interact with Wnt molecules via HS chains to modulate Wnt signaling (Baeg et al., 2001). This leads to the modulation of Wnt molecule concentration at the cell surface, which stabilizes the signaling activity (Fuerer et al., 2010). In bone, syndecan-2 controls the extracellular availability of Wnt effectors and modulates intracellular signals linked to Wnt signaling (Mansouri et al., 2015). Transgenic mice overexpressing *syndecan-2* in osteoblasts showed decreased osteogenesis associated with increased mesenchymal osteoprogenitor cell apoptosis. This phenotype results from inhibition of Wnt/β-catenin signaling and decreased production of Wnt ligands, supporting a role of syndecan-2/Wnt signaling interaction in the control of osteoblastogenesis in vivo (Mansouri et al., 2017). In addition to interacting with signaling factors that regulate osteoblasts, syndecans interact with fibronectin to facilitate cell adhesion through fibronectin–transglutaminase complexes induced by syndecan-4-dependent activation of protein kinase Cα (Wang et al., 2010). This complex supports osteoblast adhesion and rescues from cell death by anoikis in a syndecan- and β1 integrin-dependent manner (Wang et al., 2011). Thus, syndecans control osteoblast adhesion and response to exogenous factors by interacting with both ECM and signaling factors, resulting in the modulation of intracellular factors controlling cell fate.

Glypicans and perlecan

Glypicans are other cell surface proteoglycans expressed in bone. The glycosaminoglycan-bearing perlecan domain I interacts with ligands such as BMP, FGF, hedgehog, and Wnt proteins (Dwivedi et al., 2013) and thereby supports early chondrogenesis (Farach-Carson et al., 2008). In vitro, glypican-3 is involved in osteogenic commitment, as reduced *glypican-3* expression leads to decreased *Runx2* expression and osteoblast differentiation in murine osteoblastic cells

(Haupt et al., 2009). In vivo, *glypican*-KO mice showed decreased trabecular bone mass and delayed endochondral ossification due to reduced osteoclastogenesis, indicating that this HSPG plays a role in bone growth (Viviano et al., 2005). Another HSPG, perlecan, interacts with the ECM, growth factors, and receptors and influences cellular signaling (Whitelock et al., 2008). In bone, perlecan is expressed in cartilage and strongly potentiates chondrogenic differentiation in vitro (French et al., 1999). Perlecan promotes chondrocyte attachment to the matrix (SundarRaj et al., 1995) and is involved in chondrogenic differentiation in vitro (Gomes Jr et al., 2006; French et al., 2002). In vivo, *perlecan*-KO mice showed defective endochondral ossification due to decreased proliferation of chondrocytes and reduced prehypertrophic zone (Arikawa-Hirasawa et al., 1999). Consistent with a role of perlecan in growth plate development, reduced perlecan secretion resulted in achondroplasia in mice (Rodgers et al., 2007). Mechanistically, perlecan binds to FGF2 by its HS chains and enhances FGF2 binding to FGFR-1 and FGFR-3 receptors in the growth plate (Smith et al., 2007). Perlecan may also be involved in the control of osteoblastogenesis and bone formation (Lowe et al., 2014). In the bone marrow, cell-derived ECM that contains perlecan, among other matrix molecules, preserves the ability of mesenchymal stromal cells to differentiate into osteoblasts or adipocytes (Chen et al., 2007). In addition, exogenous perlecan suppresses adipogenic differentiation and promotes osteogenic differentiation of mesenchymal stem cells in vitro (Nakamura et al., 2014). This may be due in part to enhanced interaction with BMP-2, leading to increased BMP-2 bioactivity (Decarlo et al., 2012). At a later stage of osteoblast differentiation, perlecan is localized in the pericellular space of osteocytes in the lacunocanalicular system in cortical bone (Thompson et al., 2011), where it regulates solute transport and mechanosensing within the osteocyte lacunar–canalicular system (Wang et al., 2014). These studies support the notion that, in addition to being involved in cell attachment to the ECM, HSPGs control bone cell functions by interacting with signaling proteins involved in the response to extracellular signals.

CD44

CD44 is a cellular surface adhesion molecule involved in various processes. CD44 binds to hyaluronan (HA), osteopontin, fibronectin, and collagen type I and thereby may regulate bone cell function (Goodison et al., 1999). As noted earlier, CD44 is involved in chondrocyte survival (Nicoll et al., 2002; Knudson, 2003). Osteoclasts express CD44 (Nakamura et al., 1995; Suzuki et al., 2002), and the interaction of CD44 with HA or osteopontin induces intracellular signals in preosteoclasts, leading to osteoclast formation (Spessotto et al., 2002; Chellaiah et al., 2003; Chellaiah and Hruska, 2003). In vitro, osteopontin signals through calcium and NFATc in osteoclasts (Tanabe et al., 2011). Consistently, *CD44* deficiency led to inhibition of osteoclast activity and function by downregulating NF-κB/NFATc1-mediated signaling (Li et al., 2015). Moreover, receptor activator of NF-κB ligand (RANKL) induces *CD44* expression, and CD44 promotes the activation of RANKL–RANK–NF-κB-mediated signaling during osteoclastogenesis (Li et al., 2015). In vivo, *CD44*-KO mice showed normal trabecular bone volume but increased cortical thickness, suggesting a site-specific effect of *CD44* deficiency (Cao et al., 2005). Accordingly, the reduced osteoclastogenesis and osteoclast function induced by *CD44* deficiency counteracts the cortical, but not trabecular, bone loss induced by hindlimb unloading in mice (Li et al., 2015). In contrast to osteoclasts, a role of CD44 in osteoblast function is not firmly established. In vitro, galectin-9 binding to CD44 was reported to induce the formation of a CD44/BMP receptor complex, leading to Smad1/5/8 phosphorylation and osteoblast differentiation (Tanikawa et al., 2010). However, *CD44* deficiency inhibited osteoclast but not osteoblast function in hindlimb-unloading-induced bone loss in mice (Li et al., 2015), suggesting a role of CD44 in bone resorption rather than in bone formation.

Immunoglobulin superfamily members

Neural cell adhesion molecule**,** a member of the immunoglobulin superfamily, is a cell surface molecule expressed transiently during osteoblast lineage (Haÿ et al., 2000; Tanikawa et al., 2010), and its expression is associated with the osteogenic phenotype (Rundus et al., 1998). Activated leukocyte cell adhesion molecule (ALCAM or CD166) is another immunoglobulin member expressed by osteoblasts. *CD166*-deficient mice show increased osteoblast differentiation and bone formation with no change in bone resorption, suggesting that CD166 regulates bone formation (Hooker et al., 2015). Osteoblasts also express intercellular adhesion molecule (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), and the cross talk of these molecules induces interleukin-6 (IL-6) secretion by osteoblasts, suggesting that these adhesion molecules transduce activation signals that induce the production of bone-resorbing cytokines (Tanaka et al., 1995). In addition, ICAM-1 and VCAM-1 mediate cell–cell adhesion between osteoclastic precursors and bone marrow stromal cells or osteoblasts, which controls osteoclastogenesis. Neutralization of VCAM-1 in bone marrow stromal cells inhibits the formation of osteoclasts in vitro, indicating that VCAM-1 expression by stromal cells is required for osteoclastogenesis

(Feuerbach and Feyen, 1997). A fraction of osteoblasts that highly express ICAM-1 strongly adhere to osteoclast precursors, resulting in multinuclear osteoclast-like cell formation, indicating that a subpopulation of ICAM-1-expressing osteoblasts controls osteoclastogenesis (Tanaka et al., 2000). Consistent with a role of ICAM-1 in osteoclastogenesis, ICAM-1-mediated cell-to-cell adhesion of osteoblasts and osteoclast precursors was involved in RANKL-dependent osteoclast maturation stimulated by 1,25-dihydroxyvitamin D, PTH, and IL-1α (Okada et al., 2002).

Osteoactivin

Osteoactivin is a glycoprotein expressed by osteoblasts and its expression upregulates osteoblast differentiation in vitro (Abdelmagid et al., 2008). Mice with a loss-of-function mutation in *Gpnmb*, which encodes osteoactivin, showed decreased trabecular bone mass due to reduced osteoblast differentiation, confirming the positive role of osteoactivin in bone formation (Abdelmagid et al., 2014). Osteoactivin is also expressed in osteoclasts and acts as a negative regulator of osteoclast differentiation and survival, but not function (Abdelmagid et al., 2015). Consistent with these findings, transgenic mice overexpressing *osteoactivin* under the cytomegalovirus promoter showed increased trabecular bone mass and bone formation, and decreased bone resorption (Frara et al., 2016). Mechanistically, osteoactivin can bind to CD44 in osteoclasts, leading to inhibition of ERK phosphorylation and RANKL-induced osteolysis (Sondag et al., 2016). In murine osteoblastic cells, recombinant osteoactivin stimulates cell adhesion and spreading through its binding to αVβ1 integrin and HSPGs at the cell surface. This interaction results in FAK and ERK activation and osteoblast differentiation, suggesting a mechanism by which osteoactivin may control osteoblast differentiation (Moussa et al., 2014).

Chondroadherin

Chondroadherin belongs to the family of leucine-rich repeat proteins and was identified in the cartilage matrix, where it promotes attachment of chondrocytes (Larsson et al., 1991). Chondroadherin localizes near the cell surface and is highly expressed in the proliferative and hypertrophic zones of the growth plate. It is a small molecule of 38 kDa molecular weight, containing 359 amino acids. Relevant domains of chondroadherin are a putative signal peptide, a cysteine-rich region at the N-terminal tail, 11 leucine-rich repeats, and a double cysteine loop in the C-terminal tail. Among the members of the leucine-rich repeat protein family, chondroadherin exhibits the unique feature of no posttranslational glycosylation (Neam et al., 1994). The very C terminus of the protein includes a heparin-binding consensus sequence that allows its interaction with heparin (Haglund et al., 2013). This heparin-binding domain recognizes cell surface syndecans and triggers ERK1/2 phosphorylation (Haglund et al., 2013). Chondroadherin is also recognized by the α2β1 integrin expressed by chondrocytes (Camper et al., 1997). The α2β1 integrin binding site was identified in the region carrying the amino acid residues 306−318 at the C terminus of the protein. By affinity purification procedure, α2β1 integrin was confirmed to bind the chondroadherin CQLRGLRRWLEAK^{318} peptide. A longer chondroadherin peptide, spanning amino acid residues 306−326 (CQLRGLRRWEKLAASRPDATC^{326}) was made cyclic and stable through a disulfide bond occurring between the two terminal cysteines and was largely used to investigate the functional role of chondroadherin in vitro and in vivo. The peptide was confirmed to induce cell adhesion and spreading in an α2β1 integrin-dependent manner, activating ERK1/2 phosphorylation (Haglund et al., 2011).

Chondroadherin is expressed also by osteoblasts. It was found to be 50% less expressed in bone biopsies of relatively young female osteoporotic patients (ages between 50 and 65 years), and in ovariectomized mice, a model of estrogen deficiency-induced osteoporosis (Capulli et al., 2014). The cyclic CQLRGLRRWEKLAASRPDATC^{326} peptide was inactive on osteoblasts, but strongly impaired osteoclastogenesis at the late stage of the process. Specifically, the major effect was exerted by the cyclic peptide on migration of osteoclast precursors, which is mandatory for cell clustering and fusion into mature polykarya. The underlying molecular mechanism involved the decreased expression of migfilin and vasodilator-stimulated phosphoprotein (VASP) (Capulli et al., 2014). Migfilin is associated with adhesion sites and binds filamins, VASP, kindling-2 and the transcription factor CSX/NKX2-5, recruiting acting cytoskeleton and promoting cell adhesion, shape modulation, motility and gene expression (Tu et al., 2003). *Migfilin* inactivation in mice induced a severe osteopenic phenotype (Xiao et al., 2012). However, this effect was mostly due to reduced osteoblast differentiation with a parallel increase in the proosteoclastogenic cytokine RANKL, which exacerbated osteoclast differentiation. VASP is known to induce monomeric actin recruitment to the barbed end of microfilaments, preventing capping and regulating filament bundling (Krause et al., 2003). It is implicated in cell motility, adhesion, and sensory capacity, localizing in the tips of filopodia and in adhesion structures (Tokuo and Ikebe, 2004). In osteoclasts, VASP is associated with the αVβ3 integrin and is activated by NO, which promotes osteoclast motility. Consistently, knockdown of *Vasp* reduced osteoclast migration on substrate (Yaroslavskiy et al., 2005). Interestingly, cyclic chondroadherin downregulated NO synthase (*Nos2*)

in osteoclasts, and treatment with an α2β1 integrin blocking antibody increased osteoclast *Nos2* expression, suggesting an inhibitory role of the α2β1 integrin on *Nos2* triggered by chondroadherin (Capulli et al., 2014). Overall, the results obtained using the cyclic α2β1 integrin-binding domain of chondroadherin suggest that this ECM component affects osteoclastogenesis via transcriptional downregulation of *Nos2* and decreased NO, which regulates migfilin and *Vasp* expression and is required for preosteoclast migration, clustering, and fusion into multinucleated osteoclasts.

Cyclic chondroadherin peptide showed also the ability to impair osteoclastogenesis in vivo. Mice injected with cyclic chondroadherin showed enhanced bone mass and reduced osteoclast variables, while osteoblasts and bone formation were not affected (Capulli et al., 2014). This effect was evident both in normal mice and in mice subjected to ovariectomy. In this circumstance, cyclic chondroadherin blocked the increase in serum level of bone resorption biomarkers and prevented bone loss induced by estrogen deficiency, with an improvement of bone quality. These effects were observed in young and old mice and were mimicked by treatment with the NOS2 activity inhibitor (L-N^6-(1-iminoethyl)lysine dihydrochloride). Furthermore, cyclic chondroadherin was effective not only in preventative treatment started at the time of ovariectomy, but also in a curative setting, with the treatment started 5 weeks after ovariectomy, a time at which the osteoporotic phenotype was overt (Capulli et al., 2014). Given the positive response of the bone to treatment with cyclic chondroadherin, the peptide was also tested against bone metastasis-induced osteolysis, which is caused by exacerbated osteoclast activity (Rucci et al., 2015). The results of this study complemented the observations on ovariectomized mice, showing a beneficial effect of the peptide in mice injected intracardiacally or orthotopically with osteotropic breast cancer cells. The peptide reduced the in vitro motility of tumor cells and in vivo tumor growth. It also inhibited the process of tumor-induced osteoclast formation, with consequent reduction of bone resorption, development of osteolytic lesions, and cachexia. Interestingly, cyclic chondroadherin synergistically enhanced the antitumoral effect of the chemotherapeutic doxorubicin, which achieved maximal efficacy at half of the effective dose when administered alone (Rucci et al., 2015). The cyclic chondroadherin−doxorubicin treatment affected tumor cells also in vitro, confirming a synergistic impairment of cell motility at lower doses. Taken together, these results demonstrated that chondroadherin is an important regulator of cell migration, exerting this effect by binding to the α2β1 integrin and impairing the late stage of osteoclast formation and the development of metastatic osteolysis.

Conclusion

Multiple in vitro and in vivo studies have shown that integrins, cadherins, and several other adhesion molecules control bone cell function and fate during chondrogenesis, osteoblastogenesis, and osteoclastogenesis. Genetic studies in mice confirmed the importance of some of these adhesion molecules in the control of bone resorption and formation in vivo. These effects are mediated by complex interactions of these adhesion molecules with bone matrix proteins or cell surface molecules, leading to the modulation of intracellular signaling pathways controlling bone cell differentiation, function, and survival. Studies have revealed that the signaling pathways mediated by integrins, cadherins, and other cell adhesion molecules can cross talk with Wnt/β-catenin signaling to regulate osteogenic differentiation and mechanotransduction, and with other signaling mechanisms to control osteoclastogenesis. These advances led to a more comprehensive view of the role of these adhesion molecules in the signaling mechanisms controlling bone cell recruitment and function. Future studies will have to confirm that targeting specific adhesion molecules and their downstream signals may have potential therapeutic implications in reducing bone resorption or promoting bone formation in skeletal disorders.

Chapter outline

Introduction

The organization of cells in tissues and organs is controlled by molecular programs that afford cells the ability to recognize other cells and the extracellular matrix and to communicate with their neighbors. Adhesive interactions are essential not only in embryonic development, but also in the differentiation and maintenance of tissue architecture and cell polarity, the immune response and the inflammatory process, cell division and death, and tumor progression and metastases. Cell–cell and cell–matrix adhesion is mediated by four major groups of molecules: cadherins, immunoglobulin-like molecules, integrins, and selectins. Cadherins are an integral part of *adherens junctions*, which anchor cells to one another by linking their cytoskeletons. Thus, along with tight junctions and desmosomes, adherens junctions constitute the so-called anchoring junctions (Halbleib and Nelson, 2006). A different type of intercellular junction is the *gap junction*, which does not provide cell anchorage but allows direct communication via specialized intercellular channels formed by connexins (Goodenough et al., 1996).

In the adult skeleton, bone remodeling occurs via repeated sequences of bone resorptive and formative cycles, which require continuous recruitment and differentiation of bone marrow precursors. The cooperative nature of bone remodeling requires efficient means of intercellular recognition, adhesion, and communication that allow cells to sort and migrate, synchronize their activity, equalize hormonal responses, and diffuse locally generated signals. This chapter reviews current knowledge about the role of direct cell–cell interactions in the development and remodeling of the skeletal tissue, focusing on cell–cell adhesion via cadherins and cell–cell communication via gap junctions.

Adherens junctions and the cadherin superfamily of cell adhesion molecules

Cadherins are transmembrane glycoproteins that mediate calcium-dependent cell–cell adhesion through homophilic interactions (Harris and Tepass, 2010; Pokutta et al., 1994). In mammals, there are over 80 members of this large

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00018-X

superfamily, which also includes protocadherins, desmocollins, and desmogleins (Harris and Tepass, 2010; Cavallaro and Dejana, 2011). Classic cadherins are composed of five repeats of a calcium-binding extracellular domain (EC), a single transmembrane domain, and a cytoplasmic C-terminal region containing two catenin-binding domains (Ishiyama et al., 2010; Obata et al., 1998) (Fig. 18.1). Classical cadherins are further categorized as type I cadherins, including E-, M-, and N-cadherin and cadherin-4 (the human ortholog of mouse R-cadherin), and type II cadherins, comprising cadherin-5 through -12 and VE-cadherin. Typical of type I, but not type II, cadherins is a HAV (His-Ala-Val) motif in the EC1 domain (Blaschuk et al., 1990; Patel et al., 2006), which is important for their adhesive function. At the interface between the five EC domains, four Ca^{2+}-binding pockets allow classical cadherins to assume a rodlike conformation in the presence of Ca^{2+}, thus forming *cis*-dimers (through EC1−2) with adjacent cadherins and *trans*-dimers with cadherins on opposing cells (Pertz et al., 1999). *Trans*-dimerization is necessary for cell−cell adhesion, and it occurs by "strand exchange" or "β-strand swapping" between the EC1 of opposing cadherins (Vendome et al., 2011; Harrison et al., 2005). This interaction requires calcium and docking of a highly conserved Trp residue into the complementary hydrophobic pocket of the opposing cadherin (Vendome et al., 2011; Harrison et al., 2005): for type I cadherins Trp2 mediates the swap, while in type II cadherins both Trp2 and Trp4 are swapped (Patel et al., 2006; Brasch et al., 2012). Accordingly, type I and type II cadherins do not usually engage in heterotypic binding (Patel et al., 2006), while heterotypic dimerization can occur between members of the same cadherin type, for example, between N- and E-cadherin (Katsamba et al., 2009). While *trans*-dimerization is responsible for the relatively weak binding between individual cadherins on opposing cells (Harris and Tepass, 2010), *cis*-interactions account for the assembly of multiple cadherin molecules at sites of cell−cell contact (Brasch et al., 2012), thus creating cadherin clusters that are further stabilized by linkage to the cytoskeleton (Harris and Tepass, 2010; Troyanovsky, 1999).

Cadherins are linked to the cytoskeleton via binding to catenins, specifically, α-, β-, and γ-catenin (the last also known as plakoglobin) and $p120^{ctn}$, which links cadherins to actin filaments at their intracellular cytoplasmic tail. In the classic view, the cadherin intracellular domain binds to β-catenin and plakoglobin, which in turn bind to α-catenin, either directly or through other proteins, including actinin, vinculin, or zonula occludens-1 (ZO-1) (Yamada and Geiger, 1997). Importantly, α-catenin binding either to the cadherin/β-catenin complex or to actin filaments each excludes the other (Drees et al., 2005), implying that the connection between the adhesion structure and the cytoskeleton is dynamic rather than static (Yamada et al., 2005). Studies also suggest that a minimal cadherin−catenin complex, in which both α- and β-catenin can participate, can directly bind filamentous actin upon mechanical strain (Buckley et al., 2014), and that tissue-specific

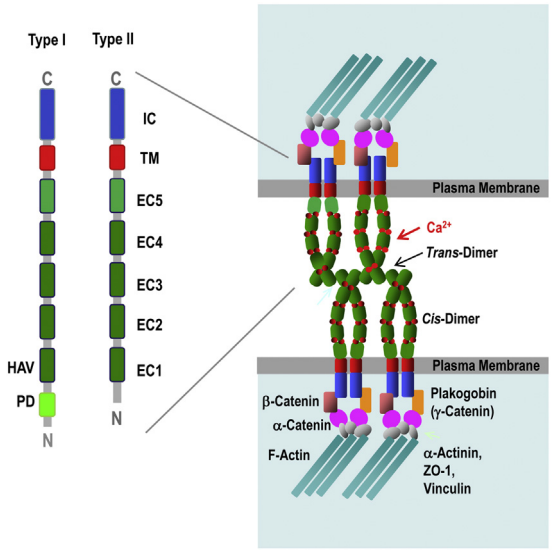

FIGURE 18.1 Cadherins and the adherens junction. (Right) Cadherins are shown with their cytoplasmic (IC), transmembrane (*TM*), and five extracellular domains (*EC1−5*). Small circles between the EC domains symbolize calcium ions. Two complete cadherin *cis*-dimers are shown side by side. These engage in binding with similar complexes from an apposing cell, thus forming *trans*-dimers. The alignment of EC1 domains forms the so-called "zipper" structure of the adhesion complex. Through their CT domain, cadherins bind to β-catenin and plakoglobin, which in turn tether the complex to the actin cytoskeleton via α-catenin and other interacting proteins, including α-actinin, zonula occludens-1 (*ZO-1*), and vinculin. Binding to $p120^{ctn}$ also contributes to stabilizing the cadherin-based adhesion structure. (Left) Enlarged schematic structure of a type I (left) and a type II (right) cadherin. Type I cadherins, such as N-cadherin, have a consensus HAV domain in EC1 important for cell−cell adhesion, and a cadherin-like prodomain (*PD*) at the extreme N terminus. Type II cadherins, such as cadherin-11, engage in cell−cell adhesion via different domains.

catenin isoforms such as αT-catenin may constitutively bind actin (Wickline et al., 2016). Other proteins, such as Lima-1 (Abe and Takeichi, 2008) and ZO-1, can mediate binding of cadherin−catenin complexes to the cytoskeleton (Itoh et al., 1997). The adhesion properties of cadherins are also dependent on the binding of $p120^{ctn}$ to other proteins, such as Rho-family GTPases (Grosheva et al., 2001), which affect membrane dynamics, signaling, and stability of the cadherin complex (Wildenberg et al., 2006). The assembly of cadherins and their associated cytoskeletal elements forms the junctional structures known as adherens junctions (Gumbiner, 2005) (Fig. 18.1).

In addition to their role in cell adhesion, catenins are also components of a signaling system, a function that may evolutionarily predate the appearance of cadherins, as catenin complexes determine cell polarity in *Dictyostelium discoideum* (Dickinson et al., 2011). As detailed later, β-catenin, plakoglobin, and $p120^{ctn}$ modulate the activity of nuclear transcription factors primarily involved in canonical Wnt signaling, a key regulator of osteolineage cell differentiation, function, and bone formation (Krishnan et al., 2006).

Cadherins in commitment and differentiation of chondro-osteogenic cells

Skeletal cells and their precursors express class I and class II cadherins, though their expression levels and functions vary according to developmental stage, lineage, and phase of cell differentiation (Marie et al., 2014; Mbalaviele et al., 2006). During mesenchyme condensation, N-cadherin (gene: *Cdh2*) and cadherin-11 (gene: *Cdh11*) are both expressed in the developing limb buds; and N-cadherin expression increases during chondrogenic differentiation, promoting cell−cell contacts and mesenchymal condensation. N-cadherin then decreases to allow chondrogenic differentiation to proceed (DeLise and Tuan, 2002). These changes in N-cadherin expression during early chondrogenesis are probably modulated by Sox9 (Panda et al., 2001) and bone morphogenetic protein-2 (BMP-2) signaling (Haas and Tuan, 1999). In vitro, inhibition of N-cadherin adhesive functions disrupts mesenchymal condensation in micromass culture and chick limb development, and a dominant-negative N-cadherin mutant is sufficient to impair BMP-2-dependent chondrogenesis (Haas and Tuan, 1999). *Cdh2*-null limb bud cultures, however, do not show major anomalies in chondrogenesis and maintain membrane-bound catenin complexes, suggesting that other cadherins—such as cadherin-11—could be compensating for N-cadherin adhesive function (Luo et al., 2005). Regulation of Wnt signaling by N-cadherin is important in chondrogenesis and in osteogenesis, as detailed later (Modarresi et al., 2005). Indeed, N-cadherin-functionalized hydrogels promote chondrogenesis from human mesenchymal precursors by favoring micromass formation and reducing Wnt signaling via decreased nuclear β-catenin translocation, transcriptional regulation of Wnt receptors, and activating kinases (Li et al., 2017).

Early osteogenic precursors express a broader range of cadherins, including P-cadherin, K-cadherin, E-cadherin, N-cadherin, and cadherin-11 (Cheng et al., 1998; Turel and Rao, 1998; Kawaguchi et al., 2001a; Shin et al., 2005; Hay et al., 2000). Upon osteogenic differentiation, R-cadherin is rapidly downregulated (Cheng et al., 1998), while cadherin-11 is upregulated and maintained through full differentiation (Cheng et al., 1998; Kawaguchi et al., 2001a; Shin et al., 2000). In fact, *Cdh11* was initially cloned in mouse osteoblasts and osteogenic cell lines (Okazaki et al., 1994) and provisionally named OB-cadherin, but it is present in multiple adult and embryonic tissues of mesenchymal origin (Alimperti and Andreadis, 2015). Supporting cadherin-11 proosteogenic action, teratomas originating from cells overexpressing *Cdh11* form preferentially bone and cartilage tissue (Kawaguchi et al., 2001a). As they differentiate into adipocytes, undifferentiated precursors downregulate both *Cdh2* and *Cdh11*, which are absent in adipocytes (Kawaguchi et al., 2001a; Shin et al., 2005), suggesting that coexpression of *Cdh2* and *Cdh11* may be permissive of commitment to osteogenic differentiation while hindering adipogenesis. After the initial increase, N-cadherin is downregulated upon in vitro osteoblast differentiation (Greenbaum et al., 2012), and it is undetectable in osteocytic cells (Kawaguchi et al., 2001a). Accordingly, in histologic sections N-cadherin is present on cells in the bone surface in both humans and rodents (Cheng et al., 1998; Hay et al., 2000; Shin et al., 2000; Castro et al., 2004), but it is absent in osteocytes (Greenbaum et al., 2012). Indeed, for the osteogenic program to proceed to terminal differentiation *Cdh2* must be downregulated (Greenbaum et al., 2012). These observations highlight partially overlapping but distinct functions of *Cdh2* and *Cdh11* at different stages of osteogenesis. Similarly, dental bud stem cells express N-cadherin and cadherin-11, whose expression is modulated during odontogenic differentiation, and they also maintain a low but stable expression of E-cadherin and P-cadherin (Di Benedetto et al., 2015). Cadherin expression in the osteogenic lineage is regulated by local and hormonal factors. BMP-2 and parathyroid hormone (PTH) upregulate both *Cdh2* (Cheng et al., 1998; Hay et al., 2000; Ferrari et al., 2000) and *Cdh11* (Cheng et al., 1998; Yao et al., 2014). *Cdh2* expression is also stimulated by fibroblast growth factor 2 (FGF2) receptor activation via protein kinase Cα (PKCα) in osteoblasts (Delannoy et al., 2001; Debiais et al., 2001), as it occurs in Apert syndrome, where FGFR2 is constitutively activated (Lemonnier et al., 2001). Conversely, stimuli that inhibit osteogenesis, such as dexamethasone, inhibit both *Cdh2* and *Cdh11* (Lecanda et al., 2000a), while proinflammatory cytokines downregulate *Cdh2* only (Tsutsumimoto et al., 1999; Tsuboi et al., 1999).

The function of N-cadherin in osteoblasts also extends to mediating interactions with tumor cells. Indeed, N-cadherin is the hallmark of epithelial-to-mesenchymal transition, which favors tumor growth and metastasis (Tran et al., 1999). Accordingly, N-cadherin has been proposed as a key factor for the establishment of the "preosteolytic" micrometastasis; and inhibition of N-cadherin in tumor cells reduces metastasis in xenograft models (Wang et al., 2015). Preliminary data from our group suggest that the action of N-cadherin in bone cells is actually inhibitory for cancer growth, and it occurs via paracrine and systemic effects (Fontana et al., 2017a). It seems likely that this "niche" function of N-cadherin might also be used for therapeutic targeting.

Cadherins in skeletal development, growth, and maintenance

Mouse models have helped establish the relevance of cadherins in bone formation and homeostasis. Germ-line deletion of *Cdh2* is lethal by day 10 of gestation, with mutant embryos displaying small and irregularly shaped somites and cardiac dysfunction (Radice et al., 1997). Heterozygous $Cdh2^{-/+}$ mice have normal skeletal morphology, but upon ovariectomy they undergo accentuated bone loss with reduced bone formation (Lai et al., 2006). Despite strong in vitro evidence of a proosteogenic action, *Cdh11*-null mice are morphologically normal, except for some widening of calvarial sutures and metaphyseal osteopenia (Kawaguchi et al., 2001b), suggesting some degree of redundancy among cadherins in osteogenesis. Indeed, heterozygous loss of *Cdh2* in a *Cdh11*-null background results in severely reduced trabecular bone, smaller and shorter diaphyses, severe osteopenia, and increased bone fragility (Di Benedetto et al., 2010). Tissue-specific overexpression and deletion models have provided more detailed evidence of the role of *Cdh2* in bone. Conditional ablation of *Cdh2* in osteogenic precursors and committed osteoblasts, using *Osx-Cre*, *Prx-Cre*, and *Col1a1-Cre* consistently results in smaller bones and reduced trabecular bone mineral density (Greenbaum et al., 2012; Di Benedetto et al., 2010; Fontana et al., 2017b), suggesting that N-cadherin has an overall positive role in the osteolineage. However, *Cdh2* overexpression in differentiation osteoblasts using *Bglap-Cre* also leads to low bone mass and delayed bone mass acquisition (Hay et al., 2009a). Work has contributed to resolving this apparent paradox by demonstrating a dual role of N-cadherin in the osteolineage: while N-cadherin supports osteogenic precursor number early in osteogenic differentiation, it also restrains progression through the osteogenic program, a function that can be linked to Wnt signaling inhibition, as discussed later. Further supporting this model, delaying *Cdh2* ablation in osteogenic cells until the postnatal stage using the *tet*-suppressible *Osx-Cre* model prevents the low-bone-mass phenotype, actually leading to expanded metaphyseal trabecularization (Fontana et al., 2017b). Indeed, transgenic mice overexpressing *Cdh2* in osteoblasts exhibit increased osteoprogenitor numbers and bone formation with aging (Hay et al., 2014), despite low bone mass in juvenile animals (Hay et al., 2009a). This observation shows that interference with N-cadherin in the adult skeleton could be targeted to enhance bone formation without potential effects on growth.

In vitro studies corroborate the model of a dual action of N-cadherin in osteogenic differentiation. Interference with N-cadherin-mediated cell−cell adhesion using a HAV inhibitory peptide (specific for type I cadherins, thus not interfering with cadherin-11 adhesion), neutralizing antibodies, antisense oligonucleotides, or transfection of a *Cdh2* mutant with dominant-negative action reduces osteoblast differentiation in vitro, probably via reduced cell−cell adhesion. Cadherin adhesive function might be important for keeping osteoprogenitors in a niche environment and preventing commitment to a lineage (Hay et al., 2000; Ferrari et al., 2000; Cheng et al., 2000). On the other hand, bone marrow stromal cells and calvaria cells isolated from *Cdh2*-haploinsufficient mice or from conditionally osteoblast/osteocyte *Cdh2*-deleted mice differentiate faster in vitro (Greenbaum et al., 2012; Fang et al., 2006); however, the number of osteoprogenitors is decreased in *Cdh2*-haploinsufficient or osteoblast *Cdh2*-deficient mice (Di Benedetto et al., 2010; Fang et al., 2006), consistent with a dual function of N-cadherin in supporting osteoprogenitor number but restraining full osteogenic differentiation (Fig. 18.2). More recent data have confirmed that the number of bone marrow $Sca1^{+}PDGF\alpha^{+}CD45^{-}Ter113^{-}$ cells, representing mesenchymal stem and progenitor cells, is very low in conditionally *Cdh2*-ablated mice. However, delaying *Osx-Cre*-driven *Cdh2* recombination until after weaning, when only committed osteoblasts are targeted (Mizoguchi et al., 2014), prevents such a decrease and associated stunted growth (Fontana et al., 2017b).

N-cadherin modulation of Wnt/β-catenin signaling in osteoblastogenesis and osteoanabolic responses

In addition to their function in the adherens junction, cadherins interfere with intracellular signaling pathways in several cell types (Knudsen and Soler, 2000; Wheelock and Johnson, 2003). Indeed, cadherins may retain signaling functions even after modifications that abrogate their adhesive properties by cleavage, shedding, or mutations (Cavallaro and Dejana, 2011). It is rather intuitive that cadherins may affect the Wnt pathway simply because cadherins bind to β-catenin, a key

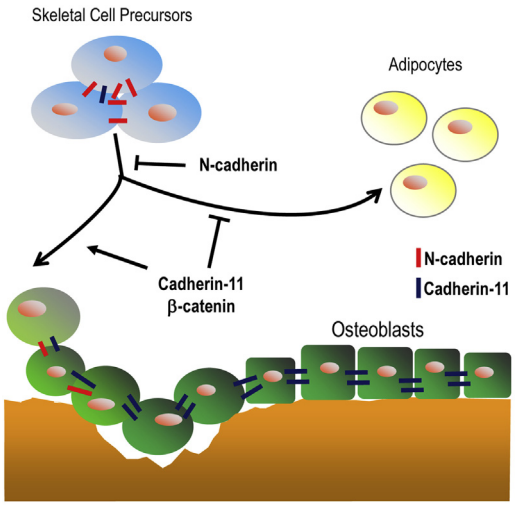

FIGURE 18.2 Cadherins in the osteogenic lineage. In their undifferentiated stage, skeletal cell precursors express a relatively wide repertoire of cadherins, including N-cadherin, cadherin-11, and R-cadherin, with the first being the most abundant. Precursor cells are held together, presumably in a niche, to which N-cadherin is an important contributor. Differentiation of precursors requires downregulation of N-cadherin, which acts as an inhibitor of lineage commitment. By contrast, upregulation of cadherin-11 favors osteogenesis, while adipogenesis is associated with downregulation of cadherin-11. Loss of N-cadherin in the chondro-osteogenic lineage leads to loss of uncommitted precursors. The switch in cadherin expression may allow more β-catenin to become available for transcriptional regulation, thus contributing to osteogenesis and anti-adipogenesis.

component of the canonical Wnt signaling pathway (Daugherty and Gottardi, 2007; Heuberger and Birchmeier, 2010). The Wnt/β-catenin pathway is activated by binding of Wnt ligands to low-density lipoprotein receptor–related protein (LRP) 5/6 and Frizzled coreceptors, followed by recruitment of a complex of Axin/Frat1/adenomatous polyposis coli/glycogen synthase kinase-3β (GSK-3β). This is turn leads to inhibition of GSK-3β, decreased β-catenin phosphorylation at specific sites near its N terminus that prevents β-catenin proteasomal degradation, cytoplasmic accumulation of β-catenin, and subsequent translocation to the nucleus where it binds T cell factor/lymphoid enhancer factor transcription factors to activate gene transcription (Logan and Nusse, 2004). Association of β-catenin with cadherins contributes to stabilizing the adhesion structure (Lilien and Balsamo, 2005), and cell–cell adhesion via cadherins promotes β-catenin phosphorylation and inactivation (Maher et al., 2009). Conversely, release of β-catenin from cadherins destabilizes the adhesion complex, thus facilitating cell movement (Nelson and Nusse, 2004). Thus, an inverse relationship exists between cell adhesion and Wnt/β-catenin signaling. More recent data demonstrate that the interplay between cadherins and signaling is more complex than predicted by a simple interaction with β-catenin at the adherens junction. Certainly, increased cadherin abundance on the cell surface results in decreased β-catenin nuclear translocation and transcriptional activity (Nelson and Nusse, 2004; Gottardi and Gumbiner, 2001; Rhee et al., 2007). As already noted, overexpression of a dominant-negative *Cdh2* mutant in differentiated osteoblasts sequesters β-catenin at the cell surface and decreases bone formation (Castro et al., 2004), as does *Cdh2* overexpression in differentiated osteoblasts (Hay et al., 2012). By contrast, deletion of either *Cdh2* or *Cdh11* or both reduces β-catenin abundance at cell–cell contacts and cell–cell adhesion with a negative effect on osteoblastogenesis and bone growth (Di Benedetto et al., 2010). N-cadherin/β-catenin association can also be modulated by mechanical stimuli, as oscillatory fluid flow releases β-catenin from adherens junctions, resulting in nuclear translocation and transcriptional activation, in turn contributing to osteogenic differentiation (Arnsdorf et al., 2009).

Skeletal biology studies have disclosed an alternative mechanism of N-cadherin interaction with Wnt signaling components via interaction with Lrp5 or Lrp6 (Hay et al., 2009a). Specifically, N-cadherin forms a complex with Lrp5/6 via Axin, thus preventing Lrp5/6 activation of β-catenin, which is instead targeted for proteasomal degradation. This results in decreased Wnt signaling and reduced osteogenic differentiation, function, and bone formation (Marie et al., 2014; Hay et al., 2009a). N-cadherin–Lrp5/6 interaction controls osteoblast differentiation and survival also by reducing endogenous Wnt3a expression and by inhibiting Wnt-dependent phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt) signaling (Hay et al., 2009b). Indeed, N-cadherin-mediated adhesion has been linked to activation of PI3K signaling in osteogenic cells (Guntur et al., 2012). Considering the negative action of N-cadherin on Wnt/β-catenin signaling, interference with N-cadherin/Axin/Lrp5/6 binding could potentially lead to osteogenesis by facilitating canonical Wnt signaling. Indeed, deletion of the N-cadherin domain interacting with Axin and Lrp5/6 promotes Wnt/β-catenin signaling and osteoblast differentiation without affecting cell–cell adhesion (Hay et al., 2012). And peptides that bind to the

N-cadherin/Axin-interacting domain of Lrp5 disrupt N-cadherin−Lrp5/6 interaction, enhance Wnt/β-catenin signaling, stimulate osteoblast function in vitro, and promote calvaria bone formation in vivo (Hay et al., 2012).

N-cadherin restraining action on Wnt signaling and its potential for therapeutic targeting to stimulate bone anabolism has been further refined. Our group has reported that the bone anabolic action of PTH is enhanced in mice lacking *Cdh2* in Osterix (Osx)-targeted cells, an effect linked to "noncanonical" β-catenin activation by PTH via the protein kinase A (PKA) pathway and increased Lrp6 association with the PTH/PTH-related protein receptor (Revollo et al., 2015). Enhanced PTH anabolism was reproduced by another group using *DMP1-Cre* to ablate *Cdh2* (Yang et al., 2016a), but was not noted in a study in which *Col1a1-Cre* was used (Bromberg et al., 2012). The reasons for such discrepancies remain unclear, but in vitro work supports a restraining effect of N-cadherin on PTH-induced activation of Wnt signaling (Revollo et al., 2015). More recently, an enhanced osteoanabolic effect of an antibody against Dkk1 was observed in *Col1a1-Cre*-driven *Cdh2*-ablated mice (Fontana et al., 2017b). In the same study, the presence of a Dkk1- and sclerostin-insensitive *Lrp5* mutant in conditional *Cdh2*-ablated mice prevented development of osteopenia but not delayed growth, further supporting the notion that regulation of bone mass accrual, but not longitudinal bone growth, by N-cadherin in young mice is dependent on Wnt signaling (Fontana et al., 2017b). If these data can be corroborated and translated to humans, they would further expand the N-cadherin biologic role in bone-forming cells and further prove that cadherins represent legitimate targets for pharmacological intervention (Fig. 18.3).

Connexins and gap-junctional intercellular communication

The need to maintain tissue integrity during skeletal remodeling demands the temporal and spatial control of bone formation and resorption. Direct intercellular communication through gap junctions allows osteoblasts, osteoprogenitors, and osteocytes to share and amplify signals that permit coordinated function. Gap junctions are intercellular channels that link the cytoplasm of adjacent cells and permit the exchange of second messengers, small molecules, ions, and metabolites that are less than about 1 kDa in molecular mass. In addition, gap junctions can also allow sharing of microRNAs among communicating cells (Valiunas et al., 2005; Plotkin et al., 2017; Zong et al., 2016; Liu et al., 2015). The monomeric subunits of a gap junction are connexins, an evolutionarily conserved family of proteins. There are 21 human connexin genes of which at least four are expressed in bone cells. Osteoblast lineage cells express connexin43 (gene: *Gja1*), connexin45 (*Gjc1*), connexin37 (*Gja4*), and connexin40 (*Gja5*). Of these, connexin43 is the most abundant. On the other hand, osteoclast lineage cells express both connexin43 and connexin37. Mutations or deletions of any these connexins in human or mouse skeletal tissue result in diseases with skeletal manifestations (see later). Pannexins (*Panx1*, *Panx2*, and *Panx3*) are a family of structurally closely related proteins that form a direct channel between the cytoplasm and the extracellular fluid, rather than between two cells. Despite their structural similarities and common sensitivity to pharmacological inhibitors, the mechanisms of action, regulation, and biological role of pannexins in bone are distinct from those of connexins (Plotkin; Stains, 2015; Plotkin et al., 2016; Ishikawa et al., 2016; Ishikawa and Yamada, 2017), thus they will not be reviewed here.

Connexin monomers have a common structure, with four transmembrane-spanning domains, two extracellular loops, an intracellular loop, and both the N and the C termini on the cytoplasmic side of the plasma membrane (Fig. 18.4). Hexamers of connexins form connexons, also called "hemichannels," which dock with connexons on adjacent cells to form an aqueous gap junction channel linking the cytoplasmic compartment of coupled cells. Under some circumstances, undocked hemichannels can also function as a plasma membrane channel that permits exchange of small molecules, such as ATP, between the cytoplasm and the extracellular fluid, acting similar to pannexins. Notably, gap junction channels aggregate into large plaques composed of up to thousands of gap junctions at cell−cell junctions. Thus, the capacity for direct intercellular exchange of small molecules can be quite large.

The size and charge permeability of gap junctions are determined by the connexin composition of a gap junction channel. For example, connexin43 permits the passage of molecules up to 1.2 kDa with a preference for negatively charged molecules (Kanaporis et al., 2011; Harris, 2009). By contrast, connexin45 permits the passage of molecules smaller than 0.3 kDa with a preference for positively charged molecules (Kanaporis et al., 2011). Connexin40 forms gap junctions of size selectivity similar to that of connexin45, while connexin37 is even more restrictive in its size exclusion limit (Kanaporis et al., 2011; Weber et al., 2004). Connexons can be composed of multiple connexin monomeric units (heteromeric gap junctions), and connexins of one type can dock with connexins of a different type, forming a heterotypic gap junction (Fig. 18.4). This variety of heterotypic and heteromeric channels can confer unique biophysical properties to the resulting channel. As most cells express multiple connexins, pairing of different heteromeric channels can tune the resultant gap junction through a wide range of molecular permeabilities. Thus, the composition of a gap junction channel directly regulates its permeability. Similarly, connexins can bind a diverse interactome of

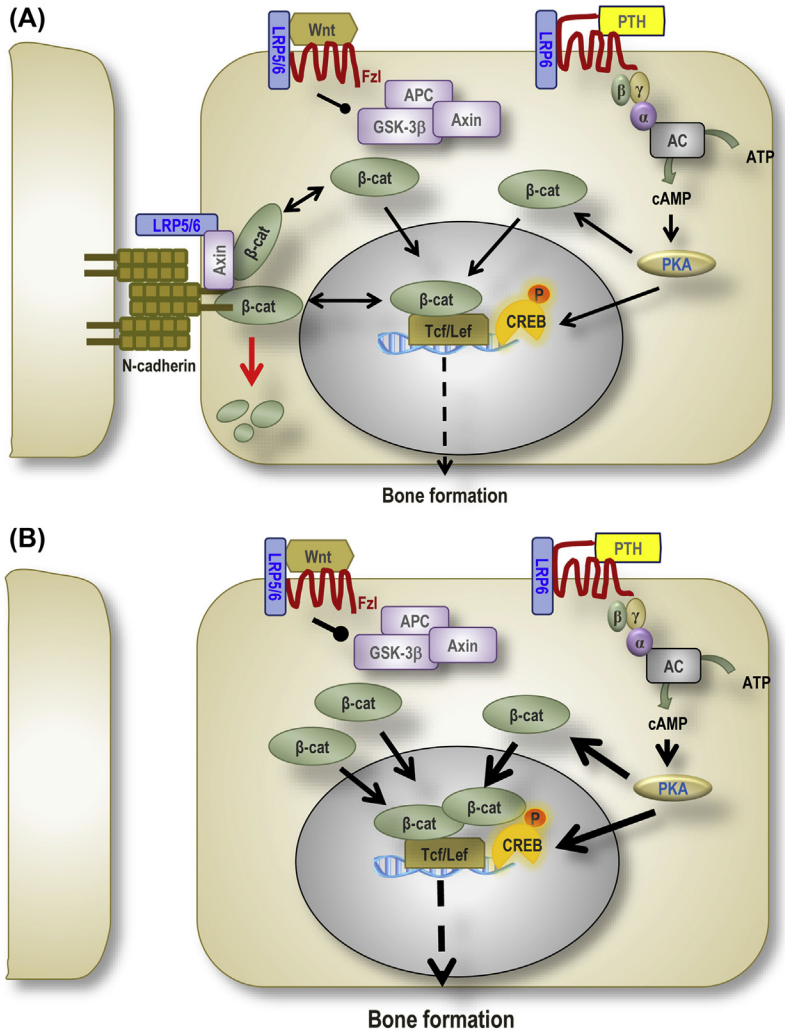

FIGURE 18.3 Cadherins and the Wnt signaling system. (A) Upon Wnt agonist activation of the LRP5/6−Fzl coreceptor complex, GSK-3β is inhibited by binding in an APC/Axin/GSK-3β complex, thus allowing β-catenin nuclear translocation and transcriptional activation. Stabilization of β-catenin can also occur by direct, "noncanonical" phosphorylation at non-GSK-3β sites by PKA, as occurs with PTH binding to PTHR1. PTHR1 can also bind LRP6, presumably also activating the canonical Wnt pathway. Binding to the adherens junction complex keeps β-catenin away from transcriptionally active pools, thus reducing signaling. Another β-catenin pool is kept on the cell surface by binding to N-cadherin via an Axin bridge, which facilitates proteasomal degradation. (B) Absence of N-cadherin releases the system from an inhibitory control mechanism, resulting in increased abundance of active β-catenin and enhanced transcriptional activity. Lack of N-cadherin also releases Lrp5/6 from inactive pools, making more of these coreceptors available for binding to Fzl or PTHR1, and in turn leading to increased β-catenin signaling. In osteogenic cells, this results in proliferation and increased bone-forming activity, in addition to inhibition of osteoclastogenesis. *AC*, adenylyl cyclase; *APC*, adenomatous polyposis coli; *β-cat*, β-catenin; *CREB*, cyclic-AMP response element binding protein; *Fzl*, frizzled; *GSK-3β*, glycogen synthase kinase-3β; *LRP5/6*, low-density lipoprotein receptor−related protein 5/6; *PKA*, protein kinase A; *PTH*, parathyroid hormone; *PTHR1*, PTH/parathyroid hormone related peptide receptor-1; *Tcf/Lef*, T-cell factor/lymphoid enhancer factor.

structural and signaling proteins, which can be connexin specific and can influence downstream signaling (Herve et al., 2012; Moorer and Stains, 2017; Leithe et al., 2018). Thus, the size, number, and composition of a gap junction channel or plaque can lend great plasticity to the ability of the cells to exchange small molecules, thus affecting their function.

Connexin diseases affecting the skeleton

Bone cells are extensively coupled by gap junctions (Yellowley et al., 2000; Doty, 1981; Civitelli et al., 1993; Wang et al., 2016). This permits rapid and efficient exchange of signals via direct intercellular communication among all cells of the bone network, thus providing a key biological mechanism for regulation of bone as a tissue (Fujita et al., 2014;

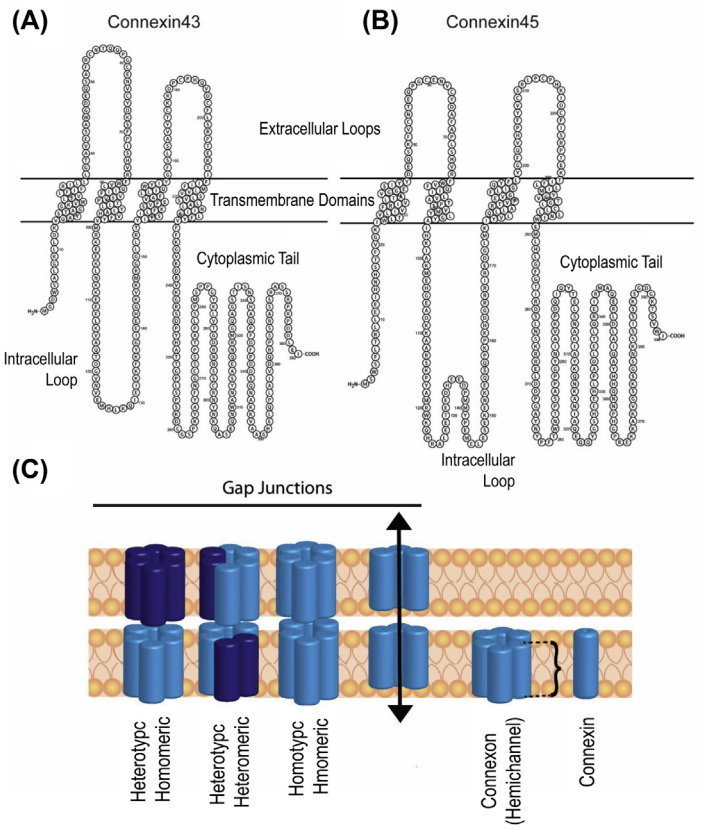

FIGURE 18.4 Connexins and gap junctions. Structure of (A) connexin43 and (B) connexin45, showing conserved topology including four transmembrane spanning domains, two extracellular loops, an intracellular loop, and both the N and C-termini on the cytoplasmic side of the plasma membrane. Images generated using Protter version 1.0 software. (C) Gap junction hemichannels can be formed by hexameric arrays of the same connexin (homomeric) or by mixed connexin hexamers (heteromeric). Likewise, hemichannels in the plasma membrane of one cell can pair with a hemichannel composed of the same (homotypic) or different connexin composition (heterotypic) in an adjacent cell. These combinations can alter the biophysical properties of the resultant gap junction channel.

Nishikawa et al., 2015; Vazquez et al., 2014; Suswillo et al., 2017). The consequences of disrupting this intercellular communication network can be profound. In humans, numerous distinct point mutations in *GJA1* (>62 reported) can lead to the pleiotropic, predominantly autosomal dominant disorder oculodentodigital dysplasia (ODDD) (Paznekas et al., 2009). Skeletal manifestations are prevalent in this disorder and include craniofacial abnormalities (pointed nose, microphthalmia), dental abnormalities (enamel hypoplasia), missing phalanges, syndactyly or camptodactyly, and broad, tubular long bones (Paznekas et al., 2009). These mutations in most cases are dominant negative for connexin43 function, resulting in abnormal gap junction channel function and impaired intercellular communication (Gong et al., 2007; McLachlan et al., 2008). Mice carrying a *Gja1* G60S missense mutation phenocopy many aspects of human ODDD, including cardiac dysfunction, craniofacial abnormalities, syndactyly, tooth enamel hypoplasia, and an alteration in the geometry of the long bones with a broader cross-sectional area at the mid-diaphysis. In addition, these mice display decreased trabecular bone volume fraction (Flenniken et al., 2005; Zappitelli et al., 2013), a feature not reported in ODDD patients, who instead have an osteosclerotic skull (Kjaer et al., 2004). Such discrepancy may reflect species differences or an effect of aging. The changes in skeletal geometry and bone mass are autonomous to the osteoblast lineage, as tissue-specific expression of a *Gja1* G138R mutant, causative of ODDD, in mice reproduces these skeletal features, except, again, the thickened skull (Dobrowolski et al., 2008; Watkins et al., 2011).

A missense mutation in the cytoplasmic tail of the human connexin43 gene (*GJA1* R239Q) has been found in patients with recessive craniometaphyseal dysplasia (CMD), a condition sharing several skeletal manifestations with ODDD, including cranial hyperostosis and widening of long bones with metaphyseal flaring (Hu et al., 2013), but lacking the syndactyly and ocular and dental abnormalities observed in ODDD. Intriguingly, the less rare dominant form of CMD is caused by mutation of a different gene, *Ank*, which encodes the progressive ankylosis protein (ANK), an inorganic pyrophosphate transporter, raising the intriguing possibility that cell−cell diffusion or secretion of pyrophosphate via

hemichannels may contribute to the mechanism of connexin43 regulation of bone cell function. In any case, because of their phenotypic and genetic similarities, ODDD and recessive CMD probably represent two manifestations of the spectrum of connexin43 disease, whose main features are a cortical modeling defect leading to metaphyseal and diaphyseal widening and craniofacial malformations. It is tempting to speculate that the more subtle phenotypic differences between ODDD and recessive CMD may be linked to selective interference by the different mutations with either gap junction channel or signaling, the two main functions of connexins.

A loss-of-function mutation (R75H) in the connexin45 gene (*GJC1*) has been linked to cardiac atrial conduction defects and severe arrhythmias, but also to skeletal manifestations, including clinodactyly and camptodactyly and dental and craniofacial abnormalities (Seki et al., 2017). Thus, despite the different biophysical properties of the gap junctions they form (Kanaporis et al., 2011), there is clear overlap in skeletal features between ODDD-causing *GJA1* mutations and the *GJC1* R75H mutation. These similarities could be related to the existence of heteromeric/heterotypic channels formed by connexin43 and connexin45 in bone cells. Hence, loss of one of the connexins would be sufficient to alter the biophysical properties of such heteromeric/heterotypic gap junctions. Ongoing studies should clarify the relative roles of the two connexins in the skeleton.

Connexins in the skeleton across the life span

As anticipated by human genetics, deletion of *Gja1* results in substantial skeletal abnormalities in mice. Germ-line *Gja1* ablation ($Gja1^{-/-}$) is postnatally lethal, but newborn mice have delayed intramembranous and endochondral ossification; brittle, misshapen ribs; and skull abnormalities that include a hypomineralized cranial vault and open parietal foramen (Lecanda et al., 2000b). These defects are consequent to a cell-autonomous defect in osteoblast differentiation with significant delays in the expression of most osteoblast genes (Lecanda et al., 2000b). Likewise, conditional deletion of *Gja1* in the osteoblast lineage leads to changes in cortical bone geometry, including an expansion of the marrow cavity with a corresponding increase in periosteal and endocortical perimeters, resulting in decreased cortical bone cross-sectional thickness (Stains et al., 2014; Grimston et al., 2013). This skeletal phenotype is more severe the earlier in the osteoblast lineage that *Gja1* is deleted in vivo (Stains et al., 2014). Hence, *Gja1* deletion in chondro-osteoblast progenitors using *Dermo1/Twist2-Cre* results in the most severe cortical bone phenotype, with a 40% greater cross-sectional area at the femoral mid-diaphysis (Watkins et al., 2011). Early lineage deletion of *Gja1* is also accompanied by increased number of endocortical osteoclasts, which are responsible for the expanded marrow cavity, but also for cortical porosity and cortical thinning. Enhanced periosteal bone formation only partially compensates for cortical thinning. Similar alterations in cortical bone are present when *Osx-Cre* is used to delete *Gja1* (Hashida et al., 2014). In contrast, deletion of *Gja1* in late osteoblasts and osteocytes using *Bglap-Cre* or *Dmp1-Cre* results a milder skeletal phenotype with only a 20%–25% increase in middiaphyseal cross-sectional area and little or no change in cortical thickness or cortical porosity (Bivi et al., 2012a,b; Zhang et al., 2011). Compromised bone strength and material properties are also common features of *Gja1* ablation models, demonstrating that connexin43 expression throughout the lineage is crucial for maintaining bone quality (Flenniken et al., 2005; Watkins et al., 2011; Bivi et al., 2012b). Accordingly, loss-of-function *Gja1* mutations phenocopy quite well the skeletal abnormalities of connexin43 diseases, with the exception of the craniofacial changes. Aging is associated with loss of osteocyte network connectivity, as the numbers of viable osteocytes and osteocyte processes and connexin43 expression decrease (Davis et al., 2017; Tiede-Lewis et al., 2017). Not surprisingly, the changes in bone architecture during aging closely resemble those seen in *Gja1* deletion or mutation (Zappitelli et al., 2013; Watkins et al., 2011; Davis et al., 2017).

Far less is known about the role of other connexins in skeletal biology. Genetic association studies have evidenced polymorphisms in *Gja4* segregating with bone mineral density in both humans (Yamada et al., 2007) and mice (Xiong et al., 2009). In mice, germ-line *Gja4* deletion results in increased trabecular bone volume, though connexin37 seems to act directly on the osteoclast rather than the osteoblast lineage, as lack of connexin37 decreases osteoclast number in vivo and impairs osteoclast fusion in vitro (Pacheco-Costa et al., 2014). A subtle and paradoxical defect in cortical bone is also observed in these *Gja4*-knockout mice, which exhibit higher cortical bone strength despite decreased cortical bone thickness. This may result from increased mineralization in a low-turnover state, or from changes in the bone extracellular matrix (Pacheco-Costa et al., 2017). As noted earlier, in humans a loss-of-function mutation of *GJC1* results in skeletal phenotypic features resembling, in part, those of *GJA1*-linked mutations (Seki et al., 2017), suggesting either overlapping function or a dominant-negative action of connexin45 on connexin43, presumably in heteromeric or heterotypic channels. However, a preliminary finding on a mouse model of osteolineage-specific *Gjc1* ablation reveals a surprising high trabecular bone mass but no modeling defects, which would suggest distinct functions of the two connexins in bone and support the notion that the overlapping skeletal features of the connexin45 mutant may be related to a dominant-negative action on connexin43 (Watkins et al., 2014). While a full report has yet to be published, these results support a role of

connexin45 in bone homeostasis. Finally, connexin40 is expressed early in the developing skeleton, where it participates in endochondral bone development; germ-line deletion or haploinsufficiency of *Gja5* results in bony fusions in the forelimbs, elongated metacarpals and phalanges, and malformations of the sternum (Pizard et al., 2005). However, the role of connexin40 in postnatal bone is less clear.

Function of connexin43 in bone cells

Gap junctions propagate signals through the osteoblast and osteocyte network to disseminate, coordinate, and equilibrate their function throughout the skeletal tissue. Indeed, a primary function of gap junctions is to help groups of cells integrate signals from various stimuli to enhance the signal-to-noise ratio (Ellison et al., 2016). The biologic effects of gap junction–communicated signals across the osteogenic lineage are multiple, including coordinating osteogenic differentiation and function, modulating osteoclastogenesis, maintaining osteocyte viability, and processing, organizing, and orienting collagen in the bone extracellular matrix (Fig. 18.5). Indeed, even small changes in this cell network connectivity can have a profound impact on the tissue level response to regulatory cues. A computer simulation of the osteocyte and bone-lining cell network predicted that a 5% loss of gap junction–coupled osteocytes in the network may reduce maximum signaling to the bone surface by 25% (Jahani et al., 2012). Connexin43 is functionally involved in the entire osteogenic program; lack of connexin43 disrupts the expression of most osteoblast genes and reduces mineralization capacity (Lecanda et al., 1998, 2000; Li et al., 1999; Gramsch et al., 2001; Schiller et al., 2001). These actions of connexin43 have been established by multiple models of *Gja1* ablation, or by induction of an ODDD-causing mutation (G138R) in mesenchymal progenitor cells. Mice carrying such mutations have defective osteogenic differentiation (McLachlan et al., 2008; Mikami et al., 2015; Talbot et al., 2018; Wagner et al., 2017; Damaraju et al., 2015; Esseltine et al., 2017), associated with a reciprocal increase in cell proliferation and expansion of the osteoblast progenitor pool, resulting in the accumulation of immature osteoblasts (Watkins et al., 2011; Moorer et al., 2017; Buo et al., 2017). Expansion of immature osteoblasts and consequent production of an abnormal matrix may contribute to increased periosteal bone formation, but also to poor bone quality and material properties despite enhanced osteoblast activity (Watkins et al., 2011; Bivi et al., 2012a,b; Zhang et al., 2011; Moorer et al., 2017). Indeed, the organic matrix of conditional *Gja1*-ablated mice exhibits a highly disorganized fibrillar collagen network, associated with altered expression of collagen-modifying genes, such as lysyl oxidase (*Lox*) and SerpinH1 (*Hsp47*) (Watkins et al., 2011; Bivi et al., 2012b; Moorer et al., 2017; Pacheco-Costa et al., 2016). Among the broad range of osteogenic cell activities regulated by

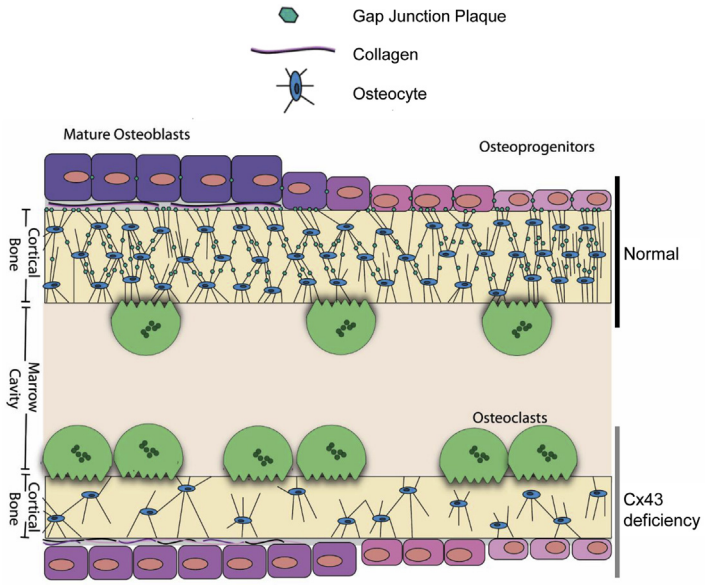

FIGURE 18.5 Connexin43 in bone. Gap junctions formed by connexin43 (*Cx43*) are abundantly present between osteoblasts and their progenitors on the bone surface, between osteoblasts and osteocytes, and at the intersection of osteocytic processes. The presence of connexin43 gap junctions within the osteoblast–osteocyte network is crucial for regulation of osteoblast differentiation, processing and organization of collagen in the bone extracellular matrix, control of osteoclastogenesis, and maintenance of osteocyte viability (top of cartoon). In the absence of connexin43 (bottom of cartoon), osteoblast differentiation is delayed with an expansion of earlier precursors, resulting in production of a disorganized and less mature collagen matrix. Osteocyte viability is reduced, leading to reduced osteocyte number. Endocortical osteoclast number is increased, resulting in expansion of the marrow cavity and thinning of cortical bone.

connexin43 is paracrine regulation of osteoclastogenesis, an action that is primarily responsible for connexin43 modulation of cortical modeling. In vivo and in vitro evidence demonstrates that connexin43 upregulates osteoprotegerin (OPG) (*Tnfrsf11b*) and downregulates receptor activator of NF-κB ligand (RANKL) (*Tnfsf11*) gene expression, resulting in higher RANKL relative to OPG and enhanced osteoclastogenesis (Zappitelli et al., 2013; Watkins et al., 2011; Zhang et al., 2011; Davis et al., 2017; Moorer et al., 2017; Lloyd et al., 2013). The reason why enhanced bone resorption in vivo occurs primarily on the endocortical surfaces, despite broad expression of connexin43 in the trabecular compartment (Watkins et al., 2011), remains to be determined. Increased osteocytic osteolysis (Lloyd et al., 2014a) and osteocyte apoptosis following *Gja1* ablation (Bivi et al., 2012a; Davis et al., 2017; Lloyd et al., 2013; Xu et al., 2015) may contribute to increased osteoclast recruitment and bone resorption, though these effects have not been universally observed. Furthermore, in adult mice, cortical thinning and low bone mass can be corrected by administration of bisphosphonates (Watkins et al., 2012), corroborating the notion that enhanced endocortical bone resorption is indeed the main mechanism causing the cortical abnormalities in conditional connexin43-deficient mice.

Cortical widening, thinning, and porosity present in *Gja1*-deficient bones recapitulate the changes in cortical bone architecture and geometry that develop in disuse osteoporosis and aging (Grimston et al., 2011; Peres-Ueno et al., 2017; Lloyd et al., 2014b). While this phenotype would suggest that connexin43 is involved in elaboration of bone anabolic signals in response to mechanical load, in vivo studies reveal a more complex mechanism. Skeletal mechanical loading by axial tibial compression or cantilever bending consistently shows that lack of connexin43 at different stages of the osteoblast lineage enhances periosteal bone apposition (Zhang et al., 2011; Bivi et al., 2013; Grimston et al., 2012) and accentuates the load-induced decrease of endocortical bone formation (Grimston et al., 2008, 2012). These results can be interpreted as suggesting that absence of connexin43 alters mechanosensing, so that bone-forming cells perceive normal mechanical loading as a disuse scenario, resulting in accentuated endocortical bone resorption, expansion of the marrow cavity, and cortical thinning. This view is further supported by attenuation of the bone-catabolic effects of experimentally induced skeletal unloading by either muscle paralysis or hindlimb suspension in conditional *Gja1*-ablated mice (Lloyd et al., 2012, 2013; Grimston et al., 2011), a finding consistent with the notion that these mice are insensitive to unloading, presumably because endocortical bone resorption is already hyperactivated as an adaptation to abnormal mechanosensing under normal loading conditions in connexin43 deficiency. Further support for this hypothesis is provided by the observation that the cortical modeling abnormalities develop postnatally, after the animal has been able to begin autonomous life (Grimston et al., 2013). Mechanistically, it has been proposed that the accentuated cortical expansion and thinning may be linked to dysregulated sclerostin expression and aberrant Wnt/β-catenin signaling, consistently observed in osteolineage-specific *Gja1*-knockout mice (Watkins et al., 2011; Bivi et al., 2012a; Lloyd et al., 2012, 2013). In support of a role of Wnt/β-catenin signaling in connexin43 action, inhibition of GSK-3β and consequent β-catenin activation improves fracture healing (Loiselle et al., 2013). However, in a genetic interaction study, double *Gja1/Sost* heterozygous mice did not show the cortical phenotype seen in *Gja1*-deficient mice, arguing against a strong interaction between *Sost* and *Gja1* in driving cortical modeling, at least under normal mechanical stimulation (Grimston et al., 2017). Other potential mechanisms may emerge from in vitro studies on mechanically activated osteocytes or osteoblasts, which suggest that multiple paracrine mediators might be involved in connexin43-mediated mechanotransduction (Vazquez et al., 2014; Suswillo et al., 2017; Romanello & D'Andrea, 2001; Genetos et al., 2007; Cherian et al., 2005).

Expression of connexin43 is also required for the bone anabolic action of PTH (Pacheco-Costa et al., 2016; Chung et al., 2006). Intriguingly, *Gja1* gene deletion driven by the 2.3-kb *Col1a1* promoter fully abrogates the anabolic action of PTH, while deletion of *Gja1* using the *Dmp1* promoter does not (Pacheco-Costa et al., 2016; Chung et al., 2006), suggesting that the osteoanabolic effect of PTH is dependent on connexin43 at earlier stages of osteogenesis, perhaps during commitment of undifferentiated precursors. This premise would be consistent with connexin43 key action at the Runx2/Osx transition, as discussed later. Similarly, the C-terminal domain of connexin43 is important for modulating the PTH response of bone cells, as such domain binds to and sequesters β-arrestin to promote PKA-dependent signaling (Bivi et al., 2011). Furthermore, the *Gja1* K258Stop mouse—a model of connexin43 C terminus truncation—failed to increase endocortical bone formation or bone strength in response to anabolic PTH administration (Pacheco-Costa et al., 2015).

Although much less studied, connexins are present and biologically relevant in the osteoclast lineage. Pharmacologic disruption of connexin43 in cell culture reduces fusion of osteoclast progenitors and bone resorption activity (Schilling et al., 2008; Glenske et al., 2014; Kylmaoja et al., 2013; Hobolt-Pedersen et al., 2014; Ransjo et al., 2003; Ilvesaro et al., 2001). However, as of this writing, connexin43 direct action in osteoclasts or their precursors has not been tested in vivo. On the other hand, connexin37 (*Gja4*) does have a function in osteoclasts, as germ-line *Gja4*-null mice have a high bone mass phenotype driven almost exclusively by a defect in osteoclastogenesis (Pacheco-Costa et al., 2014). Accordingly, all osteoclast lineage markers, including RANK, TRAP, cathepsin K, NFATc1, and DC-STAMP, are reduced in connexin37-deficient osteoclasts, as are osteoclast fusion and activity (Pacheco-Costa et al., 2014).

Mechanisms of connexin43 control of bone cell function

Connexin43 expression increases during osteoblast differentiation (Schiller et al., 2001; Donahue et al., 2000), and modulates the activity of the early osteoblast transcription factors Runx2 (Talbot et al., 2018; Lima et al., 2009; Niger et al., 2012; Li et al., 2015; Yang et al., 2016b) and Osx, indirectly (Niger et al., 2011; Stains et al., 2003), resulting in downregulation of downstream genes (Watkins et al., 2011). Functional interaction between connexin43 and Runx2 has been corroborated by in vivo studies, demonstrating that mice heterozygous for both *Gja1* and *Runx2* null mutations ($Gja^{-/+}$;$Runx2^{-/+}$) exhibit both an exacerbated cleidocranial dysplasia-like phenotype than Runx2-/+ mice and a skeletal phenotype that closely resembles that of osteoblast-lineage-specific *Gja1*-knockout mice, including increased middiaphyseal cross-sectional area with periosteal and endocortical expansion, increased endocortical osteoclast number, cortical thinning and porosity, defective osteoblastogenesis, and increased progenitor proliferation (Buo et al., 2017). Hence, connexin43-dependent signals that converge on Runx2 activation are a key mechanism by which gap junctions regulate skeletal homeostasis. Exemplifying such notion, connexin43-dependent parallel activation of the extracellular signal-regulated kinase 1/2 (ERK1/2) and PKCδ pathways converge on regulating Runx2 transcriptional activity and drive osteoblast lineage progression, an effect partly dependent on intercellular diffusion of inositol polyphosphates (Lima et al., 2009; Niger et al., 2012, 2013). Gap junctions also permit intercellular exchange of other second messengers, such as cAMP, Ca^{2+} ions, and ATP, as well as microRNAs (Davis et al., 2017; Romanello & D'Andrea, 2001; Genetos et al., 2007; Gupta et al., 2016; Ishihara et al., 2013; Guo et al., 2006; Jorgensen et al., 2003). These gap junction–communicated second messengers modulate numerous signaling pathways, including ERK1/2, Src, PI3K, 14-3-3θ, PKA, PKCδ, and β-catenin, in osteoblasts and osteocytes (Moorer et al., 2017; Loiselle et al., 2013; Bivi et al., 2011; Gupta et al., 2016; Batra et al., 2012, 2014; Plotkin et al., 2002; Tu et al., 2016). These pathways in turn affect diverse functions, from cell differentiation and survival to fracture healing and expression of paracrine regulators (Watkins et al., 2011; Lecanda et al., 2000b; Bivi et al., 2012a; Lecanda et al., 1998; Loiselle et al., 2013; Cherian et al., 2005; Chung et al., 2006; Stains et al., 2003; Gupta et al., 2016; Plotkin et al., 2002; Plotkin et al., 2008; Stains and Civitelli, 2005; Saunders & et al., 2003; Li et al., 2013; York et al., 2016). Notably, there is dynamic reciprocity, in that stimuli that signal through gap junctions also regulate the expression of gap junction proteins. For example, PTH, prostaglandin E_2 (PGE_2), mechanical load, vitamin D_3, and neuropeptides all increase connexin43 protein abundance (Donahue et al., 1995; Civitelli et al., 1998; Cheng et al., 2001; Cherian et al., 2003; Ziambaras et al., 1998; Schiller et al., 1992; Shen et al., 1986; Saunders et al., 2001; Schirrmacher and Bingmann, 1998; Ma et al., 2013). Conversely, glucocorticoids and 17β-estradiol, as well as aging, decrease connexin43 expression (Davis et al., 2017; Schirrmacher and Bingmann, 1998; Joiner et al., 2014; Roforth et al., 2015; Massas et al., 1998; Gao et al., 2016; Shen et al., 2016). In addition to small molecules, gap junctions formed by connexin43 can transmit microRNAs from cell to cell. In osteocytes, lack of connexin43 decreases the abundance of miR-21, a prosurvival signal that suppresses PTEN-Akt activity (Davis et al., 2017). The resultant increase in osteocyte apoptosis leads to enhanced osteoclastogenesis via increased RANKL/OPG ratio; extracellular release of the high-mobility-group box 1 protein, a pro-osteoclastogenic factor; and consequent bone loss (Davis et al., 2017; Zhou et al., 2008; Yang et al., 2008).

Connexin43 function is not limited to forming transcellular channels; its biologic action is in part mediated by direct interaction with components of cell signaling systems. More than 40 proteins can interact directly or indirectly with the C-terminal tail domain of the connexin43 monomer (Herve et al., 2012; Leithe et al., 2018; Laird, 2006). In bone, PKCδ, ERK1/2, β-catenin, β-arrestin, α5β1 integrin, and Src are part of the characterized connexin43 interactome, where they contribute to regulation of osteoblast signaling processes (Moorer et al., 2017; Bivi et al., 2011, 2013; Batra et al., 2012; Plotkin et al., 2002; Hebert and Stains, 2013; Niger et al., 2010). The assembly of signaling molecules at the gap junction plaque permits efficient modulation of the downstream signaling response to intracellularly communicated signals (Moorer et al., 2017; Batra et al., 2012; Hebert and Stains, 2013). In vivo experiments have confirmed the functional relevance of the C-terminal domain of connexin43 in bone. Genetic deletion of the last 124 amino acids at the connexin43 C-terminal domain (*Gja1* K258Stop) in male mice recapitulates key aspects of *Gja1* gene ablation in bone, including a reciprocal increase in osteoblast proliferation and decrease in osteoblast differentiation, exuberant periosteal osteoblast activity with poorly organized collagenous matrix, increased endocortical osteoclast number, decreased cortical thickness, increased cortical porosity, and widened marrow area (Moorer et al., 2017). Importantly, this C-terminal truncation is associated with a failure to recruit signaling molecules, such as PKCδ, ERK1/2, and β-catenin, to the mutant connexin43, consistent with the notion that the connexin43 C-terminal domain serves as a docking platform for efficient signal transduction (Moorer et al., 2017; Hebert and Stains, 2013). Interestingly, a distinct skeletal phenotype is observed in *Gja1* K258Stop female mice, which exhibit reduced trabecular bone mass (Moorer et al., 2017; Pacheco-Costa et al., 2015; Hammond et al., 2016), although subtle changes in cortical geometry, bone strength, mineral crystallinity, and collagen spacing are also present

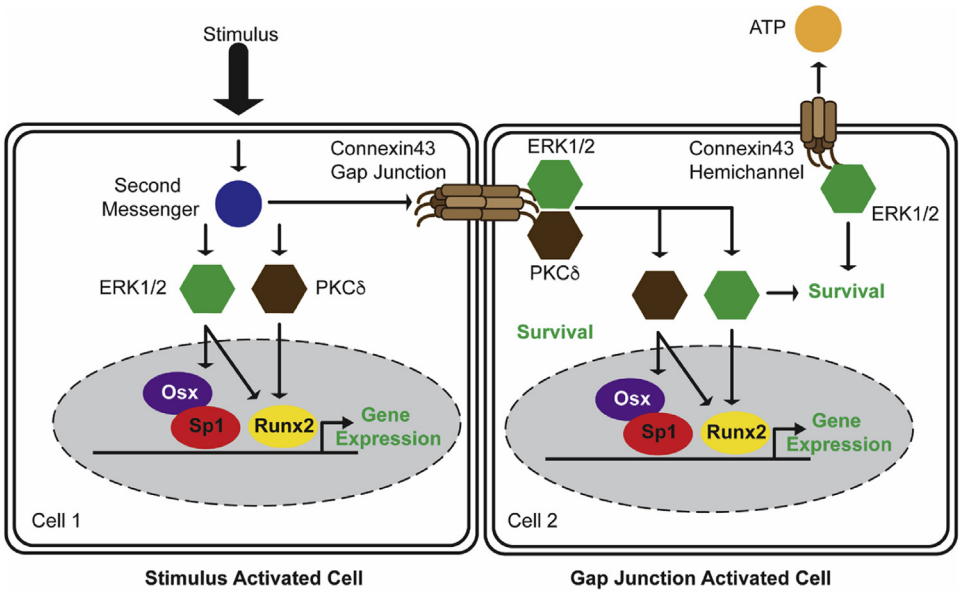

FIGURE 18.6 Intercellular communication and signaling among bone cells. Connexin43-containing gap junctions permit cells that may not be activated by a stimulus to respond as a result of second-messenger diffusion through gap junction channels. There, locally recruited signaling molecules, such as extracellular signal-regulated kinase 1/2 (*ERK1/2*) and protein kinase Cδ (*PKCδ*), are activated by the communicated second messenger resulting in activation of specific signaling cascades, which in turn regulate osteoblast gene expression by modulating the transcriptional activity of specific transcription factors, notably, Runx2, Osterix (*Osx*), and Sp-family members, and by promoting cell survival. Under certain conditions (mechanical strain), connexin43 hemichannels may open and activate signaling independent of gap-junctional communication.

(Moorer et al., 2017; Hammond et al., 2016). These data strongly support the notion that the signal modulation function of connexin43 is necessary for skeletal modeling and homeostasis, independent of or in addition to, gap junction channel function (Fig. 18.6). It should be noted that this biologic model may not apply to all systems and organs; for example, the cardiovascular malformations present in *Gja1*-null mice (*Gja1*$^{-/-}$) are not present in a C-terminus *Gja1*-truncated mutant, although lethal arrhythmias develop (Lubkemeier et al., 2013).

In cultured osteocytes, unpaired connexin43 hemichannels, which form a direct channel between the cytoplasm and the extracellular compartment of a cell, open in response to fluid shear stress and result in PGE_2 and ATP release into the extracellular fluid (Romanello & D'Andrea, 2001; Genetos et al., 2007; Cherian et al., 2005; Plotkin and Bellido, 2001; Riquelme et al., 2015). This process requires an interaction between connexin43 and α5β1 integrin, triggered by mechanical forces and activation of the Akt pathway (Batra et al., 2012). The subsequent actions of extracellular ATP and PGE_2 then regulate osteocyte responses to mechanical load (Blackwell et al., 2010; Kitase et al., 2010; Lenertz et al., 2015; Orriss et al., 2010; Agrawal and Gartland, 2015). However, there is some controversy as to whether the release of extracellular ATP from mechanically activated bone cells is indeed mediated by connexin43 hemichannels or instead by pannexins, a closely related family of proteins. In vitro, both gap junctions and pannexin channels can conduct ATP and are sensitive to the same pharmacologic inhibitors (Thi et al., 2012; Cheung et al., 2016). In any case, connexin43 hemichannels, but not gap junctions, seem to be required for an antiapoptotic effect of bisphosphonates and protection from oxidative stress in osteocytes (Plotkin et al., 2002, 2005, 2008; Kar et al., 2013). Transgenic mice overexpressing either a *Gja1* mutant that exhibits dominant-negative interference with endogenous gap-junctional communication but not hemichannel activity (R76W) or a *Gja1* mutant that exhibits dominant-negative interference with both functions (Δ130−136) have been developed to test the role of connexin43 hemichannels in vivo (Xu et al., 2015). While Δ130−136-expressing mice mimicked the skeletal phenotype observed in models of connexin43 deficiency, cortical modeling defects were less obvious in connexin43 R76W transgenic mice, suggesting that hemichannels, rather than gap-junctional communication, mediate connexin43 action on cortical modeling (Xu et al., 2015). However, these data are in sharp contrast with the evidence of a full skeletal phenotype, with cortical expansion, thinning, and increased endocortical bone resorption, in mice in which one *Gja1* allele was replaced by the G138R *Gja1* ODDD mutant (Watkins et al., 2011). Since this mutant abolishes gap junction function but allows extracellular ATP release (Dobrowolski et al., 2008), the results support the conclusion that gap-junctional communication is a key driver of the skeletal phenotype. Furthermore, ATP can be released by the opening of pannexin channels, but mice with a germ-line null mutation of *Pnx3*, which is highly

expressed in bone cells, show no cortical phenotype (Caskenette et al., 2016). Overall, data from these gene replacement or ablation models argue against a role of ATP release via either connexin43 hemichannels or pannexin channels in the genesis of the cortical modeling defect. Interference with multiple connexins or connexin-binding partners by over-expressed connexin43 mutants may complicate interpretation of the contrasting data emerging from the Δ130−136 transgenic mice.

Conclusions

The unraveling of many of the molecular mechanisms by which cadherins and connexins control skeletal biology has established the importance of direct cell−cell interactions for the achievement of adequate bone mass and maintenance of bone quality. While the necessity of an interconnected cellular communication network in bone is established, much remains to be discovered about the context-specific signals and the modulatory action of cadherins and connexins in elaborating hormonal, paracrine, and physical factors that drive bone modeling and homeostasis. Key questions about how cadherins in osteogenic cells maintain the skeletal stem cell niche, in normal homeostasis and in tumor metastases, and how N-cadherin and cadherin-11 can be leveraged as potential therapeutic targets remain to be addressed. Likewise, the mechanisms underlying mechanotransduction by connexin43, and its exquisite action on cortical modeling, via differential regulation of endocortical and periosteal bone modeling; the role of other connexins in skeletal homeostasis; and the sexual dysmorphism of some connexin actions remain exciting areas of investigation. Defining the signals communicated by gap junction networks adds a new dimension to our understanding of bone modeling and remodeling at the tissue level, opening new avenues for therapeutic intervention to affect bone quality.

Chapter 19

Histomorphometric analysis of bone remodeling

Carolina A. Moreira[1] and David W. Dempster[2,3]

[1]Bone Unit of Endocrine Division of Federal University of Parana, Laboratory PRO, Section of Bone Histomorphometry, Pro Renal Foundation, Curitiba, Parana, Brazil; [2]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, United States; [3]Department of Pathology and Cell Biology, College of Physicians and Surgeons, Columbia University, New York, NY, United States

Chapter outline

Introduction

Bone histomorphometry is a gold standard technique for evaluation of bone remodeling. It has provided great information about the metabolic bone diseases, including the changes on bone structure and remodeling following treatment.

Tetracycline labeling and the surgical procedure

Prelabeling the patient with tetracycline prior to biopsy allows the histomorphometrist to quantify precisely the rate of bone formation at the time of the biopsy (Frost, 1983). About 3 weeks prior to the biopsy, the patient is given a 3-day course of tetracycline. This is followed by 12 drug-free days and then another 3-day course of tetracycline. This is termed a 3:12:3 sequence. The biopsy should not be performed until at least 5 days after the last tetracycline dose to prevent the last label from leaching out during the processing of the biopsy. This is often denoted as a 3:12:3:5 sequence. The tetracycline binds irreversibly to recently formed hydroxyapatite crystals at sites undergoing new deposition. When the histomorphometrist cuts and visualizes thin sections of the biopsy in a microscope equipped with ultraviolet illumination, the tetracycline fluoresces to label the sites of new bone formation (Fig. 19.1). The labels can be either double labels, if bone formation at that site is continuous throughout the labeling sequence, or single labels, if formation starts after the first or stops before the second label is administered. Demeclocycline, tetracycline, and oxytetracycline can all be used as fluorochrome labels. In

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00019-1

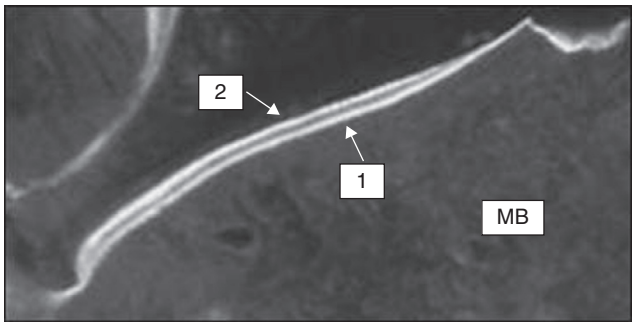

FIGURE 19.1 Double tetracycline label in an iliac crest bone biopsy. The patient was labeled with demeclocycline in a 3:12:3 sequence. *1*, label 1; *2*, label 2; *MB*, mineralized bone.

our laboratory, our preference is for demeclocycline, 600 mg/day (4 × 150-mg tablets), taken on an empty stomach. Dairy products and antacids containing aluminum, calcium, or magnesium should be avoided because they impair absorption. Tetracyclines can cause nausea, vomiting, and diarrhea in some patients, and all patients should be cautioned to avoid excessive exposure to sunlight and UV light because tetracyclines can cause skin phototoxicity. Tetracyclines should not be given to children less than 8 years of age or to pregnant women because, just as it is incorporated into bones, it is incorporated into growing teeth and discolors them.

Although the original site for bone biopsy was the rib, it is now performed exclusively at the anterior iliac crest, which is easily accessible, and the biopsy can be performed with minimal complications. This site also allows one to sample both cancellous and cortical bone in a single biopsy (Figs. 19.2 and 19.3). The structure and cellular activity at this site have been well characterized in a number of laboratories and have been shown to correlate with other clinically relevant skeletal sites, such as the spine and the hip (Bordier et al., 1964; Parfitt, 1983a; Rao, 1983; Dempster, 1988).

The biopsy generally is performed with a standard trephine with an internal diameter of at least 8 mm to obtain sufficient tissue and to minimize damage to the sample (Bordier et al., 1964; Rao, 1983). Immediately before the procedure, the patient should be sedated, usually with intravenous meperidine hydrochloride (Demerol) and diazepam (Valium). The skin, subcutaneous tissue, muscle, and, in particular, the periosteum covering both the lateral and the medial aspects of the

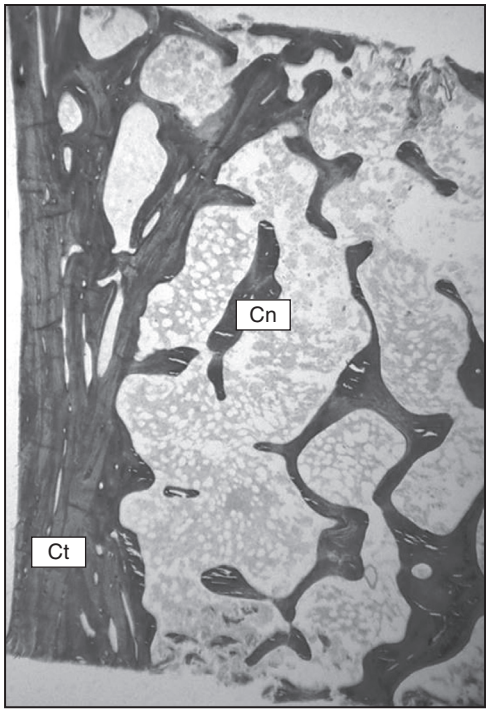

FIGURE 19.2 Low-power photomicrograph of an iliac crest bone biopsy section showing cancellous (*Cn*) and cortical (*Ct*) bone.

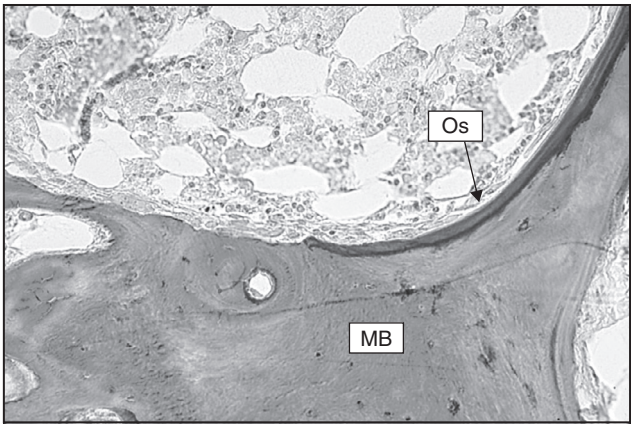

FIGURE 19.3 Photomicrograph of an iliac crest bone biopsy section showing an osteoid seam (*Os*) on the surface of mineralized bone (*MB*).

ilium, should be thoroughly anesthetized with local anesthetic. Access to the iliac crest is achieved through a 2- to 3-cm skin incision made at a point 2 cm posterior and 2 cm inferior to the anterior superior iliac spine. It is important to locate this site carefully because there is considerable variation in bone structure around this location. To avoid damage to the biopsy, which could render it uninterpretable, the trephine should be rotated back and forth with gentle but firm pressure so that it cuts rather than pushes through the ilium. The patient should refrain from excessive activity for 24 h after the procedure and a mild analgesic may be required. Significant complications from transiliac bone biopsy are rare. In an international multicenter study involving 9131 transiliac biopsies, complications were recorded in 64 patients (0.7%) (Rao, 1983). The most common complications were hematoma and pain at the biopsy site that persisted for more than 7 days; rarer complications included wound infection, fracture through the iliac crest, and osteomyelitis.

Sample preparation and analysis

The biopsy should be fixed in 70% ethanol because more aqueous fixatives may leach the tetracycline from the bone. After a fixation period of 4−7 days, the biopsy is dehydrated in ethanol, cleared in toluene, and embedded in methyl methacrylate without decalcification. The polymerized methyl methacrylate allows good-quality, thin (5−10 μm) sections to be cut on a heavy-duty microtome. The sections are then stained with a variety of dyes to allow good discrimination between mineralized and unmineralized bone matrix, which is termed "osteoid" (Figs. 19.4 and 19.5), and clear visualization of the cellular components of bone and marrow (see Fig. 19.7). Unstained sections are also mounted to allow observation of the tetracycline labels by fluorescence microscopy (see Fig. 19.1) (Baron et al., 1983a,b; Weinstein, 2002). The sections are subjected to morphometric analysis, according to standard stereological principles, using either simple "point-counting" techniques or computer-aided image analysis (Parfitt, 1983b; Malluche and Faugere, 1987; Compston, 1997).

Routine histomorphometric variables

A large number of histomorphometric variables can be measured or derived. Because the morphometric analysis is extremely time consuming, the number of variables evaluated depends on whether the biopsy specimen is being analyzed for diagnostic or research purposes. Listed next are eight indices of trabecular bone that are of particular clinical relevance. For a detailed account of more theoretical aspects of bone biopsy analysis, see Parfitt (1983a) and Frost (1983).

More recently, increased attention has been given to cortical bone, as it comprises 80% of the human skeleton and its failure contributes significantly to the nonvertebral fracture burden.

It is conventional to divide histomorphometric parameters into two categories. Static variables yield information on the amount of bone present and the proportion of bone surface engaged in the different phases of the remodeling cycle. Dynamic variables provide information on the rate of cell-mediated processes involved in remodeling. This category can be evaluated only in tetracycline-labeled biopsies. By measuring the extent of tetracycline-labeled surface and the distance between double tetracycline labels, the bone formation rate can be computed directly in a single biopsy. Conversely, the resorption rate can be calculated only indirectly, using certain indices of bone formation, in a single biopsy specimen or from two sequential biopsy specimens (Frost, 1983; Eriksen, 1986).

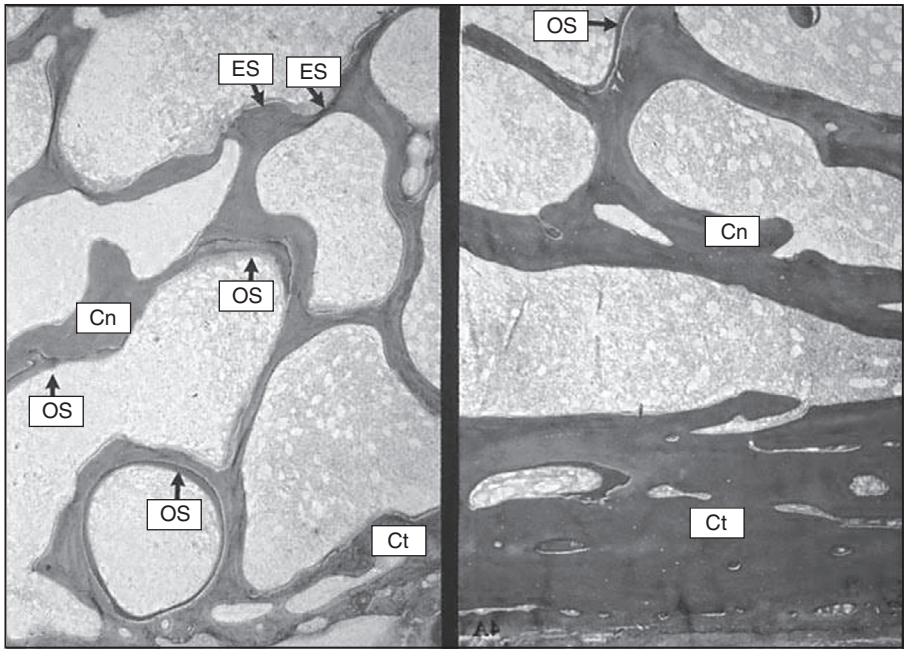

FIGURE 19.4 Photomicrographs of iliac bone biopsy sections from a subject with primary hyperparathyroidism (PHPT) (left), compared with a control subject (right). Note preservation of cancellous bone (*Cn*) and loss of cortical bone (*Ct*) in the subject with PHPT. Also note the marked extension of eroded surface (*ES*) and osteoid surface (*OS*) in PHPT.

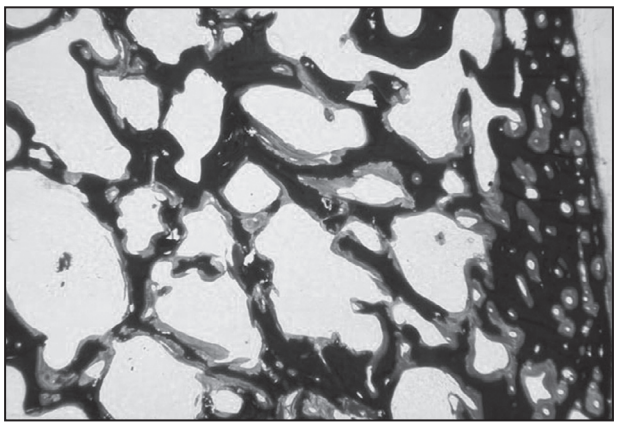

FIGURE 19.5 Photomicrograph of a bone biopsy section from a patient with severe osteomalacia. Note the dramatic extension of osteoid surface (stained *light gray*) and the increase in osteoid thickness.

Static parameters

A list of five commonly used static variables is given here. The terms and abbreviations for all histomorphometric variables have been standardized by the Histomorphometry Nomenclature Committee of the American Society for Bone and Mineral Research, whose recommendations have been widely adopted (Parfitt et al., 1987; Dempster et al., 2013).

Cancellous bone volume (Cn-BV/TV, %) is the fraction of a given volume of whole cancellous bone tissue (i.e., bone + bone marrow) that consists of mineralized and nonmineralized bone.
Osteoid volume (OV/BV, %) is the fraction of a given volume of bone tissue (mineralized bone + osteoid) that is osteoid (i.e., unmineralized matrix).
Osteoid surface (OS/BS, %) is the fraction of the entire trabecular surface that is covered by osteoid seams.

Osteoid thickness (O.Th, μm) is the average thickness of osteoid seams.
Eroded surface (ES/BS, %) is the fraction of the entire trabecular surface that is occupied by resorption bays (Howship lacunae), including both those with and those without osteoclasts.

The main cortical bone parameters are as follows.

Cortical area (Ct.Ar) is the total area of cortical bone, including inner and outer cortices.
Cortical width (Ct.Wi) is the average width of both inner and outer cortices. In growing individuals, however, in whom there are differences in bone cell activity at the internal and external cortices, they are recorded separately.
Cortical porosity number (Ct.Po.N) is the total number of pores of both inner and outer cortices.
Cortical porosity area (Ct.Po.Ar) is the total area of pores.

Dynamic parameters

Following is a list of commonly used dynamic parameters.

Mineral apposition rate (MAR, μm/day): this is calculated by dividing the average distance between the first and the second tetracycline label by the time interval (e.g., 15 days) separating them. It is a measure of linear rate of production of calcified bone matrix by the osteoblasts.
Mineralizing surface (MS/BS, %): this is the fraction of trabecular surface bearing double tetracycline label plus one-half of the singly labeled surface. It is a measure of the proportion of bone surface on which new mineralized bone was being deposited at the time of tetracycline labeling.
Bone formation rate (BFR/BS, $\mu m^3/\mu m^2$ per day): this is the volume of mineralized bone made per unit surface of trabecular bone per year. It is calculated by multiplying the mineralizing surface by the mineral apposition rate.
Many of these static and dynamic parameters described for the cancellous envelope can also be measured in the other three bone envelopes: endocortical, intracortical, and periosteal (Dempster et al., 2012, 2016b).

In the following section, we will briefly review the remodeling process in normal bone and the changes that occur in a number of common disease states, as assessed by bone histomorphometry (Table 19.1).

Normal bone

Bone undergoes a continuous process of renewal, with approximately 25% of trabecular bone and 3% of cortical bone being replaced annually. This remodeling process is referred to as a quantum phenomenon because it occurs in discrete units or "packets." Osteoclasts resorb the old bone and osteoblasts replace it. The group of cells that work cooperatively to create one new packet of bone is called a bone remodeling unit. In normal trabecular bone, approximately 900 bone remodeling units are initiated each day. In cortical bone, about 180 remodeling units are initiated per day (Frost, 1973; Parfitt, 1983a, 1988; Dempster, 2002).

Hyperparathyroidism

Increased circulating parathyroid hormone (PTH) levels increase the activation frequency of bone remodeling units, resulting in increased osteoclast and osteoblast numbers. As a result, histomorphometric analysis of a biopsy from a patient with either primary or secondary hyperparathyroidism reveals increases in eroded surface, osteoid surface, and mineralizing surface (see Fig. 19.4) (Melsen et al., 1983; Malluche and Faugere, 1987; Parisien et al., 1990; Silverberg et al., 1990). Mineralizing surface is increased, but mineral apposition rate is slightly reduced. However, the increased mineralizing surface overcompensates for the decrease in mineral apposition rate, so that the bone formation rate, the product of these two variables, is increased. Bone turnover is higher in hyperparathyroid patients with vitamin D insufficiency (Silverberg et al., 1990). Cancellous bone volume and trabecular connectivity are preserved in primary hyperparathyroidism (Parisien et al., 1992). The elevated bone turnover is often accompanied by increased deposition of immature (woven) bone and marrow fibrosis, in particular, in cases of severe secondary hyperparathyroidism. In cortical bone, there is an increase in cortical porosity and a decrease in cortical width (Fig. 19.4).

Because the biopsy reflects the long-term effects of excessive remodeling activity (e.g., increased eroded surface) it can be a sensitive indicator of parathyroid gland hyperactivity, especially when this is mild or intermittent. However, examination of the biopsy alone does not allow one to distinguish between primary and secondary hyperparathyroidism.

TABLE 19.1 Bone biopsy variables in a variety of disease states.[a]

Disease state	Cancellous bone volume	Osteoid volume	Osteoid surface	Osteoid thickness	Eroded surface	Mineral apposition rate	Mineralizing surface	Bone formation rate

Osteomalacia

The hallmark of osteomalacia, regardless of the underlying pathogenetic mechanism, is inhibition of bone mineralization. Although mineralization is inhibited, the osteoblasts continue to synthesize and secrete organic matrix, leading to an accumulation of osteoid (see Fig. 19.5). Although the cancellous bone volume is normal in osteomalacia, the amount of mineralized bone is actually reduced.

Careful analysis of the dynamic parameters is called for in suspected cases of osteomalacia. At some formation sites, mineral is still deposited, but at a reduced rate, resulting in low values for mineral apposition rate. At other sites, mineralization may be completely inhibited, resulting in reduced mineralizing surface. The decrease in both these variables markedly reduces bone formation rate. The accumulation of osteoid is reflected in increased osteoid thickness, osteoid surface, and osteoid volume. If PTH secretion is elevated, the activation frequency of bone remodeling units is enhanced and the biopsy may show an increase in eroded surface. However, as osteoid surface increases, eroded surface often declines, because osteoid is resistant to osteoclastic resorption. An elevated activation frequency, when accompanied by mineralization failure, will enhance the rate at which osteoid is deposited (Teitelbaum, 1980; Jaworski, 1983; Malluche and Faugere, 1987; Siris et al., 1987).

Renal osteodystrophy

Chronic renal failure is usually accompanied by phosphate retention and hyperphosphatemia, which leads to a reciprocal decrease in serum ionized calcium concentration and secondary hyperparathyroidism. Furthermore, as functional renal mass decreases, the plasma 1,25-dihydroxyvitamin D level falls, leading to impaired intestinal calcium absorption, which exacerbates hypocalcemia and ultimately may impair bone mineralization. As a result of these marked disturbances in metabolism, it is perhaps not surprising that the bone biopsy findings in renal osteodystrophy are heterogeneous (Malluche et al., 1976, 2011; Boyce et al., 1982; Hodsman et al., 1982; Charhon et al., 1985; Dunstan et al., 1985; Parisien et al., 1988; Salusky et al., 1988; Moriniere et al., 1989; Felsenfeld et al., 1991; Hercz et al., 1993; Sherrard et al., 1993; Coburn and Salusky, 2001; Slatopolsky and Delmez, 2002). Indeed, in allowing a better understanding of the skeletal status in patients with chronic renal failure, the bone biopsy continues to play an important role in the management of this disease (Ketteler et al., 2017). Thus, renal osteodystrophy has been subdivided into two broad types, primarily on the basis of histomorphometric features. One type is characterized by normal or high bone turnover and a second is characterized by low bone turnover.

The most frequently observed biopsy changes in patients with end-stage renal disease are the result of chronic excess PTH secretion on the skeleton. These are classified as normal/high turnover, and include osteitis fibrosa, mild hyperparathyroidism, and mixed bone disease (Fig. 19.6). These features are characterized histomorphometrically by increased eroded surface, osteoid surface, and mineralizing surface. In osteitis fibrosa, however, woven osteoid is often present and there are variable amounts of peritrabecular marrow fibrosis in contrast to the minimal or absent fibrosis observed in mild

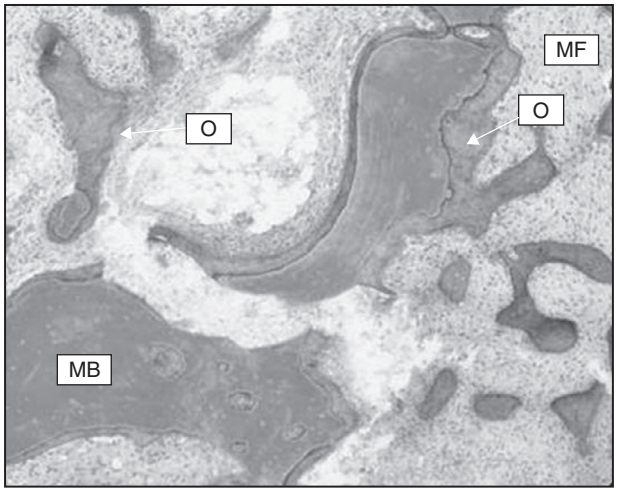

FIGURE 19.6 Photomicrograph of an iliac crest bone biopsy section from a patient with "mixed" renal osteodystrophy. Note deposition of woven osteoid (*O*) and marrow fibrosis (*MF*). *MB*, mineralized bone.

hyperparathyroidism. On the other end of the spectrum, low bone turnover is frequently observed in patients undergoing dialysis, albeit less often than high-turnover disease. The low-turnover states are classified as osteomalacia and aplastic or adynamic bone disease. Patients with osteomalacia have evidence of reduced values for dynamic variables accompanied by the accumulation of excess osteoid, whereas patients with aplastic or adynamic disease have a reduced tetracycline-based bone formation rate, but normal or reduced osteoid volume. In the 1970s and 1980s, most symptomatic patients with osteomalacia or adynamic bone disease showed evidence of aluminum accumulation, with more than 25% of surfaces displaying aluminum stain. They were considered to have aluminum-related bone disease (Boyce et al., 1982; Hodsman et al., 1982; Dunstan et al., 1985; Parisien et al., 1988). The aluminum was primarily derived from aluminum-containing phosphate binders used to control hyperphosphatemia and dialysis solutions that were contaminated with aluminum. Like tetracycline, aluminum accumulates at sites of new bone formation, where it may directly inhibit mineralization, which is manifested in an increase in osteoid thickness and osteoid surface. However, aluminum also is toxic to osteoblasts and may impair their ability both to synthesize and to mineralize bone matrix, resulting in a decrease in mineral apposition rate and the mineralizing surface. However, if matrix production is also reduced, osteoid thickness will not be elevated. With appreciation of the sources of aluminum contamination and increased use of calcium-containing phosphate binders, aluminum-related bone disease has become much less common in recent years.

Another form of low-turnover bone disease has been described that is not accompanied by significant aluminum accumulation. This is called idiopathic aplastic or adynamic bone disease. Its pathogenesis is unclear but may be related to various therapeutic maneuvers designed to prevent or reverse hyperparathyroidism in patients undergoing dialysis, including the use of dialysates with higher calcium concentrations (3.0−3.5 mEq/L), large doses of calcium-containing phosphate binders, and calcitriol therapy. As a rule, these patients have few symptoms of bone disease, and this "disease" ultimately may prove to be a histological rather than a clinically relevant form of bone disorder. However, it is unknown whether patients with adynamic bone disease are at increased risk of the development of skeletal problems in the future.

A 2011 large study by Malluche et al. (2011) provided histomorphometric data on 635 adult patients with chronic kidney disease stage 5 on dialysis. The authors employed the so-called TMV classification (turnover [T], mineralization [M], and volume [V]), which they had previously proposed (Malluche and Monier-Faugere, 2006). They reported that a mineralization defect was observed in only 3% of the subjects. This is probably due to the lower use of aluminum-containing phosphate binders nowadays, compared with the aforementioned earlier studies. The authors also noted distinct racial differences. For example, 62% of white subjects exhibited low turnover, whereas high turnover was observed in 68% of black subjects.

Osteoporosis

The classic feature of bone biopsies in osteoporosis is the reduction in cancellous bone volume. Approximately 80% of patients with vertebral crush fractures have values that are lower than normal. In postmenopausal osteoporosis the reduction in cancellous bone volume is primarily caused by the loss of entire trabeculae and, to a lesser degree, by the thinning of those that remain (Fig. 19.7) (Meunier et al., 1981; Parfitt et al., 1982; Whyte et al., 1982; Meunier, 1988; Dempster, 2000).

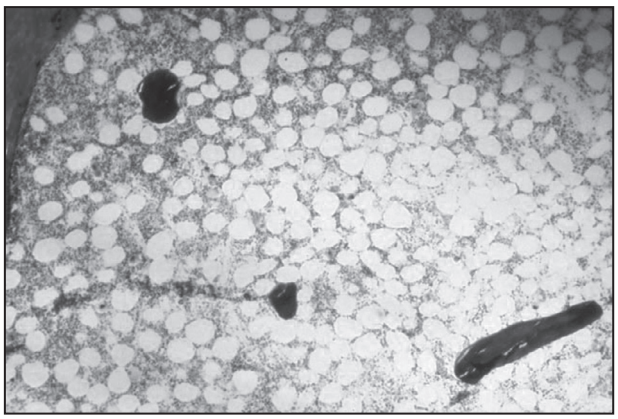

FIGURE 19.7 Photomicrograph of an iliac crest bone biopsy section from a patient with severe osteoporosis. Note marked reduction in cancellous bone volume in isolated trabecular profiles (*arrowheads*), which are cross sections of thin, rodlike structures in three dimensions.

With respect to the changes in the other static and dynamic variables in osteoporosis, there has been debate over whether patients can be stratified into high-, normal-, or low-turnover groups. Even if they can, the pathogenetic and clinical significance of this so-called histological heterogeneity in patients with osteoporosis is unclear. In a study of 50 postmenopausal women with untreated osteoporosis, two subsets of patients were identified: one with normal turnover and one with high turnover, with the high turnover representing 30% of the cases (Arlot et al., 1990). However, this conclusion was based on the finding of a bimodal distribution in the static parameter osteoid surface. The tetracycline-based bone formation rate, a dynamic measure of turnover rate, displayed a normal distribution. Based on the interval between the 10th percentile and the 90th percentile for calculated bone resorption rate in a group of normal postmenopausal women, another study classified 30% of women with untreated postmenopausal osteoporosis as having high turnover, whereas 64% and 6% had normal and low turnover, respectively (Eriksen et al., 1990). When bone formation rate was used as the discriminant variable, 19% were classified as having high turnover, 72% as having normal turnover, and 9% as having low turnover. On the other hand, in two studies of postmenopausal women with osteoporosis and their normal counterparts, the same wide variation in turnover indices was found in both groups, leading the investigators to conclude that there were no important subsets of patients with osteoporosis (Garcia Carasco et al., 1989; Kimmel et al., 1990). These studies, however, confirmed earlier observations that some patients with osteoporosis show profoundly depressed formation with little or no tetracycline uptake (Whyte et al., 1982).

From a clinical viewpoint, the desire to classify patients with osteoporosis according to their turnover status stems from the notion that the turnover rate may influence the response to particular therapeutic agents. For example, patients with high turnover rates may respond better to anticatabolic treatments. There was early evidence that this was the case for calcitonin (Civitelli et al., 1988). However, in clinical practice, the biopsy is an impractical way to determine turnover status. It was once believed that biochemical markers of bone resorption and formation would be useful in this regard, but this has yet to materialize.

Note that, in most cases, bone biopsy is performed when the disease is severe, with multiple fractures having already occurred. It is probable that, in many cases, the disturbances in bone metabolism that led to the reduction in bone mass and strength took place several years before the time of the biopsy and are no longer evident (Steiniche et al., 1994). Another confounding factor is that most patients who undergo biopsy for osteoporosis have already received treatment with one or more pharmaceutical agents.

Clinical indications for bone biopsy

In general, a bone biopsy is helpful only in metabolic bone diseases. Only rarely is a biopsy indicated in patients with localized skeletal disease such as Paget disease of bone, primary bone tumors, or bone metastases involving the iliac crest. The biopsy usually does not provide significantly greater insight into the disease process in postmenopausal women with osteoporosis. However, bone biopsy can be useful in patients who are less frequently affected by osteoporosis, such as young men and premenopausal women. Patients with osteopenia or women with postmenopausal osteoporosis should not have biopsies simply to measure cancellous bone volume to confirm the diagnosis of osteoporosis. The intraindividual and interindividual variability in cancellous bone volume is too great, and there is too much overlap between cancellous bone volume in patients with clinical osteoporosis and normal subjects to make this useful. However, bone biopsy is useful to exclude subclinical osteomalacia. In one study, 5% of patients with vertebral fractures displayed definitive evidence of osteomalacia on biopsy despite normal biochemical and radiological findings (Meunier, 1981). Moreover, the biopsy can be useful in identifying more precisely the probable cause of bone loss in individual patients with osteoporosis. For example, if the biopsy reveals or confirms a high bone turnover rate, it would be important to rule out endocrine disorders, such as hyperthyroidism and hyperparathyroidism. Finally, the biopsy is the best available way to evaluate the effect of various therapeutic maneuvers on bone cell function (e.g., Holland et al., 1994a,b; Marcus et al., 2000). This is discussed in detail in the context of therapies for osteoporosis in the following section.

As noted earlier, the bone biopsy can be extremely useful in patients with renal osteodystrophy (Ketteler et al., 2017), although the large number of patients with renal disease precludes its use in every case. In general, if a symptomatic patient has biochemical evidence of secondary hyperparathyroidism (hyperphosphatemia, hypocalcemia, and markedly elevated intact PTH levels), biopsy is not necessary because one can predict with reasonable certainty that it would reveal osteitis fibrosa. However, patients with renal disease who have bone pain and fractures without the biochemical profile of secondary hyperparathyroidism should undergo biopsy to determine whether they have osteomalacia or idiopathic, aplastic bone disease. Although aluminum accumulation is much less common nowadays, the biopsy will also permit the physician to determine whether it is a significant contributory factor. Although the biopsy can be useful in the clinical management of certain patients with bone disease, its principal use today is as a research tool.

Histomorphometric studies of the effects of osteoporosis drugs

In this section we will review what histomorphometry has revealed about the effects of drugs used to treat osteoporosis. The drugs will be covered under the headings of their two principal mechanisms of action: anticatabolic, also known as antiresorptive, and anabolic (Riggs and Parfitt, 2005).

Anticatabolic agents

Calcitonin

Intranasal calcitonin is approved to reduce the risk of vertebral fractures, but its efficacy in nonvertebral fractures has not been established (Silverman, 2003). There have been several histomorphometric studies of the effects of calcitonin in subjects with osteoporosis or with rheumatoid arthritis (Gruber et al., 1984, 2000; Marie and Caulin, 1986; Alexandre et al., 1988; Palmieri et al., 1989; Kroger et al., 1992; Pepene et al., 2004; Chesnut et al., 2005). In cancellous bone, calcitonin treatment reduced eroded surface (Kroger et al., 1982; Gruber et al., 1984) and active resorption surface (Alexandre et al., 1988) and mean resorption rate (Chesnut et al., 2005), with no observed decrease in osteoclasts (Marie and Caulin, 1986; Palmieri et al., 1989; Gruber et al., 2000). Most studies failed to reveal any differences in bone formation parameters, e.g., osteoblast number and perimeter, osteoid perimeter and thickness, mineralized perimeter, or mineral apposition rate (Gruber et al., 1984; Marie and Caulin, 1986; Alexandre et al., 1988; Chesnut et al., 2005). However, one report (Gruber et al., 2000) suggested that bone formation was not reduced to the same extent as resorption. Cancellous bone volume was shown to be unchanged (Alexandre et al., 1988; Gruber et al., 2000; Chesnut et al., 2005) or increased (Gruber et al., 1984; Alexandre et al., 1988; Palmieri et al., 1989; Marie and Caulin, 1986; Kroger et al., 1992).

Hormone therapy

Bone histomorphometry has been used by several investigators to assess the effects of hormone therapy (HT) on both cancellous and, in some studies, cortical bone of the ilium (Steiniche et al., 1989; Lufkin et al., 1992; Holland et al., 1994a,b; Eriksen et al., 1999; Vedi and Compston, 1996, Vedi et al., 2003). One of the most interesting studies was by Eriksen et al. (1999), who showed that 2 years of HT decreased resorption parameters, reducing bone formation at the basic multicellular unit level. Cancellous wall thickness was similar in treated and placebo groups, but there was a significant reduction in resorption rate in the HT group. This was in contrast to the placebo group, which showed a significant increase in erosion depth and a modest increase in resorption rate. The reduction in the size of the resorption cavity with HT was confirmed in a later study (Vedi and Compston, 1996), although that study also demonstrated a compensatory decrease in the wall width of trabecular bone packets. These findings were not replicated in a study (Steiniche et al., 1989) in which HT was given for only 1 year.

Estrogen treatment has been shown to stimulate bone formation in animal models (Chow et al., 1992a, 1992b; Edwards et al., 1992), but this remains controversial in humans (Steiniche et al., 1989; Lufkin et al., 1992; Holland et al., 1994a,b; Vedi and Compston, 1996; Wahab et al., 1997; Eriksen et al., 1999; Patel et al., 1999; Vedi et al., 1999, 2003). Standard doses of HT reduce osteoid and mineralizing surfaces and bone formation rate, with no change or a decrease in wall width (Steiniche et al., 1989; Lufkin et al., 1992; Holland et al., 1994a,b; Vedi and Compston, 1996; Eriksen et al., 1999; Patel et al., 1999; Vedi et al., 2003). On the other hand, long-term, high-dose HT was reported to increase cancellous wall width and to decrease eroded cavity area. Similarly, 6 years of subcutaneous HT increased cancellous bone volume with an increment in trabecular thickness and number as well as wall width (Khastgir et al., 2001a,b). Such anabolic actions of HT have also been reported in Turner syndrome treated with HT (Khastgir et al., 2003). The improvements in bone structure demonstrated by two-dimensional histomorphometric analysis are supported by micro-computed tomography findings of a higher ratio of plate- to rodlike structures (Jiang et al., 2005). In addition to these changes in histomorphometric variables, HT has also been shown to increase the degree of collagen cross-linking and bone mineralization, consistent with its primary action to lower bone turnover (Walters and Eyre, 1980; Holland et al., 1994a,b; Rey et al., 1995; Yamauchi, 1996; Khastgir et al., 2001a,b; Boivin and Meunier, 2002; Burr et al., 2003; Paschalis et al., 2003; Boivin et al., 2005).

Selective estrogen receptor modulators

Selective estrogen receptor modulators (SERMs) bind to the estrogen receptor and exhibit agonist actions in some tissues, such as bone, and antagonist actions in others, such as breast (Lindsay et al., 1997a,b). Bone histomorphometry studies are primarily limited to raloxifene. Two years of raloxifene treatment in the MORE trial (Ettinger et al., 1999) decreased the

bone formation rate, without changes in eroded surface or osteoclast number at the 60-mg dose, whereas the dose of 120 mg also decreased the bone formation rate and showed a trend toward a decrease in eroded surface and osteoclast number (Ott et al., 2000). Cancellous bone volume, trabecular thickness, and cortical width were unchanged compared with baseline and the placebo group (Ott et al., 2000). A significant decrease in activation frequency was observed with a higher dose (150 mg) of raloxifene (Weinstein et al., 2003). In that study, raloxifene was shown to have effects similar to those of HT. However, a 6-month treatment with 60 mg of raloxifene did not suppress activation frequency and bone formation rate to the same extent as HT (Prestwood et al., 2000). Reductions in activation frequency, bone formation rate, and resorption cavity area have also been demonstrated for another SERM, tamoxifen (Wright et al., 1994). In contrast to HT, raloxifene had little effect on mineralization density as assessed by quantitative microradiography of the biopsy sections (Boivin et al., 2003).

Bisphosphonates

The bisphosphonates have been the mainstay of osteoporosis therapy and will continue to be so for some time to come (Fleisch, 1998). The effects of alendronate, the first bisphosphonate to be approved in the United States, have been investigated in patients with postmenopausal osteoporosis (Bone et al., 1997; Chavassieux et al., 1997; Arlot et al., 2005), as well as in patients with glucocorticoid-induced osteoporosis (Chavassieux et al., 2000). Alendronate reduced osteoid surface and thickness, mineralizing surface, bone formation rate, and activation frequency. The mineral apposition rate was unchanged (Bone et al., 1997; Chavassieux et al., 1997; Arlot et al., 2005). Although the primary target of bisphosphonates is the osteoclast, alendronate, like other anticatabolic agents, had little, if any effect on histomorphometric variables of bone resorption, including eroded surface and volume, osteoclast number, and erosion depth. This is inconsistent with the marked reductions seen in biochemical markers of bone resorption. The discrepancy is most likely explained by the fact that histomorphometric indices of bone resorption are static parameters, in contrast to bone formation indices, which are dynamic. In one study (Chavassieux et al., 1997), wall thickness of trabecular bone packets was increased after 2 years of treatment, but this effect was not observed after 3 years. Histomorphometric studies failed to show an improvement in cancellous bone microarchitecture compared with placebo-treated subjects, but such an effect has been reported for three-dimensional structural parameters obtained by micro-computed tomography (Recker et al., 2005), with the assumption that alendronate prevented the loss of structural integrity experienced by the placebo-treated patients. Consistent with its primary action to reduce the activation frequency, alendronate increased the degree of mineralization of the matrix (Meunier and Boivin, 1997; Boivin et al., 2000; Hernandez et al., 2001; Roschger et al., 1997, 2001).

There have also been extensive studies of the effects of risedronate on the bone biopsy. Here, a paired biopsy design was employed, with biopsies being obtained before and after treatment in the same subjects (Eriksen et al., 2002; Dufresne et al., 2003; Borah et al., 2004, 2005, 2006; Seeman and Delmas, 2006; Zoehrer et al., 2006). Like alendronate, 3 years of risedronate treatment decreased mineralizing surface, bone formation rate, and activation frequency (Eriksen et al., 2002). Again, no significant change was noted in eroded surface and depth, but there was a significant decrease in resorption rate after risedronate treatment, with a significant increase in erosion depth in placebo-treated subjects. Also similar to alendronate's effects, risedronate preserved cancellous microarchitecture, as assessed by micro-computed tomography (Dufresne et al., 2003; Borah et al., 2004, 2005). No significant changes were seen in three-dimensional structural variables compared with baseline in risedronate-treated women, whereas trabecular microstructure deteriorated significantly in a subset of placebo-treated women who exhibited higher bone turnover at baseline (Borah et al., 2004). Furthermore, the degree of structural deterioration was positively correlated with the bone turnover, confirming that high turnover has a deleterious effect on bone structure. Similar results were reported for early postmenopausal women who were treated for just 1 year with risedronate (Dufresne et al., 2003). The reduction in bone turnover was associated with an increase in bone mineralization density, but there was no evidence of an abnormally high degree of mineralization, even when treatment was extended to 5 years (Borah et al., 2006; Durchschlag et al., 2006; Seeman and Delmas, 2006; Zoehrer et al., 2006).

There are a number of other studies on the effects of different bisphosphonates, such as zoledronate and ibandronate, on iliac bone (Recker et al., 2004, 2008). In general, the data obtained in patients with osteoporosis treated with these bisphosphonates are similar to those obtained with alendronate and risedronate (Recker et al., 2004, 2008). It should also be noted that there is evidence of dramatic improvements in bone structure and turnover in children with osteogenesis imperfecta treated with bisphosphonates (Munns et al., 2005).

Denosumab

Bone histomorphometry substudies in the FREEDOM trial have demonstrated the potent antiresorptive mechanism of action of denosumab. Denosumab is a human monoclonal antibody against receptor activator of NF-κB ligand, which

reversibly inhibits osteoclast-mediated bone resorption. Its effects on bone histomorphometry were published for the first time by Reid et al. (2010) after 24 and/or 36 months of treatment with denosumab in postmenopausal women with osteoporosis. The results demonstrated a significant reduction in eroded surface by more than 80%, whereas osteoclasts were absent from more than 50% of biopsies in the denosumab group. Double labeling in trabecular bone was observed in 19% of those treated with denosumab, while it was present in 94% of the placebo group. Bone-formation rate was reduced by 97% in the denosumab group (Reid, 2010). However, even with this important reduction at bone remodeling, the qualitative histologic evaluation of biopsies was unremarkable, showing normally mineralized lamellar bone. Furthermore, bone biopsies after denosumab treatment were compared with biopsies of subjects after treatment with alendronate in the STAND trial. In this study, dynamic indices of bone turnover tended to be lower in the denosumab group than in the alendronate group. The presence of double labeling in trabecular bone was seen in 20% of the denosumab biopsies and in 90% of the alendronate samples, suggesting that the antiresorptive action of denosumab is more potent than that of the bisphosphonate.

Data from the FREEDOM extension trial after 5 or 10 years of denosumab treatment demonstrated that long-term treatment with denosumab maintained normal bone histology and structure (Brown et al., 2014; Bone et al., 2018), Furthermore, denosumab continued to induce a low turnover state, consistent with its mechanism of action.

Osteoanabolic therapies

Bone histomorphometry has confirmed that the mechanism of action of anabolic agents is fundamentally different from that of anticatabolic drugs (Riggs and Parfitt, 2005). Rather than reducing the activation frequency of bone remodeling, anabolic agents elevate it with a positive bone balance. In each bone remodeling unit, more bone is formed than was resorbed. Bone formation is increased prior to the increase in bone resorption. Consequently, anabolic agents are able to improve, rather than simply preserve, cancellous and cortical bone microarchitecture.

PTH(1−34) and PTH(1−84)

The first bone biopsy studies of the effects of PTH(1−34) (teriparatide) were conducted in postmenopausal women with osteoporosis who were treated concurrently with PTH(1−34) and HT for 6 or 12 months (Reeve et al., 1980, 1991; Bradbeer et al., 1992). Hodsman et al. (1993, 2000) also used bone biopsy to study the effects of a cyclical regimen of 28 days of PTH(1−34) every 3 months, with or without sequential calcitonin, for 2 years. Dempster et al. (2001) and Misof et al. (2003) performed paired biopsies in men with osteoporosis treated with PTH(1−34) for 18 months, as well as in postmenopausal women treated with a combination of PTH(1−34) and HT for 3 years. Biopsy studies of the effects of monotherapy with PTH(1−34) were completed as part of a multinational fracture trial (Neer et al., 2001; Jiang et al., 2003; Dobnig et al., 2005; Paschalis et al., 2005; Ma et al., 2006). Arlot et al. (2005) compared the effects of PTH(1−34) with those of alendronate in postmenopausal women with osteoporosis. The effects of the two agents on activation frequency and bone formation rate were diametrically opposed. Compared with appropriate reference ranges (Arlot et al., 1990; Chavassieux et al., 1997), the bone formation rate was 10% of normal in the alendronate-treated group and 150% higher than normal in the PTH(1−34)-treated group. The higher activation frequency in the PTH(1−34) group led to an increase in cortical porosity, which may explain observations of transient reductions in bone mineral density following treatment with PTH(1−34) (Neer et al., 2001; Finkelstein et al., 2003; Ettinger et al., 2004). A novel labeling regimen, quadruple tetracycline, has been perform in a longitudinal study in order to evaluate of the early effects of teriparatide treatment on bone formation. Within 4 weeks of treatment, PTH(1−34) increased mineralized perimeter, mineral apposition rate, and bone formation rate (Hodsman et al., 1993, 2000; Lindsay et al., 2006). The study of Lindsay et al. (2006) suggested that PTH(1−34) stimulates osteoblastic activity in preexisting remodeling units. This could be accomplished by a variety of mechanisms, including an increase in the work rate of preexisting osteoblasts, enhanced recruitment of new osteoblasts, or a prolongation of osteoblast life span (Jilka et al., 1999). Regardless of the mechanism, one noteworthy feature of PTH(1−34) is its ability to extend formation to quiescent surfaces surrounding the original remodeling unit (Fig. 19.8) (Lindsay et al., 2006). Bone-remodeling indices were increased after 1 month (Holland et al., 1994b), 2 months (Chow et al., 1992b), and 6 months (Reeve et al., 1980; Arlot et al., 2005) of treatment, and they returned toward baseline between 12 (Reeve et al., 1991) and 36 months of continuous treatment (Hodsman et al., 2000; Dempster et al., 2001). This temporal sequence of remodeling activation and deactivation, derived from biopsy studies, is confirmed by parallel changes in bone markers (Lindsay et al., 1997a,b; Kurland et al., 2000; Cosman et al., 2001; Arlot et al., 2005; McClung et al., 2005).

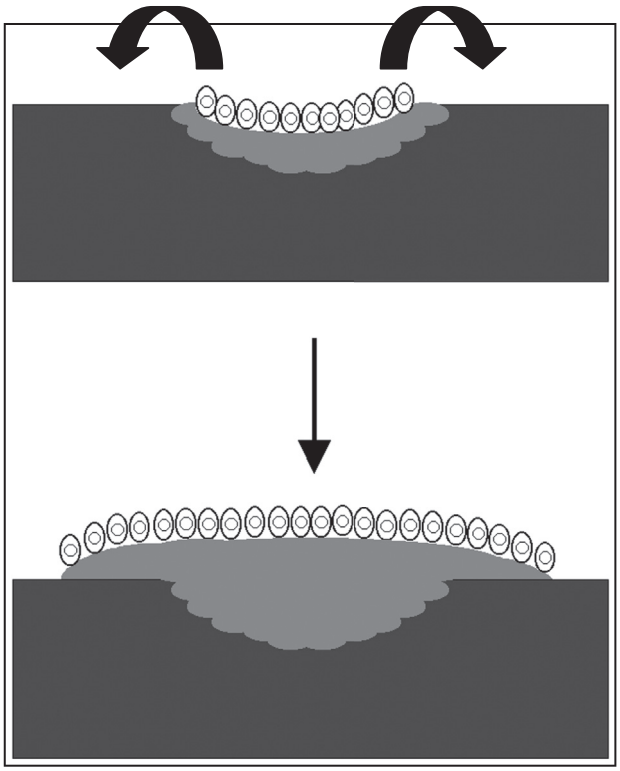

FIGURE 19.8 Proposed mechanism whereby PTH(1−34) could extend bone formation beyond the limits of the remodeling unit to annex the surrounding bone surface. *Reproduced with permission from Lindsay, R., Cosman, F., Zhou, H., Bostrom, M.P., Shen, V.W., Cruz, J.D., Nieves, J.W., Dempster, D.W., 2006. A novel tetracycline labeling schedule for longitudinal evaluation of the short-term effects of anabolic therapy with a single iliac crest bone biopsy: early actions of teriparatide. J. Bone Miner. Res. 21 (3), 366−373.*

The striking stimulation of bone formation by PTH(1−34) provides a mechanism for the reported increases in wall thickness of bone packets on cancellous and endocortical surfaces (Bradbeer et al., 1992; Hodsman et al., 2000; Dempster et al., 2001; Ma et al., 2006), which in turn leads to improvements in cancellous bone mass, trabecular connectivity, and cortical thickness (Dempster et al., 2001; Jiang et al., 2003) (Figs. 19.9 and 19.10). These improvements in cancellous bone structure were correlated with the early increases in bone formation markers (Dobnig et al., 2005). The deposition of new bone brought about an increase in the proportion of bone matrix with lower mineralization, mineral crystallinity, and collagen cross-link ratio (Misof et al., 2003; Paschalis et al., 2005).

The first study of the effects of PTH(1−34) raised the specter that the improvement in cancellous bone mass and structure may have been gained at the expense of cortical bone (Reeve et al., 1980). This was not confirmed in animal models in which cortical thickness and diameter were improved by PTH(1−34) treatment (Hirano et al., 1999, 2000; Jerome et al., 1999; Burr et al., 2001; Mashiba et al., 2001). Histomorphometric and micro-computed tomographic studies in humans revealed an increase in cortical thickness at the iliac crest, which was accompanied by stimulation of bone formation on the endosteal surface (see Figs. 19.9 and 19.10) (Dempster et al., 2001; Jiang et al., 2003; Lindsay et al., 2006). However, whether PTH(1−34) is able to stimulate periosteal bone formation in humans as it does in animals is not yet clear. Noninvasive techniques have yielded conflicting data on the effects of PTH(1−34) on bone diameter in humans (Zanchetta et al., 2003; Uusi-Rasi et al., 2005). However, biopsy studies suggest that PTH(1−34) can enhance periosteal bone formation (Ma et al., 2006; Lindsay et al., 2007). Although there are few data as of this writing, the effects of PTH(1−84) on the human ilium appear to be broadly similar to those of PTH(1−34) (Fox et al., 2005).

Abaloparatide

Abaloparatide (ABL) is a peptide designed with amino acid sequence identical to that of PTH-related peptide in the first 20 amino acids, with strategic insertions of different amino acids between residues 22 and 34 (Hattersley et al., 2016). The resulting peptide is a selective activator of the PTH type 1 receptor signaling pathway with the ability to produce anabolic

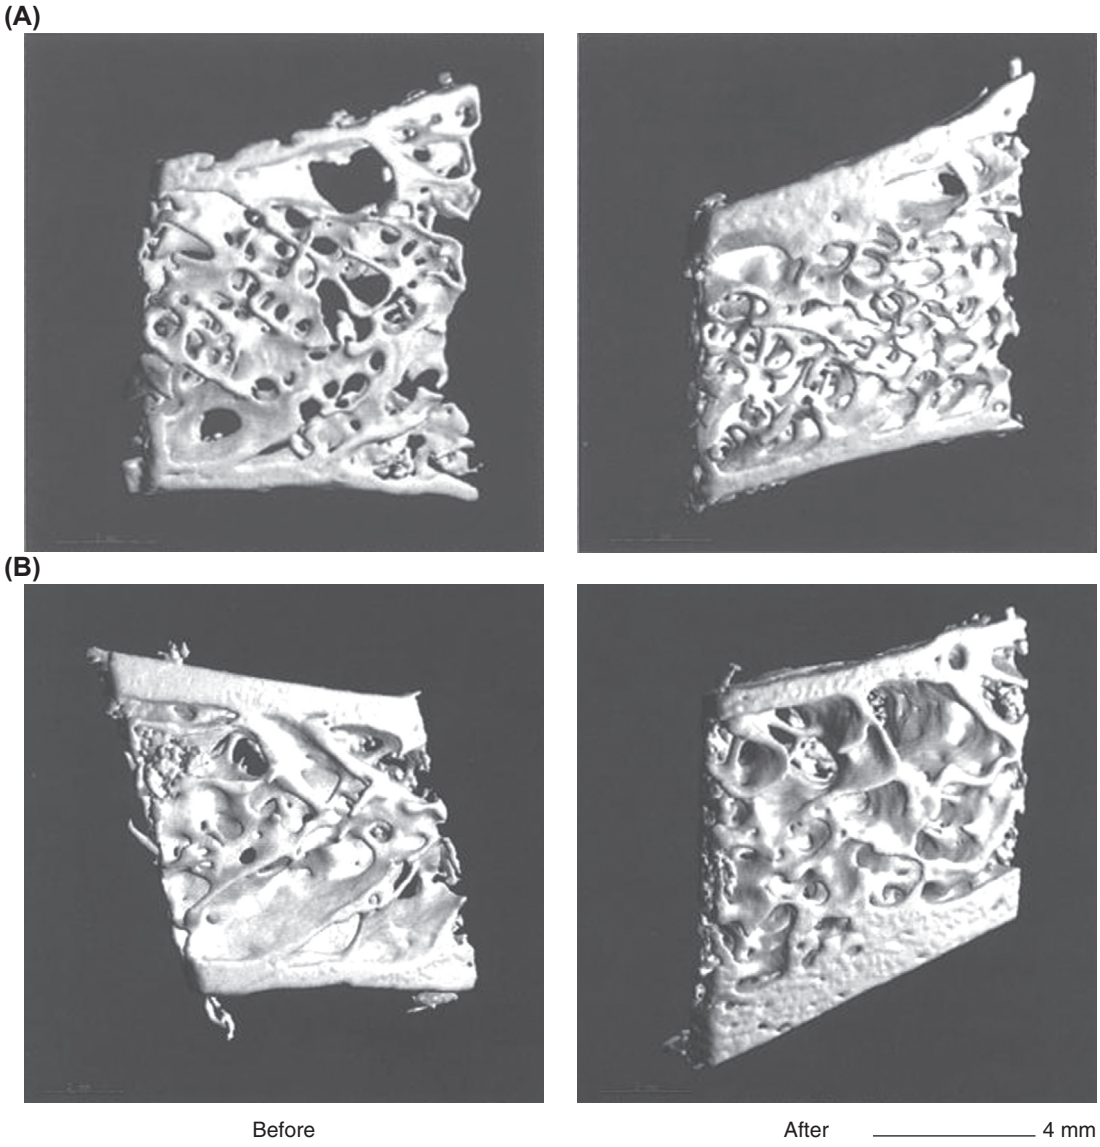

FIGURE 19.9 Micro-computed tomographic images of paired biopsies before (left) and after (right) treatment with PTH(1−34) in a 64-year-old woman (A) and a 47-year-old man (B). Note improvement in cancellous and cortical bone structure after treatment. *Reproduced with permission from Dempster, D.W., Cosman, F., Kurland, E.S., Zhou, H., Nieves, J., Woelfert, L., Shane, E., Plavetic, K., Muller, R., Bilezikian, J., Lindsay, R., 2001. Effects of daily treatment with parathyroid hormone on bone microarchitecture and turnover in patients with osteoporosis: a paired biopsy study. J. Bone Miner. Res. 16 (10), 1846−1853.*

effects with modest stimulation of bone resorption compared with PTH(1−34). In fact, ABL binds to the PTH type 1 receptor with different affinity for the R0 confirmation in comparison to PTH(1−34), resulting in less stimulation of bone resorption and formation. The Abaloparatide-SC Comparator Trial in Vertebral Endpoints (ACTIVE) was a comparative phase III, randomized, double-blind, placebo-controlled, multicenter, international study (Miller et al., 2016). Postmenopausal women were randomized to receive, blinded, daily subcutaneous injections of placebo or ABL 80 μg or open-label teriparatide 20 μg for 18 months.

Iliac bone biopsies were obtained in a subset of patients treated with placebo (n = 35), ABL(n = 36), or teriparatide (n = 34) for between 12 and 18 months.

Histological analysis revealed normal lamellar bone with normal microstructure and bone cell morphology in all three treatment groups (Moreira et al., 2016). There was no evidence of mineralization abnormality, excess woven bone or osteoid, marrow fibrosis, or marrow abnormalities. Histomorphometric analysis was performed on 78 (74.3%) of the 105 specimens. The remaining specimens were not evaluable due to significant damage or fragmentation that occurred in the

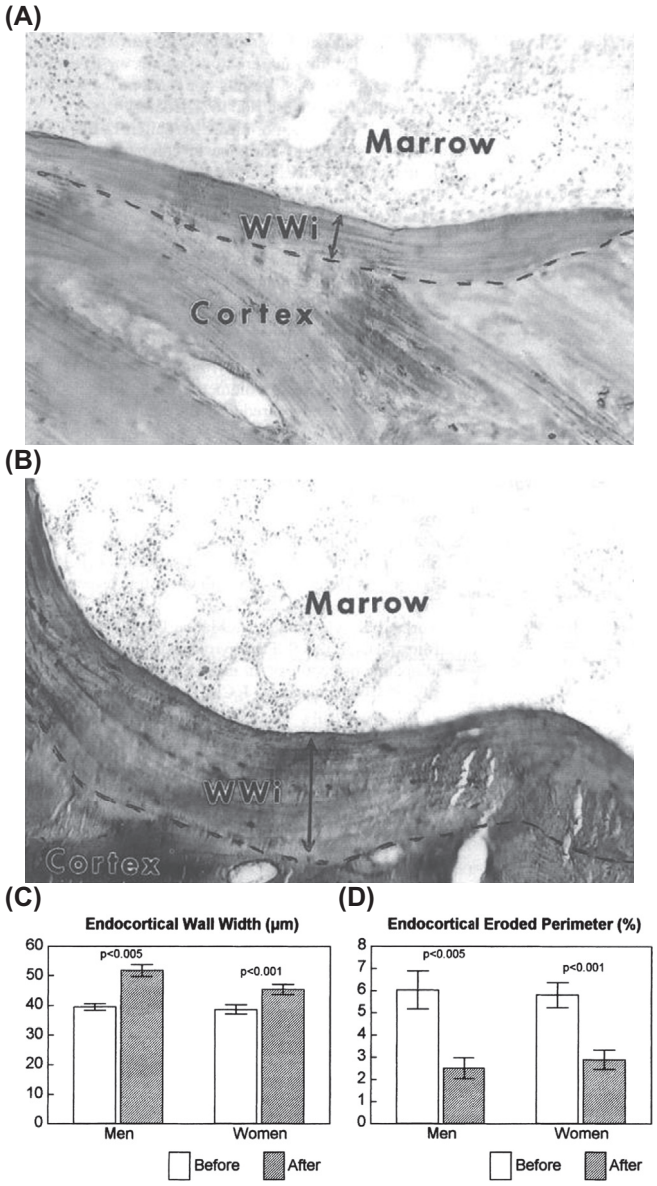

FIGURE 19.10 Bone packets on the endocortical surface of a 52-year-old man before (A) and after (B) 18 months of treatment with PTH(1−34). Note that after treatment the packet is almost twice as wide as the one before treatment. (C and D) Endocortical wall width and eroded perimeter before and after treatment of men and women with teriparatide. Note the increase in wall width and reduction in eroded perimeter after treatment. *WWi*, wall width. *Reproduced with permission from Dempster, D.W., Cosman, F., Kurland, E.S., Zhou, H., Nieves, J., Woelfert, L., Shane, E., Plavetic, K., Muller, R., Bilezikian, J., Lindsay, R., 2001. Effects of daily treatment with parathyroid hormone on bone microarchitecture and turnover in patients with osteoporosis: a paired biopsy study. J. Bone Miner. Res. 16 (10), 1846−1853.*

process of obtaining the biopsy. All specimens displayed tetracycline labels; however, double labels were not observed in three, five, and four specimens in the placebo, ABL, and teriparatide groups, respectively. There were only a few significant differences among the three groups. MAR was significantly higher in the teriparatide-treated group than in the placebo-treated group. The eroded surface was lower in the ABL-treated group than in the placebo group, suggesting a lower resorption rate. This was consistent with the biochemical marker data wherein the increase in carboxy-terminal collagen crosslinks (s-CTX) was less pronounced with ABL than with teriparatide, as well as with the lower incidence of hypercalcemia with ABL compared with teriparatide. Cortical porosity was significantly higher in both treated groups compared to placebo.

Surprisingly, activation frequency and bone formation rate were not different among the three groups, despite the fact that bone mineral density increased in the two treated groups relative to baseline and placebo in the bone biopsy cohort.

One explanation for this result was the timing of the bone biopsies that were obtained after at least 12 months of treatment. Previous histomorphometric studies with similar duration of teriparatide treatment have also not shown increases in bone turnover parameters. In fact, the largest increases in cancellous bone formation rate with teriparatide treatment have been seen with biopsies taken earlier in the course of treatment (Arlot et al., 2005; Lindsay et al., 2006). Furthermore, skeletal sites that exhibit a robust response to anabolic agents, namely the endocortical, intracortical, and periosteal envelopes (Lindsay et al., 2006; Dempster et al., 2012, 2016a), were not analyzed in this study.

Romosozumab

Romosozumab is a sclerostin antibody that has an anabolic effect (Chavassieux et al., 2017). The phase III FRAME study enrolled 7180 postmenopausal women at high risk of fracture and compared the effects of romosozumab with placebo at 12 months and after transition to denosumab at 24 months (Cosman et al., 2017). Vertebral fractures were significantly reduced in the romosozumab compared with the placebo arm at 12 months. At this writing, bone histomorphometry data following romosozumab treatment have not yet been published; however, some results have been presented (Chavassieux et al., 2017). In quadruple-labeled biopsies taken at 2 months, the bone formation rate was dramatically increased compared with pretreatment levels. However, in biopsies taken at 12 months with conventional double labeling, bone formation rate was reduced compared with placebo treatment. If the quadruple-labeling protocol had not been employed, it would have been difficult to explain the large increments in bone mineral density, cancellous bone volume, trabecular connectivity, and cortical thickness achieved by romosozumab treatment.

Comparative studies of anabolic and anticatabolic drugs

SHOTZ

The Skeletal Histomorphometry in Patients on Teriparatide or Zoledronic Acid Therapy study (SHOTZ) assessed the progressive effects of 2 years of treatment with teriparatide 20 μg/day and zoledronic acid 5 mg/year on bone remodeling in the cancellous, endocortical, intracortical, and periosteal envelopes in postmenopausal women with osteoporosis (Dempster et al., 2012, 2016b). Bone biopsies from both groups were performed at 6 and 24 months. A marked difference in the mechanism of action of these two drugs was observed, whereby teriparatide demonstrated higher bone formation indices than zoledronic acid in all four bone envelopes at both early and later time points. In the intracortical envelope, higher cortical porosity rate was observed with teriparatide compared with zoledronic acid, which is attributed to a higher intracortical remodeling rate with the pro-remodeling anabolic agent. However, the 24-month biopsies showed that haversian systems that were open at 6 months were completely filled with new bone at 24 months. In addition, the increase at BFR/BS with teriparatide seen on periosteal and, to a greater extent, on endocortical envelopes at 24 months provides a mechanistic basis for the reported increase in cortical thickness with this drug (Dempster et al., 2001; Jiang et al., 2003).

This study was able to show longitudinal changes within treatment groups with paired biopsies. In the teriparatide group, for example, dynamic indices declined from month 6 to month 24 only in the endocortical envelope. However, the median values for MS/BS and BFR/BS in the endocortical and intracortical envelopes were greater or similar to the values observed in the cancellous envelopes at both time points. Indeed, these results suggest that the anabolic effect of teriparatide is highest in the endocortical and intracortical envelopes and that the anabolic actions continue through 24 months of therapy.

In contrast to the teriparatide group, the low bone formation rate seen at month 6 in the zoledronic acid group persisted through 24 months. In fact, no difference in bone histomorphometry parameters were seen within individual bone envelopes in the zoledronic acid group over time. The only exception was noted in the intracortical envelope, where the median values for MS/BS and BFR/BS were higher compared with the cancellous envelope. This finding suggests that zoledronic acid may have limited access to the intracortical envelope, unlike teriparatide and denosumab as described earlier.

More recently, the SHOTZ study confirmed earlier studies (Lindsay et al., 2006; Ma et al., 2006) showing that teriparatide increases modeling-based formation as well as remodeling-based formation (Dempster et al., 2018). This effect was most prominent during the early course of treatment. In contrast, very little modeling-based formation was seen with zoledronic acid treatment.

AVA study: differential effects of teriparatide and denosumab on intact parathyroid hormone and bone formation indices

This open-label study was designed to evaluate whether denosumab-induced increases in endogenous PTH are able to exert some anabolic effect at the tissue level and on bone-turnover markers. The study included 69 postmenopausal women with osteoporosis and employed quadruple tetracycline labeling to enable longitudinal assessment of bone formation parameters in a single biopsy sample, which was taken at 3 months (Dempster, 2016a). Patients were randomized to teriparatide 20 μg daily for 6 months or denosumab 60 mg in a single infusion. Histomorphometric indices in all four envelopes were analyzed, as well as bone-turnover markers and endogenous intact PTH at baseline and 1, 3, and 6 months.

The results demonstrated that, while denosumab treatment resulted in a significant and prolonged increase in endogenous PTH levels, bone formation indices were decreased. By contrast, teriparatide decreased endogenous PTH but stimulated bone formation indices. These effects were reflected in the changes in bone-turnover markers, which increased with teriparatide and decreased with denosumab treatment. As in the SHOTZ study, stimulation of modeling-based formation accounted for a significant proportion of the total amount of new bone formation induced by teriparatide treatment (Dempster et al., 2017a). On the other hand, the small amount of modeling-based formation seen at baseline in the denosumab group was not affected by treatment, with the exception of a small but significant increase in the cancellous envelope.

Conclusion

Iliac crest bone biopsy and histomorphometry remains a powerful research tool, providing unique information on bone structure and remodeling activity at the tissue level. It is still the single most useful tool for understanding the mechanism of action (MOA) of bone active agents. Although it is rarely used as a diagnostic tool nowadays, a key exception is in the evaluation of renal osteodystrophy.

Chapter 20

Phosphorus homeostasis and related disorders

Thomas O. Carpenter, Clemens Bergwitz and Karl L. Insogna

Chapter outline

Introduction

Phosphorus is critical to life as we know it. In mammalian tissues, phosphorus is one of the most abundant components; it has critical roles in growth and development and is a major structural component of bone. Physiologic functions at the organism level include its ability to serve as a buffer in acid—base regulation and multiple roles in cellular metabolism. Inorganic phosphorus exists primarily as phosphate (PO_4), a stable, divalent anionic complex with four oxygen atoms. Phosphate is a requisite component of hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$), which crystallizes to form the mineral basis of the vertebrate skeleton. At the molecular level, phosphate provides the molecular backbone of DNA. The chemical bonding of two phosphate molecules creates pyrophosphate (PPi; P_2O_7), a potent inhibitor of bone mineralization, and an intricate balance between local phosphate/PPi balance regulates mineralization. The chemical nature of phosphate—phosphate bonds allows for storage of biological energy as adenosine triphosphate (ATP). In addition, phosphorus influences a variety of enzymatic reactions (e.g., glycolysis) and protein functions (e.g., the oxygen-carrying capacity of hemoglobin by regulation of 2,3-diphosphoglycerate synthesis). Phosphorus influences both the storage and the release of the principal

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00020-8

carbohydrate energy source, glucose, as glucose is phosphorylated prior to storage as glycogen, and that same phosphorylation step is reversed during glycogenolysis. Finally, bonding (or removal) of phosphorus at specific amino acid residues in proteins provides for highly evolved signaling cascades, as phosphorylation or dephosphorylation of many proteins activates or deactivates a variety of pathways.

Individuals eating a Western diet consume roughly 20 mg/kg of dietary phosphorus daily, varying somewhat by age and sex (Calvo et al., 2014). However, this estimate does not capture the large amount of phosphorus contained in food additives. The majority of phosphorus in the body is contained in mineralized tissue (600−700 g), with the remainder in soft tissues (100−200 g). Less than 1% of the total phosphorus in the body is in extracellular fluids. The plasma contains approximately 12 mg of phosphorus, the majority of which (8 mg) is contained in phospholipids, while only a small amount circulates as inorganic phosphate, either as monohydrogen phosphate or dihydrogen phosphate. The relative concentrations of these two moieties generally favor the monohydrogenated compound (4:1).

The terms "serum phosphorus" and "serum phosphate" are generally used interchangeably when referring to plasma inorganic phosphorus concentrations, because plasma inorganic phosphorus is nearly all in the form of the PO_4 ion. It should be noted that this terminology can be confusing when using mass units (i.e., mg/dL) when the weight of the phosphorus content of the phosphate is reported, yet the term "serum phosphate" is often used in the clinical setting. When using molar units the concentrations of the phosphate and of the phosphorus are equivalent, and less confusion may arise.

In adult humans, most phosphorus is found in bone (600−700 g), whereas the remainder is generally in soft tissue (100−200 g). The plasma contains 11−12 mg/dL of total phosphorus (in both organic and inorganic states) in adults. Inorganic phosphorus is largely in the form of phosphate (PO_4) and is the fraction typically measured in clinical settings. The plasma or serum concentration of phosphorus averages 3.0−4.5 mg/dL in older children and adults, but is greater in infants and younger children. Plasma phosphorus can often be as high as 8 mg/dL in small infants, gradually declining through the first year of life and then further as childhood progresses to adult values.

Rapid shifts in extracellular phosphate can occur during a variety of physiologic processes and pathologic disturbances. For example, the phosphorylation of glucose after it enters the cell explains the rapid depletion of extracellular phosphate with exogenous administration of insulin. Rapid bone remineralization ("hungry bone syndrome") can also cause rapid depletion of extracellular phosphate. Phosphorus deprivation (as occurs with the administration of phosphate-binding resins) can lead to hypophosphatemia. Furthermore, insulin induces shifts of phosphate into cells as is seen in refeeding hypophosphatemia and with the correction of diabetic ketoacidosis. Profound and sustained declines in extracellular phosphate can result in impaired muscle, leukocyte, and platelet function; rhabdomyolysis; and even cardiopulmonary compromise.

Despite the paramount importance of phosphate in mammalian physiology, the local and systemic regulation of phosphate homeostasis is poorly understood. It was not until 2000/2001 that the hormone now recognized as having a critical role in regulating the concentration of extracellular phosphate, fibroblast growth factor 23 (FGF23), was identified. That discovery, while representing a major advance in understanding phosphate homeostatic mechanisms, also highlights a crucial, and as yet unanswered, question: how do osteocytes, the cells that produce FGF23, sense extracellular phosphate and thereby regulate production of FGF23?

Phosphate transporters are present throughout the body and are the portals for entry of phosphate into cells, but their regulation and/or modulation by extracellular phosphate remains to be explored. A better understanding of the regulation of, as well as interactions between, extra- and intracellular phosphate will lead to improved insights into human physiology and better therapies for disorders of phosphate homeostasis.

Regulation of phosphate metabolism

Overview

To provide for these various functions, organisms have developed elaborate mechanisms for regulating supply and intercompartmental transport of phosphate. Various regulatory mechanisms permit modulation based on metabolic phosphorus need and exogenous phosphorus supply. This adaptive homeostatic system primarily adjusts gastrointestinal absorption and renal excretion to control total body stores, while maintaining extracellular concentration of phosphorus within a relatively narrow range. The identification of several hormones (e.g., parathyroid hormone [PTH], FGF23) and transporter proteins (e.g., NPT2, PIT) that are integral to the system has markedly increased our understanding of phosphate homeostasis, but the sensory system underlying regulation of phosphorus balance remains incompletely understood. The majority of ingested phosphate is absorbed in the small intestine, where active transport is mediated by sodium-dependent transporter proteins, and sodium-independent phosphate transport also occurs. The kidney, however, is

thought to be the dominant organ involved in the regulation of phosphorus balance, as renal tubular reabsorption of filtered phosphate is adjusted in response to various regulatory factors. Finally, in the setting of severe phosphorus deprivation, the phosphate contained in bone mineral provides a source of phosphorus for the metabolic needs of the organism. The specific roles that the intestine, kidney, and bone play in this complex process are discussed in detail in the following sections.

Hormonal regulators

Parathyroid hormone

PTH was long considered the predominant hormonal effector of phosphate homeostasis. Effects of PTH on proximal tubular phosphate transport can be mediated by both cAMP−protein kinase A (PKA) and phospholipase C−protein kinase C (PKC) signal transduction pathways, although the PKA pathway is the more important pathway in this regard. After interaction with the PTH receptor 1 (PTHR1), PTH effects a rapid removal of the inorganic phosphate transporters NPT2a and NPT2c from proximal tubular apical membranes. Stabilization of NPT2a is mediated by the sodium/hydrogen exchange regulatory cofactor NHERF1, which is phosphorylated by PTH's activation of the PKA and PKC pathways. Overall, PTH appears to serve as a regulator of renal sodium/phosphate cotransport in an acute time frame, and the regulation is determined by changes in the abundance of NPT2 proteins in the renal brush border membrane (Forster et al., 2006). Certain aspects of phosphate homeostasis at the renal level, however, are not explained by actions of PTH. For instance, after removal of the parathyroid glands, regulation of renal phosphate transport by dietary phosphorus content persists, implying that other mediators of this process are at work.

Fibroblast growth factor 23

FGF23 is the most recently identified important physiologic regulator of renal phosphate excretion (Farrow and White, 2010). This novel member of the FGF family is produced by osteocytes and, to some extent, osteoblasts, thus providing a mechanism by which skeletal mineral demands can be communicated to the kidney and thereby influence the phosphate economy of the entire organism. In rodents and humans, after days of dietary phosphate loading, circulating FGF23 levels increase, and similarly, with dietary phosphorus deprivation, FGF23 levels decrease (Antoniucci et al., 2006). FGF23 activates FGF receptors (FGFRs) on the basolateral membrane of renal tubules, resulting in removal of type II sodium-dependent phosphate transporters from the apical surface of the tubular cell by a NHERF1-dependent process, similar to the previously described mechanism for PTH. However, in contrast to PTH, FGF23 actions are mediated by activation of extracellular signal-regulated kinase 1/2 (ERK1/2) rather than the PTH-driven PKA-dependent pathway. Evidence also exists for decreased expression of type II sodium-dependent phosphate transporters via genomic mechanisms. FGF23 interacts with its receptor via a mechanism now identified as characteristic of the endocrine FGFs. FGF23 recognizes its cognate FGFR only in the presence of the coreceptor α-klotho (Urakawa et al., 2006). Activation of this complex results in downstream ERK phosphorylation and subsequently reduced expression of NPT2a and NPT2c, and *CYP27B1* (encoding the vitamin D 1α-hydroxylase), with an increase in expression of *CYP24A1* (encoding the vitamin D 24-hydroxylase). This mechanism of signaling is apparent for the endocrine FGFs, FGF19 and FGF21, which require a separate member of the klotho family (β-klotho) for tissue-specific activation of FGFRs (for a detailed review, see Belov and Mohammadi, 2013).

FGF23 contains a unique C-terminal domain, thought to be the site of the interaction with klotho. The crystal structure of the FGF23/FGFR1c/α-klotho complex has been solved (Chen et al., 2018), confirming this prediction (Fig. 20.1). The C-terminal tail of FGF23 binds both the klotho 1 and the klotho 2 domains of α-klotho, and the FGF-like domain, which is N-terminal to the RXXR furin/subtilisin protease recognition site, binds to the FGFR. α-Klotho is able to associate with "c" isoforms of FGFR1 and FGFR3, and also FGFR4 (Urakawa et al., 2006); renal signaling is thought to primarily occur via FGFR1c. The actions of FGF23 and other related proteins as mediators of disease are discussed in detail later in the section on X-linked hypophosphatemia (XLH).

The role of osteocytes

Osteocytes are the most abundant cell in cortical bone, distributed in an organized array with interconnecting canaliculi (for review, see Dallas et al., 2013). Cellular processes extending from the cell body of the osteocyte tunnel through these canaliculi and communicate with other cells and bony surfaces. The osteocyte produces several proteins involved in phosphate regulation, including: (1) PHEX (phosphate-regulating gene with homologies to endopeptidases on the X chromosome), which regulates FGF23 secretion, with loss of function resulting in elevated circulating FGF23; (2) DMP1 (dentin matrix protein 1), a SIBLING (small integrin-binding ligand N-linked glycoprotein) protein, of which loss of

function also results in elevated circulating FGF23; (3) FGF23 itself; and (4) FGFR1, which appears to be activated in osteocytes, resulting in elevated FGF23 expression. These observations have led to the consideration that osteocytes may directly respond to phosphate nutritional status, and ultimately relay, via production of FGF23, the mineral demands for bone maintenance to the kidney, where phosphate conservation is regulated. The osteocyte's response to phosphate status does not appear to be an acute process, as is observed with the extracellular calcium-sensing receptor system that regulates PTH secretion in parathyroid glands. It follows that genetic disruption of this pathway may result in the profound systemic disturbances observed in the diseases discussed herein.

In summary, the body's phosphorus status is largely adjusted at the kidney. Phosphate reabsorption is increased under conditions of greater need (rapid growth, pregnancy, lactation, and dietary restriction) and decreased during slow growth, chronic renal failure, or dietary excess. Changes in NPT2 protein abundance parallel these changes and are mediated by FGF23 and other possible factors. Removal of NPT2 cotransporters from the apical membrane of renal tubular cells is an acute process, mediated by PTH. The interaction of PTH and FGF23 in the overall process may also be important. Indeed, ablation of PTH in a murine model of excess FGF23 abrogates hypophosphatemia. Likewise, suppression of PTH may reduce phosphate losses even with persistence of high FGF23 (Bai et al., 2007; Carpenter et al., 2014), suggesting an interaction between the two pathways (Lanske and Razzaque, 2014).

Nutritional and gastrointestinal considerations

Whole-body phosphorus economy is summarized in Fig. 20.2. Dietary phosphorus is estimated at approximately 20 mg/kg/day, when not considering the phosphorus content of food additives. Based on NHANES data, dietary phosphorus intake in adults between the ages of 19 and 70 ranges from 1500 to 1700 mg/day for men and 1000 to 1200 mg/day for women (Calvo et al., 2014). Of the ingested phosphorus there is a net absorption of approximately 13 mg/kg; 16 mg/kg is unidirectionally absorbed, while 3 mg/kg is lost in endogenous gut secretions. The steady-state transit of phosphorus in and out of the skeletal compartment is balanced at roughly 3 mg/kg/day such that the daily urine phosphorus excretion largely reflects net gut absorption. The majority of the body's phosphorus (approximately 85%) is stored as hydroxyapatite in mineralized tissue. Roughly 14% is in soft tissues and only 1% is in the circulation or in the extracellular space. Eight-five percent of circulating phosphorus is ultrafilterable, the remainder is bound to serum proteins. The average woman in the United States has approximately 400 g of phosphorus stored in skeletal tissue, and men have approximately 500 g (Aloia et al., 1984).

The Western diet is awash in phosphorus, and dietary phosphorus estimates do not adequately capture the large amount of phosphorus in food additives. Estimates indicate that, at all ages, the typical phosphorus intake in the United States considerably exceeds the recommended dietary allowance by 1.5- to 2-fold (Calvo et al., 2014). This large phosphorus load may have deleterious consequences that are only now being studied. In a small clinical study, feeding healthy individuals a diet containing 1000 mg of phosphorus to which were added foods containing phosphorus additives resulted in increased circulating levels of FGF23, osteopontin, and osteocalcin, compared with the same diet with no food additives, suggesting the possibility that food additives in the context of the usual dietary phosphorus intakes could alter skeletal homeostasis (Gutierrez et al., 2015). Using NHANES data, a multiply adjusted association between high dietary phosphorus intake and all-cause mortality has been observed, with an inflection point at approximately 1400 mg/day of ingested phosphorus (Chang et al., 2014). It is noteworthy that men in the United States are estimated to have phosphorus intakes that often exceed 1400 mg/day (Calvo et al., 2014).

Intestinal phosphate absorption is highest in infancy and childhood and declines with age, but remains robust at approximately 50%–70% of bioavailable phosphorus. The majority of phosphate is absorbed in the small bowel by two pathways: the first is a passive paracellular pathway, in which phosphate moves through tight junction complexes formed by molecules, such as occludins and claudins. The second pathway is sodium-dependent phosphate cotransport, mediated by the type II sodium-dependent transporter NPT2b (encoded by *SLC34A2*) and, to a lesser extent, by the type III sodium-dependent transporter PIT1. The important role of NPT2b in intestinal phosphate absorption is highlighted by the impaired intestinal phosphate absorption in mice with genetic disruption of the gene (Sabbagh et al., 2009). The contributions of these two pathways to overall intestinal phosphate absorption vary, depending on the type and amount of dietary phosphate

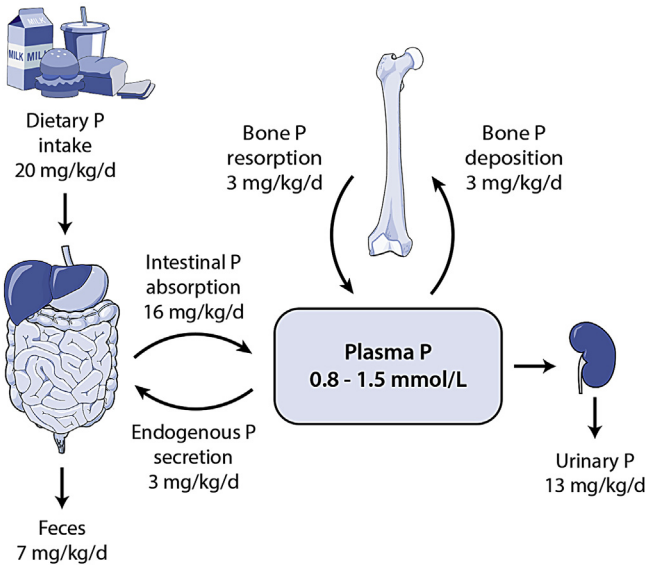

FIGURE 20.2 Summary of whole-body phosphorus economy. *From Figure 8.1, O'Brien, Kerstetter, Insogna. Chapter 8: Phosphorus; in Modern Nutrition in Health and Disease, 11th Edition. A. Ross, B. Caballero, R. Cousin, K. Tucker, T. Ziegler, eds. Lippincott, Williams and Williams. Baltimore, MD. pp 150–158. Reproduced with permission.*

presented to the gut. In experimental animals, it has been estimated that these two pathways contribute roughly equally to intestinal phosphate absorption (Lee and Marks, 2015). However, earlier estimates suggest that the paracellular pathway is the major mechanism for phosphate absorption. Both transcriptional and posttranscriptional regulation of Npt2b has been reported. For example, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$) induces expression of Npt2b via a transcriptional mechanism, while low dietary phosphorus increases the activity of this transporter by posttranscriptional mechanisms. Whether changes in dietary phosphate absorption can lead to rapid changes in renal phosphate handling via as yet uncharacterized pathways that do not involve FGF23 or vitamin D remains an intriguing, but unproven, hypothesis. An early report suggested that this might be the case and, in particular, experimentally induced changes in duodenal phosphate absorption in rats led to rapid changes in renal phosphate handling without changes in systemic mineral homeostasis, suggesting novel "direct" gut/bone communication (Berndt et al., 2007). However, no similar observations have been reported nor have there been any further studies to characterize this pathway.

Finally, a novel interaction between the gut microbiota and FGF23 has been reported in an experimental model. Germ-free mice were found to have elevated circulating levels of FGF23 in the setting of low levels of 25-hydroxyvitamin D (25-OHD) and $1,25(OH)_2D$. Conventionalization of the germ-free mice (with the microbiome of normal mice) resulted in a fall in FGF23 levels and normalization in circulating levels of 25-OHD and $1,25(OH)_2D$. The authors posited that an inflammatory pathway, mediated by gut microbiota, leads to suppression of FGF23 expression. Whether changes in gut microbiota influence systemic phosphorus homeostasis through this pathway in humans remains unclear (Bora et al., 2018).

Phosphate and bone mineralization

The principal form of mineral in bone, hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$), contains six atoms of phosphorus per crystal unit (each composed of two molecules). When the extracellular phosphorus supply is chronically deficient, mineralization is disrupted, resulting in the clinical conditions of rickets in children and osteomalacia in adults. Mineralization is essential during growth, when new bone is formed (modeling), as well as after epiphyseal closure, when replacing old bone and repairing damaged bone requires an orchestrated series of cellular events in which discrete packets of bone are removed and replaced (remodeling). Normal mineralization of bone requires the action of osteoblasts and hypertrophic chondrocytes, which secrete matrix vesicles (MVs). MVs have the ability to rapidly induce hydroxyapatite crystal formation in the presence of sufficient concentrations of extracellular calcium and phosphate (Bottini et al., 2018). Phosphate, liberated by the phosphatase PHOSPHO1 from phosphocholine, is then imported into the vesicle via the PIT1 transporter. The ambient extracellular phosphate concentration in bone is regulated by tissue nonspecific alkaline phosphatase (TNAP), which is abundant in MVs. TNAP cleaves PPi generating 2 phosphate molecules, resulting in a phosphate/PPi (Pi/PPi) ratio that favors mineralization. The process of mineralization is critically dependent on this ratio. Hydroxyapatite crystals initially form within MVs but are subsequently propagated onto the collagen matrix through as yet unclear mechanisms. The protein matrix that is eventually mineralized is composed primarily of collagen, but includes many other proteins, such as fibronectin, osteopontin, and osteocalcin.

There is currently intense interest in PPi as a central regulator of mineralization (Bottini et al., 2018; Bonucci, 2012; Zhou et al., 2012; Kim et al., 2010). In addition to TNAP, the extracellular concentration of PPi is regulated by several other proteins, including ENPP1 (ectonucleotide pyrophosphatase/phosphodiesterase 1), an exoenzyme that cleaves ATP to AMP and PPi. With genetic loss of function of ENPP1, extracellular concentrations of PPi are low, leading to rapid and aberrant mineralization of tissues, including the vasculature, a rare but devastating syndrome termed generalized arterial calcification of infancy (GACI) (Ferreira et al., 1993). Conversely, in the genetic absence of TNAP function, high PPi concentrations in the bone microenvironment prevent skeletal mineralization, resulting in the syndrome of hypophosphatasia, which in its most severe form is lethal around the time of birth (Whyte, 2017). ANKH (progressive ankylosis protein homolog) exports intracellular PPi and also plays a role in regulating the Pi/PPi ratio. Mutations in ANKH are associated with rare familial syndromes of calcium PPi deposition disease as well as autosomal dominant craniometaphyseal dysplasia (Pendleton et al., 2002; Nurnberg et al., 2001). Adding further complexity to this process is the fact that the hepatic-specific transporter ABCC6 (ATP binding cassette subfamily C member 6) also supports the extracellular concentration of PPi, since loss-of-function mutations are the basis for the syndrome pseudoxanthoma elasticum, in which serum PPi levels are low and heterotopic calcification, including in vascular tissue, can occur (Kranenburg et al., 2017). The fact that vascular calcification occurs in the genetic absence of both ENPP1 and ABCC6 points to the critical role of PPi in regulating heterotopic mineralization, particularly in the vascular tree. How these proteins modulate tissue mineralization in sites other than bone and vascular tissue remains to be fully explored.

Phosphorus also plays a critical role in chondrocyte maturation. The growth plate is a tightly regulated structure in which cells progress from resting to proliferating chondrocytes and then become prehypertrophic and finally hypertrophic chondrocytes that ultimately apoptose and are replaced by mineralized tissue. The concentration of extracellular phosphate is a key apoptotic signal for hypertrophic chondrocytes (Sabbagh et al., 2005). In the setting of low extracellular phosphate, chondrocytes fail to apoptose, which is part of the pathogenesis of the abnormal growth plate seen in hypophosphatemic rachitic disorders such as XLH. Since hypophosphatemia is also seen with nutritional rickets, the same pathology applies to that condition. A detailed molecular pathway involving ERK1/2−Raf signaling has been described as mediating the proapoptotic effect of phosphate in chondrocytes that, interestingly, is opposed by PTH-related protein, a cytokine that slows chondrocyte apoptosis (Papaioannou et al., 2017; Liu et al., 2014).

A fourth major participant in the regulation of mineralization is the hormone FGF23, which controls extracellular phosphate concentrations. Excess FGF23 levels cause systemic hypophosphatemia and impaired mineralization as described elsewhere in this chapter. In addition, it has been reported that FGF23 directly suppresses TNAP in osteocytes, allowing local concentrations of PPi to rise (Murali et al., 2016). This is another potential mechanism by which FGF23 could impair bone mineralization.

Finally, while the control of circulating levels of phosphorus by systemic hormones like FGF23, PTH, and $1,25(OH)_2D$, coupled with metabolism of PPi by TNAP, ENPP1, ANKH, and ABCC6, seems to be the major regulator of mineralization, other potential mechanisms that interact with phosphorus metabolism have been reported. Thus, the SIBLING proteins, such as osteopontin, as well as peptides derived from their incomplete metabolism in the absence of PHEX, called ASARM (acidic serine aspartate-rich MEPE-associated motif) peptides, have been reported to directly regulate phosphate metabolism and local bone mineralization (David et al., 2011; Boukpessi et al., 2017; Yuan et al., 2014). For this, the reader is referred to a discussion of the SIBLING proteins and ASARM peptides in the section of this chapter devoted to XLH.

Intracellular/extracellular compartmentalization

After absorption from the diet in the gut, phosphate is stored together with calcium as hydroxyapatite in the skeleton, and it is excreted in urine (for reviews see Forster et al., 2006; Prie et al., 2004; Liu and Quarles, 2007; Miyamoto et al., 2007; Shaikh et al., 2008; Strom and Juppner, 2008; White et al., 2006; Kurosu & Kuro-o, 2008) (Fig. 20.3). Phosphate typically moves between the intracellular and the extracellular compartments under the control of transporter proteins. The type III transporters PIT1 (*SLC20A1*) and PIT2 (*SLC20A2*) are ubiquitously expressed and are considered housekeeping transporters that mediate cellular uptake of phosphate to meet the needs of cell metabolism in many tissues. This metabolic uptake of phosphate into muscle, bone, and other tissues is regulated by various factors, such as phosphate itself (Chien et al., 1997; Wang et al., 2001), epinephrine (Suzuki et al., 2001), platelet-derived growth factor (PDGF) (Zhen et al., 1997), insulin and insulin-like growth factor 1 (Polgreen et al., 1994), basic FGF (Suzuki et al., 2000), and transforming growth factor-β (Palmer et al., 2000).

Upregulation of phosphate transporters by insulin, causing sequestration of phosphate into cells and hypophosphatemia, is encountered during refeeding in nutritionally deprived individuals following intravenous glucose infusion or oral carbohydrate intake (Petersen et al., 2005; Price et al., 1996; Butterworth and Younus, 1993; Kemp et al., 1993). Hypophosphatemia can also occur in the setting of high cellular demand for phosphate, for example, during rapid cell growth in hematological malignancies (Liamis and Elisaf, 2000; Milionis et al., 1999) or following hepatic resection (Keushkerian and Wade, 1984; Nafidi et al., 2007). In general, the circulating phosphate concentration is determined by phosphorus absorption from the intestine, excretion in urine, and balance between the intracellular and the extracellular compartments.

Mechanisms of phosphate transport

Transporter-mediated cellular absorption of dietary phosphate (Hilfiker et al., 1998), which is regulated in a $1,25(OH)_2D$-dependent manner (Wilz et al., 1979), accounts for 30% of intestinal phosphate absorption. The remaining 70% is absorbed through a poorly defined paracellular mechanism. The type II cotransporters NPT2a and NPT2c are expressed exclusively at the renal brush border membrane of the proximal tubules, where the bulk of filtered phosphate is reabsorbed (Segawa et al., 2002; Murer et al., 2004; Miyamoto et al., 2004; Shimada et al., 2004a). Based on data obtained in mice and rats, Npt2c is predicted to contribute about 15%−20% to total proximal tubular reabsorption of phosphate (TRP) (Segawa et al., 2002; Ohkido et al., 2003). Npt2c is thought to be rate-limiting only during weaning, with minimal contribution to total sodium/phosphate cotransport in adult rats (Segawa et al., 2002). The type III transporters, Pit1 and Pit2, are ubiquitously

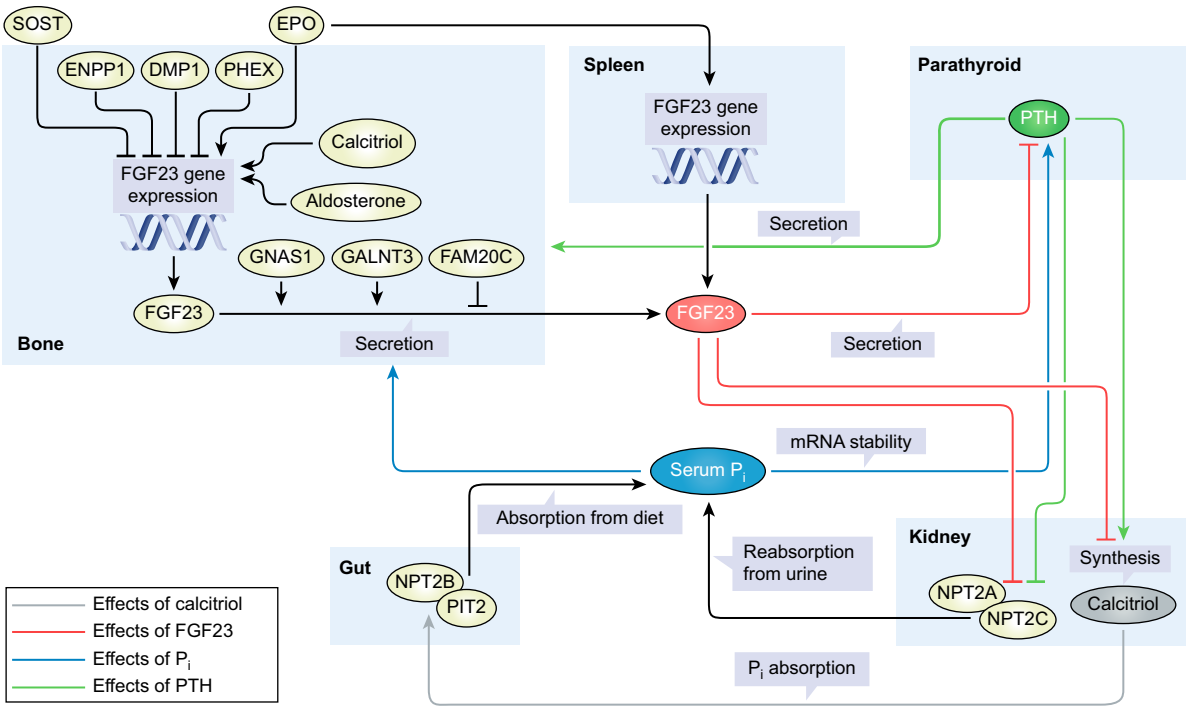

FIGURE 20.3 Regulation of phosphate homeostasis. Endocrine regulation of Pi homeostasis (originally published in Chande and Bergwitz, 2018). Serum phosphate (Pi) stimulates secretion of bioactive fibroblast growth factor 23 (FGF23) in osteoblasts and osteocytes (*blue arrow* (dark grey in print versions)), which directly or indirectly acts at the proximal tubule of the kidneys to inhibit synthesis of calcitriol and the function of NPT2A and NPT2C (*red arrows* (light grey in print versions)). Inhibition of calcitriol reduces absorption of Pi from the diet in the gut (*gray arrow*) and mobilization of Pi from bone mineral. Downregulation of NPT2A and NPT2C reduces renal phosphate reabsorption (*black arrows*). The net effect of FGF23 action is to lower blood levels of Pi. Similar to FGF23, parathyroid hormone (*PTH*) downregulates NPT2A and NPT2B and reduces renal phosphate reabsorption (*green arrows*(grey in print versions)). However, different from FGF23, PTH induces calcitriol and bone turnover, which increase blood Pi (*green arrows*). However, the net effect of PTH is to lower blood levels of Pi. Although not completely understood, golgi associated secretory pathway kinase (FAM20C), DMP1, ENPP1, and PHEX reduce FGF23 expression or secretion, whereas phosphate, iron deficiency, erythropoietin (EPO), GALNT3, and guanine nucleotide binding protein (G protein), alpha stimulating activity polypeptide 1 (GNAS1) stimulate it (*black arrows*). In addition, sclerostin (SOST) seems to negatively regulate FGF23 (*black arrows*). Furthermore, EPO might directly upregulate FGF23 gene expression in myeloid lineage stem cells of the spleen, providing a link to iron homeostasis (*black arrows*). PTH is suppressed by FGF23 in rodents but not in humans (*red arrow*). DMP1, dentin matrix acidic phosphoprotein 1; ENPP1, ectonucleotide pyrophosphatase/phosphodiesterase 1; GALNT3, UDP-*N*-acetyl-α-D-galactosamine:polypeptide *N*-acetylgalactosaminyltransferase, isoform 3; NPT2, solute carrier family 34 (type II) sodium/phosphate cotransporters (with "A", "B", and "C" species); PHEX, phosphate-regulating gene with homologies to endopeptidases on the X chromosome; PIT2, solute carrier family 20 (type III) sodium/phosphate cotransporter ("2" species).

expressed yet account for less than 1% of the mRNAs encoding the various renal sodium/phosphate cotransporters (Tenenhouse et al., 1998). All of these transporter classes utilize the transepithelial sodium gradient to transport phosphate against its electrochemical gradient into cells.

Intestinal phosphate transport

Intestinal uptake of phosphate occurs primarily by passive paracellular diffusion, while only 30% occurs via Na^+-dependent, carrier-mediated transcellular transport (Murer et al., 2000, 2004; Eto et al., 2006; Berndt & Kumar, 2009). The molecular mechanism of the former is unclear; the latter is mediated by the type IIb sodium/phosphate cotransporter NPT2b and the type III sodium/phosphate cotransporter PIT2 (Sabbagh et al., 2011; Giral et al., 2009; Xu et al., 2002, 2003, 2005; Yeh and Aloia, 1987). $1,25(OH)_2D$ and dietary phosphorus depletion are thought to be the most important physiological stimuli of intestinal phosphate absorption and act by increasing the abundance of NPT2b protein (Hattenhauer et al., 1999). Glucocorticoids (Yeh and Aloia, 1987) and estrogen (Xu et al., 2003) increase, and nicotinamide (Eto et al., 2005) decreases, intestinal phosphate transport, but the mechanism is unknown. There is no known direct effect of FGF23 or PTH on intestinal phosphate transporters (Tomoe et al., 2010), but intestine may release a factor(s) that

signals dietary phosphate availability to the kidney (Berndt et al., 2007). Evaluation of *Npt2b* (Sabbagh et al., 2009; Knöpfel et al., 2017) conditional knockout (KO) mice suggests that this transporter is probably the primary transepithelial intestinal phosphate transporter. Ablation of *Npt2b* attenuates the rise in blood phosphate seen in the setting of adenine-induced chronic kidney disease (CKD) (Schiavi et al., 2012; Sabbagh and Schiavi, 2014; Ohi et al., 2011). Furthermore, chronic adaptation to a low-phosphate diet in wild-type mice appears to go along with upregulation of *Npt2b* in the duodenum and upregulation of *Npt2a* in the proximal tubules (Giral et al., 2009). However, chronic adaptation in $Npt2b^{+/-}$ (Ohi et al., 2011), conditional $Npt2a^{-/-}$ mice (Schiavi et al., 2012), and, in our experience, $Npt2a^{-/-}$ mice (Pesta et al., 2016) suggests additional transport mechanisms.

Renal phosphate transport

Three classes of sodium/phosphate cotransporters are expressed in the kidney: the type I cotransporter, NPT1 (*SLC17A1*); the type II cotransporters, NPT2a (*SLC34A1*) and NPT2c (*SLC34A3*); and the type III cotransporter PIT2 (*SLC20A2*). Reabsorption of phosphate from the urine in the renal proximal tubules via NPT2a and NPT2c plays a key role in maintaining phosphate homeostasis, while other tubule segments are believed to be of less importance, and there are no known excretory mechanisms for phosphate. The NPT2a and NPT2c transporters preferentially transport divalent phosphate (HPO_4^{2-}) (Biber et al., 2013). Immunohistochemical analysis shows the localization of NPT2a to the apical membrane of renal proximal tubule cells (S1−S3 segments of the proximal tubule) in rodents (Murer et al., 2000, 2004; Berndt et al., 2005). Conversely, NPT2c in rodents appears to be expressed along with PIT2 only in segment 1 of the proximal tubules (Wagner et al., 2017). The NPT2c transporter, which shares approximately 54% amino acid identity with NPT2a, is not electrogenic and mediates cotransport at a ratio of 2 Na^+/1 HPO_4^{2-}. Renal expression of NPT2c in human kidneys was found to resemble the distribution seen in mice (Ohkido et al., 2007) and the response of these individuals to oral phosphorus therapy based on cross-sectional evaluation appears to resemble that described in Npt2a-KO and Npt2a;Npt2c-double-KO (DKO) mice.

Constitutive mouse KO models of Npt2a and Npt2c suggest that Npt2a mediates the bulk of renal reabsorption of phosphate, whereas the contribution of Npt2c to this process is minor and probably restricted to young mice (Miyamoto et al., 2007; Murer et al., 2000, 2004; Berndt et al., 2005; Segawa et al., 2009). Furthermore, rickets or osteomalacia is absent in both mouse models. However, Npt2a;Npt2c DKO suggest that both transporters have nonredundant roles, since these mice exhibit reduced body weight and expansion of the late hypertrophic zone in the bone, which is a characteristic feature of rickets, along with severe hypophosphatemia, hypercalciuria, and renal calcification, which can be reversed by a high-phosphorus diet (Segawa et al., 2009; Tomoe et al., 2009). In contrast to Npt2c-KO mice, humans with homozygous or compound-heterozygous loss-of-function mutations in NPT2c develop hypophosphatemic rickets in the first decade of life. These observations suggest that there may be important differences in renal phosphate handling between mice and humans.

FGF23 reduces reabsorption of phosphate by reducing expression of NPT2a and NPT2c (Yan et al., 2005). FGF23 binds to FGFR1c and its coreceptor klotho (Urakawa et al., 2006; Kuro-o, 2006) with activation of ERK1/2 at the distal convoluted tubules (Farrow et al., 2009). Alternatively, FGF23 may bind to FGFRs in the proximal tubule, leading to phosphorylation of NHERF1 via Sgk1 (Andrukhova et al., 2012). Also, a direct regulation of NPT2a activity by klotho without FGF23 has been demonstrated, whereby klotho causes cleavage and inactivation of NPT2a in the brush border membrane and subsequent internalization (Hu et al., 2010). Internalization of NPT2a from the apical membrane occurs as with receptor-mediated endocytosis (Bacic et al., 2006; Bachmann et al., 2004). Consequently, NPT2a is routed to lysosomes for degradation (Keusch et al., 1998; Pfister et al., 1998; Inoue et al., 2004). The regulation of NPT2c has been studied in less detail: in response to high phosphate, NPT2c downregulation occurs but is slower than for NPT2a (Miyamoto et al., 2007; Picard et al., 2010). Proximal TRP, to a lesser extent, is regulated by insulin, hormones of the somatotropic pituitary axis (Bringhurst and Leder, 2006), FGF7 (Carpenter et al., 2005), and possibly matrix extracellular phosphoglycoprotein (MEPE) and secreted Frizzled-related protein 4 (sFRP4) (White et al., 2006). The signaling mechanisms whereby insulin, growth hormone/IGF-1, FGF7, MEPE, and sFRP4 regulate NPT2a and NPT2c are unknown. The original description of Npt2c suggests that this transporter is exclusively expressed in mouse and rat kidney (Segawa et al., 2002). However, public RNA-sequencing expression databases (GTEx Consortium, 2013) and a qRT-PCR tissue expression analysis (Nishimura and Naito, 2008) suggest low-level expression of NPT2c in many tissues. Furthermore, data from a kidney-specific and inducible Npt2c-deficient mouse Npt2c (CKO) model (Myakala et al., 2014) suggest a role of extrarenal Npt2c in calcium homeostasis. However, the significance of widespread expression of Npt2c outside of the kidneys for human phosphorus and calcium metabolism requires further investigation.

Ubiquitous metabolic phosphate transporters

The PIT transporters serve as "housekeeping" transporters in most tissues (Kavanaugh and Kabat, 1996). Furthermore phosphate activates ERK1/2 in most cell types, and is blocked by pharmacological or genetic ablation of type III transporters (Wittrant et al., 2009). Since PIT1 is able to compensate for the loss of PIT2, intracellular phosphate may be what is "sensed" to activate ERK1/2. However, PIT transporters also bind and signal extracellular phosphate independent of phosphate transport, as shown in HeLa and vascular smooth muscle cells expressing a transporter-deficient mutation, [E70K]PIT1 (Chavkin et al., 2015; Beck et al., 2009). Furthermore, functional cooperation between PIT1 and FGFR1 appears to exist based on in vitro (Yamazaki et al., 2010) and in vivo (Xiao et al., 2014) reports. In addition to ERK1/2, the yeast second messenger inositol heptakisphosphate (IP7) (Azevedo and Saiardi, 2017; Saiardi, 2012) was found to be synthesized by inositol hexakisphosphate kinase 2 in various human cell lines, including HCT116 (colon) and U2OS (bone) cells (Koldobskiy et al., 2010). Furthermore, the highly conserved IP7 binding domain SPX is found in the xenotropic retroviral receptor 1 (XPR1) (Wild et al., 2016). Loss of function of XPR1 causes renal Fanconi syndrome in mice (Ansermet et al., 2017) and primary familial brain calcification (PFBC) in humans (Azevedo and Saiardi, 2017). These findings suggest a role for ERK1/2 and IP7 in metabolic phosphate effects, although details as to the mechanism and whether these second messengers regulate PTH, FGF23, or $1,25(OH)_2D$ remain unknown (Chande and Bergwitz, 2018).

As noted earlier intracellular phosphate may be sequestered into subcellular compartments. PIT1 can localize to the endoplasmic reticulum (ER) and contribute to regulation of ER stress in growth plate chondrocytes (Couasnay et al., 2019). The mitochondrial phosphate carrier PIC (SLC25A3) is part of a multiprotein complex, the mitochondrial permeability transition pore (MPTP), which regulates mitochondrial membrane potential and mitochondrial apoptosis (Pauleau et al., 2008), as well as being important in skeletal and cardiac muscle function (Seifert et al., 2015). The related dicarboxylate carrier (SLC25A10) (Fiermonte et al., 1999) catalyzes transport of dicarboxylates such as malate and succinate across the mitochondrial membrane in exchange for phosphate, sulfate, and thiosulfate.

Surprisingly mild bone and mineral metabolism phenotypes of the individual Pit1- and Pit2-KO mice suggest a high degree of redundance of these generally coexpressed transporters, and bone-selective ablation of Pit1 and Pit2 individually and in combination will likely shed a better light on their metabolic and endocrine functions. For example, acute chondrocyte-specific deletion of Pit1 in mice using a tamoxifen-inducible annexin-Cre in the first 2 days postnatally results in pronounced cell death, possibly as a result of phosphate-transport-independent ER stress (Couasnay et al., 2019), which in hindsight is consistent with earlier reported mildly reduced femur length in Pit1 hypomorphic mice (Bourgine et al., 2013) and the MV mineral defect observed in *collagen2a1*-Cre in Pit1;PHOSPHO1-DKO mice (Yadav et al., 2016).

Primary disorders of phosphate homeostasis

Fibroblast growth factor 23–mediated hypophosphatemic disorders

X-linked hypophosphatemia (OMIM: 307800)

In 1936, Fuller Albright reported a case of rickets unresponsive to vitamin D treatment, and thus termed the condition "vitamin D-resistant rickets "(Albright et al., 1936). In the late 1950s the cardinal feature of renal phosphate wasting, together with an X-linked dominant inheritance pattern, was recognized (Hsia et al., 1959). Subsequent studies in the *Hyp* mouse, a murine model of XLH, demonstrated defective renal tubular phosphate transport (Glorieux and Scriver, 1972; Bell et al., 1988), and decreased expression of renal sodium/phosphate cotransporters in the renal tubules (Tenenhouse et al., 1994; Collins and Ghishan, 1994). In 1974 the observation of persistent hypophosphatemia following renal transplantation in a man with classical XLH raised the consideration that the disease was due to a humoral factor rather than an intrinsic renal defect (Morgan et al., 1974). This concept was substantiated by Meyer and Meyer, who demonstrated that a normal mouse joined in parabiosis to a *Hyp* mouse became hypophosphatemic (Meyer Jr. et al., 1989).

In 1995, loss-of-function mutations in PHEX, a neutral endopeptidase, were shown to be responsible for XLH (HYP-Consortium, 1995). In 2000/2001, a circulating factor responsible for tumor-induced osteomalacia (TIO) and autosomal dominant hypophosphatemic rickets (ADHR) was identified as FGF23, a novel member of the FGF family (ADHR Consortium T, 2000; Shimada et al., 2001). It was quickly realized that FGF23 was overproduced in XLH, establishing that disorder as a classic endocrine syndrome due to overproduction of a hormone (Jonsson et al., 2003; Yamazaki et al., 2002). In XLH, FGF23 is overproduced by osteocytes (Feng et al., 2006), where PHEX is primarily expressed, but how PHEX regulates the production of FGF23 remains unclear.

Pathophysiology

FGF23 directs the kidney to excrete phosphate upon exposure to an excessive phosphate load. Its production is stimulated by increases in extracellular phosphate (and also by $1,25(OH)_2D$) but this axis is perturbed in XLH, such that FGF23 is overproduced, despite the ambient hypophosphatemia. Consequent suppression of transcription of the renal sodium/phosphate cotransporters NPT2a and NPT2c (Shimada et al., 2004b, 2004a; Erben, 2016), as well as their removal from the apical surface of the proximal renal tubule cell (Murali et al., 2016), results in reduced phosphate reclamation. FGF23 also decreases circulating $1,25(OH)_2D$, resulting in impaired intestinal calcium and phosphate absorption.

Abnormal metabolism of bone-derived extracellular matrix proteins may also contribute to the pathophysiology of XLH. Substrates for PHEX may include SIBLING proteins (osteopontin, bone sialoprotein, DMP1, dentin sialophosphoprotein, and MEPE). In vitro evidence suggests that these proteins can be metabolized by PHEX, and in the absence of normal metabolism, protein fragments—ASARM peptides—accumulate, resulting in inhibition of bone mineralization in vitro and renal phosphate wasting in vivo (David et al., 2011; Barros et al., 2013; Addison et al., 2010). Moreover, work has identified increased osteopontin in the osteomalacic osteoid of Hyp mice, and less extensive osteomalacia in the osteopontin null/Hyp (DKO mouse) compared with Hyp littermates (Hoac et al., 2018).

Prevalence

The exact prevalence of XLH is estimated as between 1 in 20,000 live births (United States and Denmark) and 1 in 60,000 (Norway) (Ruppe; Beck-Nielsen et al., 2009; Rafaelsen et al., 2016). As many as 25% of cases appear to be sporadic (Beck-Nielsen et al., 2012; Whyte et al., 1996).

Clinical manifestations

XLH causes rickets in children manifest as bowed lower extremities, short stature, and radiographically abnormal epiphyses. Both children and adults with XLH suffer from the early appearance and persistent recurrence of dental abscesses. These are associated with structural abnormalities in the tooth, including abnormal mineralization of dentin, less abundant cementum, impaired tooth attachment, and increased risk of periodontal disease (Antoniucci et al., 2006; Coyac, 2017). Pulp chambers appear to be enlarged while enamel is largely unaffected (Turan et al., 2010). How these changes relate to the pathogenesis of dental abscesses is not clear. Tooth fragility is often also reported by patients, including fracturing of teeth with normal mastication. Finally, craniosynostosis with associated Chiari malformations are not infrequent occurrences in XLH (Rothenbuhler et al., 2018).

Skeletal disease in XLH was once thought to quiesce following epiphyseal closure, but in fact, adults experience some of the worst complications of the disease. Nearly all affected adults have osteomalacia and poor bone quality leading to increased risks of clinical fracture and insufficiency fractures with little or no trauma, occurring most often in the lower extremities. Abnormal biomechanics (persisting from deformities acquired in childhood) contribute to the high incidence and early onset of osteoarthritis. Osteophytes and calcification of tendons and ligaments at insertion sites (entheses) occur, and can severely limit of range of motion, particularly of the hips, elbows, and shoulders (Liang et al., 2009; Connor et al., 2015). Degenerative changes in the spine may lead to restricted range of motion and chronic low back pain. Calcification of the spinal longitudinal ligaments can occur (Hirao et al., 2016; Forrest et al., 2016; Shiba et al., 2015), as well as spinal stenosis, result in neurologic deficits requiring surgical intervention (Chesher et al., 2018). Scoliosis is common, and hearing loss occurs (Fishman et al., 2004).

Both children and adults with XLH complain of weakness and diminished endurance, which may in part relate to impaired muscle function. Indeed, hypophosphatemia is associated with impaired ATP flux in skeletal muscle, which improves with correction of the hypophosphatemia (Pesta et al., 2016).

Therapy

Medical treatment for XLH historically included phosphate supplements with vitamin D used as a cotherapy. Limited efficacy, secondary hyperparathyroidism, and vitamin D intoxication were not infrequent. In 1980, Glorieux et al. published a landmark study comparing phosphate alone with combined therapy with ergocalciferol and phosphate and with calcitriol and phosphate (Glorieux et al., 1980). Histomorphometric improvement in osteomalacia with calcitriol and phosphate was superior to that of the other two regimens, serum phosphorus levels were improved to a greater extent, and radiographic healing of rickets was superior as well. This work led to a fundamental change in the treatment for XLH, and until 2018, calcitriol and phosphate therapy was the standard medical treatment for children. The therapy, however, does require careful monitoring to avoid hypercalcemia, hypercalciuria, and secondary hyperparathyroidism. Frequent dose adjustments are required as the skeleton grows, necessitating careful monitoring, usually every 3–6 months during rapid

growth (Carpenter et al., 2011). Adherence is particularly difficult, as multiple doses of phosphate and two doses of calcitriol daily are usually employed. Phosphate supplementation has frequent gastrointestinal side effects, such as nausea and diarrhea, which further complicate compliance. With good adherence and careful monitoring, and when initiated early in life (i.e., less than 2 years of age), linear growth is improved, and there are fewer rachitic deformities.

Despite these effects, *surgical treatment* is often additionally required in XLH. Correction of genu valgus or genu varum of the lower extremities has traditionally required osteotomies and rodding of the long bones of the lower extremities (Eyres et al., 1993). More recently, when identified early in childhood, and when the bowing deformities are mild−moderate, epiphysiodesis can be used as a less invasive approach to guide growth at the distal femur or tibial growth plates (Ghanem et al., 2011). Children with cranial stenosis sometimes have severe headaches that require surgical treatment.

Growth hormone has been used as an adjunct to standard therapy in children with XLH, with mixed results. Some studies suggest improved linear growth, while others report little long-term benefit and potential worsening of disproportion between upper and lower body segments (Baroncelli et al., 2001; Haffner et al., 2004; Zivicnjak et al., 2011).

In contrast, therapy for adults has remained less widely employed; however, calcitriol and phosphate have been shown to have efficacy in adults: calcitriol and phosphate led to a 50% healing in osteomalacia (over 4 years) and a subjective improvement in pain in an open-label trial (Sullivan et al., 1992). In that study the daily dose of calcitriol and phosphorous ranged between 1.0 and 2.0 μg/day and 1.0 and 1.5 g/day, respectively. Other cross-sectional studies have demonstrated that therapy with calcitriol and phosphate during adult life is associated with less severe dental disease (Connor et al., 2015).

Conventional therapy does prevent enthesopathy, or hearing loss. Even when initiated early in childhood the therapy does not result in a normal adult height. Male sex and obesity portend worse enthesopathy and, importantly, in a cross-sectional study, persistent secondary hyperparathyroidism tended to be associated with worse enthesopathy (Connor et al., 2015). The latter point is highlighted by a study in which paricalcitol was used to suppress PTH in patients with XLH and secondary hyperparathyroidism (Carpenter et al., 2014). Despite the expected rise in FGF23 when paricalcitol was added to conventional therapy, the renal phosphate threshold improved, and bone-specific alkaline phosphatase fell. These data suggest that PTH contributes to the renal pathophysiology in XLH and is a major driver of skeletal turnover. Whether an increase in skeletal turnover contributes to enthesopathy remains unclear, and requires further study.

In 2018, a fully humanized monoclonal blocking antibody to FGF23, burosumab, was approved for treatment of XLH in children and adults in the United States and Canada and in children in the European Union. The drug binds to FGF23, and thereby inhibits the activity of the elevated circulating levels, essentially reversing the major pathophysiologic element of the disease. Renal phosphate reclamation improves and $1,25(OH)_2D$ production is restored, limiting the tendency for PTH oversecretion. In open-label clinical trials in 5- to 12-year-old children (90% of whom were treated with conventional therapy for ~7 years) the serum phosphorus levels corrected and were maintained in the low normal range in more than 90% of the study subjects (Wolfgang et al., 2018), with accompanying improvements in rickets (Carpenter et al., 2018). More recently, in a head-to-head comparison with conventional therapy, burosumab administered every 2 weeks showed more impressive improvements in serum phosphorus, alkaline phosphatase, and radiographic healing of rickets (Imel et al., 2018). Complications in children have been thus far limited to local injection site reactions and rare occurrences of urticaria. In adults, a double-blind, placebo-controlled, 24-week trial showed that monthly administration of burosumab (1 mg/kg) improved serum phosphorus and $1,25(OH)_2D$ levels, with over 90% of patients normalizing serum phosphorus at the dose cycle midpoint (2 weeks after dosing) (Insogna et al., 2018). Stiffness was significantly improved. Comprehensive imaging identified numerous extant fractures and pseudofractures at baseline; subjects treated with burosumab had a 17-fold greater likelihood of healing fractures and pseudofractures than those receiving placebo (Insogna et al., 2018). Preliminary data from a second year of treatment support continued efficacy of the drug in adults (Portale et al., 2018). Treatment of adults with burosumab demonstrated greater than 50% healing of osteomalacia (Insogna et al., 2018) after 1 year of therapy, comparable to that seen after 4½ years in the previously mentioned open-label trial of calcitriol and phosphate. The safety profile of burosumab was good, with restless leg syndrome and local injection site reactions being the only adverse events of note. Importantly, there has not been any evidence of development of nephrocalcinosis or worsening of existing nephrocalcinosis with burosumab, and no evidence for heterotopic cardiac calcification.

Early treatment of XLH in children has been advantageous, and conventional therapy has generally been applied by 6 months of age. It is recommended that treatment of affected children with burosumab be initiated as soon as possible after the first birthday until safety and dosing parameters in infants less than one year of age is established. It is unclear which children should discontinue currently applied conventional therapy and begin treatment with burosumab. Longer term follow-up may provide important guidance in that regard, but thus far, it appears that burosumab is likely to be safer, more convenient, and more effective than conventional therapy. Importantly, adherence is likely to be far better with the parenteral, less frequent dosing regimen. One barrier to the use of burosumab is its high expense, although the

manufacturer's program to assist patients while negotiating insurance coverage for the drug has been operational in many settings. In contrast to children, there is no consensus on indications for treatment of any kind for adults with XLH. Suggested indications for treating adults with conventional therapy have been published, although these are not strictly evidenced based and largely represent recommendations from a group of experienced clinicians (Carpenter et al., 2011). Nonetheless they could serve as initial indications for burosumab. They include (1) spontaneous insufficiency fractures, (2) pending orthopedic procedures, (3) biochemical evidence of significant osteomalacia (specifically a significantly elevated bone-specific alkaline phosphatase), and (4) disabling skeletal pain.

Autosomal dominant hypophosphatemic rickets (OMIM: 193100)

Although occurring with far less frequency, ADHR is a disorder with a clinical presentation essentially identical to that of XLH, but occurring in the setting of autosomal dominant inheritance. Patients with an XLH-like phenotype in families with male-to-male transmission should be suspected as having this disorder (Harrison and Harrison, 1979; Econs and McEnery, 1997). Like XLH, hypophosphatemia secondary to renal phosphate wasting occurs, with lower extremity deformities, and rickets/osteomalacia. Affected patients also demonstrate normal serum 25-OHD levels, with inappropriately normal serum concentrations of $1,25(OH)_2D$, all hallmarks of XLH (Table 20.1). PTH levels are normal. Long-term studies indicate that a few of the affected female patients demonstrate delayed penetrance of clinically apparent disease and an increased tendency to fracture, features that appear to be less common in XLH. In addition, among patients with the expected biochemical features documented in childhood, some patients, albeit rarely, have been reported to lose the renal phosphate wasting defect after puberty. Specific missense mutations in FGF23 that result in the substitution of an arginine residue at amino acid residue 176 or 179 are present in patients with ADHR (ADHR Consortium, 2000). These mutations disrupt an RXXR subtilisin/furin protease recognition site, and the resultant mutant molecule is thereby protected from proteolysis, and resultant accumulation of unprocessed FGF23 results in elevated circulating intact FGF23 levels.

Circulating FGF23 levels can vary and reflect the activity of disease status (Imel et al., 2007). Exploration of the waxing/waning severity of disease in ADHR has indicated that iron may play a significant role in the regulation of circulating FGF23 (Imel et al., 2011). It is now evident that iron deficiency is able to upregulate FGF23 expression, and in normal individuals the unrestricted processing of the intact protein to its inactive N- and C-terminal fragments is able to compensate for the increased intact FGF23 production observed in the setting of iron deficiency. Therefore normal individuals who become iron deficient maintain normal circulating levels of intact FGF23 despite an increase in production. However, in ADHR, inefficient processing of FGF23, due to the impaired recognition of the protease site, may not be able to compensate for increased FGF23 synthesis during periods of iron deficiency, resulting in elevated active FGF23 accumulation in the circulation with the subsequent renal effects on phosphate excretion. It appears that the waxing and waning clinical severity observed in some cases of ADHR may be amenable to iron supplementation and provide a straightforward approach to therapy. Correction of serum iron levels to high normal levels allowed for discontinuation of conventional rickets medications in one report (Kapelari et al., 2015).

Autosomal recessive hypophosphatemic rickets

Autosomal recessive hypophosphatemic rickets type 1 (ARHR1; OMIM: 241520). Another gene identified as causal to FGF23-mediated hypophosphatemia is *DMP1*, which encodes the SIBLING protein dentin matrix protein 1, yet another product of the osteocyte. Biallelic loss of function mutations in *DMP1* can result in autosomal recessive phosphate wasting rickets due to excess circulating FGF23 levels. The same constellation of progressive rachitic deformities seen in both XLH and ADHR (Feng et al., 2006; Lorenz-Depiereux et al., 2006a) occurs, along with the features of hypophosphatemia, excess urinary phosphate loss and aberrant vitamin D metabolism (normal circulating 25-OHD and $1,25(OH)_2D$ levels, despite ambient hypophosphatemia), observed in XLH and ADHR. In addition to the expected phenotypic features consequential to excess FGF23, and in contrast to XLH, spinal radiographs of patients with ARHR reveal noticeably sclerotic vertebral bodies and sclerosis of the skull. The clinical diagnosis of a novel sclerosing dysplasia in adulthood led to the investigation of the causes of osteopetrosis in one recently reported family, but genetic investigation revealed *DMP1* mutations (Gannage-Yared et al., 2014). Mild hypophosphatemia was present. In addition to the enlarged pulp chamber characteristic of teeth in individuals with XLH, enamel hypoplasia can be evident in heterozygotes. Experience with long-term follow-up is not widespread in ARHR and therapeutic response or guidelines have not been definitively established, although severe adult complications of disease such as enthesopathy have been documented (Gannage-Yared et al., 2014; Karaplis et al., 2012). One 2016 study in a *DMP1*-KO animal model of the disease found that an anti-sclerostin antibody improved osteomalacia with little effect on the serum phosphorus or FGF23 levels (Ren et al., 2016).

TABLE 20.1 Human genetic disorders of phosphate homeostasis.

Disorder	Abbreviation	Inheritance	Gene	Mechanism	OMIM No.	Reference
Hyperphosphatemic disorders						
Hyperphosphatemic familial tumoral calcinosis type 1 and the allelic variant Hyperostosis–hyperphosphatemia syndrome	HFTC HSS	AR AR	GALNT3	FGF23 deficiency	211900 610233	(Topaz et al., 2004; Frishberg et al., 2004)

Hyperphosphatemic familial tumoral calcinosis type 3	HFTC	AR	KL	FGF23 resistance	211900	Ichikawa et al. (2007)
Pseudohypoparathyroidism	PHP1A PHP1B	AD AD	GNAS GNAS or up-stream regulatory region	PTH resistance FGF23 independent	103580 603233	(Weinstein et al., 1992; Juppner et al., 1998)
Familial isolated hypoparathyroidism	FIH	AD or AR	CaR GCMB PTH	PTH deficiency; FGF23 independent	146200	(Arnold et al., 1990; Pollak et al., 1994; Ding et al., 2001)
Blomstrand disease	BOCD	AR	PTHR1	PTH resistance; FGF23 independent	215045	(Zhang et al., 1998; Karperien et al., 1999)
Hypophosphatemic disorders						
X-linked hypophosphatemia	XLH	X-linked	PHEX	FGF23 dependent	307800	HYP-Consortium (1995)
Autosomal dominant hypophosphatemic rickets	ADHR	AD	FGF23	FGF23 dependent	193100	ADHR Consortium T (2000)
Autosomal dominant hypophosphatemic rickets with hyperparathyroidism	ADHR	AD	KL	FGF23 dependent	612089	Brownstein et al. (2008).
Autosomal recessive hypophosphatemia	ARHP	AR	DMP1	FGF23 dependent	241520	Lorenz-Depiereux et al. (2006)
Hereditary hypophosphatemic rickets with hypercalciuria	HHRH	AR	SLC34A3	Proximal tubular Pi wasting, FGF23 independent	241530	(Bergwitz et al., 2006; Lorenz-Depiereux et al., 2006b)

Vitamin-resistant rickets type 1	VDDR1	AR	CYP27B1	$1,25(OH)_2D$ deficiency, FGF23 independent	264700	Kitanaka et al. (1998)
Vitamin-resistant rickets type 2	VDDR2	AR	VDR	$1,25(OH)_2D$ resistance, FGF23 independent	277440	Hughes et al. (1988)
Familial hypocalciuric hypercalcemia/ neonatal severe hyperparathyroidism	FHH NSHPT	AD/AR	CaR	PTH excess, FGF23 independent	145980 239200	Pollak et al. (1993)
Jansen disease		AD	PTHR1	Constitutively active PTHR1; FGF23 dependent	156400	(Schipani et al., 1995), (Brown et al., 2009)
Normophosphatemic disorders						
Pulmonary alveolar microlithiasis	PAM	AR	SLC34A2	Reduced alveolar epithelial Pi uptake	265100	Sabbagh et al. (2009)
Normophosphatemic familial tumoral calcinosis	NFTC	AR	SAMD9	Unknown	610455	Topaz et al. (2006)
Muscular dystrophy and cardiomyopathy	MDC	AR	SLC25A3	Reduced mitochondrial Pi uptake	610773	(Bhoj et al., 2015; Mayr et al., 2011)
Primary familial basal ganglial calcification type 1	PFBC1	AR	PIT2	Reduced microglial Pi uptake	213600	Lemos et al. (2015)
Primary familial basal ganglial calcification type 6	PFBC6	AR	XPR1	Reduced vascular Pi export	616413	Legati et al. (2015)
Primary familial basal ganglial calcification type 3	PFBC4	AR	PDGFBR	Reduced PIT2 expression	615007	Keller et al. (2013)
Primary familial basal ganglial calcification type 4	PFBC5	AR	PDGFB	Reduced PIT2 expression	615483	Keller et al. (2013)

$1,25(OH)_2D$, 1,25-dihydroxyvitamin D; *AD*, autosomal dominant; *AR*, autosomal recessive; *FGF23*, fibroblast growth factor 23; *Pi*, phosphate; *PIT2*, solute carrier family 20 (type III) sodium/phosphate cotransporter 2; *PTH*, parathyroid hormone.

ARHR2 (OMIM: 613312). Another rare variant of hypophosphatemic rickets with renal phosphate wasting, ARHR2, occurs in association with GACI (Levy-Litan et al., 2010; Lorenz-Depiereux et al., 2010; Rutsch et al., 2003). ARHR2 and GACI are attributed to homozygous loss-of-function mutations of ENPP1. Loss of function of ENPP1 results in the inability to generate the mineralization inhibitor PPi, thereby disrupting the restriction of heterotopic (e.g., vascular) mineralization. GACI is often fatal, but hypophosphatemia, identified in the setting of elevated FGF23 levels in an adult with a homozygous ENPP1 mutation, raised this consideration of rickets in survivors of GACI (Lorenz-Depiereux et al., 2010). Moreover the patient's son was affected with both GACI and hypophosphatemia. The mechanism by which this enzyme influences renal tubular phosphate wasting is not evident, and further study is necessary to understand this intriguing problem. One speculated mechanism may reflect a bone cell response to a relatively hypermineralized (or high phosphate/low PPi) milieu, which results in a compensatory, prolonged secretion of FGF23. Such a mechanism may effectively signal the kidney to reduce the body's mineral load, but apparently cannot be downregulated to protect against excessive phosphate losses. Although there has been concern that the treatment of rickets in patients affected with GACI may promote worsening of vascular calcification (Rutsch et al., 2008), no evidence to sustain this concern has emerged, and one long-term observational report suggests that treatment does not worsen this finding (Ferreira et al., 2016).

Tumor-induced osteomalacia

TIO is a rare paraneoplastic syndrome caused by difficult-to-localize, usually benign tumors that secrete a circulating factor causing renal phosphate wasting. Many of the biochemical features of TIO mimic those seen in XLH, as the secreted factor in most tumors is FGF23, as occurs with XLH. TIO has been reviewed in detail and the reader is referred to that summary for additional details (Chong et al., 2011).

The differential diagnosis of TIO includes other FGF-dependent phosphate wasting disorders, which are often genetic in origin, such that a family history and documentation of time of onset of disease are useful in differentiating these conditions from TIO. Genetic testing may be useful. Among the most important clinical findings in TIO is profound weakness. Despite equivalent degrees of fasting hypophosphatemia, and often a similar extent of histologic osteomalacia, patients with lifelong hypophosphatemia, as in XLH, seem to function much better than patients with TIO, who usually acquire hypophosphatemia later in life. Patients with TIO are not infrequently crippled by their disease, with severe skeletal pain and obvious muscle weakness, manifested by difficulty with ambulation or rising from the floor or chair. Bone pain in TIO is due to the osteomalacia and resulting pseudofractures, which result from chronic phosphate wasting. Fractures occur most often in ribs and in weight-bearing bones such the spine and pelvis, femurs (included the femoral neck), and feet. The muscle weakness is presumably due to a hypophosphatemic myopathy. Correction of the hypophosphatemia often results in improvement in muscle function considerably before healing of the osteomalacia. Since the correct diagnosis is often missed for years, patients with TIO frequently suffer with poor quality of life for extended periods of time (Sanders, 2018).

TIO-causing tumors, categorized as phosphaturic mesenchymal tumors—mixed connective tissue variant (PMTs—MCT) (Folpe et al., 2004), have a varied histologic appearance, frequently with bland, spindle-shaped cells in a myxoid matrix and occasionally osteoclast-like giant cells. A microvascular component is often present. PMTs—MCT can occur in any tissue but frequently arise in soft tissues such as muscle or fat or in skeletal tissues, including bone, cartilage, and tendons. Rarely, tumors other than PMTs—MCT can cause TIO, including myeloma and prostate cancer (Narvaez et al., 2005; Nakahama et al., 1995).

As with XLH, hypophosphatemia occurs with renal phosphate wasting, circulating $1,25(OH)_2D$ levels are low, and 25-OHD levels are normal or low normal, excluding vitamin D deficiency as the cause of the patient's symptoms. PTH levels are usually normal, as is serum calcium. If the clinical index of suspicion is high and biochemical features are consistent, then measuring circulating FGF23 is an appropriate confirmatory study. Rarely, other circulating factors have been associated with TIO, including FGF7, FRP4, and MEPE (Carpenter et al., 2005; Chong et al., 2011; Jan de Beur et al., 2002). Interestingly, nearly 40% of TIO tumors have a chromosome rearrangement resulting in expression of a fusion protein in which a fibronectin molecule is fused with the FGFR1 (Lee et al., 2015). Although no direct experimental evidence has yet been reported, it has been speculated that TIO results, in part, from a feed-forward circuit in which tumor-secreted FGF23 activates this hybrid molecule and induces further FGF23 production.

Localizing the offending tumor can be challenging. A careful physical examination, focused on the head, neck, and oral pharynx, with palpation all soft tissues, can sometimes identify a PMT—MCT. Newer imaging technologies have greatly improved tumor localization. Among these is indium-111-labeled octreotide scintigraphy combined with single-photon-emission computed tomography (SPECT/CT) scanning, which allows for 3D visualization as well as taking advantage of the fact that TIO tumors often express somatostatin receptor subtype 2. Fluorodeoxyglucose positron emission tomography (FDG—PET)/CT is increasingly used to localized tumors in patients with TIO, particularly those that are not octreotide

avid or are very small. The extreme sensitivity of FDG−PET/CT, however, can lead to false positive results. 1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) (and its derivatives DOTANOC and DOTATATE) PET/CT addresses the "nonspecificity" of conventional FDG−PET/CT by employing a bifunctional chelator that binds gallium and the type 2 somatostatin receptor with high affinity (DOTA NaI^3-octreotide) (Wild et al., 2005; Hesse et al., 2007a; El-Maouche et al., 2016). Reports indicate that this approach may be more sensitive than conventional octreotide SPECT/CT (von Falck et al., 2008). Since the cranial/facial area, as well as distal extremities, can harbor TIO-inducing tumors, it is important to include the entire body in these scan images. In the past, venous sampling has been used in an effort to identify tumors, but the aforementioned imaging studies have largely supplanted the need for that more invasive diagnostic approach.

Effective treatment for TIO is complete surgical resection of the tumor when possible. Generally, these tumors are benign and slow growing with a low mitotic index. Occasionally TIO tumors can arise in a surgically inaccessible site or can be locally invasive, making complete resection impossible. We encountered such a patient, with a cervical vertebral tumor and extensive involvement of paraspinal soft tissues. Rarely TIO tumors can be frankly malignant and metastasize. In patients in whom the tumor cannot be completely resected or identified, medical management can provide significant symptomatic improvement. At this writing, treatment with calcitriol and supplemental phosphorus represents the best medical therapy for TIO. Conventional doses of calcitriol and phosphorus, in the range of 1−3 μg/day calcitriol and 1−3 g/day phosphorus in divided doses, are usually effective. Unlike in XLH, secondary hyperparathyroidism is less often encountered in TIO when using calcitriol/phosphorus, but hypercalciuria and even hypercalcemia can occur, so blood and urine calcium, in addition to serum phosphorus, needs to be monitored during treatment to avoid overreplacement. Unlike in XLH, where FGF23 levels are usually modestly elevated, in TIO FGF23 levels are also often very elevated, despite which conventional therapy seems to provide symptomatic improvement.

The use of a blocking antibody to FGF23 (burosumab) has shown promising results in the treatment of TIO. In an open-label trial, patients with TIO had significant improvement in their hypophosphatemia and marked symptomatic improvement with monthly administration of the drug at doses up to 1 mg/kg (Jan de Beur et al., 2018). A selective FGFR inhibitor (NVP-BGJ398) has, in preliminary studies, been reported to cause dramatic symptomatic improvement in a patient with metastatic TIO. In this patient the drug also caused tumor regression (Collins et al., 2015). Finally, radiofrequency ablation has been used to treat TIO tumors where a non-invasive approach was preferred (Hesse et al., 2007b).

Other FGF23-mediated hypophosphatemic syndromes

In widespread fibrous dysplasia of bone (due to mosaic-activating mutations in GNAS, as part of the McCune−Albright syndrome) (OMIM: 174800), hypophosphatemic osteomalacia/rickets can be a result of elevated circulating FGF23 levels. Indeed, variable degrees of decreased renal tubular phosphate reabsorption, as assessed by tubular maximum reabsorption of phosphate/glomerular filtration rate (TmP/GFR), occur in patients with fibrous dysplasia of bone. Of note, given that activation of GNAS in the renal proximal tubule would be expected to result in phosphaturia, it had long been considered that the mechanism of reduced renal TRP was due to a surmised renal distribution of the mosaic-activating GNAS mutation. The studies of Rimunucci et al. identified elevated circulating FGF23 levels in this condition and that the greater burden of skeletal disease is associated with more impressive hypophosphatemia. Whether the bone affected with fibrous dysplasia or normal bone under other systemic influences accounts for the increased FGF23 secretion has not been clearly settled.

Somatic mutations in HRAS and NRAS appear to generate a mechanism by which mutated skin or bone can increase secretion of FGF23, a condition known as epidermal nevus syndrome (OMIM: 162900), or more recently cutaneous skeletal hypophosphatemia syndrome (Lim et al., 2014; Ovejero et al., 2016).

Other primary skeletal disorders in which elevated FGF23 levels have been reported include osteoglophonic dysplasia (due to mutations in FGFR1) (OMIM: 166250) (White et al., 2005), Jansen metaphyseal chondrodysplasia (due to activating mutations of the PTH1 receptor) (OMIM: 156400) (Brown et al., 2009), neurofibromatosis (OMIM: 162200), and FAM20C mutations (e.g., Raine syndrome, OMIM: 259775) (Rafaelsen et al., 2013). This condition has also been referred to as autosomal recessive hypophosphatemic rickets type 3 (ARHR3). The mechanism(s) by which elevations in FGF23 occur in these settings is not certain at this time. There is evidence to support the finding that FAM20C alters phosphorylation of FGF23, thereby affecting O-glycosylation and allowing for diminished degradation (Tagliabracci et al., 2014). Alternatively, data have shown direct increases in FGF23 secretion with loss of function of FAM20C (Liu et al., 2018). Likewise, loss of function of Nuclear Factor 1 may play a role in the skeletal disease seen in neurofibromatosis by increasing FGF23 production (Kamiya et al., 2017).

Fibroblast growth factor 23–independent hypophosphatemic disorders

Hereditary hypophosphatemic rickets with hypercalciuria (OMIM: 241530)

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is a rare autosomal recessive disorder first described in 1985 in a large consanguineous Bedouin kindred (Tieder et al., 1985). HHRH is distinct from the more common XLH (HYP-Consortium, 1995; Holm et al., 1997) with respect to mode of inheritance, and distinct biochemical features associated with increased synthesis and serum levels of $1,25(OH)_2D$, particularly hypercalciuria (Tieder et al., 1985, 1987; Gazit et al., 1991).

Epidemiology

HHRH has been described in all races, although most reports describe cases of Caucasian and Middle Eastern origin. More than 40 different mutations in *SLC34A3* affecting over 35 kindreds have been reported (Rafaelsen et al., 2016; Daga et al., 2018; Pronicka et al., 2017; Schlingmann et al., 2016; Dhir et al., 2017; Dasgupta et al., 2014; Chi et al., 2014; Ichikawa et al., 2014). Based on the allele frequency of 0.002 for proven pathogenic *SLC34A3* mutations, HHRH has a predicted prevalence of 1:250,000 (Wagner et al., 2017), although the true prevalence is not known. Therefore, HHRH is approximately 10-fold less frequent than the most common inherited disorder of phosphate homeostasis, XLH (1:20,000; Burnett et al., 1964). The predicted prevalence of idiopathic hypercalciuria associated with heterozygous mutation of *SLC34A* is 1:500.

Cloning and identification of human mutations in NPT2c

The genetic defect in HHRH was identified in a combined genome-wide search for linkage and homozygosity mapping using genomic DNA from the original Bedouin kindred (Tieder et al., 1985, 1987). A homozygous deletion SLC34A3.c.228delC was found in all affected individuals, which is predicted to result in complete loss of function of NPT2c (Bergwitz et al., 2006). Different genetic mutations in the same gene were subsequently reported (Rafaelsen et al., 2016; Daga et al., 2018; Pronicka et al., 2017; Schlingmann et al., 2016; Dhir et al., 2017; Dasgupta et al., 2014; Ichikawa et al., 2014; Bhoj et al., 2015) and include missense mutations, mutations affecting potential splice sites, and smaller and larger deletions causing premature stop codons with expression of a truncated transporter protein (Fig. 20.4). Some of these mutations have been functionally characterized in vitro using opossum kidney cells and *Xenopus* oocyte expression systems (Haito-Sugino et al., 2012; Shiozaki et al., 2015; Jaureguiberry et al., 2008).

Pathophysiology

The consequence for human carriers of *SLC34A3*/NPT2c loss-of-function mutations on one or two alleles is isolated proximal tubular phosphate wasting. Renal Fanconi syndrome has not been described for carriers of *SLC34A3*/NPT2c mutations, as occurs with *SLC34A1*/NPT2a mutations. To date no genotype–phenotype correlation has been described, and there is no evidence for dominant negative effects of mutant transporters. Of interest would also be to determine whether loss of NPT2c has consequences for other proximal tubular functions such as CYP24A1 activity, sodium excretion, urine anion gap, and osteopontin and PPi levels (Tenenhouse et al., 2001; Caballero et al., 2017a,b; Li et al., 2017), all of which, together with the characteristic hypercalciuria, may contribute to formation of renal mineral deposits in HHRH and idiopathic hypercalciuria (IH). Haploinsufficiency of NPT2c can cause mild hypophosphatemia, reduced TmP/GFR, and elevations in $1,25(OH)_2D$ and/or urinary calcium excretion (Tieder et al., 1985, 1987; Bergwitz et al., 2006), but, with the exception of one report (Yamamoto et al., 2007), does not generally cause bone disease.

Clinical presentation and diagnostic evaluation

Laboratory findings and genetic testing The clinical assessment of phosphate homeostasis can be challenging: serum phosphorus concentrations are influenced by the time of day, meals, and age. Clinical methods for determination of tubular reabsorption are imprecise. To determine the cause of abnormal serum phosphorus levels in a patient with normal parathyroid and renal function, we first assess TRP (Fig. 20.5) based on the measurement of phosphorus and creatinine in a 2- to 3-h urine collection along with the corresponding serum parameters. TRP, TmP/GFR (Walton and Bijvoet, 1975), or TP/GFR, which provides a more accurate assessment of renal phosphate handling in children (Alon and Hellerstein, 1994), is then calculated. Inappropriately low %TRP in the setting of hypophosphatemia is suggestive of a proximal renal tubular defect. With respect to HHRH, further confirmation can be aided by measurement of circulating $1,25(OH)_2D$ levels. The combined reduction in both TRP and $1,25(OH)_2D$ levels suggests excess FGF23 action, whereas elevated $1,25(OH)_2D$

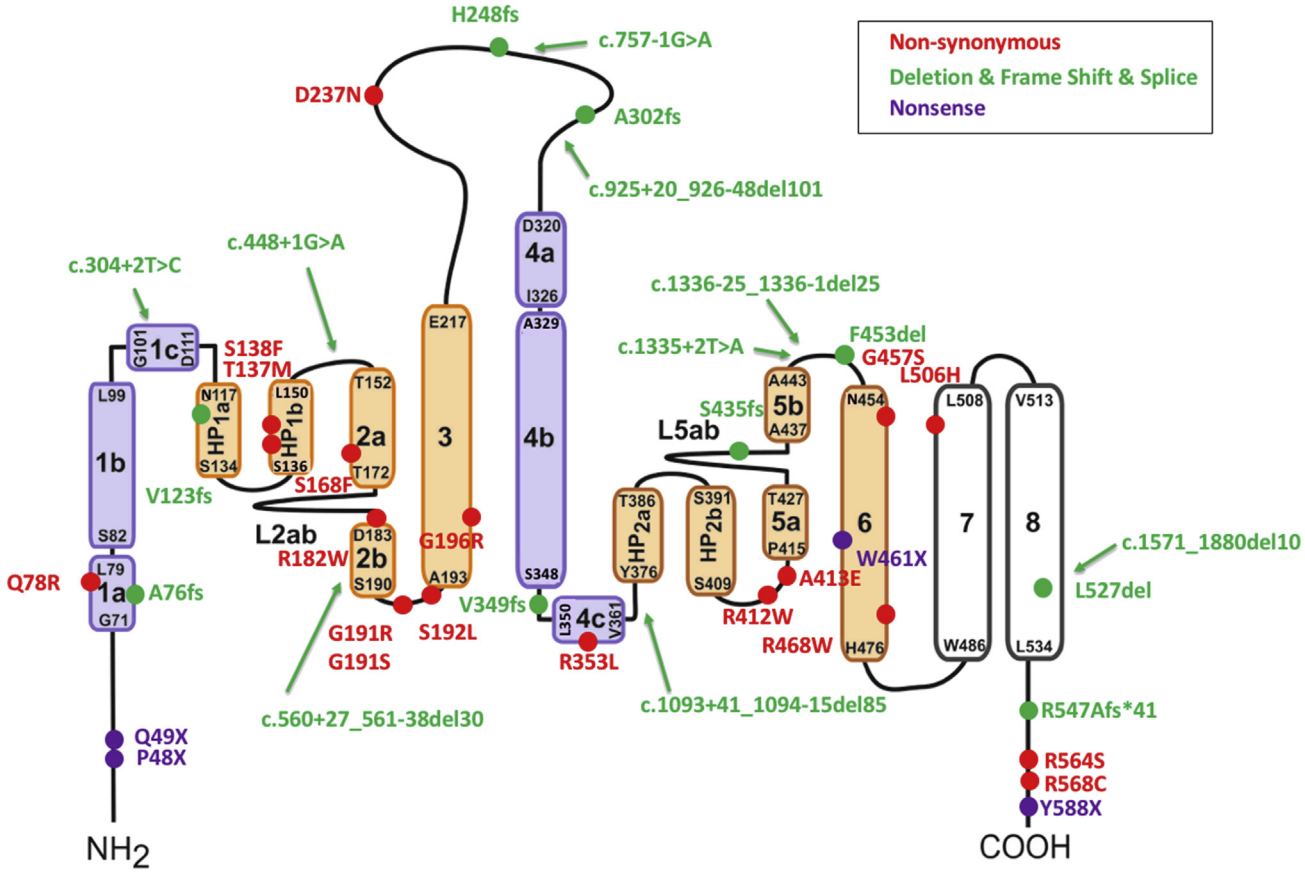

FIGURE 20.4 Reported human mutations in NPT2c. Predicted models of *SLC34A3*/NPT2c (Wagner et al., 2017) and localization of mutations identified in patients. (*Red*, missense mutations; *green*, frameshift, deletion, and splice-site mutations; *purple*, nonsense mutations). The scaffold domain is represented in lavender and the transport domain in orange as in. (Forster and Wagner, 2018; Bergwitz and Miyamoto, 2019). *For details on mutations and references see Rafaelsen, S., Johansson, S., Raeder, H., Bjerknes, R., 2016. Clinical and genetic characteristics of 15 families with hereditary hypophosphatemia: novel Mutations in PHEX and SLC34A3. PLoS One 13, e0193388. DOI 10.1371/journal.pone.0193388 PONE-D-17-39524.*

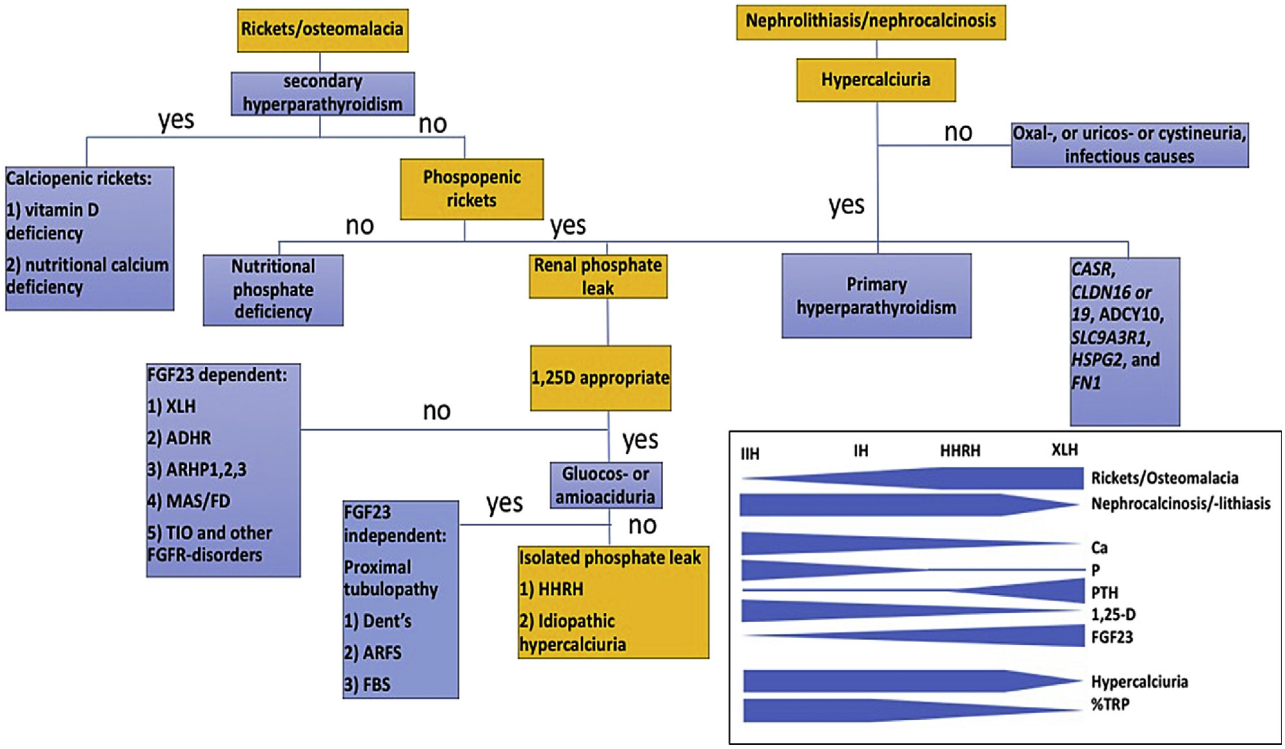

FIGURE 20.5 Differential diagnosis of hypophosphatemic disorders with and without nephrocalcinosis/nephrolithiasis. HHRH may present initially with bone disease or renal calcifications and bone disease is generally missing in heterozygous carriers of *SLC34A3*/NPT2c mutations. Presence of additional symptoms in *orange* further supports the diagnosis, while symptoms in *blue* argue against it. *ADHR*, autosomal dominant hypophosphatemic rickets; *ARFS*, autosomal recessive Fanconi syndrome; *ARHP1,2,3*, autosomal recessive hypophosphatemia type 1, 2, or 3; *FBS*, Fanconi–Bickel syndrome; *FGF23*, fibroblast growth factor 23; *FGFR*, FGF receptor; *HHRH*, hereditary hypophosphatemic rickets with hypercalciuria; *MAS/FD*, McCune–Albright syndrome/fibrous dysplasia; *PTH*, parathyroid hormone; *TIO*, tumor-induced osteomalacia; *%TRP*, percentage tubular reabsorption of phosphate; *XLH*, X-linked dominant hypophosphatemia. For gene names see text. *Originally published in Bergwitz, C., Miyamoto, K.I., 2019. Hereditary hypophosphatemic rickets with hypercalciuria: pathophysiology, clinical presentation, diagnosis and therapy. Pflügers Archiv 471, 149–163. https://doi.org/10.1007/s00424-018-2184-2.*

levels in the context of a low TRP suggest an FGF23-independent process, as would be seen in HHRH. Excess production of $1,25(OH)_2D$ may lead to increased absorption of calcium in the gut, resulting in hypercalciuria and some degree of suppression of PTH production (Tieder et al., 1985). Vitamin D deficiency may mask these findings and needs to be corrected before the aforementioned testing (Kremke et al., 2009). Circulating FGF23 levels can be determined using several commercially available enzyme-linked immunometric assays (Yamazaki et al., 2002). The C-terminal FGF23 assay (Immutopics, Inc., San Clemente, CA, USA) uses antibodies directed against two distinct epitopes within the C-terminal region of FGF23 (Larsson et al., 2005) and, as of this writing, is the only CLIA-certified assay in the United States. This assay in our experience returns FGF23 levels in the low normal range in FGF23-independent hypophosphatemic disorders such as HHRH or renal Fanconi syndrome.

Genetic testing employing whole-exome sequence analysis of leukocyte DNA is increasingly performed, allowing for screening of a panel of genes. Some centers (including the Yale Clinical Genome Research Center) employ techniques with sufficient coverage of intronic sequence to permit detection of the known intronic deletions (Daga et al., 2018; Ma et al., 2015). Single-gene sequencing may be required to detect deletions in 5′ and 3′ UTRs or in the larger intron 12, which, at this writing, is offered only by research laboratories. Fig. 20.4 indicates the locations of known mutations. More detailed information on the type and location of specific mutations is provided at several freely accessible websites: Online Mendelian Inheritance in Man (OMIM) (http://www.ncbi.nlm.nih.gov/omim/), the Exome Variant Server (http://evs.gs.washington.edu/EVS/), and the National Center for Biotechnology Information (NCBI) SNP (http://www.ncbi.nlm.nih.gov/projects/SNP/). Since compound heterozygous loss-of-function mutations in *SLC34A3*/NPT2c have been identified in HHRH (Bergwitz et al., 2006; Lorenz-Depiereux et al., 2006b), genetic evaluation of one parent may be useful to permit allele assignment when heterozygous mutations are discovered.

Musculoskeletal findings Rickets, bowing, and short stature in children and osteopenia/osteoporosis in adults are the most commonly observed features in individuals with classic HHRH. Bone pain is often present (Narchi et al., 2001; Francis and Selby, 1997). The radiological findings of rickets are evident at growth plates, and osteomalacia (undermineralization of the osteoid) may blur the trabecular architecture. Clinical consequences of these lesions include bone pain and impaired biomechanical properties, which can result in bowing, and insufficiency fractures. Swollen wrists and knees may occur due to growth plate abnormality (Donohue & Demay, 2002). The primary biochemical marker for rickets and osteomalacia is elevated total or bone-specific alkaline phosphatase (Narchi et al., 2001; Francis and Selby, 1997). Bone biopsy has shown increased accumulation of osteoid, compatible with osteomalacia, responsive to oral phosphorus supplementation (Yamamoto et al., 2007; Chen et al., 1989). Interestingly, hypomineralized periosteocytic lesions typical of XLH were absent (Yamamoto et al., 2007). Furthermore, osteoblast surface was increased, while osteoclast number was decreased (Chen et al., 1989). Rickets or osteomalacia occur in many hypophosphatemic disorders, but subtle differences can guide diagnostic and therapeutic decisions. Enthesopathy (painful or indolent mineral deposition of tendon and ligament insertion sites) occurs with XLH, ADHR, and ARHR1, but has not been reported in HHRH (Econs et al., 1994). Likewise, dental cysts, craniosynostosis, midfacial hypoplasia, frontal bossing, scaphocephaly, and Chiari I malformation, all reported in XLH (Jones et al., 2001; Tenenhouse and Econs, 2001), are not present in HHRH, possibly because of the absence of elevated FGF23 in HHRH (Econs et al., 1994; DiMeglio and Econs, 2001). Whether HHRH predisposes to accelerated bone loss in adulthood as may occur with NPT2a or NHERF1 mutations is not known (Prie et al., 2002; Karim et al., 2008).

The mechanism of muscle weakness caused by hypophosphatemia is not well understood and may be related to the role of phosphorus in intracellular signal transduction, phosphocreatine recovery (Clarke et al., 1990; Sinha et al., 2013), and/or ATP synthesis (Pesta et al., 2016; Sinha et al., 2013; Smith et al., 1984; Aono et al., 2011). Sarcopenia may develop in HHRH due to chronic hypophosphatemia. In contrast to the hypophosphatemic myopathy seen in XLH or vitamin D deficiency, HHRH presents with increased calcium, increased $1,25(OH)_2D$, and low FGF23, making this disorder uniquely suited to study of the effects of hypophosphatemia per se on muscle metabolism.

Renal findings None of the originally described HHRH patients were reported to have renal calcifications and kidney stones (Tieder et al., 1985, 1987), but subsequent investigation has revealed that renal complications are common with compound heterozygous or homozygous NPT2c mutations (Kremke et al., 2009; Ichikawa et al., 2006; Page et al., 2008; Phulwani et al., 2011; Mejia-Gaviria et al., 2010; Tencza et al., 2009). Renal calcifications are the only presenting sign in 16% of individuals with HHRH, where concomitant bone disease is not described (Romero et al., 2010; Schissel and Johnson, 2011). Even heterozygous carriers of *SLC34A3*/NPT2c mutations show an approximately threefold higher incidence of renal calcifications, probably related to their intermediate biochemical profile. Therefore, all affected individuals and their first-degree relatives should be examined for renal calcifications. It is unknown whether loss of NPT2c can cause additional proximal tubular phenotypes, such as Fanconi syndrome, as described in two patients with homozygous NPT2a mutations (Magen et al., 2004) who developed CKD later in life. Genome-wide association studies for uric acid nephrolithiasis (Tore et al., 2011), serum phosphorus levels (Kestenbaum et al., 2010), and CKD (Gudbjartsson et al., 2010) have not supported an association of hypercalciuric stone disease with the *SLC34A3*/NPT2c locus, whereas renal calcifications and impaired renal function are so associated (Arcidiacono et al., 2014; Taguchi et al., 2017; Boger et al., 2011; Pattaro et al., 2016). Our meta-analysis clearly suggests that *SLC34A3* should be added to the list of hypercalciuric stone disease genes (Dasgupta et al., 2014).

Therapy and resources

Standard therapy It is important to establish the correct diagnosis of HHRH, as patients require long-term medical therapy with phosphorus supplements (Tieder et al., 1985, 1987), and *not* supplementation with vitamin D, as in nutritional rickets (Reginato and Coquia, 2003). When HHRH is mistaken for XLH, active vitamin D analogs (i.e., calcitriol) are used with oral phosphorus (White et al., 2011), often leading to hypercalcemia, hypercalciuria, nephrocalcinosis, and potentially renal insufficiency (Jaureguiberry et al., 2008; Kremke et al., 2009). When correctly treated with oral phosphorus supplementation only, the rachitic bone disease in HHRH improves quickly. However, the long-term safety of this therapy is unknown with respect to renal calcifications, or the development of hyperparathyroidism or enthesopathy, as occurs in XLH (HYP-Consortium, 1995). Finally, genetic and biochemical data may predict risk for renal calcifications and inform management of oral phosphorus therapy. Serum phosphorus levels, urinary phosphate excretion, and serum $1,25(OH)_2D$ merit further evaluation as predictors of renal calcifications. Our studies in NPT2a-KO mice (Li et al., 2017) suggest that phosphorus can be harmful under certain conditions, suggesting that patients may need to be carefully monitored to avoid

renal calcifications despite resolution of hypercalciuria while receiving supplemental phosphorus therapy. Serum $1,25(OH)_2D$ may remain elevated long after initiation of phosphorus supplementation and thus it is not clear how suitable this measure is for assessing compliance with oral phosphorus therapy in the short term… (Yu et al., 2012).

Dent's disease (X-linked recessive hypophosphatemic rickets) (OMIM: 300009)

The initial description of X-linked recessive hypophosphatemic rickets involved a family in which males presented with rickets or osteomalacia, hypophosphatemia, and a reduced threshold for renal phosphate reabsorption (Wrong et al., 1994). In contrast to XLH, affected subjects usually exhibit hypercalciuria, elevated serum $1,25(OH)_2D$ levels, and proteinuria of up to 3 g/day. Nephrolithiasis and nephrocalcinosis with progressive renal failure occur in early adulthood. Female (heterozygous) carriers are normophosphatemic and lack biochemical abnormalities other than hypercalciuria. Three other independently reported syndromes, X-linked recessive nephrolithiasis with renal failure, Dent's disease, and low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis, have an overall similar phenotype, but manifest differences in degree of proximal tubular reabsorptive defects, nephrolithiasis, nephrocalcinosis, progressive renal insufficiency, and, in some cases, rickets or osteomalacia. Identification of mutations in the voltage-gated chloride channel gene *CLCN5*, in all four syndromes, has established that these disorders are phenotypic variants of a single disease (Lloyd et al., 1996; Thakker, 2000). The varied manifestations associated with mutations in *CLCN5*, particularly hypophosphatemia and rickets/osteomalacia, emphasize the role of environmental differences, diet, and/or modifying genetic backgrounds on phenotypic expression.

Hypophosphatemia with osteoporosis and nephrolithiasis due to SLC34A1 (OMIM: 612286) and NHERF1 mutations (OMIM: 604990)

Prie et al. investigated a heterogeneous group of patients with idiopathic hypercalciuria, osteoporosis, and renal stones. Using a candidate gene approach they found 2/20 individuals heterozygous for nonsynonymous single-nucleotide polymorphisms (SNPs) in *SLC34A1*/NPT2a (Prie et al., 2002) and 7/94 individuals heterozygous for nonsynonymous SNPs in *SLC9A3R1*/NHERF1 (Karim et al., 2008). Potential dominant negative effects of the *SLC34A1*/NPT2a mutations on proximal renal tubular phosphate reabsorption remain controversial (Virkki et al., 2003), and some of the identified NHERF1 alterations are listed in the NCBI dbSNP database as low-frequency polymorphisms (Bergwitz and Bastepe, 2008). Further study is thus required to prove that these NPT2a or NHERF1 mutations are disease-causing ones. In contrast to HHRH there is generally no history of childhood rickets in individuals with NPT2a mutations.

Autosomal recessive Fanconi syndrome (OMIM: 613388)

In 1988, Tieder et al. described a consanguineous Arab kindred with childhood rickets and defective proximal tubular handing of phosphate, amino acids, and glucose consistent with renal Fanconi syndrome (Tieder et al., 1988). Distinct from other forms of Fanconi, their patients also had elevated $1,25(OH)_2D$ levels and absorptive hypercalciuria. In 2010, homozygosity mapping of this kindred showed linkage of the disease to chromosome 5q35.1−q35.3, and subsequent sequence analysis of the *SLC34A1*/NPT2a gene in the linked interval revealed a homozygous duplication, g.2061_2081dup (p.I154V160dup) (Magen et al., 2010). Expression of the mutant NPT2a protein in *Xenopus* oocytes and opossum kidney cells showed complete loss of function and lack of membrane insertion, respectively. The two patients described in the 1988 report, who at this writing are 39 and 43 years of age, continue to have low TmP/GFR, and their FGF23 and PTH levels were recently shown to be low normal (despite impaired renal function), suggesting that their hypophosphatemia is FGF23 and PTH independent. However, their previously documented absorptive hypercalciuria due to increased $1,25(OH)_2D$ levels had normalized in the setting of vitamin D deficiency. Although symptoms of rickets were present in childhood, both patients have been relatively asymptomatic during adulthood and discontinued phosphorus supplementation. Both developed CKD stage 2−3 renal failure in their 30s, which is in contrast to the other *SLC34A1*- and *SLC34A3*-related disorders described earlier. Heterozygous carriers had normal renal function and no evidence of proximal tubulopathy, arguing against dominant negative effects of the mutant NPT2a.

Fanconi−Bickel syndrome (OMIM: 227810)

Fanconi−Bickel syndrome is a rare autosomal recessive disorder of hepatorenal glycogen accumulation, proximal renal tubular dysfunction, and impaired utilization of glucose and galactose (Santer et al., 1997, 2002), first described in 1949 and caused by defects in the facilitative glucose transporter 2 (*SLC2A2*/GLUT2) (Santer et al., 1997). Patients present early

in life with rickets and hepatomegaly. By 2 years of age enlarged kidneys are evident. Fasting hypoglycemia and postprandial hyperglycemia and hypergalactosemia, as well as hyperlipidemia, may be present. Some cases have presented with isolated but variable increases in urinary phosphate excretion (Mannstadt et al., 2012).

Intestinal malabsorption of phosphate

Primary disorders of intestinal phosphate absorption have not been reported to occur in widespread fashion. However, we have encountered a worrisome pattern of phosphate malabsorption in children with complex disorders associated with intestinal compromise. These children were fed amino acid–based elemental formulas, particularly certain Neocate products (Gonzalez Ballesteros et al., 2017). Associated tube-feeding and use of antacid medications appear to be risk factors for the development of this syndrome, and the phenomenon does not appear to occur when the formulas are used for the labeled indication of milk protein allergy in children who are otherwise healthy (Harvey et al., 2017). Without suspicion of this finding, routine monitoring of biochemical predictors of the condition are generally not monitored until overt skeletal consequences are evident, particularly rickets and fractures. Hypophosphatemia, low-to-undetectable urinary phosphate excretion, and elevated serum alkaline phosphatase levels represent the usually observed biochemical findings. We have recommended that serum phosphorus levels be monitored periodically with the use of such formulas. The disorder can be managed with either phosphate supplementation or transition to alternative formulas. We caution that the transition to an alternative formula should be done gradually, using slowly decreasing percentages of the offending formula (i.e., over 1–2 weeks), as the physiologic adaptation to phosphate deprivation will have probably resulted in marked upregulation of intestinal and renal transporters. Thus hyperabsorption of phosphate, as well as renal retention, is likely to occur initially as abundant phosphate is provided, resulting in hyperphosphatemia and a reciprocal acute hypocalcemia. The problem generally resolves in several days or a few weeks as the system is restored to a normal phosphate-handling equilibrium.

Hyperphosphatemic syndromes

Hyperphosphatemia may result from a variety of physiologic perturbations, such as phosphate loading, tumor lysis syndrome, and CKD, as discussed earlier. This section is focused on FGF23-dependent hyperphosphatemia, of interest as it provides a physiologic example of a symmetrical contrast to the hypophosphatemia seen with excess FGF23 activity.

Tumoral calcinosis

The converse pathophysiology of excess FGF23 can arise with the disorder familial hyperphosphatemic tumoral calcinosis (FHTC) (Folsom and Imel, 2015). This rare disorder is most frequently inherited in an autosomal recessive manner, presenting with findings of ectopic calcifications, often at extensor surfaces and in the pelvis, and in other locations, which appear to be amorphous calcium phosphate precipitates. The precipitates may generate the findings of chronic inflammation at their anatomic location as well (Ramnitz et al., 2016). The biochemical findings in these syndromes are the converse of those seen in XLH, with elevated TmP/GFR, consequent hyperphosphatemia, and normal or elevated $1,25(OH)_2D$ levels.

The disorder is due to deficient FGF23 activity and inherited in an autosomal recessive manner. Most reported cases are due to loss-of-function mutations in *GALNT3* (encoding UDP-*N*-acetyl-α-D-galactosamine:polypeptide *N*-acetylgalactosaminyltransferase 3) (HTC1, OMIM: 211900), resulting in impaired O-glycosylation of FGF23. The consequences of the mutation are increased proteolysis, occurring in the Golgi apparatus, before secretion into the circulation (Topaz et al., 2004). Therefore fragments are the dominant species found in the circulation, such that FGF23 levels will vary dependent on the nature of the immunoassay employed: FGF23 measured using an intact FGF23 assay is usually low, yet high values are detected when employing assays that recognize only the C terminus of the protein. FGF23 mRNA is overexpressed, indicating an intact feedback loop, presumably as the osteocyte responds to the ambient hyperphosphatemia. The disorder has variable effects on the skeleton and has been also described as a hyperostosis/hyperphosphatemia syndrome (Ramnitz et al., 2016). Dental findings may include short, blunt roots and pulpal obliteration (Vieira et al., 2015). We have identified a patient with back pain and intervertebral disc calcifications who has the biochemical phenotype of FHTC, with biallelic *GALNT3* mutations (Lee et al., 2018).

Recessive loss-of-function mutations in FGF23 itself may cause FHTC (HTC2, OMIM: 617993), with mutations evident in conserved residues of the molecule. Presumably, proteolysis is also affected, resulting in the discordance in FGF23 levels depending on the use of intact or C-terminal assays. Finally, FHTC has been reported in one patient who has

loss-of-function mutations in α-klotho, the coreceptor for FGF23 (HTC3, OMIM: 617994) (Ichikawa et al., 2007). This individual demonstrated increased levels of intact FGF23 indicating the expected resistance in the setting of the deficient coreceptor. One case of autoimmune HTC has been described, in which high titers of antibodies directed toward FGF23 resulted in resistance to FGF23 action and elevated levels of circulating FGF23 in both intact and C-terminal assays (Roberts et al., 2018). Finally, tumoral calcinosis in the absence of hyperphosphatemia has been described as secondary to CKD and in the setting of loss-of-function mutations in *SAMD9* (OMIM: 610455) (Topaz et al., 2006).

Treatment of the condition has been variably successful with low-phosphorus diet, sevelamer (or other phosphate binders), and acetazolamide. Combinations of these approaches are sometimes attempted. A 2016 report suggests the potential of topical sodium thiosulfate for this difficult to manage clinical situation (Jost et al., 2016).

Other non-FGF23-mediated hyperphosphatemic syndromes, related to hypoparathyroidism, and various forms of resistance to PTH are listed in Table 20.1. These disorders are discussed at length elsewhere (Weinstein et al., 1992; Juppner et al., 1998; Arnold et al., 1990; Pollak et al., 1994; Ding et al., 2001; Zhang et al., 1998; Karperien et al., 1999). Finally, the hyperphosphatemia is well known to increase through increasing stages of CKD, in association with reduction in serum $1,25(OH)_2D$ levels and markedly elevated circulating levels of FGF23.

Normophosphatemic disorders of cellular phosphorus metabolism

Given the widespread role of phosphate in energy metabolism, signaling, protein function, and bone matrix, disorders of phosphate homeostasis impair the function of many organ systems. The majority of disorders of phosphate homeostasis primarily alter extracellular phosphate; however, disorders that primarily change intracellular phosphate have been described. Since extracellular phosphate and intracellular phosphate are intimately related, symptoms of these disorders may overlap. For example, excess phosphate uptake into cells may result in hypophosphatemia and rickets, while reduced phosphate uptake into cells may result in hyperphosphatemia and matrix calcifications. In addition, some transporters have cell-autonomous and systemic functions. For example, loss-of-function mutations in NPT2a may reduce intracellular phosphate and stimulate renal synthesis of $1,25(OH)_2D$ thereby causing hyperabsorption of calcium and phosphate in the gut. However, the net effect of NPT2a loss-of-function mutations can be infantile hypercalcemia with hypercalciuric nephrocalcinosis, while hypophosphatemic rickets are more commonly encountered in the setting of NPT2c loss-of-function mutations.

Individuals with hypertrophic cardiomyopathy muscular dystrophy and lactic acidosis (Bhoj et al., 2015; Mayr et al., 2011) were found to carry loss-of-function mutations in PIC (*SLC25A3*), which mediates uptake of phosphate by the mitochondria. These findings suggest that phosphate is important for the function of the mitochondrial respiratory chain and ATP synthesis as has been reported by us (Pesta et al., 2016) and others (Sinha et al., 2013; Smith et al., 1984; Brown et al., 1985; Choi et al., 2008; Maldonado and Lemasters, 2014). PIC is also a component of the MPTP, which requires the presence of phosphate to permit influx of calcium into the mitochondrial matrix (Seifert et al., 2015). Detailed evaluation of the hearts in a mouse model with an inducible and cardiac-specific deletion of the *SLC25A3* gene (Kwong et al., 2014) showed reduced MPTP opening in response to calcium challenge. PIC therefore also has phosphate transport−independent roles in mitochondrial function.

Loss-of-function mutations in PIT2 (Lemos et al., 2015) and XPR1 (Legati et al., 2015) were reported in individuals suffering from PFBC or Fahr syndrome (OMIM: 213600). These individuals develop vascular calcifications in the basal ganglia of their brain, leading to seizures. Inhibition of phosphate uptake into microglia due to loss of function in PIT2 or inhibition of phosphate export from vascular smooth muscle cells due to loss of function in XPR1 may stimulate formation of calcium phosphate deposits inside these cells (Legati et al., 2015; Anheim et al., 2016). A similar phenotype was observed in human individuals and mouse models with loss-of-function mutations in the PDGFB receptor (PDGFBR) and PDGFB (Keller et al., 2013). Along with reports of a physical interaction of XPR1 with PDGFBR in mice (Yao et al., 2017), these reports suggest that PDGFB, PDGFBR, and phosphate transporters functionally interact. Interestingly, Pit2-KO mice have increased cerebrospinal fluid phosphate levels, which may suggest a role for this transporter in phosphate homeostasis of cerebrospinal fluid (Jensen et al., 2016).

Summary

Advances since the end of the 20th century have led to the identification of intricate mechanisms by which phosphorus is regulated in the whole organism. An improved understanding of P transport processes, the distribution and function of transporters, and the overall hormonal control of this process has emerged. In particular, the FGF23-mediated bone−renal phosphate axis has markedly expanded our conceptual framework for mineral homeostasis. The related disorders of

phosphate homeostasis are now better understood, allowing for new molecular targets for treatment of disease, yet raising a multitude of further questions waiting to be explored.

Patient information/web resources:

Orphanet: http://www.orpha.net
OMIM: http://omim.org
NORD: https://rarediseases.org
The XLH Network: http://www.xlhnetwork.org

Key term/acronym	Definition
ATP	Adenosine triphosphate
PPi	Pyrophosphate
PTH	Parathyroid hormone
NPT2	Solute carrier family 34 (type II) sodium/phosphate cotransporters (with "a", "b", and "c" species)
PIT	Solute carrier family 20 (type III) sodium/phosphate cotransporters (with "1" and "2" species)
PKA	Protein kinase A
PKC	Protein kinase C
NHERF1	Sodium/hydrogen exchange regulatory cofactor
GALNT3	UDP-*N*-acetyl-α-D-galactosamine:polypeptide *N*-acetylgalactosaminyltransferase, isoform 3
FGF23	Fibroblast growth factor 23
KL	α-Klotho
PHEX	Phosphate-regulating gene with homologies to endopeptidases on the X chromosome
MV	Matrix vesicle
DMP1	Dentin matrix protein 1
PXE	Pseudoxanthoma elasticum
MEPE	Matrix extracellular phosphoglycoprotein
SIBLING	Small integrin-binding ligand N-linked glycoprotein
FGFR	Fibroblast growth factor receptor
ENPP1	Ectonucleotide pyrophosphatase/phosphodiesterase 1
ANKH	Progressive ankylosis protein homolog
ABCC6	ATP binding cassette subfamily C member 6
ARHR	Autosomal recessive hypophosphatemic rickets
ASARM	Acidic serine aspartate-rich MEPE-associated motif
HHRH	Hereditary hypophosphatemic rickets with hypercalciuria
PTHR1	PTH/PTHrP receptor
VDR	Vitamin D receptor, forms heterodimer with RXR
HFTC	Hyperphosphatemic familial tumoral calcinosis
TNAP	Tissue nonspecific alkaline phosphatase
XLH	X-linked dominant hypophosphatemia
ADHR	Autosomal dominant hypophosphatemic rickets
SLC34	Solute carrier family 34 (sodium/phosphate cotransporter); members 1 and 3 are expressed in the proximal renal tubule, member 2 is expressed in the intestine
CYP27B1	Vitamin D 1-α-hydroxylase
CYP24A1	Vitamin D 24-hydroxylase
GACI	Generalized arterial calcification of infancy
TRPV	Transient receptor potential cation channel, subfamily V; members 5 and 6 are calcium selective
PMCA	Plasma membrane Ca^{2+} ATPase
VDDR1	Vitamin D–dependent rickets type 1

VDDR2	Vitamin D−dependent rickets type 2
FRP4	Frizzled-related protein 4
PFBC	Primary familial brain calcification
MPTP	Mitochondrial permeability transition pore
PIC	Mitochondrial phosphate carrier
PMT−MCT	Phosphaturic mesenchymal tumor−mixed connective tissue variant
TIO	Tumor-induced osteomalacia
PDGF	Platelet-derived growth factor

Chapter 21

Magnesium homeostasis

Karl P. Schlingmann and Martin Konrad

Department of General Pediatrics, University Children's Hospital Münster, Münster, Germany

Chapter outline

Introduction

Mg^{2+} is the most prevalent intracellular divalent cation and the fourth most abundant cation in the body. The human body contains approximately 24 g (1000 mmol) of Mg^{2+}, of which 50%−60% is present in bone, while most of the rest is stored in soft tissues. Less than 1% of total body Mg^{2+} is present in blood. Studies on body Mg^{2+} kinetics have already been conducted in the 1960s with the radioactive isotope ^{28}Mg. Avioli and Berman proposed a multicompartmental model of exchangeable Mg^{2+} pools: (1) a Mg^{2+} pool with a relatively fast turnover, comprising ∼15% of the estimated body content representing primarily the extracellular fluid, and (2) a slow-turnover intracellular pool comprising >70% of total body Mg^{2+} (Avioli and Berman, 1966).

Therefore, the assessment of Mg^{2+} status represents a difficult task. The most commonly used method for assessing Mg^{2+} status is the measurement of serum Mg^{2+} concentrations. Under physiologic conditions, serum levels are maintained at almost constant values, with a normal serum Mg^{2+} ranging between 0.75 and 1.05 mmol/L. Hypomagnesemia is usually defined as a serum Mg^{2+} level less than 0.75 mmol/L. Unfortunately, there is little correlation with specific tissue concentrations or total body Mg^{2+} stores, and normomagnesemia does not necessarily reflect a sufficient body Mg^{2+} content. Mg^{2+} deficiency and hypomagnesemia often remain asymptomatic. Clinical symptoms are mostly nonspecific and Mg^{2+} deficiency might be associated with additional electrolyte abnormalities, especially hypocalcemia and hypokalemia. Moreover, symptoms do not necessarily correlate with serum Mg^{2+} concentrations. Therefore, additional diagnostic measures have been evaluated to diagnose clinically relevant Mg^{2+} deficiency in the face of normomagnesemia. Examples for such complementary methods, which are usually not available in routine clinical practice, comprise serum ionized Mg^{2+} or erythrocyte Mg^{2+} concentrations.

Mg^{2+} homeostasis primarily depends on the balance between intestinal absorption and renal excretion. Therefore, deficiency can result from reduced dietary intake, intestinal malabsorption or losses, or renal Mg^{2+} wasting. Within physiologic limits, a diminished dietary Mg^{2+} intake is balanced by enhanced Mg^{2+} absorption in the intestine and reduced renal excretion.

In 1964, analyzing a large number of balance studies, Seelig concluded that the intake of Mg^{2+} for a healthy adult required to maintain balance is around 0.25 mmol or 6 mg/kg body weight per day (Seelig, 1964). Actually, the US Food and Nutrition Board recommends a daily intake of Mg^{2+} of 420 mg for men and 320 mg for women (Institutes of Medicine, 1997). However, NHANES data indicate that almost half of the US population consumes considerably lower amounts of Mg^{2+} from daily food (Mosfegh et al., 2006). A reduced nutritional Mg^{2+} intake does not necessarily lead to

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00021-X

symptomatic Mg^{2+} depletion. However, latent or subclinical hypomagnesemia is relatively frequent, with an estimated prevalence of around 14% in the general population (Schimatschek and Rempis, 2001). This is especially alarming as there is growing evidence of an association of Mg^{2+} deficiency with common chronic diseases such as hypertension, coronary heart disease, metabolic syndrome, or diabetes mellitus (Maier, 2003; Sontia and Touyz, 2007; Ford et al., 2007; Guerrero-Romero and Rodríguez-Morán, 2002; Song et al., 2004; Kieboom et al., 2016).

Magnesium physiology

Under physiologic conditions, around 30%–40% of nutritional Mg^{2+} is absorbed in the small intestine, with smaller amounts taken up in the colon (Quamme, 2008). Intestinal Mg^{2+} absorption occurs via two different transport pathways: (1) a saturable, active transcellular pathway and (2) a nonsaturable, passive paracellular pathway (Kerstan and Quamme., 2002). Whereas at low intraluminal concentrations Mg^{2+} is absorbed primarily via the active transcellular route, the passive paracellular pathway is increasingly used with rising intraluminal concentrations, yielding a curvilinear function for total intestinal Mg^{2+} absorption (Fig. 21.1). The discovery of *TRPM6* mutations in patients with hypomagnesemia with secondary hypocalcemia (HSH) has substantially expanded our understanding of intestinal Mg^{2+} absorption (Quamme, 2008; Schlingmann et al., 2002). The *TRPM6* gene encodes a member of the TRP (transient receptor potential) family of ion channels that is involved in the formation of the apical Mg^{2+}-permeable ion channel in intestinal epithelia as well as in kidney. Therefore, HSH patients, next to an impaired renal Mg^{2+} conservation (see later), exhibit a primary defect in intestinal Mg^{2+} absorption. However, the impaired active transcellular transport can be compensated for by increasing nutritional Mg^{2+} and intraluminal Mg^{2+} concentrations in the intestine, promoting passive paracellular Mg^{2+} uptake. Therefore, HSH patients are able to achieve at least subnormal serum Mg^{2+} levels with high-dose oral Mg^{2+} supplementation. Common acquired causes of hypomagnesemia due to a decreased intestinal absorption include malabsorption syndromes, short bowel syndrome, severe vomiting, diarrhea, or steatorrhea (Hoorn and Zietse, 2013).

The control of body Mg^{2+} homeostasis primarily resides in the kidney. Approximately 80% of total serum Mg^{2+} is filtered in the glomeruli. Thereafter, 95%–97% of filtered Mg^{2+} is reabsorbed along the kidney tubule so that under physiologic, normomagnesemic conditions, 3%–5% of filtered Mg^{2+} is finally excreted in the urine (Fig. 21.2). Fifteen to twenty percent of filtered Mg^{2+} is already reabsorbed in the proximal tubule. The majority of filtered Mg^{2+} (~70%) is reabsorbed in the thick ascending limb (TAL) of Henle's loop. Mg^{2+} reabsorption in the TAL is passive and paracellular in

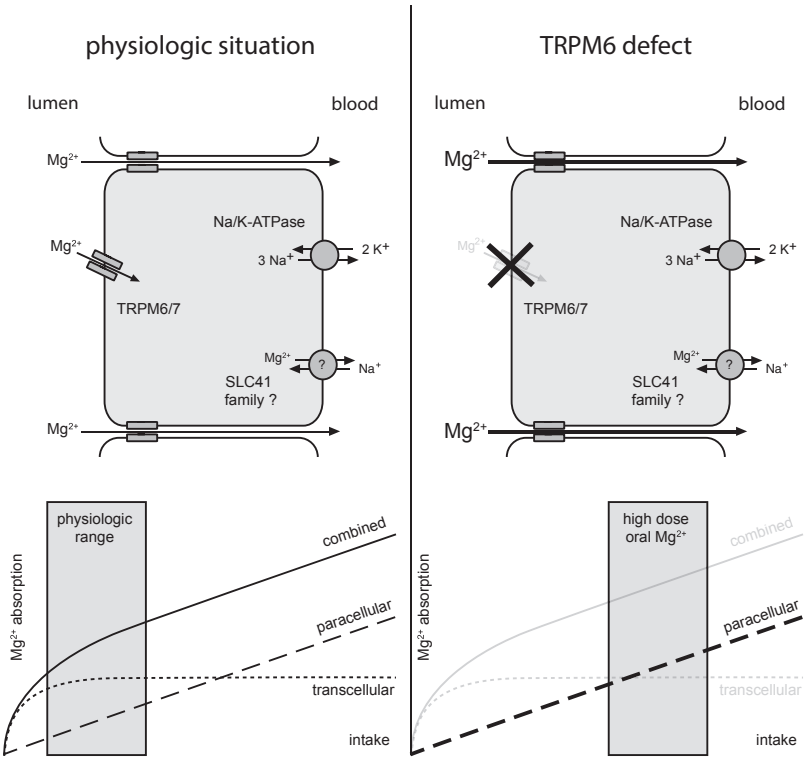

FIGURE 21.1 Intestinal Mg^{2+} absorption in health and disease. Saturable active transcellular transport (*dotted line*), which predominates at low intraluminal Mg^{2+} concentrations, and passive paracellular transport (*dashed line*), which linearly rises with increasing intraluminal Mg^{2+}, result in a curvilinear kinetic profile (left). Transient receptor potential, subfamily M, 6 (*TRPM6*) is a component of the active transcellular pathway. Hypomagnesemia with secondary hypocalcemia patients are able to compensate for TRPM6 deficiency by increasing passive paracellular absorption with high oral Mg^{2+} intake (right). *SLC41*, solute carrier 41 family.

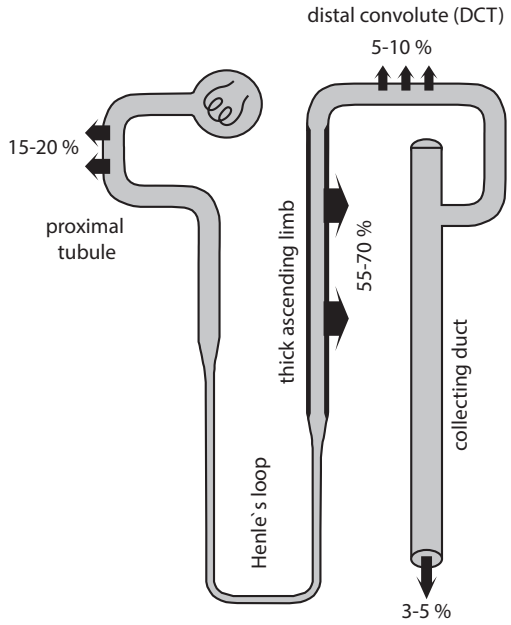

FIGURE 21.2 Renal tubular magnesium reabsorption. Approximately 80% of total serum Mg^{2+} is filtered in the glomeruli, of which 95%–97% is reabsorbed along the kidney tubule. Fifteen to twenty percent of filtered Mg^{2+} is already reabsorbed in the proximal tubule. The majority of filtered Mg^{2+} (~70%) is reabsorbed in the thick ascending limb of Henle's loop (TAL). Mg^{2+} reabsorption in the TAL is passive and paracellular in nature. Thereafter, 5%–10% of filtered Mg^{2+} is reabsorbed in the distal convoluted tubule (*DCT*) by an active and transcellular process consisting of an apical entry into the DCT cell and a basolateral extrusion into the interstitium. Finally, 3%–5% of the filtered Mg^{2+} is excreted in the urine.

nature and occurs together with calcium (Ca^{2+}) through the intercellular space. Here, specialized tight junctions composed of a specific set of proteins of the claudin family seal the paracellular space for water and electrolytes, but, on the other hand, allow for the selective passage of ions. Paracellular Ca^{2+} and Mg^{2+} transport in the TAL is driven by a lumen-positive transepithelial electric gradient that is generated by active transcellular salt reabsorption (Fig. 21.3). It is negatively regulated by the basolaterally located Ca^{2+}-sensing receptor (CaSR) (Houillier, 2013). The CaSR senses extracellular Ca^{2+} as well as Mg^{2+} concentrations in the distal nephron as well as in other tissues and thereby plays an essential role in Ca^{2+} and Mg^{2+} homeostasis (Brown et al., 1995).

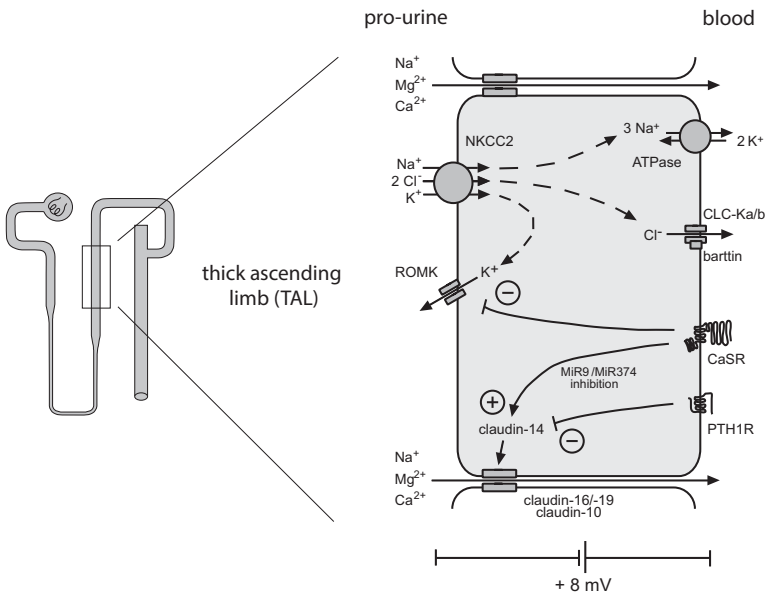

FIGURE 21.3 Mg^{2+} reabsorption in the thick ascending limb of Henle's loop. Mg^{2+} reabsorption is passive and occurs through the paracellular pathway together with Ca^{2+}. The driving force is the lumen-positive transepithelial voltage generated by active transcellular salt reabsorption. Paracellular Ca^{2+} and Mg^{2+} reabsorption occurs through specialized tight junctions. It is negatively regulated by the action of the basolateral Ca^{2+}-sensing receptor (*CaSR*) as well as the parathyroid hormone receptor (*PTH1R*), both influencing the expression of claudin-14, a tight junction protein that seals the paracellular space for both divalent cations.

Finally, 5%−10% of filtered Mg^{2+} is reabsorbed in the distal convoluted tubule (DCT), which defines the final urinary Mg^{2+} excretion as there is no significant reabsorption of Mg^{2+} in the collecting duct. Mg^{2+} reabsorption in the DCT is an active and transcellular process consisting of an apical entry into the DCT cell through a specific and regulated Mg^{2+}-permeable ion channel and a basolateral extrusion into the interstitium. The molecular nature of the apical Mg^{2+} channel was resolved by genetic studies in patients with HSH that identified TRPM6 (see later) (Schlingmann et al., 2002). Unfortunately, the molecular components involved in basolateral Mg^{2+} export are still not completely resolved. Most physiologic studies have favored a Na^{+}-dependent exchange mechanism for basolateral Mg^{2+} extrusion (Quamme, 1997); more recent data point to an involvement of Mg^{2+} transporters of the solute carrier 41 (SLC41) family (Kolisek et al., 2012). Apical Mg^{2+} entry is driven by a favorable transmembrane voltage and represents the rate-limiting step and site of regulation (Dai et al., 2001). Finally, 3%−5% of the filtered Mg^{2+} is excreted in the urine.

For the determination of renal Mg^{2+} conservation and the diagnosis of Mg^{2+} deficiency, the parallel determination of serum and urine Mg^{2+} concentrations is critical. In hypomagnesemic patients, the determination of urinary Mg^{2+} excretions allows for a differentiation between renal Mg^{2+} wasting and extrarenal losses. In the presence of hypomagnesemia, the 24-h Mg^{2+} excretion is expected to be below 1 mmol (Sutton and Domrongkitchaiporn, 1993). In contrast, a decreased 24-h Mg^{2+} excretion might indicate Mg^{2+} deficiency in normomagnesemic individuals, presuming an intact renal Mg^{2+} conservation. Similarly, Mg^{2+}/creatinine ratios and fractional Mg^{2+} excretions calculated from spot urine samples might be useful (Elisaf et al., 1997; Tang et al., 2000). Finally, the parenteral Mg^{2+} loading test (MLT) remains the gold standard for the evaluation of body Mg^{2+} status (Elin, 1994; Hébert et al., 1997). It determines the retention of a defined intravenous Mg^{2+} load as a sensitive index of Mg^{2+} deficiency. Several protocols have been published (Ryzen et al., 1985; Gullestad et al., 1994). A short-term MLT using an infusion of 0.1 mmol Mg^{2+} per kilogram body weight given over 1 h was proposed as a less elaborate alternative to the 8-h standard, yielding comparable results (Rob et al., 1996). Usually, an excretion of less than 70% of the infused Mg^{2+} is considered indicative of Mg^{2+} deficiency (Hébert et al., 1997). Moreover, the MLT can be successfully applied to differentiate between renal and extrarenal Mg^{2+} losses in hypomagnesemic patients to uncover a renal Mg^{2+} leak that becomes evident only at higher serum Mg^{2+} concentrations (Walder et al., 2002).

Hereditary disorders of magnesium homeostasis

Advances in molecular genetics identified a number of genes and their encoded proteins involved in epithelial Mg^{2+} transport (de Baaij et al., 2015b). Knowledge of the underlying genetic defects allows the definition of a growing spectrum of clinical entities underlying hereditary disorders of Mg^{2+} homeostasis. Moreover, the clarification of the molecular structures and of the pathophysiology of hypomagnesemic disorders enables an understanding of disturbances in Mg^{2+} metabolism as a frequent side effect of common drug treatments and raises the alertness of the clinician for the prevention and treatment of acquired hypomagnesemia in their patients.

Disturbed Mg^{2+} reabsorption in the thick ascending limb

In the TAL, the paracellular reabsorption pathway for divalent cations is composed of specialized tight junctions comprising different proteins of the claudin family (i.e., claudin-3, -10, -11, -14, -16, -19). Paracellular transport of divalent cations is passive in nature, driven by the lumen positive transepithelial potential. Patients with genetic defects in *CLDN16* (encoding claudin-16) and *CLDN19* genes (encoding claudin-19) suffer from an autosomal-recessive disease named familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC; MIM: 248250) (Simon et al., 1999; Konrad et al., 2006). Due to excessive renal Ca^{2+} and Mg^{2+} wasting, patients develop the characteristic triad of hypomagnesemia, hypercalciuria, and nephrocalcinosis. FHHNC patients usually present during childhood with recurrent urinary tract infections, polyuria/polydipsia, nephrolithiasis, and/or failure to thrive. Signs of profound hypomagnesemia such as cerebral seizures or muscular tetany are observed less frequently. An additional ocular involvement (including severe myopia, nystagmus, or chorioretinitis) is common in patients with *CLDN19* mutations (Konrad et al., 2006). Additional laboratory findings include elevated intact parathyroid hormone (iPTH) levels before the onset of renal failure, an incomplete distal tubular acidosis, hypocitraturia, and hyperuricemia present in the majority of patients (Weber et al., 2001). The clinical course of FHHNC patients is often complicated by a continuous decline in renal function leading to end-stage renal disease (ESRD) early in life. A significant number of patients exhibit a marked decline in glomerular filtration rate (GFR) already at the time of diagnosis, and about one-third of patients develop ESRD during adolescence (Konrad et al., 2008). Hypomagnesemia may completely disappear with the decline of GFR. In addition to oral Mg^{2+} supplementation, therapy aims at a reduction in renal Ca^{2+} excretions to prevent the progression of nephrocalcinosis and kidney stone formation, as the

extent of renal calcifications has been correlated with the progression of chronic renal failure (Praga et al., 1995). Supportive therapy is critical for the protection of kidney function, including sufficient fluid uptake and an effective treatment of bacterial infections and kidney stone disease. Data on bone mineral density or an additional bone phenotype in patients with FHHNC are sparse. A potential defect in bone mineralization caused by renal Ca^{2+} and Mg^{2+} wasting and early elevations of iPTH might overlap with renal osteodystrophy that develops with the decline in renal function. However, there are recent data on a primary defect in amelogenesis in patients with *CLDN16* mutations (Bardet et al., 2016; Yamaguti et al., 2017). Finally, there is evidence for a heterozygote effect in carriers of *CLDN16* mutations who may present with hypercalciuria, nephrolithiasis, and/or nephrocalcinosis (Weber et al., 2001; Praga et al., 1995). Another study also reported mild hypomagnesemia in family members with heterozygous *CLDN16* mutations (Blanchard et al., 2001). Thus, one might speculate that *CLDN16* mutations could be involved in idiopathic hypercalciuric stone formation.

Interestingly, physiologic data indicate that claudin-16 and claudin-19 do not just facilitate paracellular Mg^{2+} and Ca^{2+} transport (Hou et al., 2008). Rather, the authors suggest that claudin-16 also critically influences paracellular sodium (Na^+) permeability, while claudin-19 seals the paracellular space for chloride (Cl^-). Another study points to the existence of spatially distinct sets of tight junction strands that allow for the permeation of either monovalent or divalent cations (Milatz et al., 2017). In line with these findings are the observations made in mice with a deletion of claudin-10 (*cldn10*), which is thought to form a paracellular Na^+ pore (Breiderhoff et al., 2012). These mice display a decreased paracellular Na^+ permeability but an increase in paracellular Mg^{2+} and Ca^{2+} transport that phenotypically leads to hypermagnesemia and nephrocalcinosis. Similarly, patients with recessive *CLDN10* mutations exhibit a Bartter-like salt wasting phenotype with hypokalemic alkalosis and display serum Ca^{2+} and Mg^{2+} levels that are in the upper normal range or elevated (Bongers et al., 2017; Hadj-Rabia et al., 2018). Finally, the additional knockout of *cldn10* corrects the Mg^{2+} and Ca^{2+} wasting phenotype of *cldn16*-deficient mice (Breiderhoff et al., 2018). Data on bone mineralization have not been reported as of this writing for either patients or mice.

Another claudin that is expressed at tight junctions in the TAL is claudin-14 (*CLDN14*) (Gong et al., 2012). *CLDN14* has been identified in a genome-wide association study (GWAS) as a major risk gene for hypercalciuric nephrolithiasis and a reduced bone mineral density (Thorleifsson et al., 2009). The association of *CLDN14* with bone mineral density was subsequently replicated in two independent studies (Zhang et al., 2014; Tang et al., 2016). Moreover, a variant in the *CLDN14* promotor has been associated with pediatric-onset hypercalciuria and kidney stones (Ure et al., 2017). Claudin-14 interacts with claudin-16 and diminishes paracellular cation permeability in vitro (Gong et al., 2012). Under physiologic conditions, expression of claudin-14 is suppressed via a microRNA pathway (Gong et al., 2015). By activation of the CaSR, extracellular Ca^{2+} is able to relieve this suppression, induce claudin-14 expression, and inhibit paracellular divalent cation reabsorption (Hou et al., 2013). Moreover, claudin-14 expression and therefore paracellular cation transport are critically influenced by parathyroid hormone (PTH) via PTH receptor (PTH1R) signaling (Fig. 21.3). Accordingly, the TAL-specific inactivation of the PTH1R in mice leads to hypercalciuria and diminished serum Ca^{2+} levels, while expression of claudin-14 is significantly increased (Sato et al., 2017). In contrast, the deletion of *cldn14* in mice provokes hypermagnesemia, hypomagnesiuria, and hypocalciuria under a high-Ca^{2+} diet (Gong et al., 2012).

Basolaterally expressed CaSR negatively regulates Mg^{2+} and Ca^{2+} reabsorption in the TAL (Fig. 21.3) (Houillier, 2013). The CaSR senses extracellular Ca^{2+} as well as Mg^{2+} concentrations in the distal nephron (Brown, 2013). In the parathyroid, the CaSR is responsible for adjusting the rate of PTH synthesis and release to the extracellular levels of both divalent cations (Hebert and Brown, 1995). Two different hereditary disorders result from either activating or inactivating CaSR mutations. Heterozygous activating mutations lead to autosomal-dominant hypocalcemia (ADH; MIM: 601198) (Pollak et al., 1994). Patients present with hypocalcemic seizures or muscle spasms. In addition, a significant number of affected patients also exhibit hypomagnesemia (Pearce et al., 1996). Moreover, patients may develop significant renal salt wasting due to parallel inhibition of active transcellular NaCl reabsorption in the TAL (Watanabe et al., 2002). Inappropriately low iPTH levels due to the activation of the CaSR in the parathyroid gland often lead to the diagnosis of primary hypoparathyroidism. In ADH, supplementation with vitamin D and Ca^{2+} should be reserved for symptomatic patients as it may increase calciuria and renal complications (Hannan and Thakker, 2013).

In contrast, inactivating mutations on one or two *CASR* alleles result in familial hypocalciuric hypercalcemia (FHH1; MIM:145980) and neonatal severe hyperparathyroidism (NSHPT; MIM 239200), respectively (Pollak et al., 1993). FHH patients normally present with mild-to-moderate hypercalcemia, accompanied by few if any symptoms, and usually do not require treatment. Urinary excretion rates for Ca^{2+} and Mg^{2+} are markedly reduced, and affected individuals may also exhibit mild hypermagnesemia (Marx et al., 1981). In contrast, NSHPT patients with two mutant *CASR* alleles present in early infancy with severe symptomatic hypercalcemia. If untreated, hyperparathyroidism and hypercalcemia result in diffuse bone demineralization, fractures, and skeletal deformities. Traditionally, partial-to-total parathyroidectomy within the first weeks of life has been propagated and still represents the treatment of choice for most patients (Cole et al., 1997;

Mayr et al., 2016). More recent data indicate that cinacalcet, a calcimimetic drug enhancing CaSR function, may exert positive effects in a subset of patients, while a lack of effect was demonstrated in others (Atay et al., 2014; Gannon et al., 2014). As in symptomatic hypercalcemia of different origin, pamidronate has been shown to effectively lower serum Ca^{2+} levels (Waller et al., 2004). Data on Mg^{2+} metabolism in patients with NSHPT are scarce; however, elevations of serum Mg^{2+} levels to around 50% above the upper normal limit have been reported (Cole et al., 1997). The bone phenotype resulting from inactivating Casr mutations has been extensively studied in mice (Ho et al., 1995; Garner et al., 2001; Liu et al., 2011). $Casr^{-/-}$ mice exhibit markedly elevated iPTH levels, parathyroid hyperplasia, severe hypercalcemia, severe skeletal growth retardation, and premature death (Ho et al., 1995). Garner et al. performed a detailed skeletal analysis in $Casr^{-/-}$ mice and described a rickets phenotype with impaired growth plate calcification and decreased mineralization of metaphyseal bone (Garner et al., 2001).

Disturbed Mg^{2+} reabsorption in the distal convoluted tubule

Genetic studies in patients with inherited hypomagnesemia have identified numerous genes that are involved in active transcellular Mg^{2+} reabsorption in the DCT (Fig. 21.4). Mg^{2+} enters the DCT cell through a specific Mg^{2+}-permeable ion channel. As intraluminal and intracellular Mg^{2+} concentrations are of the same magnitude, the intracellularly negative membrane voltage represents the major driving force for apical Mg^{2+} entry.

Genetic studies in patients with HSH (HOMG1; MIM: 602014) led to the identification of TRPM6 as a critical component of apically located Mg^{2+}-permeable ion channels (Schlingmann et al., 2002; Walder et al., 2002; Chubanov et al., 2004). Recessive loss-of-function mutations in *TRPM6* result in the development of severe hypomagnesemia, cerebral seizures, or other symptoms of increased neuromuscular excitability during infancy as first described in 1968 (Paunier et al., 1968). Delayed diagnosis or noncompliance with treatment can even be fatal or result in permanent neurological damage. In addition to hypomagnesemia, patients exhibit suppressed iPTH levels and consecutive hypocalcemia. The hypocalcemia observed in HSH is resistant to treatment with Ca^{2+} or vitamin D. Relief of clinical symptoms, normocalcemia, and normalization of iPTH levels can be achieved only by administration of high doses of Mg^{2+} (Shalev et al., 1998). The suppression of PTH is thought to result from an inhibition of PTH synthesis and secretion in the presence of profound hypomagnesemia (Anast et al., 1972). The paradoxical block of the parathyroid gland caused by severe Mg^{2+} depletion involves intracellular signaling pathways of the CaSR with an increase in the activity of inhibitory Gα subunits (Quitterer et al., 2001). In addition, profound hypomagnesemia might result in an end organ resistance to PTH as intracellular Mg^{2+} is a cofactor for adenylate cyclase (Mori et al., 1992; Mihara et al., 1995). Finally, hypomagnesemia results in a reduction in PTH-induced release of Ca^{2+} from bone, which contributes to the development of secondary hypocalcemia (Freitag et al., 1979). The *TRPM6* gene encodes a member of the TRP family of cation channels. The TRPM6 protein is highly homologous to TRPM7, another Ca^{2+}- and Mg^{2+}-permeable ion channel regulated by Mg-ATP (Nadler et al., 2001). TRPM6 is expressed along the entire gastrointestinal tract as well as in kidney in the DCT, supporting the assumption of HSH being a combined gastrointestinal and renal Mg^{2+} wasting disorder (Voets et al., 2004).

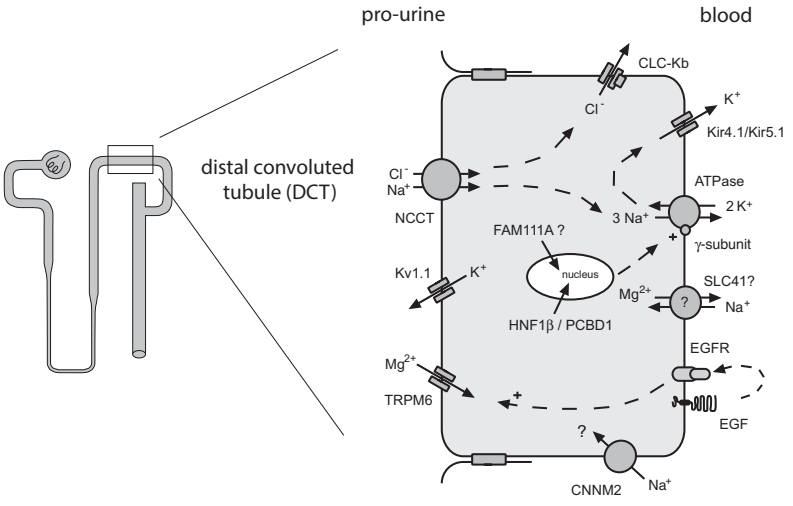

FIGURE 21.4 Mg^{2+} reabsorption in the distal convoluted tubule. Mg^{2+} transport is active and transcellular in nature. Mg^{2+} entry through transient receptor potential, subfamily M, 6 (*TRPM6*) ion channels is dependent on the negative membrane potential. The molecular identity of the basolateral Mg^{2+} extrusion mechanism is still unknown but might involve Na^+/Mg^{2+} exchangers of the solute carrier 41 (*SLC41*) family. Mg^{2+} transport is critically influenced by transcellular salt reabsorption, potassium recycling, and the paracrine action of epidermal growth factor (*EGF*), as well as the transcriptional activity of hepatocyte nuclear factor 1β (*HNF1β*). *CNNM2* might represent a basolaterally expressed Mg^{2+} sensor.

The functional characterization of TRPM6 in different overexpression systems yielded contradictory results. Voets et al. were able to express functional TRPM6 monomers and could demonstrate striking similarities to TRPM7 with respect to gating mechanisms and ion-selectivity profiles, as TRPM6 was shown to be regulated by intracellular Mg^{2+} levels and to be permeable for Mg^{2+} as well as for Ca^{2+} (Voets et al., 2004). Permeation characteristics with currents almost exclusively carried by divalent cations with a higher affinity for Mg^{2+} than for Ca^{2+} supported the role of TRPM6 as the apical Mg^{2+} influx pathway. In contrast, Chubanov and coworkers observed that TRPM6 was present at the cell surface only when associating with TRPM7 (Chubanov et al., 2004). Electrophysiological data in the *Xenopus* oocyte expression system indicated that coexpression of TRPM6 results in a significant amplification of TRPM7-induced currents (Chubanov et al., 2004). The idea of a heteromultimerization of TRPM6 with TRPM7 was also confirmed by another independent group that demonstrated that TRPM6 and TRPM7 are functionally not redundant, but that both proteins can influence each other's biological activity (Schmitz et al., 2005). This group showed that TRPM6 is able to phosphorylate TRPM7, thereby modulating its function.

The most common inherited disorder affecting magnesium conservation in the DCT is the Gitelman syndrome (GS; MIM: 263800), a primary renal salt wasting disorder with an estimated prevalence of approximately 1:40,000. GS is caused by recessive mutations in *SLC12A3* encoding the thiazide-sensitive NaCl cotransporter NCCT (Simon et al., 1996). In contrast to other forms of the Bartter syndrome spectrum, urinary-concentration ability typically is not affected and the extent of renal salt wasting is rather mild. Nevertheless, salt craving is a common clinical feature. Patients usually present at school age or in later life with muscular weakness, cramps, or fatigue. Also, a significant percentage of affected individuals are diagnosed while searching medical consultation because of growth retardation, constipation, or enuresis. Furthermore, many so-called "asymptomatic" patients have been reported, or GS is diagnosed incidentally after the assessment of serum electrolytes for other reasons. Nevertheless, it has been demonstrated that GS should not be considered a mild disorder, since none of the studied patients was truly asymptomatic (Cruz et al., 2001). Salt craving, nycturia, and paresthesia were the most frequent symptoms, all of them significantly affecting the quality of life.

Laboratory examinations in GS patients show the typical constellation of metabolic alkalosis, hypokalemia, and hypomagnesemia; urine analyses reveal hypocalciuria (Bettinelli et al., 1992). The dissociation of renal Ca^{2+} and Mg^{2+} handling was initially considered pathognomonic for GS; however, it has been observed in a number of hypomagnesemic disorders (see later). Mg^{2+} depletion causes neuromuscular irritability and tetany. Decreased renal Ca^{2+} elimination together with Mg^{2+} deficiency favors deposition of mineral Ca^{2+} as demonstrated by increased bone density as well as chondrocalcinosis (Nicolet-Barousse et al., 2005; Ea et al., 2005). Family studies demonstrated that electrolyte imbalances are present from infancy on, although the affected infants remain clinically asymptomatic. Of note, the combination of hypokalemia and hypomagnesemia exerts an exceptionally unfavorable effect on cardiac excitability, which puts these patients at high risk for cardiac arrhythmias (Foglia et al., 2004). Substitution of K^+ and Mg^{2+} represents the central treatment of this disorder. Avoidance of factors that in addition to hypokalemia and hypomagnesemia might affect cardiac excitability (in particular, QT-time prolonging drugs) is mandatory to prevent life-threatening cardiac arrhythmias (Blanchard et al., 2017). Unfortunately, the exact mechanisms compromising Mg^{2+} reabsorption while favoring reabsorption of Ca^{2+} are not yet completely understood. Studies in *Trpv5*-knockout mice with disrupted Ca^{2+} reabsorption in the DCT that were treated with thiazides to inhibit NCCT pointed to an increase in passive Ca^{2+} reabsorption in the proximal tubule underlying hypocalciuria (Nijenhuis et al., 2005). The same study demonstrated a downregulation of TRPM6 in NCC-knockout mice as well as thiazide-treated mice in parallel to the development of hypomagnesemia.

In 2009, a novel clinical syndrome with autosomal-recessive inheritance combining epilepsy, ataxia, sensorineural deafness, and renal NaCl wasting was described under the acronym EAST or SeSAME syndrome (SESAMES; MIM: 612780) (Bockenhauer et al., 2009; Scholl et al., 2009). While in early life, neurological symptoms predominate, renal salt wasting is typically recognized only later during the course of the disease. As in GS, the renal phenotype includes hypokalemic alkalosis, hypomagnesemia, and hypocalciuria. EAST/SeSAME syndrome is caused by loss-of-function mutations in *KCNJ10* encoding the K^+ channel Kir4.1 (Reichold et al., 2010). The expression pattern of Kir4.1 fits the disease phenotype with highest expression in brain, the stria vascularis of the inner ear, and the DCT. Here, Kir4.1 is thought to mediate K^+ recycling over the basolateral membrane and thereby to maintain activity and function of Na/K-ATPase (Fig. 21.4) (Bockenhauer et al., 2009). Accordingly, loss of Kir4.1 function leads to depolarization of the basolateral membrane and therefore to a reduction in the driving force for basolateral Na^+-coupled exchangers. By this mechanism, Kir4.1 defects putatively affect the proposed Na^+/Mg^{2+} exchanger, which possibly explains the Mg^{2+} wasting observed in EAST/SeSAME syndrome.

An impairment of basolateral Na/K-ATPase function had already been implicated in renal Mg^{2+} wasting when Meij et al. in 1999 discovered a mutation in *FXYD2* in two related families with isolated dominant hypomagnesemia (IDH; MIM: 154020) (Meij et al., 2000). *FXYD2* encodes an accessory γ subunit of Na/K-ATPase that is expressed in a tissue-

specific manner (Arystarkhova et al., 2002b). FXYD2 increases the apparent affinity of Na/K-ATPase for ATP while decreasing its Na^+ affinity (Arystarkhova et al., 2002a). Thus, it might provide a mechanism for balancing energy utilization and maintaining appropriate salt gradients. Expression studies of the identified mutant p.G41R γ-subunit in mammalian renal tubule cells revealed a dominant-negative effect of the mutation leading to a retention of the γ-subunit within the cell (Cairo et al., 2008). A possible explanation for the resulting defect in Mg^{2+} reabsorption is based on changes in intracellular Na^+ and K^+ levels: in addition to the presumed effect on basolateral Na^+/Mg^{2+} exchange, Meij et al. suggested that diminished intracellular K^+ might depolarize the apical membrane, resulting in a decrease in Mg^{2+} uptake (Meij et al., 2003). The index patients had presented with cerebral seizures, and laboratory analyses demonstrated profound hypomagnesemia (Geven et al., 1987). Systematic serum Mg^{2+} measurements performed in additional family members revealed hypomagnesemia in numerous additional, apparently healthy individuals. Urine analyses indicated renal Mg^{2+} wasting. Interestingly, urinary Ca^{2+} excretion rates were reduced in all hypomagnesemic individuals, a finding reminiscent of GS patients (mentioned earlier). However, no other associated biochemical abnormalities were reported, especially no hypokalemic alkalosis. Meanwhile, the identical *FXYD2* mutation has been identified in two additional families from the Netherlands and Belgium with dominant hypomagnesemia, substantiating the initial findings (de Baaij et al., 2015a). Several affected family members suffered from muscle cramps and cerebral seizures. Serum Mg^{2+} levels were found to be severely low. Interestingly, two patients exhibited hypokalemia in addition, possibly pointing to a disturbance in cellular Na^+ and K^+ handling with consecutive stimulation of the renin−angiotensin−aldosterone system. Like in the original family, urine analyses demonstrated hypocalciuria in all affected individuals (de Baaij et al., 2015a). This finding without apparent volume depletion potentially contradicts the aforementioned experimental data that favored an increase in proximal tubular Ca^{2+} reabsorption due to volume depletion in GS (Nijenhuis et al., 2005).

Another hereditary defect possibly resulting in defective apical uptake of Mg^{2+} in the DCT was discovered by Glaudemans et al. The authors described a dominant-negative missense mutation in *KCNA1* encoding the voltage-gated potassium (K^+) channel Kv1.1 in a large Brazilian family with hypomagnesemia (EA1; MIM: 176260 - 160120) (Glaudemans et al., 2009). Kv1.1 colocalizes with TRPM6 in the apical DCT cell membrane. These findings for the first time demonstrated a dependency between renal Mg^{2+} and K^+ handling at the molecular level linking Mg^{2+} reabsorption to K^+ secretion. The authors proposed a model in which Kv1.1 contributes to the establishment of a negative apical membrane potential as a prerequisite for TRPM6-mediated Mg^{2+} entry (Fig. 21.4) (Glaudemans et al., 2009). The clinical phenotype of affected patients included muscle cramps, tetanic episodes, tremor, and muscle weakness starting in infancy. Laboratory analyses demonstrated a renal Mg^{2+} leak without alterations in renal Ca^{2+} handling (see later). Interestingly, *KCNA1* mutations had previously been identified in patients with episodic ataxia with myokymia, a neurologic disorder characterized by a periodic appearance of incoordination and imbalance as well as myokymia, an involuntary, spontaneous, and localized trembling of muscles (Browne et al., 1994). Similar clinical findings were also present in members of the kindred studied by Glaudemans et al. with hypomagnesemia (Glaudemans et al., 2009).

Studying a consanguineous family with two affected sisters with isolated recessive hypomagnesemia (HOMG3; MIM: 248250), Groenestege et al. identified a homozygous missense mutation in the *EGF* gene encoding the pro−epidermal growth factor (EGF) protein (Groenestege et al., 2007). The two affected girls initially presented with cerebral seizures during infancy. Unfortunately, a delay in diagnosis resulted in significant neurodevelopmental deficits in both patients. A thorough clinical and laboratory workup at 4 and 8 years of age, respectively, revealed serum Mg^{2+} levels around 0.5−0.6 mmol/L without other associated electrolyte abnormalities. A ^{28}Mg retention study in one patient as well as renal Mg^{2+} excretion rates of 3 to 6 mmol per day in the presence of hypomagnesemia pointed to a primary renal defect, while intestinal Mg^{2+} uptake appeared to be preserved. In contrast, renal Ca^{2+} excretion rates were within the normal range.

Pro-EGF is a small peptide hormone expressed in various tissues, including the DCT in kidney (Groenestege et al., 2007). It has a single transmembrane segment that is inserted in both the luminal and the basolateral membrane of polarized epithelia. After membrane insertion it is processed into active EGF peptide by cleavage from the transmembrane section. EGF activates specialized EGF receptors (EGFRs) that are expressed in the basolateral membrane of DCT cells (Fig. 21.4). This activation was shown to lead to an increase in TRPM6 membrane trafficking and increased Mg^{2+} reabsorption (Thebault et al., 2009). The identified mutation disrupts the basolateral sorting motif in pro-EGF. Hence, the activation of EGFRs in the basolateral membrane is compromised, ultimately leading to reduced Mg^{2+} reabsorption. Despite acting in a paracrine fashion in the DCT, the authors also speculated about a role for EGF as a novel selectively acting magnesiotropic hormone (Groenestege et al., 2007).

Interestingly, renal Mg^{2+} wasting is observed as a common side effect of anti-cancer treatment with EGFR-targeting antibodies (i.e., cetuximab), supporting a critical role of the EGFR signaling pathway in regulating Mg^{2+} reabsorption in

the DCT (Tejpar et al., 2007). Inhibitors of EGFR tyrosine kinase (i.e., erlotinib) were shown to have a less pronounced effect on TRPM6 trafficking and function and renal Mg^{2+} conservation in a mouse model (Dimke et al., 2010).

Another form of hereditary hypomagnesemia has been linked to mutations in *CNNM2* (HOMGSMR1; MIM: 613882) (Stuiver et al., 2011). The authors identified heterozygous *CNNM2* mutations in two families in which the affected patients presented with a clinical spectrum ranging from seizures in early childhood to muscle weakness, vertigo, and headache during adolescence. Additional heterozygous mutation carriers from both families even remained asymptomatic. Other than hypomagnesemia, serum electrolytes were within normal ranges. There are no definitive data concerning renal Ca^{2+} conservation and the presence of hypocalciuria. Of note, a neurological phenotype was not reported in any of the four affected family members. Previously, *CNNM2*, next to its homologs *CNNM3* and *CNNM4*, as well as *TRPM6*, had already been associated with serum Mg^{2+} levels in a large GWAS (Meyer et al., 2010). The *CNNM2* gene codes for cyclin M2, a transmembrane protein that is expressed in kidney at the basolateral membranes of TAL and DCT, but also in other organs, especially in brain (Stuiver et al., 2011; de Baaij et al., 2012). Whereas a truncating frameshift mutation was identified in one of the described families, affected individuals of the second family carried a missense mutation leading to a nonconservative amino acid exchange (Stuiver et al., 2011). Contrasting the initial patient cohort, Arjona et al. identified mutations in the *CNNM2* gene in hypomagnesemic patients who presented with seizures and displayed an impaired neurological development despite adequate treatment (Arjona et al., 2014). In addition, patients showed features of autism spectrum disorder, and two affected girls demonstrated severe obesity. *CNNM2* mutations were predominantly identified in the heterozygous state and occurred de novo. Finally, two siblings from a family with suspected parental consanguinity who developed seizures already in the neonatal period and displayed a severe degree of intellectual disability were found to be carriers of a homozygous *CNNM2* mutation. Magnetic resonance imaging (MRI) in these two patients demonstrated an abnormal brain morphology, whereas MRI findings in heterozygous patients were without obvious pathological findings (Arjona et al., 2014). Clearly, the neurological phenotype, i.e., seizure severity and frequency, in these patients appeared to be independent of serum Mg^{2+} levels, suggesting a primary disturbance of brain development or function. In accordance with the human phenotype, heterozygous *Cnnm2*-knockout mice display hypomagnesemia, but in addition show significantly decreased arterial blood pressure (Funato et al., 2017).

Functional studies using overexpression of *CNNM2* in HEK293 cells demonstrated an impaired cellular uptake of Mg^{2+} for mutant in comparison with wild-type CNNM2, pointing to a loss-of-function character of identified *CNNM2* mutations (Arjona et al., 2014). Biotinylation assays demonstrated a lack of cell surface expression at least for a subset of mutated CNNM2 proteins. Yet many questions concerning the cellular localization and function of CNNM2 remain unanswered. Data point to a role for CNNM2 as a potential Mg^{2+} sensor or regulatory factor rather than as a Mg^{2+} transporter, as the authors could not detect CNNM2-mediated Mg^{2+} influx nor efflux (Sponder et al., 2016). Furthermore, the Mg^{2+} uptake stimulated by CNNM2 overexpression is not dependent on extracellular Na^{+} but is abolished by 2-aminoethoxydiphenyl borate, a known inhibitor of TRPM7 ion channels, pointing to a functional coupling of CNNM2 with Mg^{2+}-permeable ion channels (Arjona and de Baaij, 2018). The role of CNNM2 in Mg^{2+} homeostasis and human physiology will be an intriguing topic of future research, as recent GWASs have identified potential links between CNNM2 and body mass index, hypertension, and coronary artery disease, as well as schizophrenia and bipolar disorders (Lv et al., 2017; Takeuchi et al., 2010; Grigoroiu-Serbanescu et al., 2015).

Hepatocyte nuclear factor 1β (*HNF1B*; *TCF2*) is a transcription factor involved in the development of kidney and pancreas. Heterozygous *HNF1B/TCF2* mutations were implicated in a subtype of maturity-onset diabetes of the young (MODY5) before an association with developmental kidney disease was reported (Horikawa et al., 1997). The renal phenotype is highly variable, including enlarged hyperechogenic kidneys, multicystic kidney disease, renal agenesis, renal hypoplasia, and cystic dysplasia, as well as hyperuricemic nephropathy (Heidet et al., 2010). The association with both symptom complexes led to the denomination "renal cysts and diabetes syndrome" (RCAD; MIM: 137920). However, this term was later replaced by the more general description as HNF1B nephropathy because the renal cystic phenotype and the development of diabetes are not uniform clinical findings. Interestingly, approximately half of affected patients present with hypomagnesemia due to renal Mg^{2+} wasting (Adalat et al., 2009). Again, the defect in renal Mg^{2+} conservation is accompanied by hypocalciuria. HNF1B regulates the expression of numerous renal genes, including the *FXYD2* gene, which bears several HNF1B-binding sites in its promoter region (Adalat et al., 2009). Therefore, defective *FXYD2* transcription and diminished expression of the γ-subunit of Na/K-ATPase represent a putative mechanism explaining the renal Mg^{2+} wasting in patients with *HNF1B* mutations.

A similar renal phenotype comprising urinary Mg^{2+} loss has been demonstrated in patients affected with transient neonatal hyperphenylalaninemia due to recessive mutations in *PCBD1* (MIM: 264070) (Ferre et al., 2014). *PCBD1* encodes a bifunctional protein that acts in the salvage pathway for the regeneration of tetrahydrobiopterin, but also as a binding partner of the HNF1B transcription factor. Functional studies demonstrated a dimerization with HNF1B that leads

to a stimulation of the *FXYD2* promotor in the DCT (Ferre et al., 2014). Interestingly, a MODY-type diabetes was also observed in two of the described patients.

Kenny−Caffey syndrome type 2 (MIM: 127000) is clinically characterized by severe short stature, small hands and feet, craniofacial anomalies, delayed closure of the anterior fontanelle, and the occurrence of cerebral convulsions. Radiologic studies reveal a cortical thickening and medullary stenosis of tubular bones. Seizures are secondary to severe hypoparathyroidism and resulting hypocalcemia. In addition, patients may develop severe hypomagnesemia. Early manifestations in infancy with profound hypomagnesemia, hypocalcemia, and undetectable serum PTH have been described, resembling the clinical picture of HSH due to *TRPM6* mutations (Isojima et al., 2014). As magnesium repletion was able to correct the hypoparathyroidism, the authors suggested a paradoxical block in PTH synthesis and/or secretion similar to that observed in HSH (see earlier) (Abraham et al., 2017). Kenny−Caffey syndrome type 2 is caused by heterozygous mutations in the *FAM111A* gene that mostly occur de novo (Unger et al., 2013). *FAM111A* codes for an intracellular protein with homology to trypsin-like peptidases with yet undefined function. It is primarily expressed in bone and parathyroid gland and a complex role in the regulation of bone formation as well as parathyroid gland development was suggested (Abraham et al., 2017).

Finally, the clinical and biochemical evaluation of a large Caucasian family in which affected individuals presented with hypomagnesemia, hypercholesterolemia, and hypertension established another entity, termed "metabolic or mitochondrial hypomagnesemia" (MIM: 500005) (Wilson et al., 2004). The transmission of the phenotype exclusively by females suggested mitochondrial inheritance. Genetic studies identified a mutation in the mitochondrial-coded isoleucine tRNA gene, $tRNA^{Ile}$ or MTTI.

The majority of genetically affected family members exhibited at least one of the mentioned symptoms; approximately half showed a combination of two or more symptoms, and around 1/6 had all three features. Serum Mg^{2+} levels of family members in the maternal lineage greatly varied, ranging from ∼0.8 to ∼2.5 mg/dL (equivalent to ∼0.3−∼1.0 mmol/L) with approximately 50% of individuals being hypomagnesemic (serum Mg^{2+} <1.8 mg/dL). These hypomagnesemic individuals exhibited higher fractional Mg^{2+} excretions than their normomagnesemic relatives in the maternal lineage, clearly pointing to a renal Mg^{2+} leak. Interestingly, hypomagnesemia was accompanied by decreased urinary Ca^{2+} levels, a finding pointing to the DCT as the affected tubular segment.

The mitochondrial mutation affects the $tRNA^{Ile}$ gene *MTTI* and is located directly adjacent to the anticodon triplet. This position is highly conserved and critical for codon−anticodon recognition. However, the functional link between the tRNA defect and mitochondrial function remains to be elucidated in detail. As ATP consumption along the kidney tubule is highest in the DCT, the authors speculate on an impaired energy metabolism of DCT cells, which in turn could lead to disturbed transcellular Mg^{2+} reabsorption (Wilson et al., 2004).

Acquired hypomagnesemia

Cisplatin and carboplatin

The cytostatic agents cisplatin and carboplatin are widely used in various protocols for anti-cancer treatment of solid tumors. Among various side effects, nephrotoxicity receives the most attention as it represents a major dose-limiting factor. Carboplatin has been reported to have less severe side effects than cisplatin (Boulikas and Vougiouka, 2004; English et al., 1999; Goren, 2003). Hypomagnesemia due to renal Mg^{2+} wasting is regularly observed in patients treated with cisplatin (Goren, 2003; Lajer and Daugaard, 1999). The incidence of Mg^{2+} deficiency is greater than 30% but increases to over 70% with longer usage and greater accumulated doses. Interestingly, cisplatin-induced renal Mg^{2+} wasting is relatively selective (Goren, 2003). Hypocalcemia and hypokalemia may be observed but only with prolonged and severe Mg^{2+} deficiency (Mavichak et al., 1988). The effects of cisplatin may persist for months or years, long after the inorganic platinum has disappeared from the renal tissue (Bianchetti et al., 1991; Markmann et al., 1991).

Studies in cisplatin-treated rats demonstrated a downregulation of TRPM6 as well as EGF expression (van Angelen et al., 2013; Ledeganck et al., 2013). In contrast, the expression of other genes and proteins involved in tubular Mg^{2+} reabsorption remained stable or was even upregulated (*cldn16, cldn19*), potentially reflecting compensatory mechanisms (Ledeganck et al., 2013). Therefore, a defect in EGF-mediated stimulation of TRPM6 in the DCT is suggested to represent the underlying cause of renal Mg^{2+} wasting. Interestingly, cotreatment with Mg^{2+} ameliorated the cisplatin-induced downregulation of TRPM6 and hypomagnesemia and prevented a decline in renal function observed after administration of cisplatin alone (Saito et al., 2017).

Aminoglycosides

Aminoglycosides such as gentamicin induce renal impairment in a significant number of patients, depending on dose and duration of administration. Furthermore, aminoglycosides cause renal Mg^{2+} as well as Ca^{2+} wasting (Shah and Kirschenbaum, 1991). These effects occur soon after onset of therapy; they are dose dependent and reversible upon withdrawal of the drug (Elliott et al., 2000). The combined renal loss of Ca^{2+} and Mg^{2+} suggests that aminoglycosides might affect divalent cation transport in the TAL. As gentamicin is a polyvalent cation it was postulated that it may have its effects on the CaSR (Dai et al., 2001; Ward et al., 2002). As in patients with a constitutive activation of the CaSR (see earlier; Watanabe et al., 2002), a more complex, Bartter-like phenotype consisting of hypokalemic metabolic alkalosis, hypocalcemia, hypomagnesemia, and polyuria has been observed (Singh et al., 2016). In line with the assumption of a TAL defect, studies in mice demonstrated that within hours of gentamicin administration the expression of genes involved in transcellular Ca^{2+} and Mg^{2+} reabsorption in the DCT (Trpv5, Trpv6, Trpm6) is upregulated as a potential compensatory mechanism preventing further electrolyte losses (Lee et al., 2012).

Calcineurin inhibitors

The calcineurin inhibitors cyclosporine and tacrolimus (FK506) are widely used as immunosuppressants in organ transplant recipients and in patients with numerous immunologic disorders. However, patients are at high risk of developing acute and chronic renal injury, including tubular dysfunction with subsequent disturbances in mineral metabolism. Both drugs commonly lead to renal Mg^{2+} wasting and hypomagnesemia (Rob et al., 1996). Calcineurin inhibitor therapy has been shown to be associated with inappropriately high fractional excretion rates for Mg^{2+}, suggesting a distal tubular reabsorption defect (Lote et al., 2000). For tacrolimus, a downregulation of Ca^{2+} and Mg^{2+} transport proteins, including TRPV5 and TRPM6, in the DCT was demonstrated (Nijenhuis et al., 2004). It was speculated that FK506-binding proteins, which are known to regulate Ca^{2+}-permeable TRP-like cation channels, might be involved (Goel et al., 2001). More recent studies in mice demonstrated that cyclosporine downregulates TRPM6 ion channels as well as the NaCl cotransporter NCCT (Ledeganck et al., 2014). The same group also described decreased urinary EGF levels in hypomagnesemic cyclosporine-treated renal transplant patients, pointing to the involvement of the EGF axis in disturbed TRPM6 expression and function (Ledeganck et al., 2014).

Mg^{2+} deficiency has also been implicated as a contributor to calcineurin inhibitor—related nephrotoxicity and arterial hypertension. These adverse effects were shown to depend on dietary salt intake in the rat and may be prevented by oral Mg^{2+} supplementation (Mervaala et al., 1999; Miura et al., 2002).

Proton pump inhibitors

Proton pump inhibitors (PPIs) used for the reduction of gastric acidity have emerged as one of the most widely used classes of drugs worldwide. A small, but significant number of patients receiving PPIs develop moderate to severe hypomagnesemia clinically apparent as muscle cramps, tetany, or even cerebral convulsions (Cundy and Mackay, 2011). In a substantially larger number of patients receiving PPIs, hypomagnesemia or the connection between PPI use and Mg^{2+} deficiency may remain unrecognized. In their review, Cundy and Mackay summarize the data from previous publications revealing severely low serum Mg^{2+} levels of less than 0.4 mmol/L with concomitant hypocalcemia, a finding reminiscent of HSH patients with genetic TRPM6 defects (see earlier) (Cundy and Mackay, 2011). Suppressed PTH levels with consecutive hypocalcemia had already been described before in hypomagnesemic patients receiving PPIs (Epstein et al., 2006). Unfortunately, the mechanism underlying the hypomagnesemia in PPI has not been clarified in detail. As renal Mg^{2+} excretion rates have been reported to be normal or even low, a defective intestinal Mg^{2+} absorption has been suggested (William and Danziger, 2016). However, whether the proposed effects of PPIs on intestinal Mg^{2+} absorption involve the pH-sensitive regulation of TRPM6 ion channels apically located on intestinal brush border cells or other proteins involved in intestinal Mg^{2+} uptake remains to be investigated.

At any rate, it is recommended to closely monitor serum Mg^{2+} levels in patients receiving PPIs, particularly those with concomitant cardiac disease and risk for arrhythmia. The other way around, attention should be drawn to the medication of patients presenting with severe hypomagnesemia and suppressed PTH.

Chapter outline

Introduction

The skeleton is unique organ system that serves human physiology in many ways. Some of its key functions include mechanical support, protection of vital soft tissue organs, and serving as a reservoir for key minerals such as calcium, phosphorus, protons, and carbonate. The mineral phase of bone is predominantly a crystalline form of hydroxyapatite with the formula $Ca_{10}(PO_4)_6(OH)_2$. However, in actuality, in humans there is extensive substitution of the hydroxyl groups (OH^-) with anions such as fluoride, chloride, and carbonate. About 60% of the volume of bone resides in the mineral phase with about 40% in the organic matrix. And with the skeleton making up about 15% of the total body weight of an average human being, bone can be a very large storage compartment for osseous-seeking elements.

In addition, and with more relevance to this discussion, there can be extensive accumulation of toxic elements that replace calcium in the crystalline structure. These forms of apatite are referred to as "calcium-deficient hydroxyapatites." Approximately 60 cations and anions have been identified as osteotropic elements with avid bone-seeking affinities. About 20 are present in higher quantities with the rest existing in trace amounts. This affinity of charged molecules for hydroxyapatites is a common characteristic of a material with a high charge density. In fact, in the case of hydroxyapatite, its ionic properties have been exploited as a scaffold for the chromatographic partitioning of complex molecules. Thus, it is easy to understand that extending this physical chemistry to the mineral phases in the skeleton provides a large and avid reservoir for an array of molecules and ions.

Research into bone-seeking toxic elements

Surprisingly, it was during the era of the development of the atomic bomb in 1942 that the study of how heavy metals affected bone and other human tissues began in earnest. Literally dozens of elemental by-products were produced by an atomic explosion, but little to nothing was known about how they affected human tissues. The United States dealt with this problem with the launch of a large and sophisticated project known as the Manhattan Project. The project had two major

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00022-1

scientific directions. The first was centered in the physics laboratories studying the development of the bomb that was carried out in secret atomic energy facilities in Oak Ridge, Tennessee; Los Alamos, New Mexico; and Hanford, Washington. The second direction was devoted to studying how radioactive elements were harbored by specific organs and how they affected tissue function. And as expected, the properties of the skeleton provided a large and high-affinity reservoir for bone-seeking metals such as polonium, plutonium, uranium, thorium, radium, cadmium, cobalt, aluminum, and lead. These investigations were carried out in Rochester, New York, and were the impetus for the growth and development of a world-renowned bone research group in the following decades. The program in Rochester morphed into an Atomic Energy Commission−supported facility in 1947.

After World War II and with the expansion in manufacturing, most of the heavy metal toxins entering the environment were from industrial pollution (Jaishankar, 2014; Nagajyoti, 2010). Heavy metals in wastewater originated from natural sources, soil erosion, natural weathering, and, most importantly, human activities such as mining, industrial effluents, and farming control agents (Morais, 2012).

The most common metals that affect the skeleton are lead and aluminum. Both of these toxic elements contribute to well-recognized bone diseases. The exposure source for lead is generally known to be from the environment and for aluminum is known to be from the environment as well as inadvertent human dosing during clinical procedures such as renal dialysis. Other environmental trace elements that have been identified in bone include cadmium, mercury, and iron, in addition to elements such as cobalt entering humans through injudicious clinical use of orthopedic implants containing mixed metal alloys (Rebolledo, 2011).

Of the key elements that seek the hydroxyapatite of bone, two have been identified as the agents responsible for most of the toxicological pathologies. They are lead and aluminum, with lead being identified as the most dangerous to skeletal metabolism at the present time.

Lead

Much is known regarding the toxicity of lead in neural, renal, and hematopoietic development (reviewed in Wani et al., 2015). Its effects are uniformly devastating to the normal physiology of not only these well-studied tissues but virtually every organ system in the body. However, what has been underappreciated since the 1970's is that bone is also a key target for lead toxicity. This is due to two important features related to how lead interacts with the skeleton; they are the sequestering of lead in bone and the slow turnover and long half-life of lead in the mineral phase of bone.

Virtually all of the lead (94%−97%) in adult humans resides in the skeleton, with the remaining sites being (in order of content) red blood cells, liver, skeletal muscle, skin, kidney, lung, and brain (and other soft tissues) (Barry, 1975). The half-life of lead in bodily tissues is known. It is approximately 1 month in blood, approximately 2 months in soft tissues, and 25−30 years in bone (ATSDR, 2007).

Consider the implications of these facts. Essentially any individual who has been exposed to lead either from the environment or from occupational sources will carry a significant portion of that burden for his or her entire lifetime. In fact, once a person is no longer exposed to a lead source, blood and soft tissue levels may decline to low levels, but skeletal lead can remain unacceptably high and continue to adversely affect cells in the bone compartment.

The reason the skeletal half-life for lead is so long is due to two key properties of bone. First, lead is incorporated into the crystal lattice structure of hydroxyapatite by displacing calcium ions. Its affinity for the mineral phases of bone is very high, such that when lead ions are mobilized through bone resorption, they can redistribute to other mineral sites and not leave the bone compartment. Second, skeletal turnover in humans is slow. Estimates indicate that the entire skeleton turns over at a rate of approximately 10% per year, with cortical bone averaging 4% per year and trabecular bone averaging 28% per year (Manolagas, 2000). Thus, there is little opportunity to decrease the level of lead in osseous tissues through normal metabolism. Also, as might be expected, the accumulation and release of lead levels in cortical and trabecular bone follow the general metabolic activity of their particular compartments. That is, (1) acute lead exposure will lead to a more rapid rise in trabecular bone than cortical bone and (2) lead release from the skeleton will occur first from trabecular bone and later from cortical bone.

Another feature of the long half-life of lead in bone is that the skeleton can continue to dose the blood and soft tissues throughout life. That is, in low-skeletal-turnover states lead remains in the bone compartment, but in high-turnover states it is released into the circulation. This accounts for the long-standing finding that blood lead levels rise in all females during and after the menopause due to enhanced skeletal turnover upon the loss of estrogen (Silbergeld et al., 1988; Potula, 2006). In fact, any acceleration in skeletal turnover (i.e., calcium deficiency, fracture, hyperparathyroidism, pregnancy, lactation, etc.) will lead to elevated blood lead levels (ATSDR, 2007).

Measurement of lead in bone

The measurement of lead levels in a human skeleton can be performed either with invasive or with noninvasive techniques. Invasive measurements are, as one might expect, limited to situations in which an actual sample of bone can be obtained from a living subject undergoing surgery or from a cadaveric specimen. The "pros" to using a specimen of bone are (1) the quantification methods (using atomic absorption spectrometry or mass spectrometry) are highly accurate and (2) different compartments of bone (i.e., cortical vs. trabecular) can be measured separately. The "cons" to using specimens of bone are the invasiveness of the specimen procurement and the unfeasibility of making longitudinal measurements in any one person.

Interestingly, it is possible to measure lead levels in the skeleton in a noninvasive, safe way utilizing an X-ray fluorescence technique. This method was first described in 1976 by Ahlgren et al. (Ahlgren, 1976) and later perfected by the physicists at McMaster University, Hamilton, Ontario (Chettle, 1991).

The principle behind this method depends on the use of an exciting isotope (^{109}Cd) and a sensitive X-ray detection system. ^{109}Cd emits characteristic energies of gamma rays that when directed toward a bone (close to the surface of the skin) can excite an inner shell (i.e., K-shell) electron in lead atoms. Upon deexcitation of the activated lead atom, specific and characteristic X-rays are emitted and detected by the detection sensors. The magnitude of this fluorescence decay is proportional to the number of lead atoms activated by the ^{109}Cd. The system is calibrated with lead-doped samples and after the appropriate calculations are made, a value of micrograms of lead/gram of bone can be made. The "pros" for this method are that (1) it is noninvasive, (2) longitudinal measurements can be made in a single subject, and (3) the radiation dose is extremely low, with little safety concern. The "cons" are (1) accuracy of the measurements in bones with a low lead content is low, (2) the subject must remain in the scanner for 30–45 min for one measurement, and (3) there are no commercially available systems; each system must be constructed from specialty equipment. Nevertheless, the ability to make noninvasive measurements led to a flurry of activity in the 1990s using K-shell X-ray fluorescence to measure many different cohorts of people (reviewed in Hu, 1998).

Lead as an unrecognized risk factor in osteoporosis

An unexpected technical discrepancy in measuring bone mineral density (BMD) by dual-energy X-ray absorptiometry (DXA) prevented clinicians and investigators from recognizing that lead exposure could cause osteopenia and contribute to the genesis of osteoporosis. This technical anomaly occurred in the early years when first-generation DXA scanners were first being used in the diagnosis of osteoporosis. It appears that the presence of lead in bone created an artifactually elevated estimate of bone density. The reason for this is not entirely clear but might be related to the very high atomic mass of lead. Reports in the literature bore out this finding. Escribano and colleagues (1997) showed in an animal study that lead exposure in rats led to a marked decrease in the histomorphometric parameters of trabecular bone volume, number, and thickness. But when these same animals were evaluated with early models of densitometers (i.e., dual-photon absorptiometers) the rat bones showed significant elevations in bone density.

A qualitatively similar result was described by Laraque et al. (1990). In this report, the investigators showed that children with elevated blood lead levels showed a significantly higher bone mineral content (BMC) than a control cohort available at that time. The BMC measurements were made with a single-photon absorptiometer.

To definitively document these discrepancies, it would be best to make a direct comparison of bone density using both the older and the newer-generation technologies. Fortuitously, while upgrading densitometers, our research group had the opportunity to perform a direct comparison between a pencil-beam dual-photon absorptiometer (Lunar DPX-L) and a fan-beam dual X-ray absorptiometer (Lunar Prodigy). In this experiment, bovine bone was doped with known trace amounts of lead and then measured in both scanners. The (unpublished) data are shown in Fig. 22.1. The addition of "micrograms" of lead to "grams" of bone (i.e., parts per million) should not have changed the total mass of the bone sample to any measurable degree. Yet, the DPX-L scanner showed a clear increase in BMD with added lead. If this measurement were being made in a human it would have increased the patient's T score by 0.5–1.0 standard deviations. The Prodigy scanner was also affected by lead in the sample; however, the effect was not evident until a level near 1000 μg Pb/g bone was reached. A level of 1000 μg Pb/g bone is at least 100 times what an exposed human would be expected to have and has never been reported. Discrepancies in the detection and calculations for BMD between dual-photon scanners and dual-X-ray scanners have been documented in the literature (Huffman, 2005).

Two important points can be derived from these observations. First, many years ago lead exposure and its sequestration in the skeleton probably was overlooked as a risk factor for low bone density and osteoporosis. This was due to the apparent interference by lead in the photon-based methods used in bone densitometers. Second, new-generation scanners

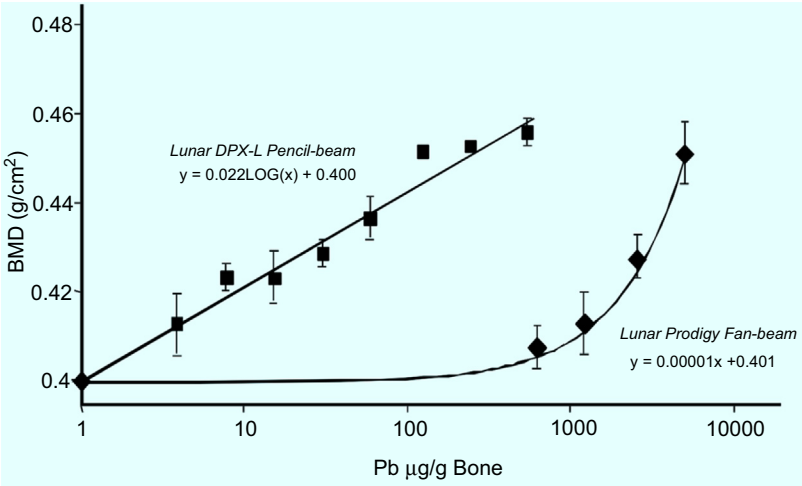

FIGURE 22.1 Bone densitometry in specimens containing measured amounts of lead. Two grams of pulverized bovine bone containing graded amounts of lead salts was scanned with a Lunar Dual-Photon DPX-L densitometer or a GE/Lunar Dual-Energy X-ray absorptiometer. The bone specimens were contained in tissue culture wells (area = 2.0 cm^2). The data are presented as areal density, i.e., "grams of mineralized bone/cm^2 versus micrograms of elemental lead per gram of bone." The bovine bone specimens were not incubated to dryness prior to making the measurements and thus their "weight percent" was approximately 40% mineral and 60% organic matrix + water. Lead (in the parts per million range) affected the bone mineral density (*BMD*) measurement at as little as 5.0 µg/g bone when scanned with the dual-photon densitometer. The dual-energy X-ray densitometer did not detect the added lead until the levels reached supratoxicological levels (approximately 1000 µg/g bone).

with the different mechanisms for generating X-rays and with different calculation algorithms do not appear to be affected by skeletal lead in the range seen in the human population.

How does lead cause low bone density?

In an adult skeleton, bone mass is controlled through regulation of bone-forming activities (by osteoblasts) and bone-resorbing activities (by osteoclasts). When these two cellular processes are in balance with each other, bone mass is maintained at a healthy, steady-state level. However, when these two processes are no longer balanced bone mass can be pathologically increased (i.e., osteopetrosis) or, more commonly, pathologically decreased (i.e., osteoporosis). The skeleton maintains an exquisite series of check and balances to prevent large swings in bone mass. This was recognized many years ago when Harris and Heaney described the kinetically coupled activities of bone-forming and bone-resorbing cells (Harris, 1969). Thus, for an agent such as lead to alter bone mass, it must disrupt the balance between osteoblastic and osteoclastic cellular activities. The question that arises is, which process is the target of lead toxicity in the skeleton?

Given the observation that lead can be easily mobilized in high-turnover states in the skeleton (as mentioned earlier) and that basic science investigations do not show any major effects on osteoclastic bone resorption (Carmouche, 2005), it seems that the important cellular target for lead toxicity is the osteoblast.

Osteoblasts and their progenitor cells residing in the bone compartment can be exposed to locally high concentrations of lead. Assuming conservative values of the lead content of the skeleton (i.e., 5 µg/g bone), the amount of bone resorbed by an osteoclast (i.e., 1 µg), and the diffusion of lead into a radius of 100 µm around a lacuna, an approximate estimate of the lead concentration at a remodeling site can be on the order of 1−10 µM. From basic science investigations, this concentration of lead is sufficient to have profound inhibitory effects on osteoblast function (Beier et al., 2015).

As expected, the in vitro effects of lead manifest themselves in whole-animal models as a decrease in bone quantity and bone quality. Exposing mice (which happen to be an excellent model for lead-induced bone loss) to lead in their drinking water will induce an osteoporotic-like phenotype (Beier et al., 2013). By altering the concentration of lead acetate in the animals' drinking water it is possible to achieve virtually any relevant concentration of the metal ion in blood and bone in 3−6 weeks (Carmouche, 2005; Beier et al., 2013). Interestingly, animals display no difficulty in drinking the water, as the addition of lead confers a pleasant sweet taste. (Unfortunately, this also occurs in human infants around lead-contaminated

materials.) After 6 weeks of exposure at 55 ppm lead in water, micro-computed tomographic and histological analyses demonstrate significant changes. They are:

- decrease in skeletal bone volume/total volume
- decrease in volumetric BMD
- decrease in trabecular number
- increase in trabecular separation
- decrease in bone apposition rate
- no change in osteoclast number

The β-catenin/sclerostin axis: is it the mechanism for lead toxicity in osteoblasts?

The *SOST* gene encodes a protein known as sclerostin. The gene is located on chromosome 17q12−q21. Osteocytes were one of the first cells shown to express sclerostin; however, it now appears that the cells from at least four tissues can produce this molecule. They include uterus, kidney, tissues of tooth development, and, most importantly, osteoblasts (Maeda, 2007; Blish, 2008; Murashima-Suginami, 2008; Tanaka, 2008; Rutger, 2005). Sclerostin is a very potent inhibitor of bone formation. It represses osteoblast function and number and can induce apoptotic pathways in these cells. The mechanism of action of sclerostin appears to occur through the Wnt/β-catenin pathway. Data suggest that sclerostin binds to low-density lipoprotein receptor−related protein 5/6, preventing association with the Wnt receptor, Frizzled. This interference blocks Wnt binding and depresses osteoblastic bone formation (van Bezooijen, 2004; Li, 2005).

What is most remarkable regarding this intracellular pathway is that when osteoblasts are exposed to lead there is a manifold upregulation of both the mRNA and the protein for sclerostin (Beier et al., 2015). This stimulation is observed in vitro (with qPCR and western blot assays) and in vivo (with immunohistochemical quantification). Thus, it is likely that during remodeling of lead-containing bone, excess sclerostin expression uncouples osteoblastic bone formation from resorption and an inadequate amount of new bone is deposited. Over many remodeling cycles this would lead to a decrease in skeletal mass.

Mechanism of action of lead: stimulation of sclerostin expression

How can a heavy metal divalent cation specifically affect a key gene in osteoblasts? This is a question that is not yet fully answered; however, the work of Beier (Beier et al. 2013, 2014, 2015) and Holz (Holz, 2012) provides some clues. Lead ion is known to interact with a number of kinase enzymes that utilize ATPase reactions to drive phosphorylation (protein kinase C, calmodulin, Na/K-ATPase, Ca-ATPase) (Flora et al, 2008; Murakami, 1993; Kramer, 1986). One of these kinases is the type 2 transforming growth factor β (TGFβ) receptor, responsible for the phosphorylation of Smad3, and thus it would be expected that lead can block Smad3 reporter activity, decrease phospho-Smad3 intracellular protein levels, and prevent phosphorylation of Smad3 in a cell-free system (Beier et al., 2015). The relevance of these observations lies in the fact that through TGFβ/Smad3 signaling, gene expression of sclerostin is repressed (Beier et al., 2015) and thus, any mechanism that interferes with phospho-Smad3 formation would derepress *SOST* gene activation and stimulate sclerostin levels. A diagrammatic representation of this regulatory pathway is presented in Fig. 22.2.

A clinical opportunity

From a clinical perspective, it may be possible to directly treat lead-induced osteoporosis with a pharmaceutical agent that was recommended in January 2019 for approval by the US FDA Advisory Panel (AMG 785, romosozumab). This humanized blocking antibody inhibits sclerostin activity. If the effect of lead in humans is mediated, even in small part, by upregulation of sclerostin, then this therapeutic agent could be extremely effective in treating the low bone mass. This is a real possibility given that romosozumab has shown very promising results in stimulating bone formation in a large phase III clinical trial (i.e., the ARCH study, Saag, 2017).

Aluminum

Aluminum (Al) toxicity-induced osteomalacia was a common complication of hemodialysis for some patients with chronic renal failure in the 1970s and 1980s, until it was discovered that high levels of aluminum in the tap water used to make the dialysis fluid was the main cause. High serum Al levels (100−800 μg/L vs. normal values of <35 μg/L) from the contaminated water resulted in so-called "dialysis" dementia as well as osteomalacia and microcytic anemia (Alfrey, 1976;

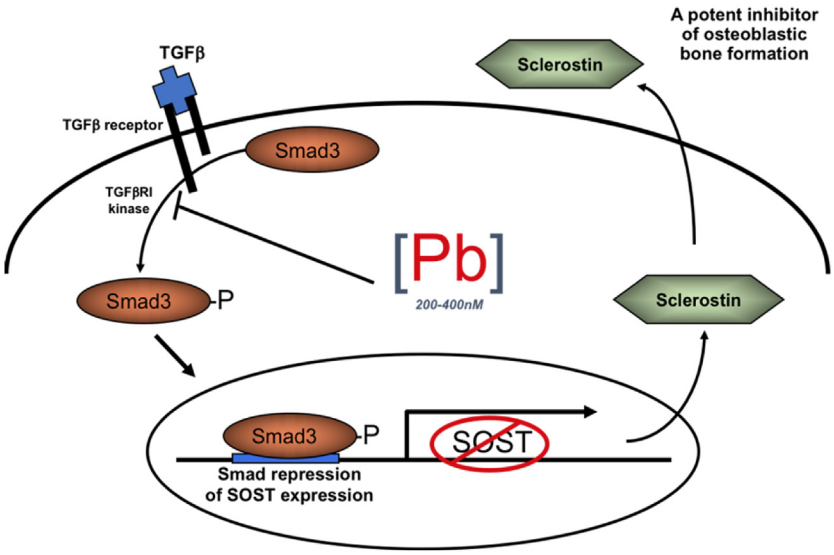

FIGURE 22.2 Intracellular mechanism by which lead induces sclerostin synthesis. Lead, in the 200−400 nM range, can block the phosphorylation of Smad3. Under normal conditions phospho-Smad3 resides in the nucleus and binds to a DNA-response element that represses *SOST* gene expression and sclerostin synthesis. However, in the presence of lead phospho-Smad3 levels are decreased and *SOST* gene activation is "derepressed," evoking a large increase in sclerostin production. *TGFβ*, transforming growth factor β.

Parkinson, 1979; Ellis, 1979; Boyce, 1982), and most patients with this dementia died of it before the cause was discovered. Aluminum is the most common metal in the earth's crust and it can be leached from surface rocks by rain, particularly acid rain (Krewski, 2007). This leaching can lead to high Al levels occurring naturally in water in some reservoirs. Thus, depending upon local conditions, levels of Al in the tap water used in dialysis units or for home dialysis can vary significantly around the world, from <30 μg/L (normal and acceptable) to ~100 μg/L (Boyce, 1982) or >200 μg/L (Krewski, 2007), which is the upper limit of the US Environmental Protection Agency's secondary maximum contaminant level for total Al in water and above which water becomes colored (Willhite, 2012).

Importantly, however, the highest levels of Al were found in water from reservoirs to which Al had been added by water authorities in the form of aluminum sulfate to cause aggregation (flocculation) and subsequent precipitation of suspended particles that discolored the water (Krewski, 2007). This fulfilled legal mandates that tap water must be clear, but it led to Al levels in water from some reservoirs being >1000 μg/L (Boyce, 1982). The Al passed directly from the dialysis fluid into patients' bloodstreams, resulting in cumulative toxicity with each dialysis, typically three per week, because Al is excreted normally by the kidneys, and the lack of renal function in dialysis patients compounded the damage (Alfrey, 1980).

After the cause of the dementia and osteomalacia was identified, Al was removed from contaminated tap water by passing it through reverse osmosis and/or deionization units before being used for dialysis. However, this did not prevent recurrence of the toxicity in all cases until it was fully appreciated that these units needed to be serviced regularly and that Al levels had to be measured in the water flowing from them to confirm that they were working efficiently. This is particularly necessary in home dialysis settings in towns where Al levels are very high as a result of the addition of aluminum sulfate and where monitoring of water Al levels in each home is the responsibility of local authorities.

The identification of aluminum toxicity as a cause of dementia then led to studies to determine if lifelong exposure to aluminum in drinking water and from other sources could be a cause of Alzheimer's disease. Some studies reported Al deposits in brains of Alzheimer's patients (Crapper, 1973; Perl, 1980) and these reports led to numerous epidemiologic studies. Although Al concentrations increase in brain and bone (Hellstrom, 2005) with age in humans, other investigators did not confirm these findings in neuritic plaques in brains from Alzheimer's patients (Landsberg, 1992). Nevertheless, improvement in cognitive function has been reported in some Alzheimer's patients given treatment to reduce blood and tissue levels of aluminum, supporting the "aluminum/dementia hypothesis" (Davenward, 2013). Overall, however, a potential causative role for Al in the pathogenesis of Alzheimer's disease remains controversial (Exley, 2014).

Aluminum toxicity can also occur as a consequence of ingestion of aluminum-containing phosphate-binding drugs given to patients with chronic renal failure to help reduce absorption of phosphate from the intestinal tract (Kaehny et al., 1977a). Serum phosphate levels are high in these patients because they are unable to excrete phosphate through their

dysfunctional kidneys. Initially, it was thought that aluminum in phosphate binders, such as aluminum hydroxide, was not absorbed from the gastrointestinal tract. However, this was proven to be wrong by the finding of high serum aluminum levels not only in patients with renal failure not yet on dialysis, but also in individuals with normal renal function taking large quantities of aluminum hydroxide as an antacid for indigestion (Kaehny et al., 1977a). Aluminum absorption from the gut is enhanced by acidic fruits, such as oranges and lemons, and orange juice. Aluminum can be leached from aluminum cooking pots and wrapping foil and this can lead to high Al concentrations, for example, in the juice from chickens wrapped and cooked in aluminum foil along with lemons (Krewski, 2007).

Lead, cadmium, and arsenic can also leach out of cooking utensils during food preparation, which may be a more pressing contemporary issue in developing countries (Weidenhamer, 2017). Aluminum was also found to be a contaminant of casein hydrolysate used as the amino acid source in some intravenous preparations for patients receiving total parenteral nutrition in the 1980s (Klein, 1982), with some patients being reported to receive 2−3 mg Al/day (Kaehny et al., 1977b). Aluminum was also found in some albumin solutions used to expand the intravascular volume in patients with acute hypovolemic states and as the replacement fluid used during plasma exchange (Maharaj, 1987). These problems have largely been solved by removal of Al from medical fluids given to patients.

Patients with end-stage chronic renal failure typically develop hypocalcemia as a consequence of inadequate phosphate excretion and calcium reabsorption in their damaged kidneys, coupled with their inability to 1-hydroxylate 25(OH) vitamin D_3 because their renal tubular cells become deficient in 1α-hydroxylase (Goodman, 2008). Consequently, they develop secondary hyperparathyroidism with associated increased bone remodeling, which can be accompanied by vitamin D deficiency-related osteomalacia unless they are given appropriate treatment to prevent these (Sherrad, 1993). These treatments include dietary phosphate restriction, phosphate binders, calcimimetics, calcitriol, or vitamin D analogs, or a combination of calcimimetics with calcitriol or vitamin D analogs, and addition of calcium to dialysis fluid (KDIGO, 2017; Jamai, 2013; Cocchiara, 2017; Vestergaard, 2011). If patients are exposed to sufficiently high levels of Al, mineralization will be inhibited because the aluminum gets deposited along the mineralization front between osteoid and calcified matrix where it prevents calcification and leads to osteomalacia (Ellis, 1979; Boyce, 1981, 1982, 1992). Al-related osteomalacia became recognized as an entity distinct from vitamin D deficiency-related osteomalacia because of its association with dementia, microcytic anemia, myopathy, fractures, and a tendency to develop hypercalcemia (Boyce, 1982). These were accompanied by a characteristic focal distribution of thickened osteoid seams on trabecular surfaces (Fig. 22.3) (Boyce, 1982) compared with the typical extensive distribution of thickened osteoid seams in vitamin D deficiency-related osteomalacia (Fig. 22.4). The fact that osteoid seams were much thicker than those seen in biopsy specimens from patients with secondary hyperparathyroidism and osteoid seams of normal thickness indicates that aluminum does not inhibit the formation and deposition of osteoid matrix by osteoblasts in vivo in many patients. Some studies have reported aluminum staining along osteoid surfaces associated with normal osteoid thickness in addition to reduced bone formation rates and osteoblast surfaces, suggesting that aluminum may inhibit mineralization and bone formation in some patients

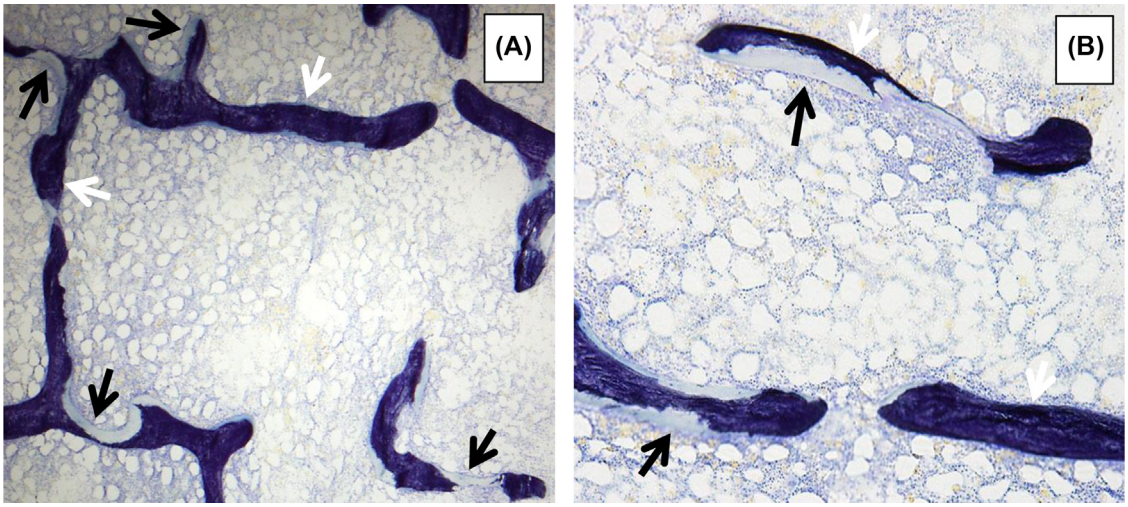

FIGURE 22.3 Undecalcified sections of an iliac crest bone biopsy specimen from a dialysis patient with chronic renal failure and aluminum-induced osteomalacia. Note the characteristic focal distribution of thickened osteoid seams (*black arrows*) on the trabecular surfaces, much of which is fully calcified (*white arrows*). Toluidine blue staining. (A) ×4 original magnification, (B) ×10 original magnification.

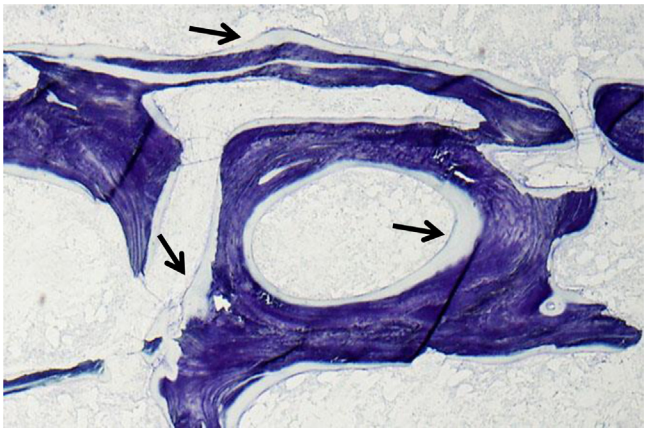

FIGURE 22.4 Undecalcified section of an iliac crest bone biopsy specimen from a patient with alcoholic cirrhosis and vitamin D deficiency–induced osteomalacia. Thickened osteoid seams (*black arrows*) are present on most of the trabecular surfaces. Toluidine blue staining, ×4 original magnification.

(de Vernejoul, 1985; Dunstan, 1984; Parisien, 1988). Indeed, inhibitory effects of aluminum have been reported on osteoblasts and mineralization in vitro (Sprague, 1993; Sun, 2016). Aluminum can be incorporated into mineralizing bone without inhibiting calcification (Chappard, 2016) and interestingly, the thickened osteoid seams can mineralize after Al sources have been removed (Boyce, 1992). The hypercalcemia in aluminum toxicity developed as a consequence of treatment with calcitriol, which enhanced the intestinal absorption of calcium, and the addition of calcium to dialysis fluid (Boyce, 1982). This hypercalcemia sometimes led to unnecessary and potentially fatal parathyroidectomy in patients who were mistakenly diagnosed with tertiary hyperparathyroidism. Aluminum toxicity has also been implicated in the pathogenesis of so-called aplastic or low-turnover renal osteodystrophy (Sherrard, 1996). In this condition, bone turnover is suppressed and osteoid seams are typically thin, and in some of these cases aluminum has been detected along mineralization fronts. It is associated with low bone mass and increased risk of fractures (Cannata-Andia, 2013). Although high concentrations of Al can be toxic to osteoblasts cultured in vitro, the cause of this low-turnover osteodystrophy in renal failure remains poorly understood.

Bone biopsy became the gold standard for the diagnosis and management of Al-induced osteodystrophy in renal failure in many academic nephrology departments in the 1970s through the 1990s. However, as water contamination with Al became more generally recognized as the cause of the osteodystrophy, and water purification measures kept dialysis water Al levels low, and Al-containing phosphate binders were replaced by others containing calcium, bone biopsy became redundant in most dialysis centers. Today, few centers use biopsy to help manage patients with chronic renal failure. Consequently, few nephrologists know how to perform the technique or have the special 6- to 8-mm-wide biopsy needles used typically to get specimens, which were taken from the iliac crest. These biopsy specimens also required special processing and embedding undecalcified in plastic. This allowed osteoid to be distinguished from calcified matrix and bone mineralization and formation rates to be measured in patients given prior double tetracycline labeling. This is not possible when specimens are decalcified and embedded in paraffin, which is how most bone samples are handled in pathology laboratories. Special heavy-duty microtomes are also required to cut sections from the plastic blocks. Most pathology departments do not have these microtomes or technicians who know how to prepare sections using them, nor do they have pathologists trained to interpret sections of undecalcified bone. There are a small number of physicians and scientists in the world today who know how to interpret undecalcified human bone biopsy specimen slides, and most are nearing or have passed retirement age. Thus, it is possible that Al toxicity remains a problem for patients with chronic renal failure and for others exposed to additional sources of Al (Chappard, 2016) but that it is going undetected.

Summary

Metal ion toxicity is an underinvestigated and underappreciated issue in skeletal biology. With the continued accumulation of environmental and industrial agents in our ecosystem that may have an adverse effect on osseous tissues, it might be expected that research on this topic would be an important and well-studied area. However, it seems that among clinicians and scientists in the musculoskeletal field there is little interest in the world of toxicological science, and in the fields of environmental health science there is little interest in bones and joints. Given the fact that human biology must cope with changes in the environment, this lack of interest is unfortunate. As discussed in this treatise, the skeleton can be an avid

reservoir for toxins, especially heavy metals. Two of these metals, lead and aluminum, are at the forefront of scientific awareness. It is now time that other skeletal health-modifying environmental compounds be researched.

Chapter 23

Biology of the extracellular calcium-sensing receptor

Chia-Ling Tu, Wenhan Chang and Dolores M. Shoback

Endocrine Research Unit, Department of Veterans Affairs Medical Center, Department of Medicine, University of California, San Francisco, CA, United States

Chapter outline

Introduction

Extracellular calcium $\left(Ca_o^{2+}\right)$ serves as a versatile modulator of numerous physiological processes including hormone secretion, muscle contraction, blood clotting, cell adhesion, and neuronal excitability (Brown, 1991). In mammals, the level of Ca_o^{2+} is maintained within a narrow range (1.1−1.3 mM) by a homeostatic mechanism involving endocrine factors such as the parathyroid hormone (PTH) and the active metabolite of vitamin D, 1,25-dihydroxyvitamin D3 ($1,25(OH)_2D_3$) (Brown, 2013). When circulating $[Ca^{2+}]$ is low, parathyroid chief cells secrete PTH, which acts on bone, kidney, and intestine to mobilize skeletal Ca^{2+}, enhance renal Ca^{2+} reabsorption, and increase intestinal Ca^{2+} absorption, respectively, and to restore normocalcemia; conversely, PTH release decreases with hypercalcemia. In parathyroid cells, there is a very steep inverse sigmoidal relationship between PTH secretion and Ca_o^{2+} concentration (Brent et al., 1988; Rudberg et al., 1982), and the response curves suggest a positive cooperativity by various agonists that could account for the narrow range of Ca_o^{2+} regulating PTH secretion (Brown et al., 1989). In addition, changes in Ca_o^{2+} levels affect several intracellular signaling pathways including cyclic AMP (cAMP)-dependent protein kinase A (PKA) (Chen et al., 1989), phospholipase C (Kifor and Brown, 1988), and inositol phosphate generation (Nemeth and Scarpa, 1987; Shoback et al., 1988) in parathyroid cells. These initial findings supported the hypothesis of an extracellular Ca^{2+}-sensitive surface receptor regulating PTH secretion by coupling to multiple G-protein-dependent pathways (Brown, 1991; Fitzpatrick et al., 1986).

The cloning and characterization of the Ca_o^{2+}-sensing receptor (CaSR), a plasma membrane G-protein-coupled receptor (GPCR), from bovine parathyroid tissue by Brown et al. confirmed the role of Ca^{2+} as an extracellular first messenger in

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00023-3

controlling parathyroid function and confirmed that other di-, tri- and polyvalent cations mimic the effects of Ca^{2+} (Brown et al., 1993). Functional clones of the CaSR were subsequently isolated from human parathyroid (Garrett et al., 1995a), kidney (Aida et al., 1995b; Riccardi et al., 1995), and thyroid C cells (Garrett et al., 1995b). CaSRs in these tissues function as the "calciostat" to coordinate Ca^{2+} homeostasis by adjusting PTH and calcitonin secretion or renal cation handling. The importance of the CaSR in systemic Ca^{2+} homeostasis is highlighted by the pathological conditions in which inactivating and activating mutations in *CASR* cause hypercalcemia and hypocalcemia, respectively. These disorders include familial hypocalciuric hypercalcemia (FHH) type 1 (FHH1), neonatal severe hyperparathyroidism (NSHPT), and autosomal dominant hypocalcemia (ADH) type 1 (ADH1) (Brown, 2013; Hannan and Thakker, 2013).

Furthermore, CaSRs are widely expressed in cells and tissues not directly involved in regulating systemic mineral ion homeostasis, such as brain (Ruat et al., 1995), liver (Canaff et al., 2001), lung (Finney et al., 2008), vasculature (Alam et al., 2009), and skin (Oda et al., 2000). In addition to Ca^{2+}, the CaSR responds to an assorted array of stimuli that instigate different intracellular signaling pathways regulating a diverse range of biological processes such as hormone secretion (Yano et al., 2004b), gene expression (Yasukawa et al., 2017), ion channel activity (Parkash and Asotra, 2011; Ye et al., 2004), inflammation (Rossol et al., 2012), and cellular proliferation and differentiation (Diez-Fraile et al., 2013; Tu et al., 2011; Zhang X. et al., 2014).

Structural and biochemical properties of the calcium-sensing receptor

The CaSR is a member of a subfamily (family C) of GPCRs that includes eight subtypes of metabotropic glutamate receptors (mGluRs), mGluR1 to mGluR8; two type B γ-aminobutyric acid receptors (GABAB-Rs), GABAB-R1 and GABAB-R2; the promiscuous L-amino acid receptor; three taste receptors; several pheromone receptors; and five orphan receptors (Brauner-Osborne et al., 2007). All these receptors have small molecules as their ligands and share similar structural features: a large extracellular ligand-binding domain (ECD) including a Venus flytrap (VFT) module in the amino-terminal portion of the receptor, a seven-helix transmembrane domain (TMD) characteristic of GPCRs, and a sizable carboxyl-terminal (C-) tail.

The human CaSR cDNA sequence predicts a 120-kDa protein with 11 potential N-linked glycosylation sites in glycosylated ECD (Bai et al., 1996), of which 8 are glycosylated and 3 are not (Ray et al., 1998). While N-glycosylation may not be essential for signal transduction (Brown and MacLeod, 2001), it is critical for normal cell surface expression of the receptor (Ray et al., 1998). An altered CaSR glycosylation pattern has been observed in some forms of FHH (Bai et al., 1996). The CaSR is expressed on the cell surface in the form of disulfide-tethered homodimer (Bai et al., 1998a; Ward et al., 1998). Dimerization occurs in the endoplasmic reticulum during biosynthesis through two disulfide bonds between the cysteine 129 and 131 of each CaSR monomer (Ray et al., 1999), but noncovalent interactions also contribute to receptor dimerization (Jiang et al., 2004). The observation that the coexpression of CaSR monomers carrying inactivating mutations in different functional domains (e.g., the ECD and tail) can reconstitute considerable biological activity suggests intimate functional interactions between the monomeric CaSR subunits in a dimer (Bai et al., 1999). Furthermore, the CaSR can heterodimerize with mGluRs (Gama et al., 2001) and GABAB-Rs (Chang et al., 2007) through disulfide and noncovalent linkages. These heterodimeric interactions alter the protein trafficking, surface expression, and signal transduction properties of the CaSR (Gama et al., 2001) (Chang et al., 2007).

The CaSR ECD is connected to the TMD by a cysteine-rich domain (CRD) that contains nine cysteine residues forming four disulfide bridges within the CRD (Hu et al., 2000). They are critical for maintaining receptor structure, expression, and function (Fan et al., 1998; Hu et al., 2000). The CaSR VFT is formed by two lobes (LB1 and LB2) separated by a cleft representing the ligand-binding site (Silve et al., 2005). It was hypothesized that the binding of ligand in the cleft between the two lobes causes the lobes to close on each other, which directly or indirectly modifies the conformation of the TMD, leading to receptor activation (Hendy et al., 2013). The VFT module is probably evolved from the family of periplasmic binding proteins in bacteria (Felder et al., 1999), which serve as receptors responding to a wide variety of small ligands (e.g., ions, amino acids, and other nutrients) to promote bacterial chemotaxis toward and cellular uptake of environmental nutrients (Tam and Saier, 1993). Studies using CaSR-mGluR chimeric receptor constructs and mutagenesis have predicted five potential Ca^{2+}-binding sites in each monomeric ECD in the hinge region between the lobes of the VFT (site 1) (Huang Y. et al., 2009; Huang Y. et al., 2007; Silve et al., 2005). Functional studies and computational simulation suggested that the interactions between other Ca^{2+}-binding sites in ECD and the ones in site 1 are essential in tuning functionally positive homotropic cooperativity of CaSR activity induced by Ca_o^{2+} (Zhang C. et al., 2014). Other studies showed that L-amino acids could increase the sensitivity of the CaSR toward Ca^{2+} (Conigrave et al., 2007a). A potential L-phenylalanine-binding pocket was identified in the VFT near site 1 (Mun et al., 2004, 2005; Zhang et al., 2002), and mutational studies indicate its importance for positive heterotropic cooperativity between Ca^{2+} and L-amino acids in CaSR-mediated

signaling (Zhang C. et al., 2014). Recent X-ray crystallographic study of the CaSR ECD revealed that the interlobe cleft of VFT, the canonical agonist-binding site (Geng et al., 2013; Kunishima et al., 2000; Muto et al., 2007), is empty in the resting state and surprisingly is occupied solely by an L-tryptophan in the active state (Geng et al., 2016). Binding of an L-amino acid closes the interlobe groove in the VFT module, thereby inducing the formation of a novel homodimer interface by LB2 and CRD between subunits (Geng et al., 2016). Four novel Ca^{2+}-binding sites were identified in each protomer in the active structure, and Ca^{2+} stabilizes the active state by enhancing homodimer interactions to fully activate the receptor (Geng et al., 2016). While the presence of Ca_o^{2+} above a threshold level was required for amino acid−mediated CaSR activation, mutations of L-tryptophan-binding residues completely blocked Ca^{2+}-induced intracellular Ca^{2+} mobilization (Conigrave et al., 2007b; Geng et al., 2016), indicating that L-amino acid and Ca^{2+} are coagonists of the CaSR. Furthermore, four anion-binding sites were identified in the interlobe cleft and LB2 in the inactive and active CaSR ECD structures; and anion, such as PO_4^{3-} , may have a negative allosteric effect on receptor activity by stabilizing inactive conformation (Geng et al., 2016).

The structural similarity between CaSR TMD and those of the rhodopsin GPCR family suggests that these receptors share a common mechanism of G protein coupling (Pin et al., 2003) via TMD. The amino acid residues in the second and third intracellular loops are involved in CaSR coupling to G-protein-mediated signaling (Chang et al., 2000). Two cysteine residues, Cys677 and Cys765, within the first and second extracellular loops are critical for maintaining conformation of the CaSR (Ray et al., 2004). A chimeric receptor with the rhodopsin ECD linking with the TMD and tail of CaSR responds to Ca^{2+} in the presence of NPS-R568, a positive CaSR allosteric modulator (Hauache et al., 2000). Computational modeling and mutagenesis studies indicated that extracellular loops 2 and 3 contain additional binding sites for Ca^{2+} and allosteric modulators. Selective positive (calcimimetics) and negative (calcilytics) allosteric modulators bind to distinct but overlapping regions of the TMD (Hu et al., 2002; Petrel et al., 2004). A recent study of specific heterodimers of two loss-of-function CaSR mutants showed that one functional allosteric site per CaSR dimer was sufficient for obtaining the modulatory effects (Jacobsen et al., 2017). In addition to its role in signal transduction, CaSR TMD may also be involved in receptor dimerization through noncovalent interactions (Zhang et al., 2001).

Unlike the ECD and TMD, very few naturally occurring mutations have been identified in the intracellular tail of the CaSR; however, it contains three common polymorphisms, A986S, R990G, and Q1011E, associated with abnormal blood Ca^{2+} levels (Scillitani et al., 2004). A membrane proximal region (residues 863−925) has been shown to be essential to the cell surface expression and biological activity of the receptor (Chang et al., 2001; Goolam et al., 2014; Ray et al., 1997), as a large PEST-like sequence motif may direct lysosomal degradation of the receptor and regulate cell surface receptor level (Zhuang et al., 2012). In addition, a region comprising amino acids 960−984 is involved in binding to accessory proteins (Hjalm et al., 2001). Within its intracellular loops and C tail, the human CaSR harbors five predicted protein kinase C (PKC) and two predicted PKA phosphorylation sites (Garrett et al., 1995a; Hofer and Brown, 2003). Studies utilizing site-directed mutagenesis have demonstrated that phosphorylation of a single key PKC site at Thr888 inhibited most CaSR-mediated stimulation of PLC (Bai et al., 1998b; Davies et al., 2007; Jiang et al., 2002). Phosphorylation of Thr888 was increased by Ca_o^{2+} or calcimimetic and inhibited by calcilytics (Davies et al., 2007). Therefore, PKC-induced phosphorylation of Thr888 at the CaSR tail confers a negative feedback regulation to limit further activation of the PLC pathway. PKA phosphorylation per se plays a minor role in the regulation of CaSR, although one study found that PKA and PKC synergistically inhibited CaSR-mediated activation of PLC (Bosel et al., 2003).

Agonists, antagonists, and modulators of the calcium-sensing receptor

Cationic agonists of the calcium-sensing receptor

The CaSR has a broad spectrum of ligands in addition to Ca^{2+} and other di- and trivalent cations (Be^{2+}, Sr^{2+}, Ni^{2+}, Mn^{2+} Mg^{2+}, Ba^{2+}, Gd^{3+}, and La^{3+}) that bind at the orthosteric site within the interlobe crevice of the VFT module. Organic polycations including polyamines (i.e., spermine, spermidine, and putrescine), aminoglycoside antibiotics (e.g., neomycin, gentamycin), β-amyloid peptides, and basic polypeptides (e.g., polylysine and polyarginine) have been found to bind unidentified sites in VFT (Quinn et al., 1997; Saidak et al., 2009b). Cations and polyamine with higher positive charge density have higher potency as CaSR agonists (Quinn et al., 1997; Riccardi, 2002). All CaSR polycation agonists have been shown to potentiate one another's stimulatory effects on the receptor. In addition to the ECD of the receptor, studies using chimeric receptors indicated that the extracellular loops in TMD may contain binding sites for Ca^{2+} and allosteric modulators (Hammerland et al., 1999; Hauache et al., 2000).

Among these polycation agonists, however, only Ca^{2+}, Mg^{2+}, and spermine are thought to be physiological CaSR agonists. Mg^{2+} behaves as a partial agonist, as it is about twofold less potent than Ca^{2+} on a molar basis in activating the

CaSR (Butters et al., 1997). In the presence of physiological Ca_o^{2+} levels, $Mg^{2+}{}_o$ positively modulates CaSR function (Ruat et al., 1996). Mg^{2+}, in addition to Ca^{2+}, inhibits Ca^{2+} reabsorption in renal cortical thick ascending limb cells (de Rouffignac and Quamme, 1994). Persons with hypercalcemia due to heterozygous or homozygous inactivating mutations of the CaSR (e.g., FHH and NSHPT) manifest varied degrees of hypermagnesemia (Aida et al., 1995a). Conversely, patients with moderate to severe hypomagnesemia also exhibit impaired PTH secretion and develop hypocalcemia (Brown et al., 1999).

Allosteric modulators

Allosteric modulators bind outside of the orthosteric site, most likely changing the three-dimensional receptor conformation and thus affecting receptor affinity and/or ligand-binding efficacy (Hu, 2008). Positive allosteric modulators (PAMs) and negative allosteric modulators respectively increase and decrease CaSR agonist sensitivity. Well-known natural PAMs include aromatic L-amino acids (L-Phe, L-Tyr, L-His, and L-Trp) and short aliphatic amino acids (L-Thr and L-Ala) (Conigrave et al., 2000), which bind at or adjacent to the orthosteric site within the VFT module (Geng et al., 2016; Mun et al., 2005; Zhang et al., 2002). Activation of the CaSR by L-amino acids requires a threshold Ca_o^{2+} level of 1 mM (Conigrave et al., 2000). Acute elevations of amino acid concentrations stimulate Ca_i^{2+} mobilization and suppress PTH secretion in human parathyroid cells in vitro by enhancing the sensitivity of the CaSR to Ca_o^{2+} (Conigrave et al., 2004). These observations support that the CaSR not only is a Ca^{2+}- (and probably an Mg^{2+}-) receptor but also functions as a general "nutrient" sensor. Coordinating mineral ion and protein metabolism might be particularly relevant in the gastrointestinal tract. Indeed, the CaSR has been clearly identified in transgenic mouse studies as an L-amino acid sensor regulating macronutrient-dependent hormone secretion (Brennan et al., 2014).

Polypeptides such as polyarginine, polylysine, protamine (Ruat et al., 1996), and γ-glutamyl peptides (Broadhead et al., 2011; Wang et al., 2006), as well as β-amyloid peptide (Ye et al., 1997), which is excessively produced in the brain of patients with Alzheimer's disease, and polyvalent aminoglycoside antibiotics (McLarnon et al., 2002), are positive modulators that bind in the receptor's VFT domain. Interestingly, the CaSR was found to be activated by glutathione (γ-Glu-Cys-Gly) and its analog γ-Glu-Val-Gly, which can elicit the kokumi taste response and sapid compound denatonium (Maruyama et al., 2012; Rogachevskaja et al., 2011). Coinciding with the fact that these taste-enhancing substances have a positive allosteric effect on the receptor, functional CaSRs have recently been identified in mammalian taste cells (Bystrova et al., 2010; San Gabriel et al., 2009). Glutathione and its analogs may also act as neuromodulators by activating CaSRs on neurons and/or glial cells in the central nervous system (Conigrave and Hampson, 2010).

The CaSR is negatively modulated by pH and ionic strength (e.g., alterations in the concentration of NaCl). Elevated ionic strength suppresses Ca_o^{2+} sensitivity, and reduced ionic strength enhances it (Quinn et al., 1998). On the other hand, raised pH enhances Ca_o^{2+} sensitivity while reduced pH suppresses it (Quinn et al., 2004). Ion strength may have an impact on the binding efficacies of polyvalent cations to CaSR, thereby changing the responsiveness of the receptor to agonists (Quinn et al., 1998). The alterations in CaSR agonist sensitivity by pH are thought to result from changes in the ionization of the charges on CaSR agonists and changes in the conformation of the receptor (Quinn et al., 2004). The impact of changing ionic strength and pH on the responsiveness of the CaSR to divalent cations may be especially relevant in particular microenvironments where ionic strength and pH can vary greatly (Quinn et al., 1998). For instance, Ca_o^{2+}-induced CaSR-mediated acid secretion from intercalated cells in the distal convoluted tubule may be attenuated as local pH falls (Tyler Miller, 2013), and CaSR expression in the subfornical organ may contribute to the ionic strength-dependent regulation of vasopressin secretion and blood pressure (Yano et al., 2004a). Furthermore, anions have a negative allosteric effect on the receptor, as the CaSR ECD contains four anion-binding sites, and the binding of anions, such as SO_4^{2-} and PO_4^{3-}, stabilizes inactive conformation (Geng et al., 2016). SO_4^{2-} decreases Ca_o^{2+}-stimulated IP accumulation in CaSR-expressing HEK-293 cells (Geng et al., 2016). It is assumed that polycation agonists could compete with positively charged residues at anion-binding sites to bind to anions, thereby promoting the dissociation of anions from CaSR ECD and releasing their inhibitory effect on the receptor. This would drive the CaSR toward its active-state conformation (Geng et al., 2016).

Synthetic modulators

Several pharmacological agents that positively modulate CaSR signaling (calcimimetics) or negatively modulate CaSR signaling (calcilytics) (Nemeth, 2002; Nemeth et al., 1998) have been developed. In contrast to cationic agonists that bind to the ECD (Hammerland et al., 1999), selective calcimimetics and calcilytics bind to distinct but overlapping regions in the extracellular loops of the CaSR TMD (Hu, 2008; Petrel et al., 2004). Besides modulating CaSR activity, calcimimetics

and calcilytics have been shown to increase and decrease the level of receptor expression by controlling the susceptibility of the receptor to endoplasmic reticulum (ER)-associated degradation (Huang and Breitwieser, 2007).

Calcimimetics such as NPS R-467 and NPS R-568 are small hydrophobic derivatives of phenylalkylamines that activate the CaSR by increasing its affinity for Ca^{2+} (Nemeth et al., 1998). One calcimimetic compound, cinacalcet, has been approved for the treatment of primary hyperparathyroidism in patients with parathyroid carcinoma and the treatment of secondary hyperparathyroidism in patients on dialysis for end-stage renal disease (Nemeth et al., 1998). Cinacalcet targets the parathyroid CaSR and effectively lowers circulating PTH levels, reduces serum phosphorus and FGF23 concentrations, improves bone histopathology, and may diminish skeletal fracture rates and the need for parathyroidectomy (Nemeth and Shoback, 2013). Recent studies demonstrated that a novel therapeutic regimen combining calcimimetics and PTH produced more robust anabolic effects on bones than those resulting from intermittent PTH treatment (Santa Maria et al., 2016). Because CaSRs expressed in chondrocytes, osteoblasts, and osteoclasts have nonredundant roles in modulating the recruitment, proliferation, survival, and differentiation of these cells (Chang et al., 2008), it was hypothesized that calcimimetics in the presence of elevated local $Ca^{2+}{}_o$ levels induced by PTH activate endogenous CaSRs in the skeletal tissues, resulting in increased osteoblastic functions and reduced osteoclast-mediated bone resorption (Santa Maria et al., 2016).

Calcilytics, including NPS 2143 and Calhex 231, are CaSR antagonists that stimulate the secretion of PTH and have been tested for the treatment of osteoporosis (Nemeth and Shoback, 2013). Calcilytics might achieve the same osteoanabolic effects as those of intermittent PTH by suppressing parathyroid CaSR activation and producing a "pulse" of endogenous PTH secretion (Gowen et al., 2000; Kumar et al., 2010). Although several calcilytic compounds were evaluated as orally active anabolic therapies for postmenopausal osteoporosis, clinical development has stopped due to lack of efficacy. Calcilytics may be adapted for the treatment of ADH1 or potentially other disorders (Nemeth and Goodman, 2016).

Ligand-biased signaling

"Biased signaling" is the phenomenon by which distinct ligands stabilize distinct receptor conformational states that activate preferred signaling pathways (Leach et al., 2015). The CaSR is subject to biased signaling in response to its endogenous ligands. Aromatic amino acids such as L-Phe have a greater influence on CaSR-mediated mobilization of Ca_i^{2+} (Conigrave et al., 2000, 2004) than on the activation of PI-PLC (Rey et al., 2005), extracellular-signal-regulated kinases (ERKs) 1/2 (Lee et al., 2007), and CREB (Avlani et al., 2013). Similarly, small-molecule drugs such as the calcimimetics NPS-R568 and cinacalcet, and the calcilytic NPS-2143, instigate biased signaling that prefers $Ca^{2+}{}_i$ mobilization to ERK1/2 phosphorylation in CaSR-expressing HEK-293 cells (Davey et al., 2012). Certain CaSR mutants underlying disorders of calcium homeostasis also manifest altered biased signaling (Leach et al., 2012). Thus, biased signaling from the CaSR may have important pathophysiological and therapeutic implications.

Calcium-sensing receptor intracellular signaling

Calcium-sensing receptor–mediated signaling

The CaSR activates signaling pathways downstream through three main groups of heterotrimeric G proteins, $G_{q/11}$, $G_{i/o}$, and $G_{12/13}$, and in certain circumstances also activates G_s (see Fig. 23.1). The CaSR's second and third intracellular loops (Chang et al., 2000) and its proximal C-terminus (Chang et al., 2001; Ray et al., 1997) provide key interaction sites with its associated heterotrimeric G proteins—i.e., $G_{q/11}$. CaSR activation in parathyroid cells and other systems elicits $G_{q/11}$-mediated activation of PI-PLCβ, and with the breakdown of membrane phospholipid PIP_2 to IP_3 and diacylglycerol, induces Ca_i^{2+} mobilization and the activation of various isoforms of PKC (Bai et al., 1998b; Brown et al., 1993). The importance of this mechanism for CaSR-mediated inhibition of PTH secretion was demonstrated by the finding that mice with parathyroid-specific deletion of the α-subunit of G_q on a global G_{11} α-subunit-null background developed severe hyperparathyroidism (Wettschureck et al., 2007) similar to that seen in global CaSR exon 5–null mice (Ho et al., 1995) and humans with NSHPT (Pollak et al., 1994).

Besides PLC, the CaSR is able to activate two other phospholipases, phospholipase D (PLD) and phospholipase A2 (PLA2) (Kifor et al., 1997). Studies using specific inhibitors show that PKC and Rho are involved in CaSR-mediated PLD activation (Huang et al., 2004; Kifor et al., 1997). The CaSR primarily modulates PLA2 activity by increasing Ca_i^{2+} levels via activation of the G_q–PLC pathway (Handlogten et al., 2001). The increase in Ca_i^{2+} activates calmodulin and calmodulin-dependent protein kinases, leading to activation of cytosolic PLA2 (Handlogten et al., 2001) and generation of

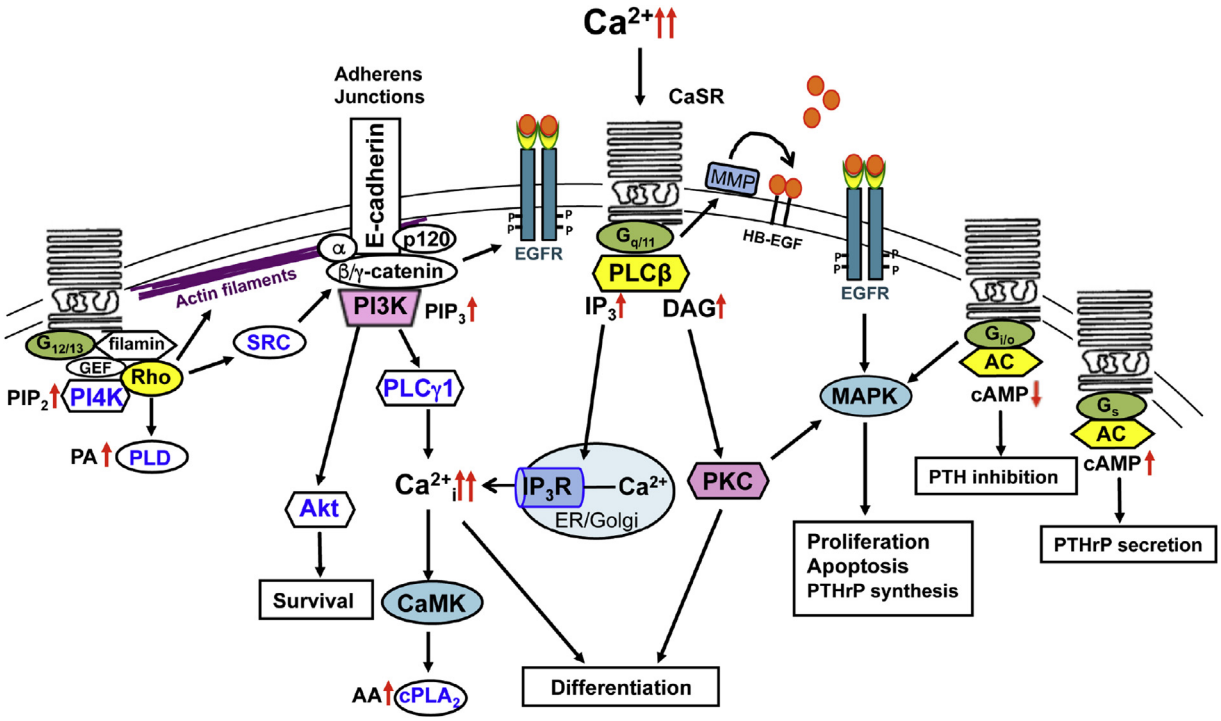

FIGURE 23.1 Schematic representation of calcium-sensing receptor—mediated intracellular signaling. The calcium-sensing receptor (CaSR) typically interacts with three heterotrimeric G protein subfamilies, $G_{q/11}$, $G_{i/o}$, and $G_{12/13}$, and in certain cancer cell types, G_s. Activation of $G_{q/11}$ induces phospholipase C (PLC)-mediated Ca^{2+} mobilization from intracellular stores and protein kinase C (PKC) activation. The increased $Ca^{2+}{}_i$ activates Ca^{2+}/calmodulin-dependent protein kinases (CaMKs) and cytoplasmic phospholipase A2 ($cPLA_2$). Instigating $G_{12/13}$ stimulates Rho-mediated activation of phosphatidylinositol 4-kinase (PI4K) to generate PIP_2, phosphatidylinositol 3-kinase (PI3K) to produce PIP_3 and to activate the downstream effectors Akt and PLCγ1, and cytoskeleton reorganization to promote the formation of stress fibers, cadherin/catenin adhesion complexes, and membrane ruffling. CaSR-mediated activation of phospholipase D (PLD), producing phosphatidic acid, also involves Rho and PKC. Adenylyl cyclase is inhibited by $G_{i/o}$ but activated by G_s in breast cancer cell lines, resulting in decreased or increased cytoplasmic cyclic AMP (cAMP) concentrations, respectively. Activation of the mitogen-activated protein kinase (MAPK) extracellular-signal-related kinases (ERKs) 1/2 involves transactivation of the epidermal growth factor receptor (EGFR) either via liberation of EGF-like ligands by extracellular matrix metalloproteinases (MMPs) or through an E-cadherin-mediated ligand-independent EGFR recruitment and activation. Activation of ERK1/2 also involves PKC and Gi/o-mediated signaling.

second messengers such as arachidonic acid. In kidney, this PLA2 signaling axis mediates the effects of hypercalcemia. However, CaSR-induced activation of PKC and ERK may also contribute to the phosphorylation and activation of PLA2 (Handlogten et al., 2001; Kifor et al., 2001).

In CaSR-expressing HEK-293 cells, elevating Ca_o^{2+} induces sinusoidal oscillations in Ca_i^{2+} (Szekely et al., 2009; Young and Rozengurt, 2002). The repetitive oscillations result from the dynamic phosphorylation and dephosphorylation of a key residue, T888, the primary PKC phosphorylation site of the CaSR located in the proximal intracellular domain (Bai et al., 1998b; Davies et al., 2007; McCormick et al., 2010; Young et al., 2002). Ligand-induced activation of PKC leads to phosphorylation of T888 to uncouple the receptor from $G\alpha_{q/11}$-induced PLC activation and Ca_i^{2+} mobilization (Bai et al., 1998b; Jiang et al., 2002). PKC activation by phorbol esters overcomes the inhibitory effect of high Ca_o^{2+} and increases PTH secretion, whereas disruption of the T888 PKC phosphorylation site increases receptor Ca_o^{2+} sensitivity (Brown et al., 1992; Membreno et al., 1989). The naturally occurring CaSR mutant T888M has been linked to sustained CaSR-mediated suppression of PTH secretion at low Ca_o^{2+} levels causing ADH (Lazarus et al., 2011), demonstrating that the T888 residue and its regulation by PKC are critical for physiological CaSR function in vivo. The phosphorylation state of CaSR T888 depends not only on PKC but also on the dynamic activity of PP2A, a phosphatase that induces dephosphorylation (McCormick et al., 2010). Also, the PLC/Ca_i^{2+}-mediated control of chemotaxis of preosteoblasts to sites of bone resorption may involve a G_{12}-dependent mechanism that sustains Ca_i^{2+} elevations via the activation of PP2A and dephosphorylation of T888 (Godwin and Soltoff, 2002; Zhu et al., 2004, 2007).

Elevated Ca_o^{2+} typically suppresses cAMP levels in CaSR-expressing cells via pertussis toxin-sensitive $G_{i/o}$, which suppresses the activity of various isoforms of adenylyl cyclase. $G_{i/o}$ is responsible for mediating the inhibitory control of

PTH and PTH-related protein (PTHrP) secretion by various CaSR ligands including Ca_o^{2+} (Fitzpatrick et al., 1986; Mamillapalli and Wysolmerski, 2010). Nevertheless, CaSR-mediated activation of PI-PLC provides a $G_{i/o}$-independent mechanism for the inhibition of cAMP synthesis via Ca_i^{2+}-dependent inhibition of adenylyl cyclase isoforms 5, 6, and/or 9 or via phosphodiesterase isoform-1, which breaks down cAMP in response to elevated Ca_i^{2+}/calmodulin (Brown and MacLeod, 2001). This pathway supports Ca_o^{2+}-induced suppression of renin secretion from renal juxtaglomerular cells (Atchison and Beierwaltes, 2013; Beierwaltes, 2010) and vasopressin-induced aquaporin-2 expression in water-reabsorbing principal cells of the collecting ducts (CDs) (Procino et al., 2012). However, the CaSR stimulates rather than inhibits adenylyl cyclase in certain cancers (e.g., breast cancer cells) (Mamillapalli et al., 2008) and in At-T20 pituitary cells, which secrete adrenocorticotropic hormone and PTHrP (Mamillapalli and Wysolmerski, 2010). In normal mammary epithelial cells, CaSR preferably couples to $G_{i/o}$, but the receptor-dependent coupling is switched to G_s in breast cancer cells (Mamillapalli et al., 2008). In contrast, Ca_o^{2+}-induced activation of adenylyl cyclase isoforms 1 and 8 may provide an alternative mechanism for the CaSR-mediated elevation of cAMP (Cooper, 2003).

$G_{12/13}$ modulate receptor-mediated control of shape change, cell migration, and gene expression through the activation of Rho kinase and phosphorylation of serum-response factor (Siehler, 2009). Ca_o^{2+} and the calcimimetic NPS R-467, but not L-amino acids, induced Rho kinase-dependent formation of actin stress fibers in CaSR-expressing HEK-293 cells (Davies et al., 2006); yet G_{12} and Rho are required for L-amino acid-induced Ca_i^{2+} mobilization (Rey et al., 2005). $G_{12/13}$-mediated pathways promote osteoblast differentiation through Wnt3a-β-catenin signaling (Rybchyn et al., 2011) and inhibit osteoclastogenesis by suppressing the expression of receptor activator of nuclear factor kappa-B ligand (RANKL) and promoting the expression of osteoprotegerin (Brennan et al., 2009). $G_{12/13}$ also activates adenylyl cyclase isoform-7 (Jiang et al., 2008), and this pathway may contribute to $Ca^{2+}{}_o$-stimulated cAMP synthesis in primary mouse osteoblasts (Choudhary et al., 2004).

Calcium-sensing receptor–associated intracellular signaling effectors

CaSR activation is linked to proproliferative stimuli in many cell systems, involving the activation of mitogen-activated protein kinases (MAPKs) including ERK1/2, p38, and JNK (Brennan and Conigrave, 2009; Magno et al., 2011b). Ca_o^{2+}-induced ERK1/2 is typically activated through the CaSR–Src–Ras–Raf–MEK–ERK pathway (Hobson et al., 2000). Nevertheless, pertussis toxin, the PLC inhibitor U73122, and PKC inhibitor GF109203X all have been shown to partially inhibit Ca_o^{2+}-induced ERK1/2 phosphorylation in bovine parathyroid and HEK-293 cells expressing the CaSR (Holstein et al., 2004; Kifor et al., 2001). These findings indicate that the CaSR can activate tyrosine kinases and stimulate ERK activity through the $G_{q/11}$–PLC–PKC pathway and by coupling to G_i (Kifor et al., 2001). CaSR-mediated activation of ERK1/2 via G_i requires dynamin/β-arrestin-dependent receptor internalization (Holstein et al., 2004). In addition, CaSR-mediated ERK phosphorylation can occur through a transactivation mechanism in which CaSR stimulates matrix metalloproteinase-mediated release of membrane-bound epidermal growth factor (EGF)-like peptide, which in turn activates EGF receptor (EGFR) and downstream Ras–Raf–MEK–ERK signaling (MacLeod et al., 2004; Yano et al., 2004b). This pathway drives CaSR-mediated cell proliferation in human MCF-7 breast cancer cells (El Hiani et al., 2009b) and PTHrP secretion in human PC-3 prostate cancer cells (Yano et al., 2004b). Furthermore, the engagement of E-cadherin in newly formed cell contacts provides an alternate mechanism for the recruitment and sensitization of EGFR to allow $Ca^{2+}{}_o$ to activate downstream MAPK and Rac1 signaling cascades, together supporting epithelial proliferation (Betson et al., 2002) (Fedor-Chaiken et al., 2003) (Pece and Gutkind, 2000). CaSR-mediated ERK activation in CaSR-expressing HEK-293 cells and ovarian surface epithelial cells may involve the phosphatidylinositol 3-kinase (PI3K) (Hobson et al., 2003). The mouse osteoblastic cell line, MC3T3- E1, responds to CaSR agonists with increased phosphorylation of p38 MAPK (Yamaguchi et al., 2000). CaSR-mediated p38 MAPK signaling modulates the release of PTHrP in CaSR-expressing HEK-293 cells and rat H-500 Leydig cancer cells (MacLeod et al., 2003; Tfelt-Hansen et al., 2003) and regulates vitamin D receptor (VDR) expression in a proximal tubule human kidney epithelial cell line, HK-2G (Maiti et al., 2008). JNK has been shown to control CaSR-mediated proliferation in rat calvarial osteoblasts (Chattopadhyay et al., 2004). JNK and p38 MAPK have also been implicated in other CaSR-mediated pathways regulating proliferation and apoptosis (Corbetta et al., 2000).

In addition to MAPK cascades, CaSR controls cell survival, proliferation, and differentiation through multiple distal effectors. Activation of the CaSR stimulates the expression of Fos, Egr-1, and cyclin-D to promote G1/S cell cycle transition (Chattopadhyay et al., 2004). CaSR-mediated signaling via the PI3K pathway stimulates phosphorylation and activation of the antiapoptotic protein kinase Akt in fetal rat calvarial cells (Dvorak et al., 2004) and opossum kidney cells (Ward et al., 2005). Conversely, CaSR stimulates NF- κB activation and promotes expression of cell death genes such as p53, c-Myc, and Bcl-2 in mature rabbit osteoclasts (Mentaverri et al., 2006). CaSR-mediated apoptosis is induced by $Ca^{2+}{}_i$

overload and activation of the mitochondrial apoptotic pathways and involves the upregulation of caspase-3 and cytochrome *c* as well as Fas/FasL expression (Xing et al., 2011; Zheng et al., 2011). Moreover, CaSR promotes cell differentiation in keratinocytes and colonic epithelial cells (Chakrabarty et al., 2005; Tu et al., 2008, 2011). Stimulating the CaSR increased the expression of E-cadherin in colon carcinoma cells and concomitantly reduced the activation of β-catenin/T-cell factor and suppression of tumor malignancy (Chakrabarty et al., 2005). In keratinocytes, physical interactions between the CaSR, filamin A, and RhoA stimulate E-cadherin-mediated recruitment and the activation of downstream kinases, and also facilitate cell differentiation (Tu et al., 2011). CaSR activators induce the secretion of Wnt5a and expression of Wnt5a receptor Ror2, leading to the inhibition of canonical Wnt/β-catenin signaling and stimulation of cell differentiation in colonic epithelial cells and keratinocytes (Macleod, 2013; Popp et al., 2014).

In kidney, CaSR is coupled to the metabolism of arachidonic acid by cytochrome P450 (Ferreri et al., 2012) and regulates renal calcium excretion in the thick ascending limb independently of PTH by modulating the calcineurin−NFAT1c−microRNA−claudin 14 signaling axis (Toka, 2014). In thyroid C cells, the CaSR controls calcitonin secretion through the activation of voltage-gated Ca^{2+} channels (Freichel et al., 1996). The CaSR has been shown to form signaling complexes with integrins to facilitate cell migration and differentiation in neurons (Tharmalingam et al., 2016). CaSR activation stimulates cyclooxygenase pathways in osteoblasts via a G_i- and PKA-dependent mechanism (Choudhary et al., 2004). Additionally, the CaSR plays a significant role in bone metastasis in renal carcinoma, breast cancer, and prostate cancer (Breuksch et al., 2016). CaSR-mediated activation of ERK1/2, Akt, and PLC signaling determines the tumor cells' ability to proliferate, migrate (Liao et al., 2006; Saidak et al., 2009a), and secrete PTHrP (Mamillapalli and Wysolmerski, 2010), which in turn increases the expression of RANKL in immature osteoblasts and stimulates osteoclastogenesis (Chirgwin and Guise, 2000). These processes promote osteoclast-mediated osteolysis, resulting in the enhanced secretion of growth factors and calcium, again activating tumor cells (Breuksch et al., 2016; Tfelt-Hansen et al., 2003).

Calcium-sensing receptor interacting proteins

The CaSR is a GPCR that operates in the constant presence of agonists, sensing small changes with minimal functional desensitization. Resistance to desensitization requires the maintenance of a functional receptor pool at the cell surface and persistent coupling of the receptor to its heterotrimeric G proteins and downstream signaling pathways. CaSR cell surface expression is maintained by an unusual phenomenon termed agonist-driven insertional signaling (ADIS) (Breitwieser, 2013), in which CaSR activation drives its own trafficking to the plasma membrane. ADIS has potential therapeutic implications for disorders of Ca^{2+} homeostasis in which CaSR expression is impaired due to loss-of-function mutations in the *CASR* gene found in FHH1 and NSHPT (Hannan and Thakker, 2013). However, CaSR-associated disorders can also be caused by different mechanisms. Recent studies revealed that FHH or ADH phenotypes can be associated with mutations on partner proteins associated with CaSR-mediated signaling—e.g., loss-of-function mutations of the sigma subunit of adaptor protein-2 (AP2) and mutations on G protein subunit-α11(GNA11) (Nesbit et al., 2013b; Rogers et al., 2014). A number of molecular binding partners of the CaSR are involved in controlling receptor trafficking to the cell surface and its desensitization, degradation, and signaling (Grant et al., 2011; Huang and Miller, 2007; Ray, 2015).

Once synthesized in the ER, improperly folded CaSR proteins will be moved toward the proteasome for degradation, a process involving osteosarcoma-9 protein, which targets immature CaSRs (Ward et al., 2018). Receptors passing the quality control process will traffic to the plasma membrane or other cellular compartments via interaction with chaperones and small GTP-binding proteins (Breitwieser, 2014). Several proteins interact with the CaSR when the receptor exits the ER. P24A (Strating and Martens, 2009), Sar1 (Zhuang et al., 2010), receptor activity-modifying proteins (Bouschet et al., 2012), and Rab1 (Zhuang et al., 2010) are found to facilitate CaSR trafficking from the ER to the Golgi and increase its plasma membrane expression. On the other hand, the 14-3-3 proteins are predicted to interact with the arginine-rich domain (amino acids 890−898) of the CaSR C-terminal tail and may lead to the retention of the CaSR in the ER (Arulpragasam et al., 2012; Grant et al., 2011). The surface expression of CaSR is also influenced by the interaction of calmodulin (CaM) at residues 871−898 at the C-terminal tail of CaSR, a region involved in phosphorylation and biased signaling (Davey et al., 2012; Leach et al., 2012). CaM binding may stabilize the CaSR on the cell membrane via modulation of anterograde trafficking and thus increase the potency of its functional activity (Bai et al., 1998b; Huang et al., 2010). In addition, dimerization of the CaSR is essential, although not sufficient, for membrane trafficking and full receptor function (Bai et al., 1999).

After CaSRs are inserted into plasma membrane, their interactions with a variety of proteins direct them to different subcellular localizations. Caveolin binds to CaSR intracellular loops 1 and 3 and keeps the receptor highly enriched in invaginations of the plasma membrane, called caveolae, in parathyroid chief cells and cardiac myocytes (Kifor et al., 1998; Sun and Murphy, 2010). Filamin A, an actin-binding scaffold/adaptor protein with the ability to bind various components

in MAPK and Rho-GTPase-mediated signaling cascades, interacts with the C-terminal tail of the CaSR (Awata et al., 2001; Hjalm et al., 2001; Pi et al., 2002). Filamin A potentiates CaSR expression in parathyroid cells by protecting the receptor from degradation (Zhang and Breitwieser, 2005). CaSR-dependent activation of downstream ERK1/2 and Rho also relies, in part, on its physical interaction with filamin A (Pi et al., 2002; Rey et al., 2005; Tu et al., 2011). In keratinocytes, disruption of the CaSR−filamin interaction prevents Ca_o^{2+}-induced RhoA activation and the formation of E-cadherin−catenin adhesion complex on the cell membrane, thereby impairing cell−cell adhesion (Tu et al., 2011; Tu and You, 2014). In addition, the CaSR modulates cell adhesion and migration via direct interactions with integrins in developing cerebellum granule cell precursors and medullary thyroid carcinoma cells (Tharmalingam et al., 2011, 2016). Heterodimerization of CaSR with mGluR (Gama et al., 2001) and subunits of GABAB-R (Kim et al., 2014) is found in certain regions of bovine and rat brains. These interactions affect trafficking and surface expression of CaSR as well as receptor signaling to the PLC/IP_3 pathway (Chang et al., 2007; Gama et al., 2001). Testin, a focal adhesion protein, binds to the intracellular tail of the CaSR and positively modulates CaSR-stimulated Rho kinase (Magno et al., 2011a). The binding of hypoxia-induced mitogenic factor to the membrane proximal region in the CaSR tail enhances CaSR-mediated Ca_i^{2+} signaling and hypoxia-evoked proliferation of pulmonary artery smooth cells, leading to the development of pulmonary vascular remodeling and pulmonary hypertension. Additionally, the CaSR's C-terminal tail has been shown to interact directly with two potassium channels, Kir4.1 and Kir4.2, an interaction that inhibits the activities of these channels in the renal thick ascending limb (Huang C. et al., 2007).

Surface-expressed CaSR may undergo endocytosis initiated through phosphorylation by GPCR kinases or PKC (Lorenz et al., 2007; Pi et al., 2005). β-arrestin subsequently binds to the phosphorylated receptor to decrease its capacity to activate G proteins (Lorenz et al., 2007). Endocytosis of CaSR is facilitated by Rab7, Rab11a (Reyes-Ibarra et al., 2007), and AP2 (Nesbit et al., 2013b; Zhuang et al., 2012). The endocytosed receptors are either recycled to the cell membrane, thereby contributing to receptor resensitization, or translocated to lysosomes for degradation (Ray, 2015). Two mechanisms are involved in degradation of the CaSR: (1) CaSR proteins are targeted to the proteasome after being ubiquitinated by the E3 ubiquitin ligase, dorfin, via binding to the C-terminal tail (Huang et al., 2006; Zhuang et al., 2012), or (2) they are degraded in lysosomes, elicited by the binding of AMSH, a deubiquitinating enzyme, to the PEST-like sequence in the C-terminal tail of the CaSR (Herrera-Vigenor et al., 2006; Zhuang et al., 2012). Furthermore, CaSR proteins are sensitive to m-calpain-dependent destruction, adding an additional mechanism for regulating CaSR protein expression (Kifor et al., 2003). These mentioned secretory pathways and endocytosis mechanisms work collaboratively in the continuous presence of agonist stimulation, resulting in a net increase in CaSR expressed on the plasma membrane (Breitwieser, 2013).

Regulation of calcium-sensing receptor gene expression

The human *CASR* gene is located on chromosome 3q13.3−21, and rat and mouse *Casr* genes reside on chromosomes 11 and 16, respectively (Janicic et al., 1995). The *CASR* gene has seven exons (Pearce et al., 1995): Exon 1 contains two alternative promoters for transcription (Chikatsu et al., 2000; Garrett et al., 1995a). Exon 2 encodes a common upstream untranslated region (5′-UTR) and the translation initiation codon ATG. Exons 2 to 6 encode various regions of the ECD, while exon 7 encodes the entire TMD and the C-terminus tail. *CASR* transcripts may have different 3′-untranslated regions (3′-UTRs) derived from two alternative polyadenylation signal sequences in exon 7 (Aida et al., 1995b; Garrett et al., 1995a). Like the human *CASR* gene, mouse and rat genes are organized in a similar manner and have at least two promoters (Hendy et al., 2013). Promoter P1 has TATA and CCAAT boxes upstream to the initiation site, and promoter P2 has Sp1/3 motif at the transcriptional start site; both promoters drive significant levels of basal activity, with P2 more active than P1 (Canaff and Hendy, 2002). Direct analyses of transcripts revealed that transcripts from P2 are expressed at much higher levels than for P1-derived transcripts in human parathyroid, thyroid C cells, and renal proximal tubular cells (Canaff and Hendy, 2002; Mizobuchi et al., 2009). Transcripts from the P1 promoter are reduced in parathyroid adenomas and colorectal carcinomas (Chikatsu et al., 2000; Kallay et al., 2003a). Several factors including active vitamin D, proinflammatory cytokines, and the transcription factors glial cells missing-2 (GCM2) and thyroid transcription factor 1 (TTF1) control *CASR* transcription, and functional cis-elements in *CASR* promoters responsive to these modulators have been characterized (Hendy et al., 2013; Suzuki et al., 1998). Studies of colon carcinomas and neuroblastomas have indicated that epigenetic changes, such as histone deacetylation and promoter hypermethylation of the GC-rich P2 (Casala et al., 2013; Fetahu et al., 2014; Hizaki et al., 2011), contribute to reduced *CASR* expression in these tumors. Although the increased expression of several microRNAs has been proposed as a cause for *CASR* silencing in colorectal tumors (Fetahu et al., 2016; Singh and Chakrabarty, 2013), direct involvement of microRNA in regulating receptor gene expression has not been confirmed.

Alternative spliced *CASR* transcripts have been reported. An exon 3−deleted variant, in which fusion of exons 2 and 4 produces a truncated receptor protein unable to reach the cell surface, is found in placental cytotrophoblast (Bradbury et al., 1998) and parathyroid, thyroid, and kidney tissues (D'Souza-Li et al., 2001). A mouse model of human FHH1 and NSHPT (Ho et al., 1995) in which exon 5 of the *Casr* gene is deleted unexpectedly generates an alternatively spliced *Casr* variant lacking exon 5 in the skin, kidney, and growth plate (Oda et al., 1998; Rodriguez et al., 2005). Although this variant encodes a protein with a 77-amino acid in-frame deletion in the exodomain and exerts a dominant-negative effect on the full-length receptor, reducing its response to Ca_o^{2+} in vitro (Oda et al., 1998), it apparently compensates for the absence of the full-length receptor in bone and cartilage (Rodriguez et al., 2005).

High levels of both Ca_o^{2+} and $1,25(OH)_2D_3$ upregulate CaSR expression in certain cell types. High Ca_o^{2+} increases the expression of the CaSR in mouse pituitary AtT-20 cells (Emanuel et al., 1996) and rat parathyroid glands (Mizobuchi et al., 2004), whereas administration of $1,25(OH)_2D_3$ elevates *CASR* mRNA levels in vivo in kidney and parathyroid gland in rat (Brown et al., 1996; Canaff and Hendy, 2002; Yao et al., 2005). Upregulation of CaSR in the parathyroid gland by $1,25(OH)_2D_3$ increases the responsiveness of the gland to Ca_o^{2+}, thereby reinforcing the negative action of Ca_o^{2+} on PTH synthesis and secretion and parathyroid cell proliferation. Conversely, kidney CaSR expression is downregulated in VDR-null mice and in *Cyp27*$^{-/-}$ mice lacking the 25-hydroxyvitamin D-1α-hydroxylase enzyme (Li et al., 2003). Likewise, reduced CaSR expression in patients with chronic kidney disease could result in part from a concomitant decrease in circulating levels of $1,25(OH)_2D_3$ (Williams et al., 2009). Modulation of the activity of *CASR* promoters by Ca_o^{2+} was shown in vitro by transfecting promoter-reporter constructs in human kidney proximal tubule cells and mouse distal convoluted tubule cells (Hendy and Canaff, 2016). $1,25(OH)_2D_3$ has been shown to potentiate CaSR-mediated antineoplastic effects in differentiated human colon carcinoma cells (Aggarwal et al., 2016). Although functional vitamin D response elements are present in both promoters in the *CASR* gene (Canaff and Hendy, 2002; Klein et al., 2016), Ca_o^{2+} and $1,25(OH)_2D_3$ additively stimulate transcription from promoter P2 but not P1 (Chakrabarty et al., 2005).

GCM2 is a transcription factor essential for the development of the parathyroid gland in terrestrial vertebrates (Okabe and Graham, 2004). The expression of CaSRs in parathyroid cells correlated with GCM2 levels, and the inactivating mutations of *GCM2* gene cause familial isolated hypoparathyroidism (Mannstadt et al., 2008; Okabe and Graham, 2004). GCM2 transactivates the *CASR* gene via GCM2 response elements in promoters P1 and P2 (Canaff et al., 2009). In adenomatous tissue from patients with primary hyperparathyroidism, reduced CaSR expression may be attributed to underexpression of the *GCM2* gene (Correa et al., 2002). TTF1 is present in rat thyroid C cells and parathyroid cells, and it is expressed inversely with the CaSR. TTF1 suppresses the promoter activity of the *Casr* gene via interactions with specific elements on the 5′-flanking regions (Suzuki et al., 1998). However, the regulation of CaSR expression by TTF1 is modulated by $Ca^{2+}{}_i$ levels and may involve other transcription factors (Suzuki et al., 1998).

Expression of the CaSR is regulated physiologically and pathologically at the gene level. CaSR is highly expressed in the developing fetus, with the highest expression levels found in the central and peripheral nervous systems, heart, lung, and cartilage (Riccardi et al., 2009). CaSR plays important roles in neuronal growth (Vizard et al., 2008), lung morphogenesis (Finney et al., 2008), and skeletal development (Chang et al., 2008). In the adult, CaSR expression has been detected in a myriad of cells and tissues. It regulates cellular fate in the parathyroid gland, bone, kidney, blood, and skin as well as in reproductive, cardiovascular, and gastrointestinal tissues (Diez-Fraile et al., 2013). Altered expression of the CaSR has been associated with various disorders in humans. In atherosclerosis, the loss of CaSR expression in vascular smooth muscle cells (VSMCs) leads to vascular calcification (Alam et al., 2009). Animal models of renal insufficiency (Mathias et al., 1998; Toka et al., 2012) show that deficiency of renal CaSR causes PTH-independent hypocalciuria, as the reduction of renal CaSR increases tubular Ca^{2+} reabsorption (Brown and MacLeod, 2001). In genetic forms of hypercalciuria, dysregulation of CaSR expression by vitamin D metabolites may be a critical factor for kidney stone formation. In a rat model of hypercalciuric nephrolithiasis, renal VDR and CaSR levels are elevated and renal Ca^{2+} reabsorption is reduced (Bai and Favus, 2006; Yao et al., 2005). Activation of CaSR inhibits cell proliferation in parathyroid cells, keratinocytes (Tu et al., 2001), and cells of the colon crypts (Rey et al., 2010). CaSR expression is reduced or absent in parathyroid glands of patients with primary or severe uremic secondary hyperparathyroidism (Cetani et al., 2000; Corbetta et al., 2000; Kifor et al., 1996) and in many colon cancers (Bhagavathula et al., 2005; Kallay et al., 2003b). Impaired Ca_o^{2+}-sensing may increase cell proliferation and contribute to parathyroid neoplasia and colorectal tumors. In contrast, the CaSR is overexpressed in breast and prostate cancers with high bone metastatic potential (Liao et al., 2006; Mihai et al., 2006; Saidak et al., 2009a). CaSR activation promotes cancer progression by stimulating secretion of PTHrP, thus contributing to osteolytic bone destruction (Guise et al., 2005; Liao et al., 2006). Moreover, the CaSR is found to be overexpressed in the hippocampus neurons of mice sustaining traumatic or ischemic brain injury (Kim et al., 2011, 2014) and in a model of Alzheimer's disease (Gardenal et al., 2017), leading to calcium overload and neuronal death in brain. The

administration of calcilytics, allosteric CaSR inhibitors, renders neuroprotection against the detrimental effects of CaSR overactivation in these pathological conditions (Chiarini et al., 2017; Kim et al., 2013, 2014).

Roles of calcium-sensing receptor in calciotropic tissues

Calcium-sensing receptor in parathyroid glands

CaSRs coevolved with the parathyroid glands in terrestrial vertebrates to maintain systemic Ca^{2+} homeostasis via the close control of the secretion of PTH—the hormone that ultimately controls Ca^{2+} handling by the intestine, kidney, and bone. PTH therefore balances the uptake, storage in bone, and excretion of Ca^{2+} in the body according to systemic needs.

CaSRs enable parathyroid cells to respond to supra- and subphysiological Ca_o^{2+} levels by respectively suppressing and enhancing PTH secretion (Brown, 2013). These critical actions of the parathyroid CaSR are established by the identification of inactivating and activating mutations of the *CASR* in humans with FHH1 and autosomal dominant hypoparathyroidism type 1 (ADH1), respectively (Hannan et al., 2018; Vargas-Poussou et al., 2016). This idea is further supported by the observation that there is a right-shifted Ca_o^{2+}/PTH secretion set point in parathyroid glands cultured from mice with *Casr* deficiency (Cheng et al., 2013). How CaSR activation inversely couples to PTH secretion remains unclear. The ability of homomeric CaSRs to stimulate $G_{q/11}$ proteins and downstream signaling cascades is thought to result from major pathways suppressing PTH secretion at high Ca_o^{2+} concentrations (Conigrave and Ward, 2013). This concept is supported by the development of a phenotype of severe hyperparathyroidism in mice with parathyroid cell-targeted *Gnaq* and *Gna11* double-gene knockouts (Wettschureck et al., 2007) and the association of inactivating and activating *GNA11* mutations in patients afflicted with FHH type 2 (Hannan et al., 2018) and ADH type 2 (Nesbit et al., 2013a) (Howles et al., 2016; Roszko et al., 2016). The linkage of loss-of-function mutations of the sigma subunit of the adapter protein 2 with FHH type 3 (Hovden et al., 2017) further indicates roles for clathrin-mediated endocytosis, receptor trafficking, and receptor reinsertion into the membrane in mediating normal CaSR function in physiological states (Gorvin et al., 2017; Hannan et al., 2016). In contrast, the ability of CaSR to stimulate intracellular Ca^{2+} mobilization can be blunted by the overexpression of regulator of G protein signaling 5 (RGS5) (Balenga et al., 2019), whose expression levels are increased in parathyroid tumors (Koh et al., 2011), indicating an inhibitory action of RGS5 on CaSR signaling. In addition to regulation of acute PTH secretion, CaSR activation suppresses transcription of the PTH gene (Garrett et al., 1995a) and cell growth. The latter is well demonstrated by the presence of significant parathyroid cellular hyperplasia in mice with global knockout of both alleles of *Casr* (Ho et al., 1995) as well as the ability of calcimimetics to prevent parathyroid hyperplasia in rats subjected to the induction of chronic kidney disease (Colloton et al., 2005; Wada et al., 1998). Klotho has also recently been shown to be involved in cross talk with CaSR signaling to suppress PTH synthesis and glandular growth in parathyroid tissue in mice (Fan et al., 2018), implicating a role of FGF23 signaling in mediating parathyroid function.

The ability of parathyroid cells to sense changes in extracellular levels of Ca^{2+} is fundamentally important for skeletal development and maintenance. Deletion of both *Casr* alleles in the parathyroid glands of mice retards perinatal skeletal development in these $^{PTC}Casr^{-/-}$ mice (Chang et al., 2008). While $^{PTC}Casr^{-/-}$ mice recapitulate most biochemical (severe hyperparathyroidism, hypercalcemia, and hypophosphatemia) and skeletal (expansion of growth plate, osteopenia, osteiod accumulation, and excess fractures with poor healing) phenotypes of NSHPT in patients and in mice with global *Casr* knockout ($Casr^{-/-}$ mice) (Ho et al., 1995), they manifest hypercalciuria, in contrast to hypocalciuria in $Casr^{-/-}$ mice. This is because normal CaSRs are still functioning in the kidney to promote Ca^{2+} excretion in response to the marked hypercalcemia of this conditional knockout mouse ($^{PTC}Casr^{-/-}$ mice).

Given that *Casr* genes are unaltered outside of PTCs in $^{PTC}Casr^{-/-}$ mice, severe PTH excess appears to be sufficient to cause skeletal defects regardless of the status of CaSR function in other tissues. In contrast to severe PTH excess, milder forms of hyperparathyroidism studied in $^{PTC}Casr^{\pm}$ mice with heterozygous *Casr* gene knockout targeted specifically to the parathyroid are anabolic to trabecular bone by protecting the bones from aging-induced bone loss (Cheng et al., 2013). However, these protective effects are at the expense of cortical thinning and demineralization, indicating differential responses of osteoblasts and osteocytes to mild PTH elevations. Given that $^{PTC}Casr^{\pm}$ mice also manifest hypercalcemia, the direct activation of CaSR in osteoblasts, osteocytes, and/or osteoclasts in their skeletons cannot be ruled out as a secondary effect of hyperparathyroidism that contributes to skeletal changes.

Calcium-sensing receptor in the kidney

Molecular mechanisms responsive to changes in the need for Ca^{2+} conservation and the excretion of Ca^{2+} when in excess were postulated to be present in different segments of the kidney long before CaSR cDNA was identified in the parathyroid

(Brown et al., 1993) and later in kidney (Riccardi et al., 1995). This was because evidence had accumulated, from a large body of in vitro and in vivo animal studies, on the many effects that divalent cations (Ca^{2+} and Mg^{2+}) were known to have on renal function, water and solute handling, and ion transport. Aberrant perception of ambient serum Ca^{2+} concentration in the human disorders of FHH and NSHPT lent further support to the critical importance of renal Ca^{2+}- (and Mg^{2+}-) sensing mechanisms operating in human physiology and altered in disease states. Patients with FHH had notable hypocalciuria despite hypercalcemia and normal or even mildly elevated PTH levels (Marx, 2018). This phenotype, when it became clearly evident in the 1970s and 1980s (Attie et al., 1983) (Marx et al., 1978a, 1978b, 1981a, 1981b, 1982a, 1982b, 1985), along with the typical autosomal dominant mode of inheritance of FHH, predicted the condition to be due to a genetic defect with a high degree of penetrance. The phenotypic features further predicted that the responsible gene would be strongly expressed in both parathyroid and renal cells. The fact that many individuals with FHH also had mild hypermagnesemia emphasized that the Ca_o^{2+}-sensing defect of FHH also involved defective Mg_o^{2+}-sensing. The diagnosis of FHH is assessed for clinically by the use of the Ca^{2+}—creatinine clearance ratio, which directly reflects the handling of Ca^{2+} by the kidney in relation to renal function and serum Ca^{2+} levels, and this clearance calculation is widely used (Christensen et al., 2008).

Fluctuations in $[Ca^{2+}]_o$ can exert several different effects on renal function. Increased levels of Ca_o^{2+} promote renal Ca^{2+} excretion, and this response occurs in the absence of PTH. It was observed that patients with FHH who underwent total parathyroidectomy to treat their hypercalcemia continued to demonstrate hypocalciuria, indicating that this was an intrinsic property of the kidney and not a PTH-dependent phenomenon (Attie et al., 1983).

Renal sensitivity to Ca_o^{2+} involves many functions and locations in the kidney (Riccardi and Valenti, 2016). Areas in the nephron and renal functions include (1) Ca^{2+} transport in the thick ascending limb of the loop of Henle (TAL), which is the main site of abnormal Ca^{2+} handling in individuals with FHH (Attie et al., 1983); (2) proximal tubule; (3) CD; (4) distal convoluted tubule; and (5) juxtaglomerular apparatus (JGA).

Where exactly and to what extent CaSR mRNA and protein are expressed within different segments of the nephron have been controversial topics over the years (Riccardi and Valenti, 2016). A lack of reliable reagents for definitively identifying and quantifying the often-low levels of CaSR expression has hindered the development of a clear picture of the sites where CaSRs are expressed. Expression of CaSRs in the TAL is widely accepted and is among the strongest in the kidney. The renal CD is another site where water handling and urinary concentration occur and where CaSRs are prominently expressed. Other sites of CaSR expression include the glomerulus (in podocytes and mesangial cells) and in proximal tubular cells.

Extensive studies have been done in various renal cell systems and mouse models. In cultured mesangial cells, CaSR activation stimulated inositol trisphosphate production and $Ca^{2+}{}_i$ mobilization, similar to the signaling pathways activated by high Ca_o^{2+} and Mg_o^{2+} concentrations and calcimimetics in parathyroid cells (Brown et al., 1993; Riccardi and Valenti, 2016). CaSR activation is also linked to the opening of the transient receptor potential channels (TRPCs) TRPC3 and TRPC6 in these cells (Oh et al., 2011).

The JGA is the principal source of renin release, which is negatively regulated (suppressed) by high Ca_o^{2+} levels but positively regulated by many other important physiological factors. Similar to the signaling pathways activated by high Ca_o^{2+} levels in parathyroid cells, CaSR activation involves Ca_i^{2+} mobilization (via a Gq mechanism) in modulating renin secretion as well as inhibition of cyclic AMP accumulation and adenyl cyclase activity (Beierwaltes, 2010).

Several functions of proximal tubular cells are Ca^{2+}-regulated. One such critical function is phosphate reabsorption. PTH, through its receptor (PTH1R), is a key regulator of phosphate reabsorption. When the PTH1R is stimulated, phosphate excretion increases. CaSR activation by high Ca_o^{2+} or calcimimetic can blunt the ability of PTH to stimulate phosphaturia. This has been used to advantage with the calcimimetic cinacalcet in treating disorders of phosphate wasting such as tumor-induced osteomalacia. High Ca_o^{2+} concentrations also inhibit proximal tubular 1-alpha hydroxylase activity and thereby dampen the production of $1,25(OH)_2D_3$, which will ultimately lower serum Ca^{2+} levels. Acute PTH administration can also reduce CaSR expression in that region of the kidney (Riccardi and Valenti, 2016). Other actions of CaSR signaling in the proximal tubule include luminal acidification and fluid reabsorption (Riccardi and Valenti, 2016). $1,25(OH)_2D_3$ can modulate CaSR expression in the distal tubule, where this hormone promotes Ca^{2+} transport and thereby contributes to the raising of serum Ca^{2+} levels.

A great number of mechanistic studies have been done to clarify the pathways by which CaSRs modulate Ca^{2+} reabsorption in the TAL (Riccardi and Valenti, 2016). PTH stimulates Ca^{2+} reabsorption by increasing Ca^{2+} permeability. CaSRs in the cortical TAL are involved in the actions of hormone-mediated cAMP accumulation such as that due to calcitonin or vasopressin. Decreased cAMP accumulation in these cells will reduce overall Ca^{2+} permeability and thereby Ca^{2+} transport and reabsorption. Ca^{2+} permeability in this portion of the nephron requires NaCl uptake across the lumen of the nephron segment. The transepithelial K^+ gradient that ultimately becomes established in this segment is the driving

force of the reabsorption of Ca^{2+}, Mg^{2+}, and Na^{+}. Paracellular Ca^{2+} permeability in the TAL is importantly regulated by various members of the family of claudin proteins. Human disorders of Ca_o^{2+}-sensing also shed light on the role of CaSRs in Ca^{2+} reabsorption by the kidney and in Ca^{2+} excretion. Individuals with germline-activating mutations in the CaSR (ADH1) may have hypercalciuria as a result of their activated renal CaSRs. Renal-specific *Casr* deletion in a mouse model (Toka et al., 2012) produces hypocalciuria along with normal serum Ca^{2+} and PTH levels. This is evidence that renal CaSRs operate to control renal Ca^{2+} excretion independently of changes in PTH in vivo.

The distal convoluted tubule also plays a role in Ca^{2+} reabsorption (Riccardi and Valenti, 2016), and multiple membrane channels and transporters play essential parts in that process. An especially prominent role is played by transient receptor potential cation channel (TRPV) 5, which moves Ca^{2+} across the apical membrane of the distal tubular cell. Other ion transport mechanisms cooperatively participate in Ca^{2+} reabsorption thereafter.

CaSRs are strongly expressed along the CD (Riccardi and Valenti, 2016). In that nephron segment, if high $[Ca^{2+}]_o$ is present, there is urinary acidification due to the activation of an H^{+}-ATPase. CaSRs are also expressed in this nephron segment along with aquaporin 2 water channels. Both CaSRs and aquaporin 2 channels are colocated within the same vesicles in the CD. In this portion of the nephron, the activation of CaSRs is thought to inhibit vasopressin-mediated insertion of aquaporin 2 water channels into the membrane and thereby reduce water reabsorption. This yields water diuresis and "resistance" to the effects of vasopressin when increased levels of CaSR activation are present. The interrelationships between CaSR activity and vasopressin action in this portion of the kidney are thought to underlie the nephrogenic diabetes insipidus commonly seen in individuals with significant hypercalcemia. Thus, there are multiple areas of the kidney where CaSR activation plays a central role in transport and/or permeability to water, Ca^{2+}, Mg^{2+} phosphate, acid, and other ions. CaSR activation also modulates kidney responses to critically important hormones that modulate its function including vasopressin, calcitonin, and others. Human disorders of Ca_o^{2+}-sensing help to underscore the importance of specific physiological pathways and integrate them into in vivo responses.

Calcium-sensing receptor in bone cells

Long before the CaSR cDNA was identified in 1993 by Brown and colleagues (Brown et al., 1993) with an expression cloning strategy using parathyroid gland cRNA in *Xenopus laevis* oocytes, it was clear that changes in the extracellular concentration of Ca^{2+} had significant effects on the function of several different cell types in bone (Dvorak et al., 2004) (Chang et al., 2008; Goltzman and Hendy, 2015). These studies were largely in vitro in cell culture systems of transformed osteosarcoma cell lines and often required higher-than-physiological $[Ca^{2+}]_o$ to achieve effects on signaling pathway activation, Ca_i^{2+} mobilization, or functional or biochemical outcomes (mitogenesis, mineralization, and so forth). The pharmacology of these responses led to controversy in the field as to whether the putative parathyroid Ca_o^{2+}-sensing mechanism responsible for mediating the effects of Ca_o^{2+} on PTH secretion (in a tight physiological range) was the same molecular mechanism operating in different bone cell populations. Once the CaSR cDNA became available, along with highly specific antibodies directed against CaSR epitopes, it became clear, by immunocytochemistry and in situ hybridization, that CaSRs were present in osteoblasts, osteocytes, osteoclasts, marrow mononuclear cells, and macrophages (Chang et al., 1999; Dvorak et al., 2004). Speculations from earlier studies were subsequently supported by strong evidence that CaSRs were playing critical roles in bone and were responsible for the effects of changes in $[Ca^{2+}]_o$ on the activation of signaling responses, alterations in gene expression, and mineralization in bone cell systems (Chang et al., 2008; Dvorak et al., 2004; Goltzman and Hendy, 2015; Rybchyn et al., 2011). Furthermore, the receptor was implicated in regulating bone development and mass in vivo (Chang et al., 2008; Dvorak et al., 2007; Dvorak-Ewell et al., 2011).

The phenotype of global *Casr* knockout mice, $Casr^{-/-}$, generated by Ho et al. (Ho et al., 1995) confirmed the critical role of CaSRs in mediating the control of PTH secretion by Ca_o^{2+}. These mice showed severe hyperparathyroidism, hypercalcemia, and hypophosphatemia and died at 2–3 weeks of age. Dramatic skeletal demineralization was present along with growth retardation and failure to thrive. Given the severe mineral and hormonal disturbances in these mice, it was difficult to ascertain what role bone CaSRs might be playing in the skeletal aspects of their phenotype, because the hyperparathyroidism and serum Ca^{2+} and phosphate derangements in these mice can alone have profound effects on bone growth, development, and mineralization. Knockout mouse models in which the *Pth* gene was deleted on the background of this global $Casr^{-/-}$ mouse (i.e., a double-knockout, $Pth^{-/-}/Casr^{-/-}$) had relatively normal-appearing bone by histology; however, these animals had markedly low PTH levels (Goltzman and Hendy, 2015; Kantham et al., 2009). Similarly, when PTH was eliminated by creating a double-knockout using $Gcm2^{-/-}$ mice in whom parathyroid glands did not develop on the background of this global $Casr^{-/-}$ mouse (i.e., $Gcm2^{-/-}/Casr^{-/-}$), a similarly normal skeletal histology was noted (Tu et al., 2003). This led investigators to surmise that CaSRs were not critical to skeletal development. Thus, it

became necessary to generate and assess conditional knockout mice with *Casr* deletion selectively targeted to specific bone cell populations without the complicating features of hypo- or hyperparathyroidism present in the prior models.

The most compelling data for Ca^{2+} as a ligand and CaSR activation as an anabolic pathway in bone emerged from conditional knockout mouse models (Chang et al., 2008). When CaSRs were deleted across the osteoblastic lineage in mice (under control of the 2.3 or 3.6 kb type 1 collagen [Col1] promoter-driven Cre recombinase), the bone phenotypes were dramatic (Chang et al., 2008; Dvorak-Ewell et al., 2011). These bone-specific conditional knockout mice (e.g., $^{2.3Col1}Casr^{-/-}$ and $^{3.6Col1}Casr^{-/-}$ mice) showed growth retardation, spontaneous fractures, low trabecular and cortical bone mass, undermineralized bone, osteoblast and osteocyte apoptosis, and gene expression profiles indicative of arrested osteoblast differentiation (Chang et al., 2008; Dvorak-Ewell et al., 2011). When the conditional knockout of *Casr* was restricted to mature osteoblasts and osteocytes using a *Cre* mouse in which Cre expression was driven by the osteocalcin promoter, markers of osteoblast gene expression were delayed and trabecular bone mass and microarchitecture were reduced (Chang et al., 2008; Dvorak-Ewell et al., 2011), but the phenotype was much milder. These observations in vivo are supported by work in osteoblast cell lines by many labs (Chang et al., 2008; Goltzman and Hendy, 2015; Santa Maria et al., 2016), confirming that CaSR activation by agonists (e.g., high $[Ca^{2+}]_o$) is critical for osteoblast proliferation and differentiation and the maintenance of bone mass.

CaSR activation also modifies the function of mature osteoclasts and other cells within the osteoclastic lineage (monocytes and macrophages) (Goltzman and Hendy, 2015). In osteoclast lineage cells, CaSR activation suppresses resorptive function, expression of markers of osteoclast differentiation, and cell survival (Goltzman and Hendy, 2015; Kameda et al., 1998; Kanatani et al., 1999; Olszak et al., 2000; Santa Maria et al., 2016; Yamaguchi et al., 1998). High $[Ca^{2+}]_o$ also inhibits the resorption of mature osteoclasts. The concentrations of Ca_o^{2+} at which these phenomena are observed are in general much higher than those in the circulation but are ones likely to be present in the bone microenvironment and in the vicinity of resorbing osteoclasts (Datta et al., 1989; Malgaroli et al., 1989; Moonga et al., 1990; Zaidi et al., 1991). Osteoclasts also undergo apoptosis in response to high concentrations of Ca_o^{2+}, and the pathway responsible involves phospholipase C and NF-kappa B (Mentaverri et al., 2006). That a dominant-negative *Casr* construct interferes with these effects is highly supportive of CaSRs as involved in these events in osteoclasts. However, calcimimetics, which stimulate CaSRs and suppress PTH secretion, and calcilytics, which block CaSRs and enhance PTH secretion, do not have the effects predicted of straightforward CaSR activation and inhibition in osteoclasts (Shalhoub et al., 2003) (Gowen et al., 2000).

Observations from certain single-knockout and double-knockout mouse models have shed further light on the interaction of CaSRs with other key molecules involved in Ca^{2+} homeostasis such as PTH and PTH1R and $1,25(OH)_2D_3$. CaSR activation is key in the full actions of PTH on bone compartments. PTH-induced cortical bone demineralization is reduced in $Pth^{-/-}/Casr^{-/-}$ mice compared with $Pth^{-/-}$ mice (Xue et al., 2012), indicating that intact CaSRs are important in the actions of PTH-mediated bone resorption. In addition, the hypercalcemic actions of $1,25(OH)_2D_3$ are at least in part mediated by CaSRs, because deletion of *Casr* in mice on the background of *Cyp27b1* knockout produces less hypercalcemia (Richard et al., 2010). Isolated marrow cells from $Pth^{-/-}/Casr^{-/-}$ mice showed reduced RANKL expression and osteoclastogenesis in response to PTH versus responses in marrow cells from $Pth^{-/-}$ mice (Xue et al., 2012). These studies indicate that in addition to the effects of solitary CaSR activation in bone, there are cooperative effects of CaSR signaling in mediating the actions of PTH and PTH1R and $1,25(OH)_2D_3$, and likely its receptor as well.

Calcium-sensing receptor in the breast

Mammary CaSR plays pivotal roles in modulating maternal Ca^{2+} metabolism and neonatal bone development during lactation. CaSR levels are low during postnatal mammary gland development through late pregnancy but increase to a peak during lactation (VanHouten et al., 2004), when the receptor is expressed primarily on the basolateral surface of ductal epithelial and alveolar cells (Cheng et al., 1998; VanHouten et al., 2004, 2007). During milk production, the mammary gland synthesizes and secretes PTHrP into milk and into the circulation, where it activates bone resorption to mobilize skeletal calcium (Wysolmerski, 2012). Delivery of Ca^{2+} to the mammary gland induces the plasma membrane Ca^{2+}-ATPase 2 (PMCA2) to transport Ca^{2+} from breast epithelial cells across the apical membrane and into the acinar lumen (Reinhardt et al., 2004) (VanHouten and Wysolmerski, 2007). Although the CaSR does not have a dominant role in regulating morphological development or differentiation in the normal mammary gland (Kim and Wysolmerski, 2016), the CaSR adjusts transcellular Ca^{2+} transport, overall milk secretion, and PTHrP production in response to Ca^{2+} availability in the maternal circulation during milk production (Mamillapalli et al., 2013; Vanhouten and Wysolmerski, 2013). The mammary CaSR adjusts milk PTHrP levels in a manner inverse to milk Ca^{2+} content to coordinate maternal and neonatal bone and Ca^{2+} metabolism. In normal mammary epithelial cells, CaSR activation increases milk Ca^{2+} content by

stimulating Ca^{2+} pumping and ATPase activity of PMCA2 (VanHouten et al., 2007) while it suppresses PTHrP production via coupling to Gαi to decrease cAMP production by adenylate cyclase and subsequent PKA activation (Mamillapalli et al., 2008). Systemic hypocalcemia reduces overall milk production and Ca^{2+} content and decreases the skeletal Ca^{2+} accrual of suckling pups (Ardeshirpour et al., 2006; VanHouten et al., 2004) but increases PTHrP production, an effect that can be prevented by treatment with a calcimimetic (VanHouten et al., 2004).

The CaSR is overexpressed by many breast cancers; however, CaSR signaling seems to have opposing effects on proliferation and cell death in breast cancer cells. Certain studies have shown that increasing $Ca^{2+}{}_o$ concentration above the physiological range inhibits proliferation, invasion, and anchorage-independent growth of breast cancer cells and that the CaSR mediates growth-inhibitory effects by downregulating the expression of survivin, an antiapoptotic factor (Liu et al., 2009; Promkan et al., 2011). On the contrary, other studies have shown that activation of CaSR promotes cell proliferation and the migration of breast cancer cells via stimulation of PLC, ERK1/2, and EGFR activation, upregulation of phosphocholine and cytokine production, and activation of TRPC1 (El Hiani et al., 2009a; El Hiani et al., 2009b; Hernandez-Bedolla et al., 2015; Huang C. et al., 2009; Saidak et al., 2009a). Knocking out the *Casr* gene or treating breast cancer cells with calcilytic has been shown to inhibit tumor cell proliferation and increase Ca^{2+}-mediated cell death (Kim et al., 2016). Furthermore, CaSR expression was correlated directly with PTHrP protein levels in human breast cancers (Kim et al., 2016; Mu et al., 2012; VanHouten et al., 2010). Unlike normal breast cells, activation of the CaSR in breast cancer cells with Ca_o^{2+}, spermine, aminoglycoside antibiotics, or allosteric calcimimetics upregulates PTHrP secretion through the stimulation of cAMP production (Mamillapalli et al., 2008; Sanders et al., 2000). A switch in G protein usage, by which the CaSR couples to Gαs instead of Gαi, underlies the opposing effects of the CaSR on PTHrP expression in malignant and normal breast cells (Mamillapalli et al., 2008). Nuclear PTHrP stimulates cell proliferation by decreasing the levels of the cell cycle inhibitor p27 kip1 and protects against Ca_o^{2+}-mediated cell death by preventing the nuclear accumulation of apoptosis-inducing factor (Kim et al., 2016). The alteration in PTHrP production has important consequences for the progression of bone metastases (Mihai et al., 2006). Increased PTHrP secretion in response to high Ca_o^{2+} levels acts in a paracrine fashion to accelerate osteolysis (Mamillapalli et al., 2008; Wysolmerski, 2012). As a result of bone resorption, release of growth factors such as TGF-β, IGFs, and FGFs from the bone matrix further stimulates the growth of bone-metastasizing tumors and increases PTHrP production, developing a vicious cycle of osteolysis (Patel et al., 2011; Theriault and Theriault, 2012).

Noncalciotropic roles of the calcium-sensing receptor

Calcium-sensing receptor in the pancreas

CaSR is expressed in the endocrine and exocrine pancreas including β-islet cells, α-cells, duct cells, acinar cells, and various nonexocrine cells such as intrapancreatic nerves and blood vessels (Bruce et al., 1999) (Gray et al., 2006; Racz et al., 2002), whereas somatostatin-secreting δ-cells do not express the CaSR (Squires, 2000). Activation of the CaSR in α-cells stimulates glucagon secretion from human islets (Gray et al., 2006). Within the islet, glucagon can increase insulin secretion despite its counteracting effect on energy homeostasis.

CaSR regulates glucose-evoked insulin secretion by β-cells (Jones et al., 2007; Rybczynska et al., 2017). Elevation of plasma glucose concentration leads to an increase in the ATP/ADP ratio mediated by glucokinase, which closes ATP-dependent K^+ channels, depolarizing the cell membrane and opening voltage-dependent Ca^{2+} channels (VDCCs) to increase Ca_i^{2+} levels and induce insulin release (Squires, 2000). In human islets and insulin-secreting MIN6 cell lines, activation of the CaSR by elevating Ca_o^{2+} induced transient MAPK activation and insulin secretion (Devis et al., 1975; Gray et al., 2006; Squires, 2000). Calcimimetic activation of the CaSR not only enhanced the maximal secretory response to glucose in human and rodent β-cells, but also transiently increased insulin secretion in the absence of an increase in associated nutrient stimulation (Gray et al., 2006). CaSR may modulate insulin secretory responses through the stimulation of β-cell proliferation and cell−cell communication (Hills et al., 2012). Calcimimetic activation of the CaSR in MIN6 increased the expression of E-cadherin and L-type VDCCs and stimulated MAPK-mediated cell proliferation, thereby augmenting cell−cell adhesion and β-cell function to promote the insulin secretion of neighboring cells (Hills et al., 2012; Kitsou-Mylona et al., 2008). Colocalization and spatial interactions between the CaSR and L-type VDCCs may also enhance glucose-induced secretion of insulin (Parkash, 2011). Conversely, cell turnover and glucose-evoked insulin secretion in MIN6 pseudoislets was reduced when CaSR expression was knocked down (Kitsou-Mylona et al., 2008). CaSR-dependent regulation of insulin secretion involves complex signaling cascades including ERK1/2, PLC/IP_3/intracellular Ca^{2+}, and CAMKII (Gray et al., 2006). However, persistent activation of CaSR in human β-cells has been shown to inhibit insulin secretion (Squires et al., 2000). Mice with gain-of-function CaSR mutations manifested hypocalcemia in

association with impaired glucose tolerance and insulin secretion (Babinsky et al., 2017; Dong et al., 2015). In one ADH1 mouse model, pancreas islet mass was reduced, and both α-cell and β-cell functions were impaired (Babinsky et al., 2017). The rectification of glucose intolerance and hypoinsulinemia in these mice by a calcilytic highlighted a potential therapeutic application of these compounds for disordered glucose metabolism (Babinsky et al., 2017; Dong et al., 2015).

CaSR is highly expressed in pancreatic duct cells and regulates their proliferation (Racz et al., 2002). It has been reported that the activation of CaSR in the rat pancreas duct luminal membrane increased ductal HCO_3^- secretion (Bruce et al., 1999). These observations suggest that CaSR is able to monitor and regulate Ca^{2+} concentration in pancreatic juice by triggering ductal electrolyte and fluid secretion, and this could reduce the risk of calcium carbonate stone formation and progression to pancreatitis (Racz et al., 2002). Clinical genetic linkage studies have identified that mutations in the CaSR gene and the pancreatic secretory trypsin inhibitor gene in patients with FHH are associated with susceptibility to acute and/or chronic pancreatitis (Felderbauer et al., 2006; Muddana et al., 2008).

Calcium-sensing receptor in the gastrointestinal system

The CaSR is present along the gastrointestinal tract and plays key roles in glandular and fluid secretion and in the occurrence of digestive disease. CaSRs are expressed in the stratified squamous esophageal epithelium (Justinich et al., 2008) and regulate the proliferation, differentiation, cell−cell adhesion, and cytoskeletal organization of epithelial cells (Abdulnour-Nakhoul et al., 2015). Activation of CaSR in the esophageal epithelial cell line HET-1A increases Ca_i^{2+} mobilization and activates MAPK (ERK1/2) signaling pathways to stimulate the secretion of cytokine IL-8 (Justinich et al., 2008). CaSR is implicated in the proliferative response to injury and the pathogenesis of esophagitis, as CaSR expression is increased in eosinophilic esophagitis and Barrett's adenocarcinoma (Abdulnour-Nakhoul et al., 2015). Under the condition of esophagitis, CaSR can be activated by eosinophil-released major basic protein to stimulate FGF9 secretion and activate downstream proliferation-related genes in esophageal epithelial cells (Mulder et al., 2009).

In the stomach, the CaSR is expressed on the basolateral membrane of parietal cells and on both the basolateral and the apical surface on gastrin-releasing G-cells (Cheng et al., 1999). The CaSR is considered a key modulator of gastric acid secretion and gastric luminal pH because it can be activated by the same dietary components (amino acids, amines, calcium) that activate gastrin release from G-cells. Activation of basolateral CaSR by agonists (e.g., Ca^{2+}, Gd^{3+}, and L-type amino acids) stimulates H+ and K+ ATPase and results in the increased production and secretion of gastric acid (Buchan et al., 2001; Busque et al., 2005; Dufner et al., 2005). In contrast, $Casr^{-/-}$ animals cannot respond to high intraluminal calcium and L-type amino acid concentrations with gastrin secretion (Feng et al., 2010). The intracellular signal cascades underlying CaSR-mediated H+ and K + ATPase induction include Ca_i^{2+}, PLC, MAPK, and PKC (Kopic et al., 2012; Remy et al., 2007).

Low pH in the gastric lumen produces ionized Ca^{2+} to be absorbed by the small intestine. CaSR participates in the regulation of intestinal secretion and absorption of Ca^{2+} in cooperation with 1,25-dihydroxy vitamin D_3 (Favus et al., 1980, 1981). CaSR is predominantly expressed on both apical and basolateral membranes of colonic crypts in the intestine brush border (Alfadda et al., 2014) and is also localized on the neuronal plexuses, Meissner and Auerbach (Cheng, 2012). Activation of the apical receptor by high luminal Ca^{2+} results in an increase in NaCl, water, and Ca^{2+} absorption. Consequently, elevated levels of blood Ca^{2+} activate intestinal basolateral CaSR to inhibit the absorption, forming a negative feedback loop (Alfadda et al., 2014). CaSR also acts as an important regulator of intestinal enteroendocrine activity in response to nutrient and nonnutrient stimuli. CaSR is involved in the L-amino acid stimulation of gut peptide secretion by K-cell and L-cell in the rat small intestine (Mace et al., 2012) and cholecystokinin secretion in isolated intestinal I cells (Liou et al., 2011). Furthermore, the CaSR plays a central role in intestinal fluid transport. Activation of the colonic CaSR by Ca^{2+}, Gd^{3+}, polyamines, or neomycin induces a rapid increase in $Ca^{2+}{}_i$ levels in both surface and crypt cells and reduces the stimulatory effect of forskolin on net fluid secretion in perfused crypts (Cheng et al., 2002, 2004). While secretagogues such as forskolin and cholera toxin could induce fluid secretion by increasing cyclic nucleotides, activation of either the luminal or the basolateral CaSR by Ca^{2+} and spermine can reverse forskolin-stimulated fluid secretion via facilitation of the destruction of cAMP and cGMP, inhibiting Cl^- secretion and stimulating Na^+ absorption (Geibel et al., 2006). CaSR deficiency in the intestinal epithelium induced a proinflammatory immune response, compromised intestinal barrier function, and altered the composition of the microbiota (Cheng et al., 2014). These findings suggest that CaSR activator and CaSR-based nutrients might provide an effective treatment for disorders such as inflammatory bowel disease, enterocolitis, and secretory diarrhea (Cheng, 2016; Owen et al., 2016).

CaSR negatively modulates colonic epithelial growth and the inactivation of CaSR due to promoter hypermethylation, and defective histone acetylation (Fetahu et al., 2014) plays a key role in colorectal tumorigenesis (Rogers et al., 2012; Singh et al., 2013). High dietary Ca^{2+} intake promotes colonic mucosal epithelial cell differentiation, decreases cell

growth, and reduces risk for the development of colorectal cancer (Lamprecht and Lipkin, 2001). Conditional knockout of CaSR in intestinal epithelial cells increases nuclear β-catenin localization, enhances cell proliferation, and diminishes the differentiation of colonic crypts (Rey et al., 2012). Activation of the CaSR by raising Ca_o^{2+} in Caco-2 cells leads to a decrease in c-Myc proto-oncogene expression and abrogates its proproliferative effect (Kallay et al., 1997). Activation of the CaSR in human carcinoma cell lines by elevating Ca_o^{2+} levels decreases cell growth and promotes cell differentiation in correspondence with increased E-cadherin expression and suppressed β-catenin activation (Chakrabarty et al., 2003; Van Aken et al., 2001; Wong and Pignatelli, 2002). Increased E-cadherin stimulated by CaSR can interact with β-catenin to enhance cell−cell and cell−matrix adhesion via remodeling of the actin-cytoskeleton (Brembeck et al., 2006). Meanwhile, the activation of CaSR also prevents nuclear translocation of β-catenin, thereby reducing the formation of β-catenin−TCF4 complex and downregulating c-Myc and cyclin D1 expression (Chakrabarty et al., 2003). In addition, activation of CaSR stimulates the noncanonical Wnt pathway (Wnt5a/Ror2) to inhibit overly active Wnt signaling in colon cancer cell lines (MacLeod et al., 2007) and to decrease the risk of colitis-associated colon cancer by suppressing NFκ-B activity and reducing TNFα secretion and TNFR1 expression (Kelly et al., 2011) (Macleod, 2013). Restoration of CaSR expression in colorectal cancer cells reduces proliferation and increases differentiation and apoptotic potential (Aggarwal et al., 2015) and results in the concurrent reversal of stem cell markers, drug resistance, and epithelial−mesenchymal transition-related transcription factors (Singh and Chakrabarty, 2013). Taken together, these data support a role of CaSR as a tumor suppressor.

Calcium-sensing receptor in the peripheral vascular system

Although arterial blood pressure is regulated by the centrally located circulatory centers in the medulla oblongata, long-term blood pressure is controlled primarily by the volume balance of blood vessels. In addition to the central control mechanisms mediated by vegetative neuronal innervation and hormone secretion, blood vessels are able to independently control their perfusion locally via the actions of the CaSR (Smajilovic et al., 2011). CaSR expression is found in several cell types in vasculature including the endothelium (Ziegelstein et al., 2006), VSMCs (Schepelmann et al., 2016), and the perivascular nerve (Bukoski et al., 1997). The activation of CaSR in rat mesenteric branch arteries induced neuronal release of cannabinoid, causing endothelium-independent hyperpolarization of VSMCs and subsequent relaxation of the arteries (Ishioka and Bukoski, 1999). The CaSR of endothelial cells participates in Ca^{2+}-induced vasorelaxation by two mechanisms, endothelial hyperpolarization and nitric oxide release (Weston et al., 2005) (Greenberg et al., 2016). In mesenteric arteries, activation of CaSR by Ca_o^{2+} or calcimimetic led to the opening of the Ca^{2+}-sensitive K^+ channel, which induced hyperpolarization of endothelium and VSMCs (Greenberg et al., 2016). In the human aorta, activation of CaSR by spermine induced an increase in $Ca^{2+}{}_i$ concentration and nitric oxide (NO) production, resulting in decreased vascular tone (Loot et al., 2013; Ziegelstein et al., 2006). It was suggested that the heteromeric TRPV4/TRPC1 channels in vascular endothelial cells play a role in CaSR-induced NO production and vasorelaxation (Ma et al., 2011) (Greenberg et al., 2017). On the other hand, rises in Ca_o^{2+} induced endothelium-independent contractility in the aorta and mesenteric artery (Schepelmann et al., 2016; Wonneberger et al., 2000). Ablation of CaSR in VSMCs led to lower diastolic and mean arterial blood pressures in *Casr* knockout mice (Schepelmann et al., 2016). Activation of the CaSR of smooth muscle cells induced ERK1/2 phosphorylation and a subsequent increase in proliferation with no elevation in the IP_3 level (Smajilovic et al., 2006). Thus, vascular CaSR plays a dual role in controlling blood vessel tone and heart rate with prorelaxing actions in the endothelium (Lopez-Fernandez et al., 2015) and procontractile effects in vascular smooth muscle (Schepelmann et al., 2016). Nonetheless, a recent study revealed another mechanism for the CaSR to control regional blood flow and blood pressure. Lee et al. emonstrated that activating the CaSR in the olfactory epithelium of rat with Ca_o^{2+} or CaSR agonists increased sympathetic efferent nerve activities and arterial blood pressure and subsequently decreased renal blood flow and renal, hepatic, and enteral microcirculation (Lee et al., 2019). In addition, the suppressive effect on renal perfusion was antagonized by calcilytic NPS-2143 and abolished by mechanic denervation (Lee et al., 2019), supporting a direct coupling between CaSR activation and increased peripheral vascular resistance by sympathetic excitation.

Reduced vasorelaxation by low CaSR expression or function has been linked to the complications of diabetic vasculopathy (Loot et al., 2013). Decreased expression of CaSR is also associated with the development of cardiovascular calcification in individuals with advanced chronic kidney disease (London et al., 2005). In vitro studies show that calcimimetic treatment increases CaSR expression and reduces vascular mineralization (Alam et al., 2009) (Henaut et al., 2014; Molostvov et al., 2015). Additionally, calcimimetic treatments were shown to exert antihypertensive effects in patients with chronic kidney disease (Zitt et al., 2011) and reduced the risk of cardiovascular events in elderly hemodialysis patients (Parfrey et al., 2015; Sumida et al., 2013), possibly because of their ability to restore CaSR expression levels in the vasculature (Henaut et al., 2014).

Calcium-sensing receptor in the lung

CaSR is expressed in both epithelium and smooth muscle in developing fetal lungs (Riccardi et al., 2013). The CaSR has been identified as an important regulator of intraluminal pressure and lung development. A crucial part of lung development is branching morphogenesis during the pseudoglandular stage. Exposure of isolated fetal lung buds to increased Ca_o^{2+} or calcimimetic induced elevations in Ca_i^{2+} and had a suppressive effect on branching because of the inhibition of cell proliferation (Finney et al., 2008). This CaSR-mediated suppression of the lung branching program requires PLC-dependent Ca_i^{2+} release and the activation of PI3K (Finney et al., 2008). Furthermore, higher Ca_o^{2+} or calcimimetic induced lumen distension by increasing luminal fluid volume and stimulating transepithelial fluid transport (Finney et al., 2008). CaSR is also found in the neuroepithelial bodies of the postnatal mouse lung and is implicated in coordinating intercellular communication through Ca_i^{2+} signaling in this intrapulmonary airway stem cell niche (Lembrechts et al., 2013).

Greater expression and function of CaSR in pulmonary arterial smooth muscle cells has been linked with the onset of idiopathic pulmonary arterial hypertension (PAH) (Yamamura et al., 2012) and the development of asthma (Yarova et al., 2015). Unlike the largely protective properties of CaSR in the peripheral vascular system, CaSR is involved in hypoxic vasoconstriction in the pulmonary vasculature and in vascular remodeling during the development and progression of PAH (Peng et al., 2014; Tang et al., 2016; Zhang et al., 2012). Nonetheless, recent work demonstrated that calcilytics can significantly improve the remodeling process of lung vessels in cases of PAH (Yamamura et al., 2015, 2016).

Asthma is characterized by airway accumulation of a group of polycationic proteins, particularly eosinophilic cationic proteins and major basic proteins, due to chronic inflammation (Kurosawa et al., 1992; North et al., 2013). Activation of CaSR by polycations increases Ca_i^{2+} levels and cell proliferation in airway smooth muscle cells, leading to airway hyperresponsiveness, bronchoconstriction, and inflammation in allergic asthma. It was postulated that CaSR may also control the recruitment and activation of inflammatory cells, which in turn release cytokines that subsequently elevate CaSR expression, thus creating a positive feedback loop in asthma (Yarova et al., 2015). These effects, however, could be ameliorated by CaSR ablation from the airway smooth muscle or prevented by nebulized calcilytics (Yarova et al., 2015). The protective effects of nebulized calcilytics are mediated by preventing Ca_i^{2+} increases and by abrogating the signaling pathways associated with airway contractility, such as ERK1/2, p38 MAPK, and PI3K/Akt (Yarova et al., 2015).

Calcium-sensing receptor in the epidermis

The epidermis consists of multiple layers of keratinocytes that differentiate and produce a permeability barrier that provides protection against desiccation, xenobiotic infection, and other environmental insults. Ca_o^{2+} is essential for initiating keratinocyte differentiation and maintaining epidermal functions. Activating CaSR by raising Ca_o^{2+} levels increases Ca_i^{2+} levels through coupling to the $G_{q/11}$/PLC pathway (Bikle et al., 2012) and induces cell−cell adhesion by stimulating the formation of the E-cadherin−catenin protein complex via the activation of Rho small GTPases and Src family tyrosine kinase signaling pathways (Calautti et al., 1998, 2002). The E-cadherin−catenin adhesion complexes in the cell membrane recruit and activate PI3K, Akt, PLCγ1, and EGFR, important regulators of cell proliferation, survival, and differentiation (Calautti et al., 2005; Tu et al., 2018; Xie and Bikle, 2007).

The CaSR is expressed throughout all keratinocyte layers in the epidermis (Komuves et al., 2002) with predominant intracellular perinuclear localization (Tu et al., 2001). Fluorescence immunostaining and coimmunoprecipitation studies revealed that CaSR colocalized and formed a protein complex with PLCγ1, IP_3R, and SPCA1 in the *trans*-Golgi (Tu et al., 2007). Inactivation of CaSR in keratinocytes profoundly reduced releasable Ca_i^{2+} pools (Tu et al., 2007), suggesting that the CaSR may coordinate Ca^{2+} release and the replenishment of stores and Ca^{2+} entry through membrane channels via direct interactions with $Ca^{2+}{}_i$ modulators such as PLC and Ca^{2+}-ATPase. Besides the initial Ca^{2+} release via PLC activation, the CaSR sustains increases in Ca_i^{2+} levels via E-cadherin-mediated signaling (Tu et al., 2008). Ca_o^{2+} stimulates interactions among the CaSR, filamin A, Rho-GEF Trio, RhoA, and E-cadherin at the cell membrane and facilitates CaSR signaling through the Rho and E-cadherin pathways (Tu et al., 2011; Tu and You, 2014). In Casr-deficient keratinocytes, the ability of Ca_o^{2+} to stimulate Ca_i^{2+} mobilization is severely inhibited, and the ineffectual Rho signaling fails to stabilize the E-cadherin−catenin adhesion complex and activate PI3K and PLCγ1, resulting in decreased basal Ca_i^{2+} level, impaired intercellular adhesion, increased cell apoptosis, and reduced differentiation (Tu et al., 2008, 2011). Additionally, depleting CaSRs suppresses keratinocyte proliferation by downregulating the E-cadherin/EGFR/MAPK signaling axis (Tu et al., 2018). Furthermore, the control of keratinocyte proliferation and differentiation by CaSR may involve activation of the Wnt/β-catenin signaling cascade (Popp et al., 2014; Turksen and Troy, 2003).

The physiological importance of CaSR in epidermal development and maintenance is made clear by animal models in which the CaSR gene has been overexpressed or deleted. The skin of keratinocyte-specific CaSR knockout ($^{Epid}Casr^{-/-}$) mice exhibits the loss of an innate epidermal Ca^{2+} gradient, aberrant keratinocyte differentiation, and retarded epidermal repair after injury due to impaired Ca_i^{2+}- and E-cadherin-mediated signaling (Tu et al., 2012, 2018). CaSR abrogation also delays the formation of the permeability barrier during prenatal development and impairs skin barrier function in adults (Tu et al., 2012). On the other hand, transgenic mice with constitutive expression of CaSR in basal keratinocytes manifest advanced differentiation and epidermal permeability barrier formation during embryologic development as well as accelerated hair growth at birth (Turksen and Troy, 2003). These changes in epidermal differentiation may be attributed to enhanced cross talk between CaSR and the Wnt/β-catenin signaling pathway in the CaSR transgenic epidermis (Turksen and Troy, 2003). Similarly, stimulating endogenous epidermal CaSR with calcimimetic NPS-R568 accelerated wound reepithelialization through enhancing of the epidermal $Ca^{2+}{}_i$ signals and E-cadherin membrane expression (Tu et al., 2018). These findings demonstrated a critical role for the CaSR in epidermal homeostasis and the therapeutic potential of calcimimetics for improving skin wound repair.

Chapter outline

The parathyroid hormone gene

Organization of the parathyroid hormone gene

The human parathyroid hormone (PTH) gene is localized on the short arm of chromosome 11 at 11p15 (Antonarakis et al., 1983; Zabel et al., 1985). The human and bovine genes have two functional TATA transcription start sites, and the rat has only one. The two homologous TATA sequences flanking the human PTH gene direct the synthesis of two human PTH gene transcripts, both in normal parathyroid glands and in parathyroid adenomas (Igarashi et al., 1986; Kronenberg et al., 1986). The PTH genes in all species that have been cloned have two introns or intervening sequences and three exons (Kronenberg et al., 1986). Strikingly, even though fish do not have discrete parathyroid glands, they do synthesize PTH using two distinct genes that resemble mammalian PTH and that share the same exon–intron pattern found in tetrapod PTH genes (Danks et al., 2003; Gensure et al., 2004). Fish, as well as other vertebrates except mammals, also express a PTH-like gene (PTH4 or PTH-L) that bears some resemblance to PTH-related protein (PTHrP) and may contribute to calcium homeostasis as well (Suarez-Bregua et al., 2017). The elephant shark, which is a jawed cartilaginous fish, has at least two Pth genes and one Pthrp gene. The expression of several Pth gene family members in the elephant shark suggests that the Pthrp and Pth genes evolved in a common ancestor of jawed vertebrates even before the development of bone (Liu et al., 2010).

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00024-5

Intron A splits the 5′ untranslated sequence of the mRNA five nucleotides before the initiator methionine codon (Bell et al., 2005a,b,c). Intron B splits the fourth codon of the region that codes for the pro sequence of prepro-PTH. The three exons that result are roughly divided into three functional domains. Exon I contains the 5′ untranslated region (UTR). Exon II codes for the pre sequence, or signal peptide, and most of the pro sequence and exon III codes for PTH as well as the 3′ UTR. The structure of the PTH gene is thus consistent with the proposal that exons represent functional domains of the mRNA (Bell et al., 2005a,b,c; Kemper, 1986). Although the introns are at the same location, the large intron A in human is about twice as large as those in the rat and bovine. It is interesting that the human gene is considerably longer in both intron A and the 3′ UTR of the cDNA compared with bovine, rat, and mouse. Both introns have the characteristic splice-site elements. The second exon, containing 106 and 121 nucleotides in the human and bovine pre-mRNA, is much smaller and more homologous in size among the genes than intron A. Of interest, the elephant shark Pth1 and Pth2 genes both contain introns in the 5′ UTR and in the coding region at identical positions that are totally conserved in Pth genes from other vertebrates (Liu et al., 2010). The genes for human PTH and PTHrP are located at similar positions on sibling chromosomes 11 and 12. It is therefore likely that they arose from a common precursor by chromosomal duplication.

Promoter sequences

Regions upstream of the transcribed structural gene often determine tissue specificity and contain many of the regulatory sequences for the gene. For PTH, analysis of this region has been hampered by the lack of a parathyroid cell line. The 5 kb of DNA upstream of the start site of the human PTH gene was able to direct parathyroid gland-specific expression in transgenic mice (Hosokawa and Leahy, 1997). Computer analysis of the human PTH promoter region identified a number of consensus sequences (Kel et al., 2005). These include a sequence resembling the canonical cAMP-responsive element (CRE) 5′-TGACGTCA-3′ at position −81 with a single residue deviation. This element was fused to a reporter gene (chloramphenicol acetyltransferase, or CAT) and then transfected into different cell lines. Pharmacological agents that increase cAMP led to an increased expression of the CAT gene, suggesting a functional role for the CRE. The role of this putative CRE in the PTH gene in the parathyroid remains to be established. Specificity protein (Sp) and the nuclear factor-Y (NF-Y) complex are ubiquitously expressed transcription factors associated with basal expression of a host of gene products. Sp family members and NF-Y can cooperatively enhance transcription of a target gene. A highly conserved Sp1 DNA element present in mammalian PTH promoters has been identified and characterized (Alimov et al., 2005; Koszewski et al., 2004). Coexpression of Sp proteins and NF-Y complex leads to synergistic transactivation of the human PTH promoter, with alignment of the Sp1 DNA element essential for full activation (Alimov et al., 2005). A similar arrangement of DNA-response elements and synergism is present in the bovine PTH promoter, suggesting that this may be a conserved mechanism to enhance transcription of the PTH gene.

Several groups have identified DNA sequences that may mediate the negative regulation of PTH gene transcription by 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$). Demay et al. (1992) identified DNA sequences in the human PTH gene that bind the $1,25(OH)_2D_3$ receptor (VDR). Nuclear extracts containing the VDR were examined for binding to sequences in the 5′ flanking region of the human PTH gene. A 25-bp oligonucleotide containing sequences from −125 to −101 from the start of exon I bound nuclear proteins that were recognized by monoclonal antibodies against the VDR. The sequences in this region contained a single copy of a motif (AGGTTCA) that is homologous to the motifs repeated in the upregulatory $1,25(OH)_2D_3$-response element of the osteocalcin gene. When placed upstream of a heterologous viral promoter, the sequences contained in this 25-bp oligonucleotide mediated transcriptional repression in response to $1,25(OH)_2D_3$ in GH4C1 cells but not in ROS 17/2.8 cells. Therefore, this downregulatory element differs from upregulatory elements both in sequence composition and in the requirement for particular cellular factors other than the VDR for repressing PTH transcription (Demay et al., 1992). Russell et al. (1999) have shown that there are two negative vitamin D-response elements (VDREs) in the rat PTH gene, with different binding affinities to a VDR/RXR heterodimer. Transfection studies with VDRE−CAT constructs showed that they had an additive effect. Liu et al. (Alon et al., 2008; Liu et al., 1996) have identified such sequences in the chicken PTH gene and demonstrated their functionality after transfection into an opossum kidney cell line. They converted the negative activity imparted by the PTH VDRE to a positive transcriptional response through selective mutations introduced into the element. They showed that there was a p160 protein that specifically interacted with a heterodimer complex bound to the wild-type VDRE, but was absent from complexes bound to response elements associated with positive transcriptional activity.

The parathyroid hormone mRNA

Complementary DNAs encoding human, bovine, rat, mouse, pig, chicken, dog, cat, horse, macaque, fugu fish, and zebrafish PTH have all been cloned. The PTH gene is a typical eukaryotic gene with consensus sequences for initiation of RNA synthesis, RNA splicing, and polyadenylation. The primary RNA transcript consists of RNA transcribed from both

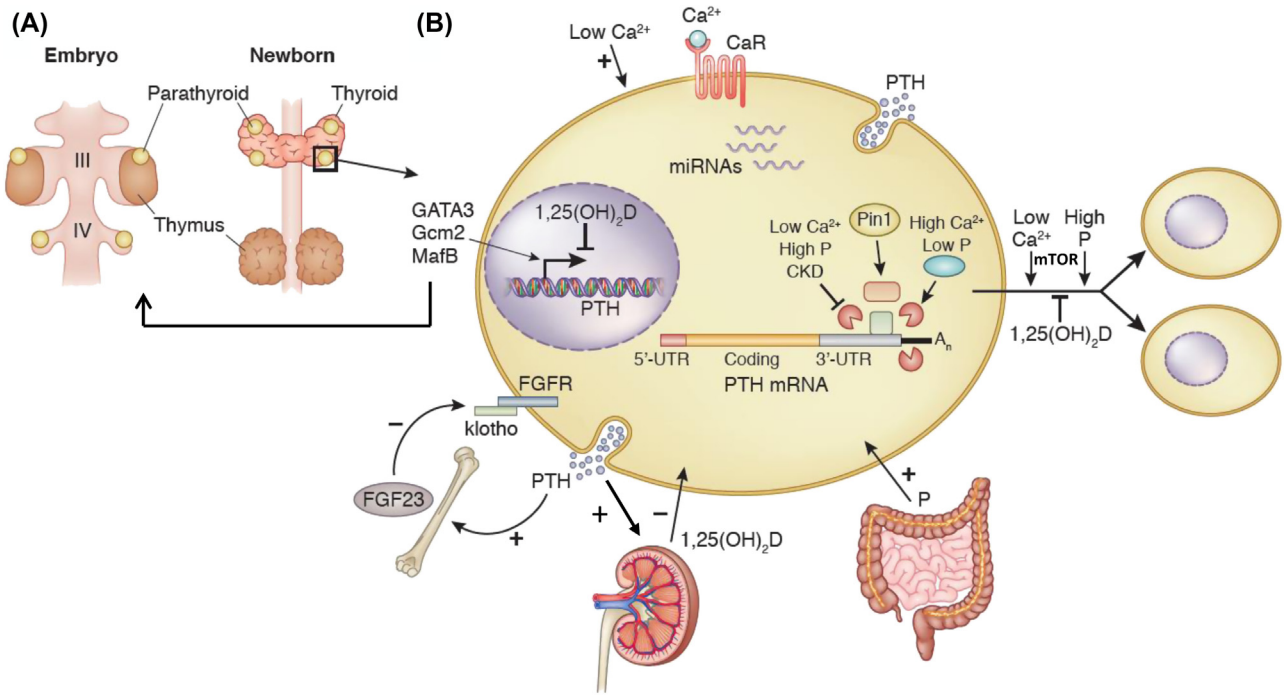

FIGURE 24.1 Parathyroid embryonic development and the regulators of PTH expression and parathyroid cell proliferation. (A) Diagram of the third and fourth pharyngeal pouches showing the embryonic location of the parathyroid- and thymus-fated domains in humans and the postnatal position of the parathyroids adjacent to the thyroid glands. (B) Schematic presentation of a parathyroid cell and daughter cells. The different regulators of PTH gene expression, secretion, and parathyroid cell proliferation are shown. Calcium, 1,25(OH)$_2$D$_3$, the high phosphate of uremia, and FGF23 all regulate PTH secretion and PTH gene expression through transcriptional and posttranscriptional mechanisms. In prolonged hypocalcemia and uremia, there is also parathyroid cell proliferation mediated by mTOR signaling, as shown by the two small cells on the right. miRNAs are also essential for the activation of the parathyroid in secondary hyperparathyroidism. Among the factors affecting parathyroid organogenesis, GATA3, Gcm2, and MafB are all essential for normal gland development and physically interact to activate the PTH gene promoter postnatally. *1,25(OH)$_2$D*, 1,25-dihydroxyvitamin D$_3$; *CaR*, calcium-sensing receptor; *CKD*, chronic kidney disease; *FGF23*, fibroblast growth factor 23; *FGFR*, fibroblast growth factor receptor; *miRNAs*, microRNAs; *PTH*, parathyroid hormone; *UTR*, untranslated region; *mTOR*, mammalian target of rapamycin. *Modified with permission from* Kidney International *(Naveh-Many, T., Silver, J., 2018. introns and exons, and then RNA sequences derived from the introns are spliced out. The product of this RNA processing, which represents the exons, is the mature PTH mRNA, which will then be translated into prepro-PTH (Figs. 24.1 and 24.2). There is considerable identity among mammalian PTH genes, which is reflected in an 85% identity between human and bovine proteins and 75% identity between human and rat proteins. There is less identity in the 3′ noncoding region. The initiator ATG codons for the human and bovine have been identified by sequencing in vitro translation products of the mRNAs (Habener et al., 1975; Kemper et al., 1976). In the bovine sequence, the first ATG codon is the initiator codon, in accord with many other eukaryotic mRNAs (Kozak, 1991). The human and rat sequences have ATG triplets prior to the probable initiator ATG, which are present 10 nucleotides before the initiation codon and are immediately followed by a termination codon. The termination codon immediately following the codon for glutamine at position 84 of PTH indicates that there are no additional precursors of PTH with peptide extensions at the carboxyl position. A more extensive review of the structure and sequences of the PTH gene has been published elsewhere (Bell et al., 2005a,b,c).

Mutations in the parathyroid hormone gene

Rare patients have been found with abnormal PTH genes that result in hypoparathyroidism (Gafni and Levine, 2005). The PTH gene of a patient with familial isolated hypoparathyroidism (Ahn et al., 1986) has been studied by Arnold et al. (1990), and a point mutation in the hydrophobic core of the signal peptide–encoding region of prepro-PTH was identified. This T-to-C point mutation changed the codon for position 18 of the 31-amino-acid prepro sequence from cysteine to arginine, and in functional studies the mutant protein was processed inefficiently. The mutation impaired interaction of the nascent protein with signal recognition particles and the translocation machinery, and cleavage of the mutant signal sequence by solubilized signal peptidase was slow (Karaplis et al., 1995). A novel mutation of the signal peptide of the

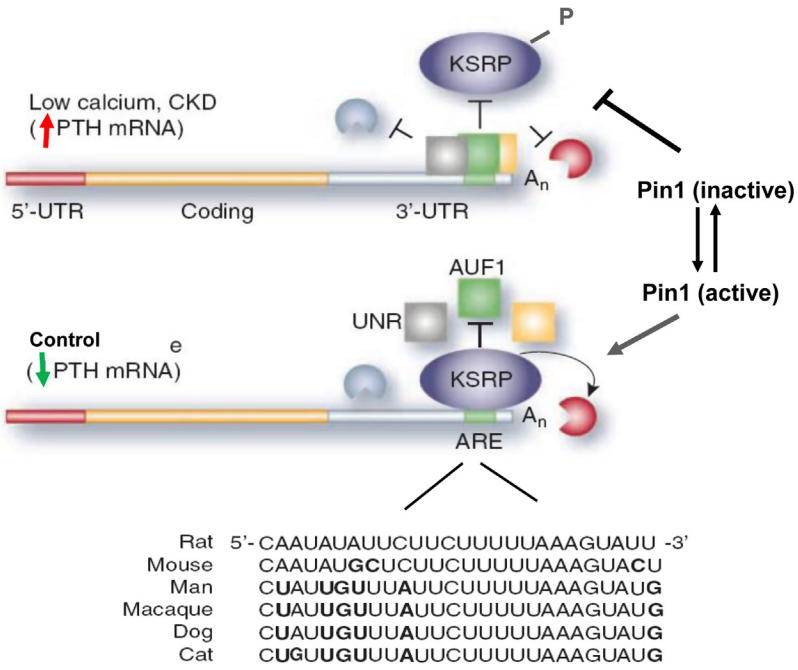

FIGURE 24.2 Model for the regulation of parathyroid hormone (*PTH*) mRNA stability by changes in calcium and kidney failure. A schematic representation of the PTH mRNA and binding proteins and the nucleotide sequence of the 26-nucleotide *cis* element in different species. Nucleotides that differ from the rat sequence are in *bold*. AU-rich binding factor (*AUF1*) and upstream of NRAS (UNR) stabilize and K-homology splicing regulator protein (*KSRP*) destabilizes PTH mRNA. Pin1 is upstream of KSRP and leads to KSRP dephosphorylation and activation. In hypocalcemic and experimental chronic kidney disease (*CKD*) rats, the enzymatic activity of the peptidyl-prolyl *cis/trans* isomerase Pin1 is reduced. As a result, KSRP is phosphorylated and hence less active. The stabilizing proteins AUF1 and UNR then bind the PTH mRNA 3′ UTR AU-rich element (*ARE*) with a greater affinity leading to increased PTH mRNA stability and levels. *Modification of a model shown in* Endocrinology *(Naveh-Many, T., 2010. Minireview: the play of proteins on the parathyroid hormone messenger ribonucleic acid regulates its expression. Endocrinology 151 (4), 1398−1402).*

prepro-PTH gene was associated with autosomal recessive familial isolated hypoparathyroidism (Sunthornthepvarakul et al., 1999). The affected members in this family presented with neonatal hypocalcemic seizures. Their intact PTH levels were undetectable during severe hypocalcemia. A replacement of thymine with a cytosine was found in the first nucleotide of position 23 in the 25-amino-acid signal peptide. This results in the replacement of the normal Ser (TCG) with a Pro (CCG). Only affected family members were homozygous for the mutant allele, whereas the parents were heterozygous, supporting autosomal recessive inheritance. Because this mutation is at the −3 position in the signal peptide of the prepro-PTH gene, the authors hypothesized that the prepro-PTH mutant might not be cleaved by signal peptidase at the normal position and might be degraded in the rough endoplasmic reticulum. The only mutation discovered in the coding region of secreted human PTH is an arginine-to-cysteine mutation at residue 25 of mature PTH(1−84). This ligand has a decreased affinity for the PTH receptor and fails to stimulate hypercalcemia when infused into mice (Lee et al., 2015). Parkinson et al. (Parkinson and Thakker, 1992) studied one kindred with autosomal recessive isolated hypoparathyroidism and identified a G-to-C substitution in the first nucleotide of intron B of the PTH gene. Restriction enzyme cleavage revealed that the patients were homozygous for mutant alleles, unaffected relatives were heterozygous, and unrelated normals were homozygous for the wild-type alleles. Defects in mRNA splicing were investigated by the detection of illegitimate transcription of the PTH gene in lymphoblastoid cells. The mutation resulted in exon skipping with a loss of exon II, which encodes the initiation codon and the signal peptide, thereby causing PTH deficiency. Goswami et al. (2004) studied 51 patients with sporadic idiopathic hypoparathyroidism. Neither the clinical manifestations nor the biochemical indexes of the disease were related to the occurrence of mutations or single-nucleotide polymorphisms in the PTH gene. Autosomal dominant hypocalcemia type 1 and type 2 are genetically distinct disorders that were found to be associated with germ-line gain-of-function mutations of CaR and G11α proteins, respectively (Hannan et al., 2016; Nesbit et al., 2013).

Development of the parathyroid

The parathyroid glands develop from a shared initial organ primordium together with the thymus. Both organs arise from the third pharyngeal pouch endoderm and surrounding neural crest cells. Humans have two additional superior parathyroid

glands that develop from the fourth pouch. In mice, the third pouch forms during embryonic days (E) 9−10.5. A transcriptional network involving Hoxa3, Pax1/Pax9, Eya1, Tbx1, Sox3, and Six1/Six4 controls early pouch patterning and formation of the parathyroid/thymus common primordium (Han et al., 2015; Chojnowski et al., 2014). After third pouch formation, it becomes subdivided into two molecularly distinct domains. The parathyroid-destined domain can be distinguished from E10.5 by the expression of the transcription factor Gcm2 (glial cells missing 2), which is required for parathyroid differentiation and survival (Liu et al., 2007). Foxn1 (Forkhead box N1) expression marks the thymus domain. Each primordium separates into a single parathyroid gland and a thymic lobe at E12.5−13.5. The parathyroids are "dragged" along by the migrating thymus lobes until the separation process is complete and then move to their eventual adult locations by about E14.5, adjacent to or embedded in the thyroid glands (Kamitani-Kawamoto et al., 2011; Manley, 2015) (Fig. 24.1). Mice that lack Hoxa3, Pax1/9, Eya1, and Six1/4 have normal initial pouch formation, but then fail to form or have hypoplastic parathyroids and thymus. *Hoxa3*$^{-/-}$ mutants fail to initiate the formation of the parathyroid/thymus primordia. In these mutants, Gcm2 is expressed in its normal domain, but at very low levels, indicating that Hoxa3 upregulates Gcm2 expression. Eya1 and Six1/4 are also required for Gcm2 expression, and mutations result in the loss of parathyroid precursor cells through apoptosis. As loss of Gcm2 itself is sufficient to cause apoptosis, it is possible that the effects of all of these genes, either individually or as a pathway, are mediated by their effect on Gcm2 expression (Manley, 2015).

The DiGeorge syndrome is a human genetic condition resulting from deletion of contiguous genes. The specific gene causing the hypoparathyroidism found in DiGeorge syndrome and the closely related CATCH-22 syndrome (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, associated with chromosome 22 microdeletion) is likely to be Tbx1 (Lindsay et al., 2001). In the DiGeorge syndrome, malformations include absence of the parathyroid glands and thymus as well as the heart outflow tract, and most DiGeorge syndrome patients are hemizygous for a 1.5- to 3.0-Mb region of 22q11. In mice, deletion of one copy of Tbx1 (in the equivalent genetic region in the mouse) affects the development of the fourth pharyngeal arch arteries, whereas homozygous mutation severely disrupts the pharyngeal arch artery system (Lindsay et al., 2001; Merscher et al., 2001). These data in mice suggest that Tbx1 has a major role in the molecular etiology of the DiGeorge syndrome phenotype.

Gata3 (GATA-binding protein 3), Gcm2, and MafB (transcriptional activator v-maf musculoaponeurotic fibrosarcoma oncogene homolog B) transcription factors constitute a genetic cascade regulating parathyroid development and PTH expression (Han et al., 2015). GATA3 haploinsufficiency results in congenital hypoparathyroidism, deafness, and renal dysplasia syndrome in humans. *Gata3*$^{-/-}$ embryos lack Gcm2 expression and exhibit gross defects in the third and fourth pharyngeal pouches, including absent parathyroid−thymus primordia (Grigorieva et al., 2010). *Gata3*$^{+/-}$ mice are viable and have apparently normal parathyroid glands. However, when fed a low calcium and vitamin D diet, plasma PTH levels and calcium concentrations are lower than those in wild-type mice, indicating partial parathyroid dysfunction in the *Gata3*$^{+/-}$ mice (Grigorieva et al., 2010). Gata3 directly binds and regulates Gcm2 expression. Gcm2 is expressed predominately in the pharyngeal pouches and, at later stages, in the developing and mature parathyroid glands. Once the parathyroid domain is established, upregulation of Gcm2 expression is necessary and sufficient for parathyroid differentiation and survival (Manley, 2015). Mutations of the *GCM2* gene in humans lead to familial isolated hypoparathyroidism. Genetic ablation of *Gcm2* in mice results in parathyroid agenesis and hypoparathyroidism. Without Gcm2 function, parathyroid precursor cells fail to differentiate and then undergo apoptosis by E12, resulting in the aparathyroid phenotype (Manley, 2015). Serum PTH levels were low or undetectable in *Gcm2*-knockout mice. In conditional *Gcm2*-knockout mice, immunoreactive PTH was identified within a few thymus cells in wild-type and homozygous knockout mice, consistent with the proposal that expression of PTH in medullary thymic epithelial cells provides a source of self-antigen for negative selection. Work has excluded the thymus as a source of circulating PTH in humans and mice (Yuan et al., 2014). It is possible that the normal process of parathyroid organogenesis in both mice and humans leads to the generation of multiple small parathyroid clusters in addition to the main parathyroid glands (Manley, 2015).

MafB is a basic leucine zipper transcription factor expressed in the developing parathyroid after E11.5 and postnatally. MafB expression is lost in the parathyroid primordium of *Gcm2*-null mice. The parathyroid glands of *MafB*$^{+/-}$ mice are mislocalized between the thymus and the thyroid. In *MafB*$^{-/-}$ mice, the parathyroids do not separate from the thymus during embryological development (Kamitani-Kawamoto et al., 2011). Therefore, MafB regulates later steps of parathyroid development, the separation from the thymus, and migration toward the thyroid.

Among Gata3, Gcm2, and MafB transcription factors, Gata3 is the most upstream, followed by Gcm2, and then MafB, which is the most downstream in parathyroid development (Han et al., 2015). This cascade is critical for parathyroid development. However, expression of Gata3, Gcm2, and MafB persists after parathyroid morphogenesis (Kamitani-Kawamoto et al., 2011), suggesting that they are components of a gene regulatory program that governs parathyroid-specific gene expression and function. Gata3, Gcm2, and MafB form a transcriptional complex that mediates

parathyroid-specific PTH expression. Recent in vitro analyses in heterologous cells revealed that Gata3, Gcm2, and MafB physically interact and synergistically activate the *PTH* gene promoter (Han et al., 2015). The in vivo functions of Gata3 and Gcm2 and MafB in parathyroid physiology and disease have been shown. Morito et al. (2018) showed a role for MafB in experimental secondary hyperparathyroidism. Deletion of MafB had no effect on serum PTH levels or mineral metabolism under normal conditions, but decreased serum PTH levels at postnatal day 0 in $MafB^{-/-}$ mice (Kamitani-Kawamoto et al., 2011). Stimulation of the parathyroid by prolonged uremia in $MafB^{+/-}$ mice resulted in an impaired increase in serum PTH, PTH mRNA, and parathyroid cell proliferation. Both PTH and cyclin D2, but not cyclin D1, expression was blunted in $MafB^{+/-}$ uremic mice, suggesting that MafB contributes to the increased PTH and cyclin D2 expression in secondary hyperparathyroidism. Acute hypocalcemia-induced PTH secretion and PTH mRNA were also impaired in $MafB^{+/-}$ and in global *MafB*-knockout mice. Therefore, MafB plays a role in regulation of PTH secretion but this effect may be less important than its role in controlling the development and differentiation of the parathyroid gland. It is intriguing that transcription factors that affect parathyroid morphogenesis are expressed and functional in parathyroid physiology (Fig. 24.1).

Okabe and Graham (2004) have performed elegant studies that demonstrate a role for Gcm2 even in fish, which do not have discrete parathyroid glands. They showed that the parathyroid gland of tetrapods and the gills of fish both express Gcm2 and require this gene for their formation. They also showed that the gill region expresses mRNA encoding the two PTH genes found in fish, as well as mRNA encoding the calcium-sensing receptor (CaR). The conserved role of Gcm2 in forming pharyngeal structures is established, but the relationship between Gcm2 and PTH-producing cells in fish is not clear.

Regulation of parathyroid hormone gene expression

1,25-Dihydroxyvitamin D_3

PTH regulates serum concentrations of calcium and phosphate, which, in turn, regulate the synthesis and secretion of PTH. $1,25(OH)_2D_3$ has independent effects on calcium and phosphate levels and also participates in a well-defined feedback loop between $1,25(OH)_2D_3$ and PTH.

PTH increases the renal synthesis of $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ then increases blood calcium largely by increasing the efficiency of intestinal calcium absorption. $1,25(OH)_2D_3$ also potently decreases transcription of the PTH gene. This action was first demonstrated in vitro in bovine parathyroid cells in primary culture, where $1,25(OH)_2D_3$ led to a marked decrease in PTH mRNA levels (Silver et al., 1985; Russell et al., 1984) and a consequent decrease in PTH secretion (Cantley et al., 1985; Karmali et al., 1989; Chan et al., 1986). The physiological relevance of these findings was established by in vivo studies in rats (Silver et al., 1986). The localization of VDR mRNA to parathyroids was demonstrated by in situ hybridization studies of the thyroparathyroid and duodenum. VDR mRNA was localized to the parathyroids in the same concentration as in the duodenum, the classic target organ of $1,25(OH)_2D_3$ (Naveh-Many and Silver, 1990). Rats injected with amounts of $1,25(OH)_2D_3$ that did not increase serum calcium had marked decreases in PTH mRNA levels, reaching $<4\%$ of control at 48 h (Fig. 24.1). This effect was shown to be transcriptional in both in vivo studies in rats (Silver et al., 1986) and in vitro studies with primary cultures of bovine parathyroid cells (Russell et al., 1986). When 684 bp of the 5′ flanking region of the human PTH gene was linked to a reporter gene and transfected into a rat pituitary cell line (GH4C1), gene expression was lowered by $1,25(OH)_2D_3$ (Okazaki et al., 1988). These studies suggest that $1,25(OH)_2D_3$ decreases PTH transcription by acting on the 5′ flanking region of the PTH gene. The effect of $1,25(OH)_2D_3$ may involve heterodimerization with the retinoic acid receptor. This is because 9-*cis*-retinoic acid, which binds to the retinoic acid receptor, when added to bovine parathyroid cells in primary culture, led to a decrease in PTH mRNA levels. Moreover, combined treatment with retinoic acid and $1,25(OH)_2D_3$ decreased PTH secretion and prepro-PTH mRNA more effectively than either compound alone (Macdonald et al., 1994). Alternatively, retinoic acid receptors might synergize with VDRs through actions on distinct sequences.

A further level at which $1,25(OH)_2D_3$ may regulate the PTH gene would be at the level of the VDR. $1,25(OH)_2D_3$ acts on its target tissues by binding to the VDR, which regulates the transcription of genes with the appropriate recognition sequences. Concentration of the VDR in $1,25(OH)_2D_3$ target sites could allow a modulation of the $1,25(OH)_2D_3$ effect, with an increase in receptor concentration leading to an amplification of its effect and a decrease in receptor concentration dampening the $1,25(OH)_2D_3$ effect. Naveh-Many and Silver (1990) injected $1,25(OH)_2D_3$ into rats and measured the levels of VDR mRNA and PTH mRNA in the thyroparathyroid tissue. They showed that $1,25(OH)_2D_3$ in physiologically relevant doses led to an increase in VDR mRNA levels in the parathyroid glands in contrast to the decrease in PTH mRNA levels. This increase in VDR mRNA occurred after a time lag of 6 h, and a dose response showed a peak at 25 pmol.

Weanling rats fed a diet deficient in calcium were markedly hypocalcemic at 3 weeks and had very high serum $1,25(OH)_2D_3$ levels. Despite the chronically high serum $1,25(OH)_2D_3$ levels, there was no increase in VDR mRNA levels; furthermore, PTH mRNA levels did not fall and were increased markedly. The low calcium in the bloodstream may have prevented the increase in parathyroid VDR levels, which may partially explain PTH mRNA suppression. Whatever the mechanism, the lack of suppression of PTH synthesis in the setting of hypocalcemia and increased serum $1,25(OH)_2D_3$ is crucial physiologically because it allows an increase in both PTH and $1,25(OH)_2D_3$ at a time of chronic hypocalcemic stress. Russell et al. (1993) studied the parathyroids of chicks with vitamin D deficiency and confirmed that $1,25(OH)_2D_3$ regulates PTH and VDR gene expression in the avian parathyroid gland. Brown et al. (1995) studied vitamin D-deficient rats and confirmed that $1,25(OH)_2D_3$ upregulated parathyroid VDR mRNA. Rodriguez et al. (2007) showed that administration of the calcimimetic R568 resulted in increased VDR expression in parathyroid tissue. In vitro studies of the effect of R568 on VDR mRNA and protein were conducted in cultures of whole rat parathyroid glands. Incubation of rat parathyroid glands in vitro with R568 resulted in a dose-dependent decrease in PTH secretion and an increase in VDR expression. Together with previous work on the effect of extracellular calcium to increase parathyroid VDR mRNA in vitro (Garfia et al., 2002), they concluded that activation of the CaR upregulates the parathyroid VDR mRNA.

All these studies show that $1,25(OH)_2D_3$, and calcium in certain circumstances, increases the expression of the VDR gene in the parathyroid gland, which would result in increased VDR protein synthesis and increased binding of $1,25(OH)_2D_3$. This ligand-dependent receptor upregulation would lead to an amplified effect of $1,25(OH)_2D_3$ on the PTH gene and might help explain the dramatic effect of $1,25(OH)_2D_3$ on the PTH gene.

Vitamin D may also amplify its effect on the parathyroid by increasing the activity of the calcium receptor (CaR). Canaff et al. (Canaff and Hendy, 2002) showed that in fact there are VDREs in the human CaR promoter. The CaR, expressed in parathyroid chief cells, thyroid C cells, and cells of the kidney tubule, is essential for maintenance of calcium homeostasis. They showed that parathyroid, thyroid, and kidney CaR mRNA levels increased twofold at 15 h after intraperitoneal injection of $1,25(OH)_2D_3$ in rats. Human thyroid C-cell (TT) and kidney proximal tubule cell (HKC) CaR gene transcription increased approximately twofold at 8 and 12 h after $1,25(OH)_2D_3$ treatment. The human CaR gene has two promoters yielding alternative transcripts containing either exon IA or exon IB 5′ UTR sequences that splice to exon II some 242 bp before the ATG translation start site. $1,25(OH)_2D_3$ stimulated P1 activity 2-fold and P2 activity 2.5-fold. VDREs, in which the half-sites (6 bp) are separated by three nucleotides, were identified in both promoters and shown to confer $1,25(OH)_2D_3$ responsiveness to a heterologous promoter. This responsiveness was lost when the VDREs were mutated. In electrophoretic mobility-shift assays specific protein−DNA complexes were formed in the presence of $1,25(OH)_2D_3$ on oligonucleotides representing the P1 and P2 VDREs. In summary, functional VDREs have been identified in the CaR gene and probably provide the mechanism whereby $1,25(OH)_2D_3$ upregulates parathyroid, thyroid C-cell, and kidney CaR expression.

The use of $1,25(OH)_2D_3$ is limited by its hypercalcemic effect, and therefore a number of $1,25(OH)_2D_3$ analogs have been synthesized that are biologically active but are less hypercalcemic than $1,25(OH)_2D_3$ (Brown, 2005). These analogs usually involve modifications of the $1,25(OH)_2D_3$ side chain, such as 22-oxa-$1,25(OH)_2D_3$, which is the chemical modification in oxacalcitriol (Nishii et al., 1991), or a cyclopropyl group at the end of the side chain in calcipotriol (Kissmeyer and Binderup, 1991). However, detailed in vivo dose−response studies showed that in vivo $1,25(OH)_2D_3$ is the most effective analog for decreasing PTH mRNA levels, even at doses that do not cause hypercalcemia (Naveh-Many and Silver, 1993). The marked activity of $1,25(OH)_2D_3$ analogs in vitro compared with their modest hypercalcemic actions in vivo probably reflects their rapid clearance from the circulation (Bouillon et al., 1991).

The ability of $1,25(OH)_2D_3$ to decrease PTH gene transcription is used therapeutically in the management of patients with chronic renal failure. They are treated with $1,25(OH)_2D_3$, or its prodrug 1α(OH)-vitamin D_3, to prevent the secondary hyperparathyroidism of chronic renal failure. The poor response in some patients may well result from poor control of serum phosphate, decreased VDR concentration in the patients' parathyroids (Fukuda et al., 1993), an inhibitory effect of a uremic toxin(s) on VDR−VDRE binding (Patel and Rosenthal, 1985), or tertiary hyperparathyroidism with monoclonal parathyroid tumors (Arnold et al., 1995).

Another possible level at which $1,25(OH)_2D_3$ may regulate PTH gene expression involves calreticulin. Calreticulin is a calcium-binding protein present in the endoplasmic reticulum of the cell and may have an additional nuclear function. It regulates gene transcription via its ability to bind a protein motif in the DNA-binding domain of nuclear hormone receptors of sterol hormones. It has been shown to prevent vitamin D's binding and action on the osteocalcin gene in vitro (Wheeler et al., 1995). Sela-Brown et al. (1998) showed that calreticulin inhibits the action of vitamin D on the PTH gene. Hypocalcemic rats had increased levels of calreticulin protein in their parathyroid nuclear fraction, which may explain why hypocalcemia leads to increased PTH gene expression, despite high serum $1,25(OH)_2D_3$ levels.

Calcium

In vitro studies

A remarkable characteristic of the parathyroid is its sensitivity to small changes in serum calcium, which leads to large changes in PTH secretion. This remarkable sensitivity of the parathyroid to increase hormone secretion after small decreases in serum calcium levels is unique to the parathyroid. All other endocrine glands increase hormone secretion after exposure to high extracellular calcium. Calcium sensing also regulates PTH gene expression and parathyroid cell proliferation (Fig. 24.1). In vitro and in vivo data agree that calcium regulates PTH mRNA levels, but data differ in important ways. In vitro studies with bovine parathyroid cells in primary culture showed that calcium regulated PTH mRNA levels (Russell et al., 1983; Brookman et al., 1986), with an effect mainly of high calcium to decrease PTH mRNA. These effects were most pronounced after more prolonged incubations, such as 72 h. The physiologic correlates of these studies in tissue culture are hard to ascertain, as the parathyroid calcium sensor may well have decreased over the time period of the experiment (Mithal et al., 1995). This may explain why the dose response differs from in vivo data, but the dramatic difference in time course suggests that in vivo data reflect something not seen in cultured cells.

In vivo studies

Calcium and phosphate both have marked effects on the levels of PTH mRNA and secretion in vivo. The major effect is for low calcium to increase PTH mRNA levels and low phosphate to decrease PTH mRNA levels. Naveh-Many et al. (1989) showed that a small decrease in serum calcium from 2.6 to 2.1 mmol/L led to large increases in PTH mRNA levels, reaching threefold that of controls at 1 and 6 h. A high serum calcium had no effect on PTH mRNA levels even at concentrations as high as 6.0 mmol/L. Interestingly, in these same thyroparathyroid tissue RNA extracts, calcium had no effect on the expression of the calcitonin gene (Naveh-Many et al., 1989, 1992a,b). Thus, while high calcium is a secretagogue for calcitonin, it does not regulate calcitonin gene expression. Yamamoto et al. (Yamamoto et al., 1989) also studied the in vivo effect of calcium on PTH mRNA levels in rats. They showed that hypocalcemia induced by a calcitonin infusion for 48 h led to a sevenfold increase in PTH mRNA levels. Rats made hypercalcemic (2.9−3.4 mM) for 48 h had the same PTH mRNA levels as controls that had received no infusion (2.5 mM); these levels were modestly lower than those found in rats that had received a calcium-free infusion. In further studies, Naveh-Many et al. (1992a,b) transplanted Walker carcinosarcoma 256 cells into rats. Serum calcium levels increased to 18 mg/dL at day 10 after transplantation. There was no change in PTH mRNA levels in these rats with marked chronic hypercalcemia (Naveh-Many et al., 1992a,b). Differences between in vivo and in vitro results probably reflect the instability of the in vitro system. Nevertheless, the physiological conclusion is that common causes of hypercalcemia in vivo do not importantly decrease PTH mRNA levels; these results emphasize that the gland is geared to respond to hypocalcemia and not hypercalcemia.

The mechanism whereby calcium regulates PTH gene expression is particularly interesting. Changes in extracellular calcium are sensed by a calcium sensor that then regulates PTH secretion (Brown et al., 1993; Yano and Brown, 2005). Signal transduction from the CaR involves activation of phospholipase C, D, and A_2 enzymes (Kifor et al., 1997). It is not known what mechanism transduces the message of changes in extracellular calcium leading to changes in PTH mRNA. However, it has been shown that the response to changes in serum calcium involves the protein phosphatase type 2B, calcineurin (Bell et al., 2005a,b,c). In vivo and in vitro studies demonstrated that inhibition of calcineurin by genetic manipulation or pharmacologic agents affected the response of PTH mRNA levels to changes in extracellular calcium (Bell et al., 2005a,b,c).

Okazaki et al. (1992) identified a negative calcium regulatory element (nCaRE) in the atrial natriuretic peptide gene, with a homologous sequence in the PTH gene. They identified a redox factor protein (ref1), which bound a putative nCaRE, and the level of ref1 mRNA and protein were elevated by an increase in extracellular calcium concentration. They suggested that ref1 had transcription repressor activity in addition to its function as a transcriptional auxiliary protein (Okazaki et al., 1992). Because no parathyroid cell line is available, these studies were performed in nonparathyroid cells, so their relevance to physiologic PTH gene regulation remains to be established.

Moallem et al. (1998) have performed in vivo studies on the effect of hypocalcemia on PTH gene expression. The effect is posttranscriptional in vivo and involves protein−RNA interactions at the 3′ UTR of the PTH mRNA (Moallem et al., 1998). A similar mechanism is involved in the effect of phosphate on PTH gene expression so the mechanisms involved will be discussed later in this chapter.

Phosphate

The demonstration of a direct effect of high phosphate on the parathyroid, independent of calcium and $1,25(OH)_2D_3$, has been difficult. One of the reasons is that the various maneuvers used to increase or decrease serum phosphate invariably lead to a change in the ionized calcium concentration. In moderate renal failure, phosphate clearance decreases and serum phosphate increases; this increase becomes an important problem in severe renal failure. Hyperphosphatemia has always been considered central to the pathogenesis of secondary hyperparathyroidism, but it has been difficult to separate the effects of hyperphosphatemia from those of the attendant hypocalcemia and decrease in serum $1,25(OH)_2D_3$ levels. In the 1970s, Slatopolsky and Bricker (1973) showed in dogs with experimental chronic renal failure that dietary phosphate restriction prevented secondary hyperparathyroidism. Clinical studies demonstrated that phosphate restriction in patients with chronic renal insufficiency is effective in preventing the increase in serum PTH levels (Lucas et al., 1986; Portale et al., 1984; Aparicio et al., 1994; Lafage et al., 1992; Combe and Aparicio, 1994; Combe et al., 1995). The mechanism of this effect was not clear, although at least part of it was considered to be due to changes in serum $1,25(OH)_2D_3$ concentrations. In vitro (Tanaka and DeLuca, 1973; Condamine et al., 1994) and in vivo (Portale et al., 1984, 1989) phosphate directly regulates the production of $1,25(OH)_2D_3$. A raised serum phosphate decreases serum $1,25(OH)_2D_3$ levels, which then leads to decreased calcium absorption from the diet and eventually a low serum calcium. The raised phosphate complexes calcium, which is then deposited in bone and soft tissues and decreases serum calcium. However, a number of careful clinical and experimental studies suggested that the effect of phosphate on serum PTH levels was independent of changes in both serum calcium and $1,25(OH)_2D_3$ levels. In experimental chronic renal failure in dogs, phosphate increased parathyroid cell activity by a mechanism independent of its effect on serum $1,25(OH)_2D_3$ and calcium levels (Lopez-Hilker et al., 1990). Therefore, phosphate plays a central role in the pathogenesis of secondary hyperparathyroidism, by its effects on both serum $1,25(OH)_2D_3$ and serum calcium levels and possibly independently. A raised serum phosphate also stimulates the secretion of fibroblast growth factor 23 (FGF23), which in turn decreases PTH gene expression and serum PTH levels. This effect would act as a counterbalance to the stimulatory effect of phosphate on the parathyroid and is discussed separately in this chapter.

Kilav et al. (1995) were the first to establish in vivo that the effects of serum phosphate on PTH gene expression and serum PTH levels were independent of any changes in serum calcium or $1,25(OH)_2D_3$ (Fig. 24.1). They bred second-generation vitamin D-deficient rats and then placed the weanling vitamin D-deficient rats on a diet with no vitamin D, low calcium, and low phosphate. After one night of this diet, serum phosphate had decreased markedly with no changes in serum calcium or $1,25(OH)_2D_3$. These rats with isolated hypophosphatemia had marked decreases in PTH mRNA levels and serum PTH (Kilav et al., 1995). To establish that the effect of serum phosphate on the parathyroid was indeed a direct effect, in vitro confirmation was needed, which was provided by three groups. Rodriguez et al. showed that increased phosphate levels increased PTH secretion from isolated parathyroid glands in vitro; the effect required maintenance of tissue architecture (Almaden et al., 1996). The effect was found in whole glands or tissue slices but not in isolated cells. This result was confirmed by Slatopolsky et al. (1996). Olgaard's laboratory provided elegant further evidence of the importance of cell−cell communication in mediating the effect of phosphate on PTH secretion (Nielsen et al., 1996). The requirement for intact tissue suggests either that the sensing mechanism for phosphate is damaged during the preparation of isolated cells or that the intact gland structure is important to the phosphate response.

The parathyroid responds to changes in serum phosphate at the level of secretion, gene expression, and cell proliferation, although the signaling involved is unknown. The effect of high phosphate to increase PTH secretion may be mediated by phospholipase A_2-activated signal transduction. Bourdeau et al. (1992, 1994) showed that arachidonic acid and its metabolites inhibit PTH secretion. Almaden et al. (2000) showed in vitro that a high-phosphate medium increased PTH secretion, which was prevented by the addition of arachidonic acid.

Protein−PTH mRNA interactions determine the posttranscriptional regulation of PTH gene expression by calcium, phosphate, and uremia

Diet-induced hypocalcemia and adenine/high phosphorus−induced chronic kidney disease (CKD) increase PTH mRNA levels, and diet-induced hypophosphatemia decreases PTH mRNA levels (Fig. 24.1). In both instances, the effect is posttranscriptional, as shown by nuclear transcript run-on experiments (Moallem et al., 1998; Kilav et al., 2005). Parathyroid cytosolic proteins bind in vitro-transcribed PTH mRNA. Interestingly, this binding was increased with parathyroid proteins from hypocalcemic and CKD rats (with increased PTH mRNA levels) and decreased with parathyroid proteins from hypophosphatemic rats (with decreased PTH mRNA levels). Proteins from other tissues bound to PTH mRNA, but

only parathyroid proteins bound PTH mRNA in a way that was regulated by calcium and phosphate. Intriguingly, binding required the presence of the terminal 60 nucleotides of the PTH transcript.

An in vitro degradation assay showed that the effects of hypocalcemic and hypophosphatemic parathyroid proteins on PTH mRNA stability reproduced the differences in PTH mRNA levels observed in vivo (Moallem et al., 1998). Moreover, the difference in RNA stability stimulated by the parathyroid extracts was dependent on an intact 3′ UTR and, in particular, on the terminal 60 nucleotides. Proteins from other tissues in these rats subjected to hypocalcemia, hypophosphatemia, or uremia did not affect PTH mRNA stability in this in vitro assay. Therefore, calcium, phosphate, and CKD change the properties of parathyroid cytosolic proteins, which bind specifically to the PTH mRNA 3′ UTR and determine its stability (Fig. 24.2). What are these proteins?

A conserved sequence in the PTH mRNA 3′ UTR binds parathyroid cytosolic proteins and determines mRNA stability

We have identified the minimal sequence for protein binding in the PTH mRNA 3′ UTR and determined its functionality (Fig. 24.2) (Kilav et al., 2001). A minimum sequence of 26 nucleotides was sufficient for PTH RNA−protein binding. To study the functionality of the sequence in the context of another RNA, a 63-bp cDNA PTH sequence consisting of the 26-nucleotide and flanking regions was fused to growth hormone cDNA. The conserved PTH RNA protein-binding region was necessary and sufficient for responsiveness to calcium and phosphate and determines PTH mRNA stability and levels (Kilav et al., 2001).

The PTH mRNA 3′-UTR-binding element is AU rich and is a type III AU-rich element (ARE). Sequence analysis of the PTH mRNA 3′ UTR of different species revealed a preservation of the 26-nucleotide protein-binding element in rat, murine, human, macaque, feline, and canine 3′ UTRs (Fig. 24.2) (Kilav et al., 2001; Bell et al., 2005a,b,c). In contrast to protein coding sequences that are highly conserved, UTRs are less conserved. The conservation of the protein-binding element in the PTH mRNA 3′ UTR suggests that this element represents a functional unit that has been evolutionarily conserved. The *cis*-acting element is at the 3′ distal end in all species in which it is expressed.

The PTH mRNA 3′-UTR-binding proteins that determine PTH mRNA stability

AU-rich binding factor

Affinity chromatography using the PTH RNA 3′ UTR identified AU-rich-binding factor (AUF1) as a PTH mRNA-binding protein (Sela-Brown et al., 2000; Brewer, 1991). Added recombinant AUF1 stabilized the PTH transcript in the in vitro degradation assay. Therefore, AUF1 is a protein that binds to the PTH mRNA 3′ UTR and stabilizes the PTH transcript. The regulation of protein−PTH mRNA binding involves posttranslational modification of AUF1 (Bell et al., 2005a,b,c; Sela-Brown et al., 2000; Levi et al., 2006). The balance between the stabilizing and the destabilizing proteins determines mRNA levels in response to physiological stimuli (Fig. 24.2) (Brewer, 1991; Naveh-Many, 2010; Nechama et al., 2008; Barreau et al., 2006).

K-homology splicing regulator protein

The mRNA decay-promoting protein K-homology splicing regulator protein (KSRP) binds to PTH mRNA in intact parathyroid glands and in transfected cells (Nechama et al., 2008, 2009; Nechama et al., 2009a,b,c; Gherzi et al., 2004). This binding of KSRP is decreased in glands from calcium-depleted or experimental uremic rats in which PTH mRNA is more stable, compared with parathyroid glands from control and phosphorus-depleted rats in which PTH mRNA is less stable. The differences in KSRP−PTH mRNA binding counter those of AUF1. PTH mRNA decay depends on the KSRP-recruited exosome in parathyroid extracts. In transfected cells, KSRP overexpression and knockdown experiments showed that KSRP decreases PTH mRNA stability and steady-state levels through the PTH mRNA ARE. Overexpression of the PTH mRNA-stabilizing protein AUF1 blocks KSRP−PTH mRNA binding and partially prevents the KSRP-mediated decrease in PTH mRNA levels (Nechama et al., 2008). Therefore, calcium or phosphorus depletion, as well as CKD, regulates the interaction of KSRP and AUF1 with PTH mRNA and its half-life. The balance between the stabilizing and the destabilizing proteins determines PTH mRNA levels in response to physiological stimuli (Fig. 24.2).

Most patients with CKD develop secondary hyperparathyroidism with disabling systemic complications. Calcimimetic agents are effective tools in the management of secondary hyperparathyroidism, acting through allosteric modification of the CaR on the parathyroid gland to decrease PTH secretion and parathyroid cell proliferation. R568 decreased both PTH mRNA and serum PTH levels in adenine/high phosphorus-induced uremia (Nechama et al., 2009a,b,c). The effect of the calcimimetic, similar to that of uremia on PTH gene expression, was posttranscriptional and correlated with differences in

protein−RNA binding and posttranslational modifications of AUF1 in the parathyroid. AUF1 modifications were reversed compared with those of normal rats by treatment with R568. Therefore, uremia and activation of the CaR mediated by calcimimetics modify AUF1 posttranslationally. These modifications in AUF1 correlate with changes in protein−PTH mRNA binding and PTH mRNA levels (Nechama et al., 2009a,b,c). In addition, KSRP−PTH mRNA binding was decreased in parathyroids from rats with adenine-induced CKD, a condition in which PTH mRNA is more stable. KSRP−PTH mRNA binding was increased by treatment with R568, correlating with decreased PTH gene expression. This destabilizing effect of R568 was dependent on KSRP and the PTH mRNA 3′ UTR. Therefore, the calcimimetic R568 decreases PTH mRNA levels by altering the balance between KSRP and AUF binding to the PTH mRNA 3′ UTR.

The peptidyl-prolyl isomerase Pin1 determines parathyroid hormone mRNA stability and levels in secondary hyperparathyroidism

Pin1 activity is decreased in parathyroid protein extracts from hypocalcemic and uremic rats. Pharmacologic inhibition of Pin1 increases PTH mRNA levels posttranscriptionally in vivo in the parathyroid and in transfected cells (Nechama et al., 2009a,b,c). Pin1 regulates PTH mRNA stability and levels through the PTH mRNA 3′ UTR *cis*-acting element. Pin1 interacts with the PTH mRNA destabilizing protein, KSRP, and leads to KSRP dephosphorylation and activation. In the parathyroid, Pin1 inhibition in secondary hyperparathyroidism decreases KSRP−PTH mRNA interaction that contributes to the increased PTH gene expression. Furthermore, *Pin1*$^{-/-}$ mice had increased serum PTH and PTH mRNA levels. Therefore, Pin1 determines basal PTH expression in vivo and in vitro, and decreased Pin1 activity correlates with increased PTH mRNA levels in CKD and hypocalcemic rats (Nechama et al., 2009a,b,c). These results demonstrate that Pin1 is a key mediator of PTH mRNA stability and indicate a role for Pin1 in the pathogenesis of the secondary hyperparathyroidism of CKD (Fig. 24.2) (Naveh-Many, 2010; Nechama et al., 2009a,b,c; Kumar, 2009).

Dynein light-chain M_r 8000 binds the PTH mRNA 3′ untranslated region and mediates its association with microtubules

mRNA expression cloning identified dynein light-chain M_r 8000 (LC8) as a 3′-UTR PTH mRNA-binding protein. LC8 is part of the cytoplasmic dynein complexes that function as molecular motors that translocate along microtubules. Recombinant LC8 bound the PTH mRNA 3′ UTR as assessed by RNA mobility-shift assay. PTH mRNA colocalized with polymerized microtubules in the parathyroid gland, as well as with a purified microtubule preparation from calf brain, and this was mediated by LC8 (Epstein et al., 2000). This was the first report of a dynein complex protein binding an mRNA and acting as a motor for the transport and localization of mRNAs in the cytoplasm and the subsequent asymmetric distribution of translated proteins in the cell.

MicroRNA in the parathyroid

Parathyroid-specific deletion of Dicer-dependent microRNA

A further level of posttranscriptional regulation of PTH gene expression is by microRNA (miRNA). miRNAs downregulate gene expression and have vital roles in biology but their functions in the parathyroid have been unexplored. The final step in miRNA maturation is cleavage by Dicer protein in the cytoplasm (Lee et al., 2003). We generated parathyroid-specific Dicer 1-knockout (PT-*Dicer*$^{-/-}$) mice, in which parathyroid miRNA maturation is blocked only in the parathyroid (Shilo et al., 2015). Despite normal basal PTH, under conditions of stress, deletion of Dicer and the subsequent absence of mature miRNA in the mouse parathyroid had surprising effects on parathyroid function. Remarkably, the PT-*Dicer*$^{-/-}$ mice did not increase serum PTH in response to acute hypocalcemia compared with the greater than fivefold increase in controls. PT-*Dicer*$^{-/-}$ glands cultured in low-calcium medium secreted fivefold less PTH at 1.5 h than controls. Chronic hypocalcemia increased serum PTH greater than fourfold less in PT-*Dicer*$^{-/-}$ mice compared with control mice, with no increase in PTH mRNA levels and parathyroid cell proliferation compared with the two- to threefold increase in hypocalcemic controls (Shilo et al., 2015). The importance of our findings is highlighted by the fact that uremic PT-*Dicer*$^{-/-}$ mice with normal serum calcium had an impaired increase in serum PTH similar to their failure to respond to hypocalcemia (Shilo et al., 2015). Therefore, parathyroid miRNAs are necessary for the development of secondary hyperparathyroidism not only of chronic hypocalcemia but also of CKD (Holmes, 2015) (Fig. 24.3). In contrast to the impaired increase in PTH by hypocalcemia and uremia, the PT-*Dicer*$^{-/-}$ mice decreased serum PTH as expected after activation of the parathyroid CaR by both hypercalcemia and a calcimimetic, demonstrating that these processes that suppress PTH secretion are dicer independent. In conclusion, miRNAs are essential for activation of the parathyroid by both acute and chronic hypocalcemia and uremia, the major stimuli for PTH secretion (Shilo et al., 2015, 2016) (Fig. 24.3).

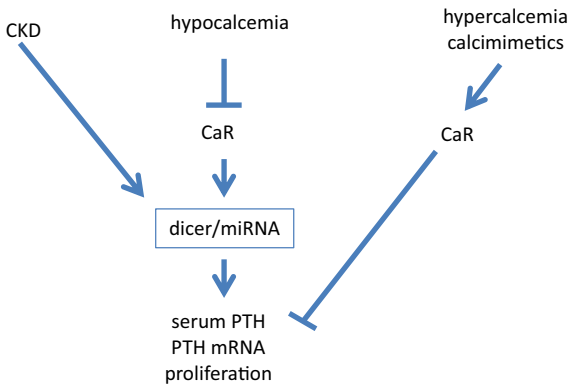

FIGURE 24.3 Model for the role of microRNAs (*miRNA*) in stimulation of the parathyroid by hypocalcemia and chronic kidney disease (*CKD*) but not in suppression of the parathyroid by hypercalcemia or a calcimimetic. Parathyroid miRNAs are essential for the increase in parathyroid gland activity by acute and chronic hypocalcemia and uremia, mediating the increase in parathyroid hormone (*PTH*) mRNA levels, PTH secretion, and parathyroid cell proliferation. Suppression of parathyroid activity by hypercalcemia or a calcimimetic is miRNA independent. *CaR*, calcium-sensing receptor. *With permission from* Current Opinion in Nephrology and Hypertension *(Shilo, V., Silver, J., Naveh-Many, T., 2016. Micro-RNAs in the parathyroid: a new portal in understanding secondary hyperparathyroidism. Curr. Opin. Nephrol. Hypertens. 25 (4), 271–277).*

Let-7 and miRNA-148 regulate parathyroid hormone levels in secondary hyperparathyroidism

miRNA profiling of parathyroid glands from mice and rats with experimental CKD and dialysis patients by miRNA deep sequencing showed that human and rodent parathyroids share similar profiles (Shilo et al., 2017). Parathyroids from uremic and normal rats segregated on the basis of their miRNA expression profiles, and a similar finding was observed in humans. There were several parathyroid miRNAs that were dysregulated in experimental secondary hyperparathyroidism, including miR-29, miR-21, miR-148, miR-30, and miR-141 (upregulated) and miR-10, miR-125, and miR-25 (downregulated). Inhibition of the abundant let-7 family increased PTH secretion in normal and CKD rats, as well as in mouse parathyroid organ cultures. Conversely, inhibition of the upregulated miR-148 family prevented the increase in serum PTH level in CKD rats and decreased levels of secreted PTH in parathyroid cultures. The evolutionary conservation of abundant miRNAs in normal parathyroid glands and the regulation of these miRNAs in secondary hyperparathyroidism indicate their importance for parathyroid function and the development of hyperparathyroidism. Specifically, let-7 and miR-148 antagonism modified PTH secretion in vivo and in vitro, implying roles for these specific miRNAs in the parathyroid (Shilo et al., 2017).

Sex steroids

PTH is anabolic to bone and is an effective means of treating postmenopausal osteoporosis. In postmenopausal women with osteoporosis, time series analysis has shown that there is a loss in the periodicity of PTH secretion (Prank et al., 1995; Fraser et al., 1998). This suggests that estrogens may have an effect on the parathyroid. Estradiol and progesterone both increased the secretion of PTH from bovine parathyroid cells in primary culture (Greenberg et al., 1987). However, transdermal estrogen did not increase serum PTH levels in postmenopausal patients (Prince et al., 1990). Estrogen receptors were not detected in parathyroid tissue by a hormone-binding method (Prince et al., 1991), but were detected by immunohistochemistry and PCR for the estrogen receptor mRNA (Naveh-Many et al., 1992a,b). Moreover, in vivo in ovariectomized rats, both estrogen and progestins regulated PTH gene expression (Naveh-Many et al., 1992a,b).

Further studies were performed on the effects of progestins on PTH gene expression (Epstein et al., 1995). The 19-nor progestin R5020 given to weanling rats or mature ovariectomized rats led to a twofold increase in thyroparathyroid PTH mRNA levels. In addition, in vitro, in primary cultures of bovine parathyroid cells, progesterone increased PTH mRNA levels. The progesterone receptor mRNA was demonstrated in rat parathyroid tissue by in situ hybridization and in human parathyroid adenoma by immunohistochemistry. PTH mRNA levels varied during the rat estrous cycle (Epstein et al., 1995). These results confirm that the parathyroid gland is a target organ for the ovarian sex steroids estrogen and progesterone and they are of physiological relevance, as shown by the changes during estrus. In a rat model of CKD with ovariectomy, estrogen treatment decreased PTH mRNA and serum levels, unlike the increase after estrogen in control rats (Epstein et al., 1995; Carrillo-López et al., 2009). In the CKD rats, estrogens significantly increased FGF23 mRNA and serum levels, suggesting that estrogens may regulate PTH indirectly through FGF23 (Carrillo-López et al., 2009).

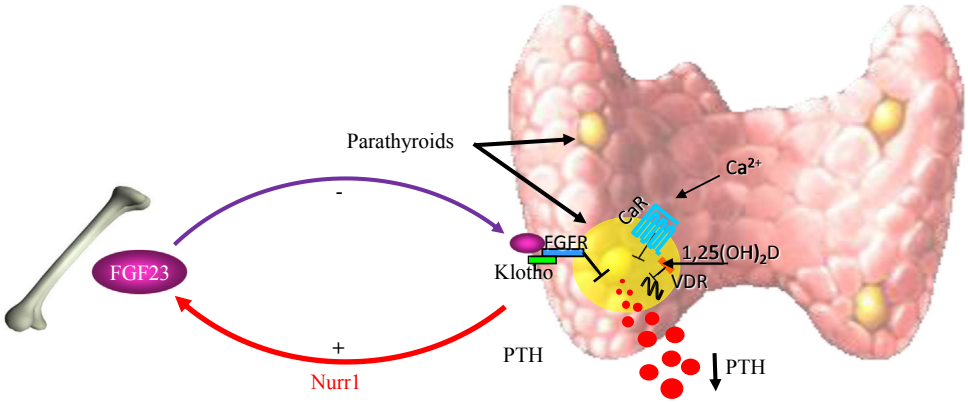

FIGURE 24.4 A bone–parathyroid endocrine loop of fibroblast growth factor 23 (*FGF23*) and parathyroid hormone (*PTH*). Parathyroid function is decreased by calcium through the calcium sensing receptor (*CaR*) and $1,25(OH)_2D_3$ through the vitamin D receptor (*VDR*). FGF23 is secreted by bone and acts on the parathyroid to also decrease PTH synthesis, secretion, and parathyroid cell proliferation by acting on the parathyroid klotho–FGFR1c receptor. PTH in turn increases FGF23 expression by activating the Nurr1 transcription factor in osteoblasts and osteocytes. *Modified from* Kidney International *with permission (Silver, J., Naveh-Many, T., 2009. Phosphate and the parathyroid. Kidney Int. 75 (9), 898–905).*

Fibroblast growth factor 23

Fibroblast growth factor 23 decreases parathyroid hormone expression

Phosphate homeostasis is maintained by a counterbalance between efflux from the kidney and influx from intestine and bone. FGF23 is a bone-derived phosphaturic hormone that acts on the kidney to increase phosphate excretion and suppress biosynthesis of $1,25(OH)_2D_3$. FGF23 signals through FGF receptors (FGFRs) bound by the transmembrane protein klotho (Kurosu et al., 2006; Urakawa et al., 2006). Klotho protein is expressed not only in the kidney but also in the parathyroid, pituitary, and sinoatrial node (Takeshita et al., 2004). Ben Dov et al. (2007) identified the parathyroid as a target organ for FGF23 in rats (Fig. 24.4). The parathyroid gland expressed klotho and FGFRs. The administration of recombinant FGF23 led to an increase in parathyroid klotho levels. In addition, FGF23 activated the mitogen-activated protein kinase (MAPK) pathway in the parathyroid through extracellular signal-regulated kinase 1/2 phosphorylation and increased Egr1 (early growth response) mRNA levels. FGF23 suppressed PTH secretion and PTH gene expression both in vivo in rats and in vitro in parathyroid cultures (Ben Dov et al., 2007). These data indicate that FGF23 acts directly on the parathyroid through the MAPK pathway to decrease serum PTH. Krajisnik et al. (2007) showed similar results using bovine parathyroid cells in primary culture. Interestingly, they also showed that FGF23 led to a dose-dependent increase in the expression of the 1α-hydroxylase enzyme in the parathyroid (Krajisnik et al., 2007). The increased $1,25(OH)_2D_3$ may then act in an autocrine manner to decrease PTH gene transcription. In addition, PTH increases FGF23 expression in bone (Lavi-Moshayoff et al., 2010). PTH increases the levels of the orphan nuclear receptor, Nurr1, in osteocytes and osteoblasts in vivo and in osteoblast-like UMR106 cells, which then acts on the FGF23 promoter to increase FGF23 transcription (Meir et al., 2014). The bone–parathyroid endocrine feedback loop of PTH and FGF23 adds a new dimension to the understanding of mineral homeostasis (Fig. 24.4).

Resistance of the parathyroid to FGF23 in chronic kidney disease

In CKD both serum FGF23 and serum PTH levels are increased. Several studies have shown that a decrease in klotho–FGFR1 expression and signal transduction may explain the resistance of the parathyroid to FGF23 in CKD. In experimental CKD, quantitative immunohistochemistry and qRT-PCR using laser capture microscopy showed that klotho and FGFR1 protein and mRNA levels were decreased in parathyroid sections of rats with adenine diet–induced advanced CKD (Galitzer et al., 2010). Similar results have been shown using the parathyroids from patients with advanced CKD (Komaba et al., 2010). Moreover, in parathyroids of rats with advanced CKD, recombinant FGF23 failed to decrease serum PTH or activate the MAPK pathway. In rat parathyroid organ culture, FGF23 decreased secreted PTH and PTH mRNA levels in control or early CKD rats but not in rats with advanced CKD (Galitzer et al., 2010). Therefore, in advanced experimental CKD, there is a decrease in parathyroid klotho and FGFR1 mRNA and protein levels in rats and in patients with CKD. This decrease corresponds with the resistance of the parathyroid to FGF23 in vivo, which is sustained in parathyroid organ culture in vitro. The increased levels of FGF23 do not decrease PTH levels in established CKD because

of a downregulation of its receptor heterodimer complex klotho−FGFR1c. Olauson et al. (2013) showed by genetic and functional studies that a klotho-independent, calcineurin-mediated FGF23 signaling pathway in parathyroid glands can mediate suppression of PTH in the absence of klotho. The presence of klotho-independent FGF23 effects in a klotho-expressing target organ represents a paradigm shift in the conceptualization of FGF23 endocrine action and suggests the centrality of the suppression of FGFR1 more than that of klotho in the resistance to FGF23 in renal failure (Olauson et al., 2013).

Parathyroid cell proliferation and mammalian target of rapamycin

Phosphorylation of ribosomal protein S6 mediates mammalian target of rapamycin−induced parathyroid cell proliferation in secondary hyperparathyroidism

Secondary hyperparathyroidism is characterized by increases in PTH expression and parathyroid cell proliferation (Naveh-Many et al., 1995; Denda et al., 1996; Cozzolino et al., 2005; Silver and Naveh-Many, 2013). Decreased expression of the calcium, $1,25(OH)_2D_3$, and FGF23 receptors contributes to the increased parathyroid cell proliferation in uremia (Garfia et al., 2002; Galitzer et al., 2010; Lewin et al., 2002). Expression of transforming growth factor-α and its receptor, the epidermal growth factor (EGF) receptor (EGFR), is increased in uremic rats and patients (Cozzolino et al., 2005; Gogusev et al., 1996; Drueke, 2000). A dominant negative EGFR gene expressed specifically in the parathyroid glands prevented the activation of endogenous EGFR and the increase in parathyroid gland enlargement and serum PTH (Arcidiacono et al., 2008, 2015; Dusso et al., 2010). Other cell cycle regulators such as cyclin D1 also induce parathyroid cell proliferation, as shown in transgenic mice overexpressing cyclin D1 only in the parathyroid (Imanishi et al., 2001).

Mammalian target of rapamycin (mTOR) integrates signaling pathways to regulate cell growth and proliferation. mTOR is regulated by binding partners found in two complexes, mTOR complex 1 (mTORC1) and mTORC2. Rapamycin inhibits mTORC1 and proliferation in many cell types (Shimobayashi and Hall, 2014; Xu et al., 2015). Different stimuli activate mTORC1 through Akt phosphorylation. 4E-binding protein 1 and the ribosomal protein S6 kinase 1 (S6K1) are mTORC1 targets (Shahbazian et al., 2006). S6K1 phosphorylates ribosomal protein S6 (rpS6) on a cluster of five serine residues at the carboxy terminus. Knock-in mice encoding a mutant rpS6 harboring alanine substitutions at all five phosphorylation sites ($rpS6^{P-/-}$ mice) have reduced size, glucose intolerance, muscle weakness, and impaired renal hypertrophy after uninephrectomy (Ruvinsky et al., 2005, 2009). Volovelsky et al. (2016) have shown that the mTOR pathway is activated in the parathyroid of rats with secondary hyperparathyroidism induced by either chronic hypocalcemia or CKD, as measured by increased phosphorylation of rpS6, a downstream target of the mTOR pathway (Fig. 24.5). This

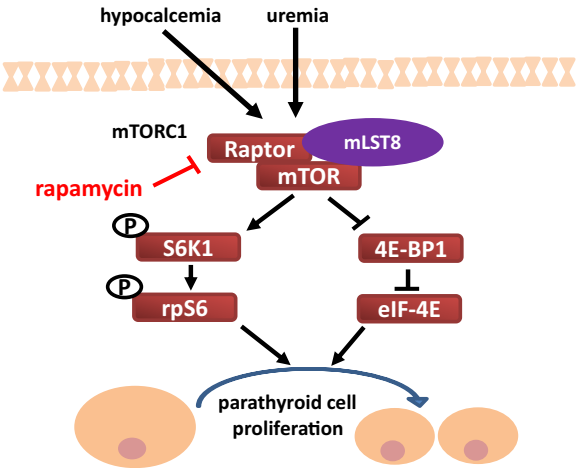

FIGURE 24.5 Mammalian target of rapamycin (*mTOR*) complex 1 (*mTORC1*) induces parathyroid cell proliferation in secondary hyperparathyroidism (SHP) through ribosomal protein S6 (*rpS6*) phosphorylation. The mTOR pathway is activated in the parathyroids of rats and mice with SHP induced by either chronic hypocalcemia or uremia. On activation, mTORC1 phosphorylates and activates S6 kinase 1 (*S6K1*), which then phosphorylates rpS6. mTORC1 also disinhibits eukaryotic translation initiation factor-4E (*eIF-4E*) by inhibiting 4E-binding protein 1 (*4E-BP1*). rpS6 phosphorylation is necessary for the increased parathyroid cell proliferation of SHP. Inhibition of mTORC1 by rapamycin decreases and prevents parathyroid cell proliferation in SHP. *With permission from* Journal of the American Society of Nephrology *(Volovelsky, O., Cohen, G., Kenig, A., Wasserman, G., Dreazen, A., Meyuhas, O., et al., 2016. Phosphorylation of ribosomal protein S6 mediates mammalian target of rapamycin complex 1-induced parathyroid cell proliferation in secondary hyperparathyroidism. J. Am. Soc. Nephrol. 27 (4), 1091−1101).*

activation correlated with increased parathyroid cell proliferation. Inhibition of mTORC1 by rapamycin decreased or prevented parathyroid cell proliferation in rats with secondary hyperparathyroidism and in vitro in uremic rat parathyroid glands in organ culture. Knock-in $rpS6^{p-/-}$ mice, in which rpS6 cannot be phosphorylated, had impaired PTH secretion after experimental uremia. Uremic $rpS6^{p-/-}$ mice had no increase in parathyroid cell proliferation compared with a marked increase in uremic wild-type mice. These results highlight the importance of mTOR activation and rpS6 phosphorylation for the pathogenesis of secondary hyperparathyroidism and indicate that mTORC1 is a significant regulator of parathyroid cell proliferation through rpS6 (Fig. 24.5) (Volovelsky et al., 2016). mTORC1 responds to growth factors, such as insulin, IGF-1, and EGF. The EGFR also activates the Akt−mTORC1 pathway (Huse and Holland, 2010). Therefore, the mTORC1 and EGFR pathways may act together to stimulate parathyroid cell proliferation in secondary hyperparathyroidism.

Summary

The PTH mRNA consists of three exons that are roughly divided into the 5′ UTR, the signal peptide sequence and PTH, and the 3′ UTR. The parathyroid glands develop from a shared initial organ primordium together with the thymus. A transcriptional network determines the embryological development of the parathyroid. $1,25(OH)_2D_3$ decreases PTH gene transcription. The major regulator of the parathyroid is hypocalcemia. Hypocalcemia regulates PTH gene expression in vivo by increasing PTH mRNA levels, and this is mainly posttranscriptional. Phosphate also regulates PTH gene expression, and this effect is independent of the effect of phosphate on serum calcium and $1,25(OH)_2D_3$. The effects of phosphate and uremia are also posttranscriptional. *Trans*-acting parathyroid cytosolic proteins bind to a defined *cis* element in the PTH mRNA 3′ UTR. This binding determines the degradation of PTH mRNA and thereby the PTH mRNA half-life. Changes in the balance of stabilizing and degrading factors on PTH mRNA determine the posttranscriptional effects of calcium, phosphate, and uremia on PTH gene expression. Pin1 regulates protein−PTH mRNA interactions, leading to more rapid PTH mRNA decay. In secondary hyperparathyroidism, Pin1 is less active and is associated with an increase in PTH mRNA stability and levels and thus increased PTH secretion. A further level of the posttranscriptional regulation of PTH gene expression is through miRNAs that are necessary for the increased PTH in acute and chronic hypocalcemia and uremia. mTOR is activated in secondary hyperparathyroidism, correlating with the increase in parathyroid cell proliferation. Inhibition of mTOR decreases parathyroid cell proliferation in both chronic hypocalcemia and CKD. FGF23 acts on its receptor, the klotho−FGFR1c receptor, to decrease PTH mRNA levels and secretion. In advanced CKD there is resistance of the parathyroid to the high FGF23 levels due to downregulation of the FGF23 receptor. $1,25(OH)_2D_3$, hypercalcemia, calcimimetics, hypophosphatemia, and rapamycin all decrease PTH gene expression and parathyroid cell proliferation (Fig. 24.1).

Chapter 25

Paracrine parathyroid hormone–related protein in bone: physiology and pharmacology

T. John Martin and Natalie A. Sims

St. Vincent's Institute of Medical Research, Melbourne, Australia; Department of Medicine at St. Vincent's Hospital, The University of Melbourne, Melbourne, Australia

Chapter outline

Introduction: discovery of parathyroid hormone–related protein

When he carried out 650 autopsies on patients with breast cancer, the English surgeon Stephen Paget noted the remarkable frequency of secondary growths in bone, especially at the ends of the femora and in the skull (Paget, 1889). This led him to write: "in cancer of the breast, the bones suffer in a special way, which cannot be explained by any theory of embolism alone. Some bones suffer more than others, the disease has its seats of election." In that series, he also reported six subjects with breast cancer who had no bone metastases, but who appeared to have a generalized susceptibility of the skeleton to fracture. No explanation of the findings of Paget was forthcoming, but some decades later, the discovery of parathyroid hormone–related protein (PTHrP) as the cause of hypercalcemia in many patients with cancer provided new insights into the pathogenesis of the skeletal complications of malignancy (Suva et al., 1987). Two other chapters (Chapter 54, Goltzman; Chapter 55, Sterling) will consider this topic in more depth, but it is appropriate to introduce the topic of PTHrP in bone with some relevant background.

When Fuller Albright in 1941 was discussing a patient with hypercalcemia accompanying a hypernephroma that had metastasized to the ilium, he suggested that the hypercalcemia might be due to production by the cancer of parathyroid hormone (PTH) (Albright, 1941). This was an influential comment that played a part in the adoption within the next years of the concept of "ectopic" production of PTH by tumors. This became a commonly used explanation through the 1960s and into the 1970s for hypercalcemia in cancer with no or minimal bone metastases (Lafferty, 1966). This seemed at that time to fit with a more general concept of ectopic production of hormones by cancers, for example, with adrenocorticotropic hormone production resulting in hypercorticolism in certain patients with cancer (Meador et al., 1962).

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00025-7

The first radioimmunoassays for PTH appeared to support this view, with apparently elevated circulating levels of PTH in unselected patients with bronchogenic carcinoma (Berson and Yalow, 1966). When further assays were developed whose specificities were better defined (Riggs et al., 1971), the observations were made that PTH levels in cancer hypercalcemia were lower than those in primary hyperparathyroid subjects with the same degree of elevation of calcium and, furthermore, that immunoreactivity of cancer hypercalcemia samples differed from PTH in that it was nonparallel to PTH standards (Melick et al., 1972; Benson et al., 1974). These findings suggested that the circulating and tumor-derived activity measured in some patients with hypercalcemia in cancer differed immunochemically from authentic PTH itself. Strong support for this was provided by a study in which immunoreactive PTH could not be detected in plasma or tumor extracts from a number of patients whose tumor extracts resorbed bone in vitro (Powell et al., 1973), despite the use of several antibodies of differing specificities. Thus, the term "humoral hypercalcemia of malignancy" (HHM) was used to describe patients with cancer and hypercalcemia without bone metastases (Martin and Atkins, 1979).

A defining step in progress was made with three clinical studies each showing that in patients with HHM the mimicry of PTH action extended beyond the calcium and phosphorus effects to increased excretion of cyclic AMP (cAMP) (Kukreja et al., 1980; Rude et al., 1980; Stewart et al., 1980). This consolidated the view that the tumor activity resembled PTH biologically, resulting in even greater interest in the pathogenesis. By that time rapid, sensitive assays of PTH-like activity that made use of cAMP responses in osteosarcoma (OS) cells had been developed (Majeska et al., 1980; Partridge et al., 1981). These were applied to cancer cell cultures and to tumor extracts from patients with HHM, and resulted in the purification, sequencing, and cloning of what came to be called PTHrP (Moseley et al., 1987; Suva et al., 1987). This newly identified molecule, related to PTH by an evolutionary gene duplication event (Mangin et al., 1990), was recognized as a potent bone-resorbing agent in vivo and in vitro, providing an explanation for the pathogenesis of hypercalcemia in HHM through its actions on bone and kidney. Subsequent to this, PTHrP production by cancer cells was found to favor the establishment and growth of secondary cancer deposits in bone (Powell et al., 1991; Guise et al., 1996), illustrating its behavior as a paracrine agent, analogous with its physiological paracrine/autocrine roles in many normal tissues, including bone.

From its discovery in cancer as a result of its PTH-like actions, PTHrP soon emerged as a paracrine/autocrine mediator of essential processes in endochondral bone formation during skeletal development, and in bone remodeling in the adult skeleton. This chapter will discuss those roles, beginning by considering the unique structural features of PTHrP that equip it to exert biological activities, not only through the common G-protein-coupled receptor that it shares with PTH, but also through other unique recognizable domains within the molecule.

Primary structure, active domains, processing, and secretion

Whereas PTH consists of 84 amino acids, molecular cloning predicted human PTHrP to have three alternatively spliced products of 139, 141, and 173 amino acids (Mangin et al., 1988; Thiede et al., 1988; Yasuda et al., 1989). While the human PTHrP gene undergoes alternative 3′ splicing, the rat and mouse PTHrP genes have a much simpler structure and produce only one form of PTHrP cDNA (Mangin et al., 1990). PTH and PTHrP have identical amino acids in 8 of their first 13 residues, but other similarities within the sequences are no more than would be expected by chance (Martin, 2016). The marked conservation of the PTHrP amino acid sequence in human, rat, mouse, chicken, and canine up to position 111 indicates that important functions are likely to reside in this region.

PTHrP promotes bone resorption, in a manner identical to that of PTH, by acting upon the receptor it shares with PTH (PTHR1). From the time of its discovery, the structural requirements within PTHrP that activate the PTHR1 were recognized to be the same as those required with PTH (Tregear and Potts, 1975; Kemp et al., 1987). Biological assay showed that recombinant PTHrP and synthetic shorter amino-terminal forms were equipotent on a molar basis with one another and with PTH(1−34) in generating cAMP in osteoblast-like cells (Hammonds et al., 1989). They were also recognized equally on a molar basis when measured in a radioimmunoassay directed at the amino terminus of PTHrP (Grill et al., 1991), indicating that the N-terminal region, with high homology to PTH, activates cAMP formation.

Despite their equal ability to activate cAMP via PTHR1, it was clear from the earliest work, even with peptides up to the first 14 residues of PTHrP, that highly specific antibodies that discriminate between PTH and PTHrP could be generated (Moseley et al., 1987). Such antibodies against PTHrP that neutralized its effects in promoting cAMP production completely in vitro, without any detectable neutralizing effect on PTH, were used to prevent and treat hypercalcemia in nude mice bearing xenografts of PTHrP-secreting human cancers (Kukreja et al. 1988, 1990).

PTHrP can be divided into different domains on the basis of its primary amino acid sequence (Fig. 25.1). Intracellular "pre-pro" and "pro" precursors of the mature peptide, essential for intracellular trafficking, are encoded by the first 36 amino acids (−36 to −1); this domain is cleaved from the molecule when it is secreted. The next domain includes the first

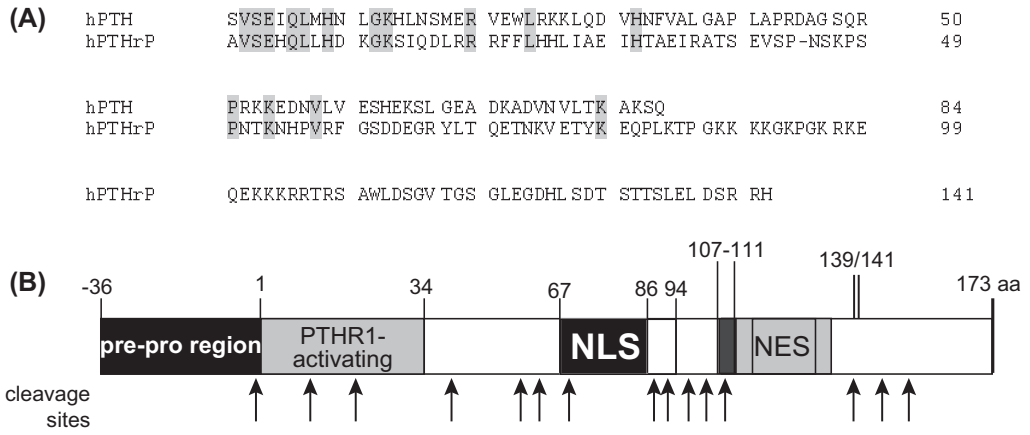

FIGURE 25.1 Protein structure of parathyroid hormone–related protein (PTHrP). (A) Amino acid alignment of the secreted portions of human PTH (*hPTH*) and human PTHrP (*hPTHrP*). Amino acid homologies are marked in *gray*. *Boxes* indicate the common PTH receptor (*PTHR1*)-activating region and the unique nuclear localization sequence (*NLS*) of PTHrP. (B) Protein structure of PTHrP including the amino acid numbers and approximate locations of cleavage sites. Structural domains described in the text are shown, including the pre-pro region, required for PTHrP secretion; the PTHR1-activating region that has high homology with PTH; the NLS; and the nuclear export sequence (*NES*).

13 residues of the mature protein showing the sequence homology with PTH. This domain is critical for most of the agonist effects of PTH and PTHrP on their shared PTHR1 receptor (Kemp et al., 1987). The following residues, PTHrP(14–36), although having almost no homology with PTH, appear to be critical for binding of PTHrP to PTHR1 (Juppner et al., 1991).

Molecular details of the actions of amino acids 36–139/141, including the nuclear localization sequence (NLS), are less well established. The midmolecule portion, between residues 35 and 84, has been shown to be responsible for promoting placental calcium transport, making calcium available for fetal skeletal development (Rodda et al., 1988; Abbas et al., 1989; Kovacs et al., 1996). Residues 107–111 have been reported to inhibit osteoclast activity and bone resorption in vitro (Fenton et al., 1991a; Fenton et al., 1991b) and in vivo (Cornish et al., 1997), and to be mitogenic for osteoblasts (Cornish et al., 1999).

The final tail region of PTHrP, amino acids 142–173, is found only in humans and is encoded by only one of the three human PTHrP mRNA isoforms. Its significance in terms of tissue distribution, processing, or function is unknown, although immunoreactivity for PTHrP(141–173) has been reported in plasma (Burtis et al., 1990) and in amnion (Bruns et al., 1995). It is presumed that the actions ascribed to regions of the molecule beyond the N-terminal 34 amino acids are mediated by non-receptor-mediated actions, or by unique PTHrP receptors, although these have yet to be discovered.

The realization that PTHrP was probably an important paracrine regulator in many tissues directed attention to mechanisms of PTHrP secretion and the nature of the secreted molecule. This topic has increased in interest with the advent of therapeutic approaches for osteoporosis aimed at mimicking PTHrP local action as a skeletal anabolic agent (Neer et al., 2001; Miller et al., 2016).

Two secretory pathways exist in eukaryotic cells: the regulated pathway whereby the proteins are packaged into secretory granules and the constitutive pathway through which the secreted proteins are found in the endoplasmic reticulum (Burgess and Kelly, 1987); PTHrP makes use of both these pathways depending on the cell type. In neuroendocrine cells, PTHrP is secreted via the regulated pathway. PTHrP is a neuroendocrine protein in the sense that it undergoes extensive posttranslational processing in a fashion analogous to that of chromogranin A or somatostatin, and it is a product of a broad variety of neuroendocrine cell types (e.g., pancreatic islet cells, parathyroid cells, adrenal medullary cells, pituitary cells, central nervous system neurons, etc.) (Philbrick et al., 1996; Matsushita et al., 1997; Martin, 2016). In these cells, PTHrP is packaged into secretory granules.

PTHrP is also produced by a broad range of constitutively secreting cell types (e.g., vascular smooth muscle cells, hepatocytes, osteoblasts, osteocytes, keratinocytes, chondrocytes, and renal tubular cells). In these cells, which do not contain the neuroendocrine machinery, PTHrP would be expected to be secreted in a constitutive fashion, analogous to the cytokines and growth factors whose actions it resembles. Indeed, secretion of PTHrP by the constitutive pathway was shown in nonendocrine cell types by Plawner et al. (Plawner et al., 1995), but in that study the nature of the secreted form was not defined, although three region-specific immunoradiometric assays detected secreted products. The first study to define the nature of PTHrP secreted by nonendocrine cells was carried out in osteocytes, of the osteoblast lineage, showing

secretion of full-length PTHrP, with no evidence of secretion of any shorter biologically active form (Ansari et al., 2017). This will be discussed later in further detail ("PTH and PTHrP in adult bone: PTHrP in physiology and PTH in pharmacology").

Interaction with parathyroid hormone receptor 1

The discovery of PTHrP was possible because of its very similar biological action compared with that of PTH, in that it promotes adenylyl cyclase activity in cells known to be targets of PTH. The sequencing and cloning data, followed by synthesis of active peptides (Kemp et al., 1987), confirmed this, showing that the structural features within the amino-terminal PTHrP that were required for activation of PTHR1 were closely similar to those in PTH, and that PTH and PTHrP shared actions upon a common receptor, PTHR1 (Juppner et al., 1991), a member of the B class of G-protein-coupled receptors.

Sequence similarity between PTHrP and PTH is contained within the first half of the N-terminal domain (Fig. 25.1), in which 8 of the first 13 residues are identical between the two. Structural studies have helped explain the similar actions of PTHrP and PTH at the receptor, with nuclear magnetic resonance data indicating that there is a relatively stable α-helical portion within amino acids 15−34 of each peptide (Gardella and Vilardaga, 2015). With the use of mutant receptors and altered ligands, a model of interaction of ligand with PTHR1 has been proposed, in which the carboxy-terminal portion of the (1−34) peptide binds to the extracellular domain of the receptor, and then the amino-terminal portion interacts with the receptor's transmembrane domain to induce the conformational change that results in intracellular signaling (Gardella and Vilardaga, 2015). Although the (15−34) sequences of PTH and PTHrP are quite different, in the absence of evidence to the contrary, it must be assumed that the conformation of this portion of PTHrP is sufficiently similar to that in PTH to confer receptor binding capability upon it. Later chapters will consider details of the interaction with PTHR1 (Chapter 28, Gardella and Potts) and postreceptor signaling pathways (Chapter 27, Friedman).

The dominant signaling pathway mediating responses to PTHrP and PTH is the cAMP/protein kinase A (PKA) pathway, with activation by either PTH or PTHrP resulting in coupling of PTHR1 predominantly to Gαs/adenylyl cyclase/cAMP/PKA signaling (Fig. 25.2). Chapter 27 (Bisello and Friedman) considers these activation mechanisms in detail as well as the involvement of other PTHR1-mediated pathways. Downstream effectors include the cAMP-response element binding protein (CREB) and activator protein 1 transcription factors. By using peptide analogs, it has been concluded that cAMP signaling plays the major role in mediating the renal phosphaturic (Nagai et al., 2011) and anabolic responses in bone through the PTHR1 (Yang et al., 2007a).

In light of these very similar actions through the PTHR1, it was not surprising that the effects of pharmacologic PTHrP administration in vitro and in vivo were similar to those of PTH. Thus, addition of exogenous PTHrP(1−34) promoted

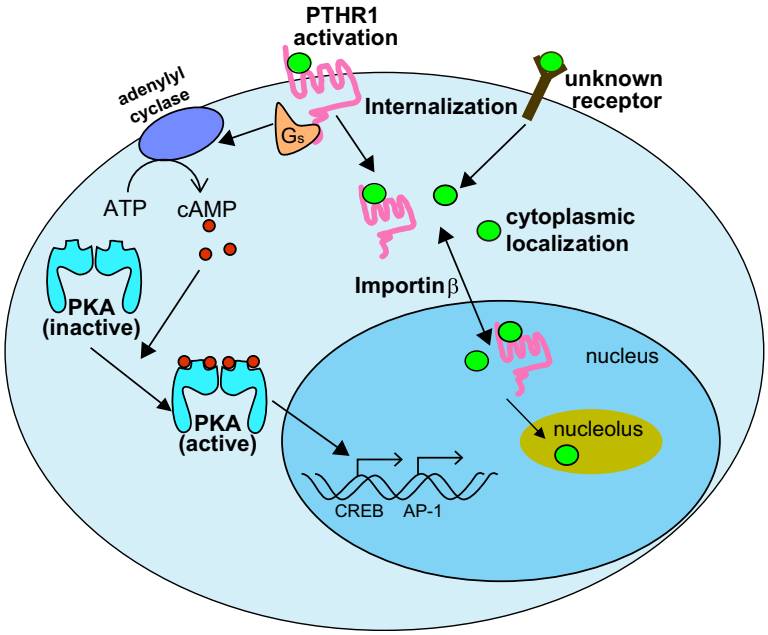

FIGURE 25.2 Multiple known pathways of parathyroid hormone−related protein (PTHrP) action. (1) PTHrP (green (grey in print versions) circle) acts through the G-protein-coupled PTH receptor (*PTHR1*), and via G_s protein, activates adenylyl cyclase to generate cyclic AMP (*cAMP*) from ATP. cAMP activates protein kinase A (*PKA*), which then induces transcription of cAMP-response element binding protein (*CREB*)- and activator protein 1 (*AP-1*)-responsive genes in the nucleus. (2) PTHrP is also internalized by the cell through mechanisms either dependent on the PTHR1 or that make use of an alternative, unknown receptor. PTHrP is also localized within the cytoplasm. PTHrP, both bound to the receptor and unbound, is transported into the nucleus via importin β and can be transported out of the nucleus and into the nucleolus.

bone resorption in organ culture (Kemp et al., 1987), although its lesser potency compared with PTH(1−34) probably reflected its greater susceptibility to proteolytic inactivation in these 48-h cultures (see Fig. 25.1B). Similar effects were observed with amino-terminal PTHrP peptides up to full-length PTHrP (Pilbeam et al., 1993), again with significantly less potency than with PTH(1−34). Such peptides also stimulated osteoclast formation in cocultures of osteoblasts with hemopoietic cells, and both PTHrP(1−34) and the full-length molecule promoted phosphate excretion in the rat when administered intravenously (Kemp et al., 1987; Zhou et al., 1989).

The first demonstration of an anabolic effect of amino-terminal PTHrP in vivo was obtained in the ovariectomized rat, where a dose-dependent anabolic effect of treatment with PTHrP(1−34) was clearly established, but PTHrP(1−34) potency was approximately 25% that of PTH(1−34) in the same experiment (Hock et al., 1989). Lesser potency in vivo of amino-terminal PTHrP peptides was found in virtually all studies (Horwitz et al. 2006, 2013). It might relate to the very marked susceptibility of PTHrP to proteolytic degradation (Diefenbach-Jagger et al., 1995), with the result that when dosage schedules the same as those with PTH are used, less of the injected PTHrP will reach the target cells having avoided degradation. This will be discussed in more detail in a later section ("PTHrP analogs in pharmacology: could this change the approach to skeletal anabolic therapy?"). Comparison of the activities of synthetic and recombinant peptides of various lengths have shown consistently that PTHrP(1−141), (1−84), (1−108), (1−36), and (1−34) are equally potent on a molar basis with one another and with PTH(1−34) in promoting cAMP formation in target cells (Kemp et al., 1987; Hammonds et al., 1989; Li et al., 2012). These assays measure cell responses that are sufficiently rapid that peptide inactivation plays little or no part, unlike prolonged organ culture responses or in vivo effects. These matters need to be taken into consideration in light of the finding that the form of PTHrP released locally, at least by osteocytes, is the full-length molecule (Ansari et al., 2017) (*vide infra*), without any evidence of any shorter forms capable of action through PTHR1. Thus, the form of PTHrP presenting locally as a physiological paracrine/autocrine agent is likely to be the full molecule.

PTHrP tissue distribution and function as a cytokine: the vascular tissue example

It soon became recognized that, apart from its role as a cancer cell product, PTHrP is produced in many tissues throughout the body. The common receptor, PTHR1, is also expressed in these many tissues, often in the same cells as those expressing PTHrP, or closely adjacent to them. Such colocalization was considered consistent with the function of PTHrP as a paracrine/autocrine factor in the developing embryo, particularly in epithelia at many locations and in a number of adult tissues, and raised the possibility that PTHrP is a multifunction cytokine whose actions might influence cell growth and differentiation (Martin et al., 1997; Philbrick, 1998). A body of evidence, particularly in epithelial cells, cancer cells, smooth muscle cells, and osteoblasts, supported this notion, although precise roles are not established in all these cell types.

PTHrP mRNA or protein has been detected in the following human tissues: adrenal, bone, brain, heart, intestine, kidney, liver, lung, mammary gland, ovary, parathyroid, placenta, prostate, skeletal muscle, skin, spleen, stomach, and smooth muscle (Moseley and Gillespie, 1995). PTHrP protein was identified immunologically in normal human and rat fetal bone and cartilage (Moseley et al., 1991; Guenther et al., 1995; Tsukazaki et al., 1995; Suda et al., 1996) and in fetal rat long bones in culture (Nijs-de Wolf et al., 1991), and PTHrP mRNA was detected by RT-PCR in human and rat osteogenic sarcoma cell lines (Rodan et al., 1989; Suda et al., 1996). In situ hybridization analyses localized PTHrP mRNA to active osteoblasts on the bone surface of newborn rat calvarial sections (Suda et al., 1996) and also to spindle-shaped cells of the periosteum, which may represent immature preosteoblasts (Lee et al., 1996; Suda et al., 1996; Rihani-Basharat and Lewinson, 1997). In areas of endochondral bone formation, PTHrP mRNA was detected by in situ hybridization in the perichondrium and maturing chondrocytes in a cell-type and stage-specific manner during fetal rat development (Lee et al., 1996). In a model of intramembranous bone formation in the rabbit, PTHrP mRNA and protein were strongly expressed in osteoblastic cells throughout the bone formation process, including in mature, actively synthetic osteoblasts and in osteocytes (Kartsogiannis et al., 1997).

The vasodilatory effect of PTHrP interacting with PTHR1 on smooth muscle (Roca-Cusachs et al., 1991; Maeda et al., 1996; Massfelder et al., 1998) is instructive in illustrating PTHrP as a physiological paracrine regulator of smooth muscle tone. Decades before the discovery of PTHrP it was known that PTH injection in several animal species resulted in dilatation of vascular beds, increased total blood flow, and decreased blood pressure (Charbon, 1968; Charbon and Hulstaert, 1974; Wang et al., 1984; Mok et al., 1989). These were puzzling observations, not fitting with the accepted role of PTH in regulating blood calcium levels.

The finding that vasoconstrictors such as angiotensin II induced a rapid rise in PTHrP production (Pirola et al., 1993) suggested that vasoconstriction is physiologically limited or reversed through the relaxant action of PTHrP on vascular smooth muscle. For example, in cultured aortic smooth muscle cells subject to stretch, PTHrP responsiveness to angiotensin II was greatly increased and accompanied by increased secretion of PTHrP protein (Noda et al., 1994). In human

coronary arteries, the level of PTHrP mRNA expression by smooth muscle cells has been correlated with the degree of coronary atherosclerosis (Nakayama et al., 1994). In coronary arteries restenosing after angioplasty, expression of PTHrP was greatly increased (Ozeki et al., 1996), consistent with a role for PTHrP in the pathogenesis of vascular stenosis. A physiological role of PTHrP was indicated when mice with transgenic overexpression of PTHrP in vascular smooth muscle cells exhibited low blood pressure (Qian et al., 1999). A less conclusive outcome came from conditional knockdown of PTHrP in vascular smooth muscle in mice; no change in blood pressure was found, but renal blood flow was decreased in targeted mice, particularly with saline volume expansion (Raison et al., 2013).

Thus, the discovery of PTHrP and its production and action in vascular smooth muscle provided an explanation for the long-recognized pharmacological response to PTH injection. Despite evidence of a role for PTHrP as a cardiac hormone, a vasodilatory agent, and a local paracrine regulator of smooth muscle tone, PTHrP-null mutant mice develop normal cardiovascular systems (Karaplis et al., 1994). Although this might indicate that PTHrP is not essential for cardiovascular development, any functions for PTHrP in vascular remodeling, local regulation of vascular flow, and vascular response to injury in adult animals might remain undefined, because the animals die at birth of skeletal defects (see "PTHrP in fetus: early development and endochondral ossification").

Nuclear import of parathyroid hormone–related protein

In addition to its actions through the PTHR1, there is evidence that PTHrP also has intracellular signaling capacities (Fig. 25.2). The first evidence of this was the identification of nuclear and nucleolar localization of PTHrP in chondrocytes (Henderson et al., 1995), where its translocation was dependent upon a highly basic region of PTHrP(87–107) homologous to known NLSs within human retroviral regulatory proteins (Truant and Cullen, 1999). Nuclear localization was essential for the ability of PTHrP to confer enhanced survival on the chondrocytes following serum starvation (Henderson et al., 1995). Although the evidence for translocation of PTHrP to the nucleus in both malignant and normal cells is compelling, the molecular mechanisms by which PTHrP acts in the nucleus remain unclear.

The NLS of PTHrP was defined by Lam and colleagues as between residues 67 and 94 (Lam et al. 1999, 2000) (see Fig. 25.1); however there was debate over the precise region required. Others proposed that PTHrP has a bipartite NLS (Massfelder et al., 1998) (Massfelder et al., 1998; Massfelder et al., 1998) and that residues 87–107 include a second NLS that is required for nuclear localization (Henderson et al., 1995). The region 67–94 was found to include the residues necessary for efficient binding to the nuclear transport factor importin β1 (Lam et al. 1999, 2000), rather than to the conventional NLS-binding importin α subunit. In support of this, importin β1 and the monomeric GTP-binding protein Ran were shown to mediate the nuclear import of PTHrP in vitro via the nuclear pore complex in the absence of importin α (Lam et al., 1999). Further, deletion of the basic residues of the NLS resulted in complete cytoplasmic localization of PTHrP. Studies using a series of alanine-mutated PTHrP constructs and truncated importin β1 derivatives showed that PTHrP residues 83–93 are absolutely essential for importin β1 recognition, with residues 71–82 additionally required for high-affinity binding (Lam et al., 2001). The region of 67–94 also includes a candidate nucleus (CcN) motif and a nucleolus-localizing motif. A CcN motif is a type of nuclear localization signal regulated by dual phosphorylation. When its CK2 substrate site is phosphorylated, the rate of NLS-dependent nuclear import is elevated, and when the cdc2 kinase substrate site is phosphorylated, nuclear transport is inhibited. The CcN motif in PTHrP is similar to that described for the archetypal CcN-containing protein, SV40 T-antigen (Jans et al., 1991; Jans, 1995), and for the N-terminal domain of prointerleukin-16 (pro-IL-16) (Wilson et al., 2002) and pro-IL-1α (Stevenson et al., 1997), comprising also in each case consensus protein kinase CK2 and confirmed cyclin-dependent kinase phosphorylation sites. In the case of PTHrP, a threonine residue at amino acid 85 in PTHrP functions as a p34cdc2 kinase phosphorylation site, with its phosphorylation status determining the nuclear localization of PTHrP (Lam et al., 1999).

Most importantly, support for this region of PTHrP as the NLS comes from the crystal structure of importin β bound to PTHrP(67–94), which identified the specific binding sequence within importin β (Cingolani et al., 2002). It remains possible that there may be more than one contributing segment to nuclear translocation. This could even include the triple-arginine motif at position 19–21, which is highly conserved across species (Fig. 25.1A) and which could mediate nuclear trafficking of a recently identified circulating PTHrP(12–48) isoform (Washam et al., 2013).

Nuclear actions: intracrine and autocrine

In studying how PTHrP gains access to the nucleus it was found that when PTHrP(1–141) was transiently expressed in COS-1 cells, it could be detected in cytoplasm and nucleus as well as at the cell membrane (Aarts et al., 1999a,b). This raised the possibility of intracrine actions of PTHrP, for which evidence then came from studies showing that initiation of

translation downstream of the methionine initiation site gave rise to forms of PTHrP that could not be secreted, but would be available for nuclear transport (Nguyen et al., 2001). Such a mechanism had been proposed for a second eukaryotic protein, fibroblast growth factor 3 (FGF3), which initiates translation at both a classic AUG codon and an upstream CUG site. For both FGF3 and PTHrP, if the AUG codon is used, the protein may follow the secretory pathway, whereas if the CUG codon is used, the protein may be translocated first to the cytosol and then the nucleus, without secretion (Massfelder et al., 1997; Amizuka et al., 2000; Nguyen et al., 2001). This introduced a new biological concept. Having been discovered as a hormone in cancer, PTHrP was then realized to be an autocrine/paracrine factor in normal physiology, with a nuclear role that could be either autocrine (action by PTHrP is secreted and then internalized) or intracrine (by PTHrP that acts within the cell without requiring secretion).

In vascular smooth muscle cells, nuclear PTHrP localization increased cell proliferation, whereas extracellular PTHrP treatment decreased cell proliferation and enhanced muscle relaxation in the same cells by acting through PTHR1 (Massfelder et al., 1997; de Miguel et al., 2001). This indicates a striking dichotomy of outcome that depends on the mode of delivery of PTHrP to the cell, and needs to be kept in mind when considering any organ in which PTHrP acts in an autocrine/paracrine manner. Perhaps even more remarkably, the increased mitogenesis in vascular smooth muscle cells resulting from PTHrP transfection was found to require not only the NLS, but also the C-terminal 108−139 domain of the molecule (de Miguel et al., 2001), suggesting that additional nonnuclear actions are involved in the intracrine action of PTHrP. The importance of the NLS was illustrated further by the finding that adenoviral delivery at angioplasty of PTHrP lacking the NLS markedly inhibited vascular smooth muscle proliferation and cell cycle progression (Fiaschi-Taesch et al., 2009). The importance of C-terminal intracrine actions has yet to be elucidated.

There are at least two mechanisms by which autocrine PTHrP may gain entry to the nucleus from outside the cell: PTHR1 dependent and PTHR1 independent. Internalization and nuclear localization of fluorescein isothiocyanate-labeled PTHrP(1−108) in keratinocytes required PTHR1 expression (Lam et al., 1999). Similarly, in a study using PTHrP mutant constructs in the MC3T3-E1 osteoblastic cell line, it was concluded that PTHrP needs to be secreted and then internalized via the PTHR1 for NLS-mediated shuttling to the nucleus (Garcia-Martin et al., 2014). In other work though, PTHrP gained entry into chondrocytes independent of PTHR1, with PTHrP(1−141) being transported to the nucleus after binding to the cell surface; this mechanism was dependent on the presence of an intact NLS (Aarts et al., 1999a,b). This effect was abrogated by pretreatment with PTHrP(74−113) alone; since it does not bind to PTHR1, this that indicates endocytosis-dependent nucleolar translocation does not involve PTHR1, but an as-yet undefined cell surface receptor.

In cells in which PTHR1-dependent nuclear translocation of PTHrP is used, if the mechanism is similar to that operating with IL-5, growth hormone (Jans et al., 1997), and vascular endothelial growth factor (Liu et al., 2012), the PTHR1 should be found in the nucleus. There is some evidence for that, with the PTHR1 being found by immunostaining in the nucleus of some cells of all tissues examined in the rat—kidney, liver, small intestine, uterus, and ovary—with PTHrP mRNA protein and mRNA localized in the same or adjacent cells (Watson et al., 2000; Watson et al., 2000). Nuclear localization of PTHR1 was also observed in UMR106, ROS 17.2/8, MC3T3-E1, and SaOS-2 cells (Watson et al., 2000; Watson et al., 2000). Furthermore, the cytoplasmic tail of the PTHR1 at residues 471−488 has a putative NLS similar to that of PTHrP, though whether this is required for nuclear transport has not been shown (Patterson et al., 2007).

In vascular smooth muscle cells (Okano et al., 1995) and keratinocytes (Lam et al., 1997), PTHrP expression was found to be cell cycle dependent. In keratinocytes the highest levels of PTHrP mRNA appeared in response to mitogenic factors only at the G_1 phase of the cell cycle, during which PTHrP localized to the nucleolus (Lam et al., 1997). The possession of a CcN motif and cell cycle regulation of kinases by PTHrP are consistent with a role for PTHrP in cell cycle regulation and/or cell proliferation. This has been the case with a number of other proteins containing CcN motifs, e.g., SV40 T-antigen, nucleoplasmin, interferon-inducible nuclear factor, γ-interferon-inducible protein 16, and p53 (Jans et al., 1991; Robbins et al., 1991; Briggs et al., 2001). Although clearly implicated in delaying apoptosis and promoting proliferation in certain cell types, the precise role of PTHrP in the nucleus/nucleolus remains unclear, and has not been investigated in the osteoblast. RNA has been shown to bind PTHrP (Aarts et al., 1999a,b) through a distinct motif in the nucleolar targeting sequence (Pache et al., 2006), and PTHrP inhibits rRNA synthesis (Aarts et al., 2001). This might indicate a role, perhaps in conjunction with other proteins, as a nuclear export factor for RNA. This would be consistent with the ability of PTHrP to shuttle between nuclear/nucleolar and cytoplasmic compartments. Among the most important tasks will be to identify nuclear binding partners for PTHrP, including the possibility that it could bind DNA directly as a transcription factor.

Several lines of evidence therefore converge to indicate that PTHrP is likely to exert many functions from within the cell: (1) the finding of the CcN motif, (2) the redistribution within the cell as a result of phosphorylation at T85, (3) the striking cell cycle dependence of PTHrP location, (4) the identification of nuclear localization of exogenously supplied PTHrP, (5) the participation of the PTHrP NLS with importin β in a specific, regulated nuclear import process, and (6) the involvement of other sequences within PTHrP in intracrine action. In the many tissues in which PTHrP plays a potent local role,

including bone and cartilage, these observations need to be studied further, rather than assuming all local actions of PTHrP can be ascribed to its effects through PTHR1. The fact that PTHrP nuclear localization is integral to its function in any cell studied so far implies that strategies to block PTHrP nuclear localization could have important effects on target cell function.

C-terminal PTHrP and osteostatin

The concept that PTHrP has actions that do not involve signaling through the PTHR1 developed early with the finding that PTHrP promoted the transport of calcium from mother to fetus, making it available for mineralization of the fetal skeleton (Rodda et al., 1988; Kovacs et al., 1996). This action was ascribed to a midmolecule domain of PTHrP when calcium transport could be achieved by placental perfusion with PTHrP(67−86) (Care et al., 1990) or PTHrP(38−94) (Wu et al., 1996). The placental calcium transport data were strongly suggestive of a receptor for PTHrP other than PTHR1. This has not been identified, but a 2014 comprehensive review by Kovacs summarizes the role of PTHrP in the process (Kovacs, 2014).

An alternative receptor for PTHrP has also been long suggested from the outcome of pharmacological experiments using its C-terminal portion. Up to residue 111 a remarkable degree of conservation of PTHrP primary sequence is maintained among human, rat, mouse, dog, cow, and rabbit, with some significant divergence in the remainder of the molecule (Martin, 2016). Interest in the C-terminal domain began with the finding that PTHrP(107−139) inhibited osteoclast activity and bone resorption by isolated rat osteoclasts in vitro. That effect was exerted by the pentapeptide TRSAW (residues 107−111), which was then named "osteostatin" (Fenton et al., 1991; Fenton et al. 1991; Fenton et al. 1993). Similar equipotent inhibitory effects were observed in osteoclasts from embryonic chickens using human or chicken PTHrP(107−139), and the human (TRSAW) and chicken (ARSAW) pentapeptides (Fenton et al., 1994). Although injection of PTHrP(107−139) over the calvariae in mice was found to inhibit bone resorption (Cornish et al., 1997), the antiresorptive effect of TRSAW in organ culture has been controversial, with some investigators not finding this effect in vitro (Sone et al., 1992; Kaji et al., 1995; Murrills et al., 1995).

Although no receptor has yet been identified, both TRSAW and PTHrP(107−139) increased protein kinase C activity in rat splenocytes at low picomolar concentrations (Whitfield et al., 1994), with similar actions in ROS 17.2/8 OS cells (Gagnon et al., 1993). The same group of authors reported protein kinase C activation in OS cells by PTH(28−34) and PTHrP(28−34) (Jouishomme et al., 1992; Gagnon et al., 1993). The actions of these peptides on osteoblasts have been difficult to interpret, since in UMR106 OS cells PTHrP(107−139) and TRSAW inhibited proliferation (Valin et al., 1997), whereas both increased proliferation of fetal rat osteoblasts (Cornish et al., 1999). Others reported that PTHrP(107−139) enhanced human osteoblast differentiation (Alonso et al., 2008) and survival (de Gortazar et al., 2006) through interaction with the vascular endothelial growth factor receptor-2.

In addition to these many in vitro observations, some biological effects of TRSAW and PTHrP(107−139) on bone have been reported in vivo. When neonatal mouse bones were labeled with [^{3}H]tetracycline, TRSAW treatment inhibited PTHrP(1−34)-induced bone resorption, indicated by the release of radioactivity (Rihani-Basharat and Lewinson, 1997). Treatment of streptozotocin-diabetic mice with PTHrP(107−139) promoted bone healing after marrow ablation (Lozano et al., 2011), and perhaps most surprising of all these phenomena and very difficult to explain, high doses of PTHrP(1−34) and PTHrP(107−139) were claimed to be similarly effective in treating mice after initiation of ovariectomy-induced bone loss (de Castro et al., 2012).

Among these reported pharmacologic effects of C-terminal PTHrP(107−139) and TRSAW, many of the in vitro findings were dose dependent and made use of control peptides, but the problems remain that there has still been no receptor identified for any such actions, no non-receptor-mediated internalization mechanism described, nor any signaling pathway that could be held responsible. Furthermore, in most of these studies reported in various species, the C-terminal peptide used was predominantly human PTHrP(107−139). The C-terminal domain is the least conserved among species, with only TRSAW being conserved among mammals. It should be noted that in many of the cited studies, the TRSAW peptide reproduced faithfully the effects of PTHrP(107−139). Thus, this short sequence seems likely to be the most important contributor to the host of pharmacologic effects reported, in which case it could provide a pathway to receptor identification. Although there can be no certainty of any physiological implications, possible roles for the C-terminal domain should continue to be sought, and this would include studies in bone.

PTHrP in fetus: early development and endochondral ossification

Studies using immunohistochemistry, in situ hybridization, or northern blot analyses revealed that PTHrP production took place in the early embryo in mouse (van de Stolpe et al., 1993), chicken (Schermer et al., 1991), rat (Senior et al., 1991), and human (Moseley et al., 1991; Dunne et al., 1994).

In the mouse, the temporal and spatial distribution of PTHrP expression has been described in fetal and adult skeletal and extraskeletal tissues such as brain, kidney, lung, heart, liver, small intestine, skin, and skeletal muscle (Kartsogiannis et al., 1997). Similarly, an extensive range of tissue in the rat expressed PTHrP (Campos et al., 1991; Senior et al., 1991; Lee et al., 1995). Analogous profiles of PTHrP expression were also reported in the human fetus (Moniz et al., 1990; Moseley et al., 1991; Dunne et al., 1994). In the fetus at 7−8 weeks of gestation, ectodermal structures strongly positive for PTHrP expression include the epidermis, the otic placode, and the tooth bud (Dunne et al., 1994). PTHrP-expressing tissues of endodermal origin include the lung, liver, pancreas, stomach, intestine, and hindgut, while those of mesodermal origin include the perichondrium and the developing skeleton. In most of these tissues, PTHrP protein seems to be confined to the epithelial layer, while the mRNA is sometimes seen in mesenchymal components (Moseley et al., 1991; Dunne et al., 1994). Later in embryonic development (18−20 weeks of gestation), PTHrP expression is also apparent in cardiac and skeletal muscle, vascular smooth muscle, neural tissues, and areas of both endochondral and intramembranous osteogenesis in the limb buds and calvariae, respectively (Moniz et al., 1990; Moseley et al., 1991; Dunne et al., 1994). The expression of PTHrP was highest in tissues where active growth and differentiation were occurring, thus favoring the idea that PTHrP may be closely associated with the regulation of fetal, and perhaps neonatal, cellular growth and differentiation.

The spatial and temporal distribution of PTHrP associates strongly with that of the PTHR1 (Karperien et al., 1994). The relative expression levels of PTHrP and its receptor are often inversely correlated within a tissue or in certain locales along a border of apposition. Such a tight inverse coupling of expression would seem to imply either feedback downregulation of the receptor or a precise coordinated regulation of the two genes during the course of fetal development (Lee et al., 1996).

With such evidence of production of PTHrP in many tissues throughout fetal life in a number of species, it was perhaps to be expected that functional evidence of a role for PTHrP and its receptor in mammalian fetal development might come from studies of animals that are transgenic or have gene-targeted knockouts; these models, including later cell-specific models, are summarized in Table 25.1. The first evidence of a physiological role for PTHrP came soon after the discovery of PTHrP, with a dramatic phenotype in mice null for the *Pthlh* gene following homologous recombination (Amizuka et al., 1994; Karaplis et al., 1994; Karaplis and Kronenberg, 1996; Lee et al., 1996). Neonatal mice homozygous for *Pthlh* gene ablation exhibited severe skeletal abnormalities at birth and died within 24 h, with their abnormal ribcage development not allowing adequate respiration and this respiratory distress accentuated by reduced surfactant production and impaired type II alveolar cell development. Whereas the nonskeletal organs and tissues of the *Pthlh* homozygous mutant mice appeared grossly normal, the mice at birth had a domed skull, short snout and mandible, protruding tongue, and disproportionately short limbs. Phenotypic abnormalities were evident throughout the endochondral skeleton (axial as well as appendicular), while, in contrast, no abnormality was noted in skeletal structures that develop entirely by intramembranous ossification.

In the growth plates of $Pthlh^{-/-}$ mutant mice there was a marked reduction in the height of the resting and proliferating chondrocyte zones. This resulted from decreased cell division, and was associated with disorganization of the cartilage columns in the hypertrophic zone and altered deposition of matrix molecules such as type II collagen (Karaplis and Kronenberg, 1996). PTHrP thus proved to be necessary for normal chondrocyte proliferation, and the premature maturation of the skeleton was presumably a consequence of the reduced proliferation and accelerated differentiation/premature hypertrophy and apoptosis of growth plate chondrocytes. These findings were substantiated by a study in which transgenic mice overexpressing PTHrP in chondrocytes (using the mouse collagen type II promoter) were found to have an opposing form of short-limbed dwarfism, in which endochondral ossification was significantly delayed as a result of persistent chondrocyte proliferation and spatially and temporally abnormal chondrocyte hypertrophy (Weir et al., 1996). The delay in endochondral ossification was initially so profound that mice were born with cartilaginous endochondral skeletons. However, by 7 weeks of age in the mice overexpressing *Pthlh* in chondrocytes, this delay in chondrocyte differentiation and ossification was largely corrected, leaving foreshortened and misshapen but histologically near-normal bones.

The alterations in chondrocyte differentiation at the growth plate and ultimate histological healing noted in mice transgenically overexpressing PTHrP in chondrocytes (Weir et al., 1996) are reminiscent of those seen in patients with Jansen's metaphyseal chondrodysplasia, a condition arising from constitutive activation of the PTHR1 (Schipani et al. 1995, 1996, 1997) and in transgenic mice with expression of a constitutively active PTHR1 targeted to the growth plate (Schipani et al., 1997). In the latter study, targeted expression of constitutively active PTHR1 corrected at birth the growth plate abnormalities of $Pthlh^{-/-}$ mice and allowed for their prolonged survival. These "rescued" animals lacked tooth eruption and showed premature epiphyseal closure, indicating the requirement of PTHrP in both processes. Therefore, overexpression of *Pthlh* or constitutive activation of the PTHR1 in the growth plate ultimately result in a similar pattern of abnormalities in endochondral bone formation. Even further evidence for the part played by the PTHrP/PTHR1 signaling pathway comes from the study of Blomstrand's chondrodysplasia, a rare syndrome resulting from loss-of-function

TABLE 25.1 Skeletal phenotypes in mouse models of parathyroid hormone (PTH)–related protein and PTH receptor 1 deficiency.

—, not reported; results with question mark indicate that changes were reported to occur, but were not statistically significant.

mutations within the *PTH1R* gene, in which the human syndrome is recapitulated in mice rendered null for *Pth1r* (Wysolmerski et al., 2001).

It was noted that, just as PTHrP and the PTHR1 localize to the growth plate region of long bones, so too does Indian hedgehog (Ihh) (Lanske et al., 1996; Vortkamp et al., 1996). Ihh belongs to the hedgehog family of genes (McMahon, 2000), which is involved in the regulation of *Drosophila* segment polarity and regulates embryonic patterning during development in many organisms (Goodrich et al., 1996; Iwamoto et al., 1999). Overexpression of *Ihh* in developing chick limbs blocked chondrocyte differentiation in a manner similar to that seen with overexpression of *Pthlh* in chondrocytes. The findings of Lanske et al. (Lanske et al., 1996) and Vortkamp et al. (Vortkamp et al., 1996) showed that PTHrP and the PTHR1 form a negative feedback loop with the Ihh pathway to establish the correct spatial and temporal progression of chondrocyte differentiation and thereby determine the rate and extent of long bone formation. In this instance, the role of PTHrP is a paracrine one, making use of activation of the PTHR1 by locally generated PTHrP. Indeed genetically altered mice with PTHR1 deletion targeted to chondrocytes and their progeny using *Col2Cre* or *Prx1Cre* resulted in a similar shortened bone/accelerated chondrocyte differentiation phenotype compared with the global knockout (Hirai et al., 2015; Fan et al., 2016) (see Table 25.1 for comparison). There has been no investigation of possible actions in chondrocyte differentiation of other functional domains of PTHrP or non-PTHR1-mediated actions, since the comparison of these genetically altered mouse models provides substantial evidence that PTHrP regulates chondrocyte differentiation through the PTHR1.

PTHrP in bone after endochondral ossification

The discovery of the crucial part played by PTHrP in endochondral bone formation in development was a dramatic outcome of the earliest mouse genetic studies. Much more was to come though, when the recognition of widespread production of PTHrP led to evidence of its production in bone (Moseley and Gillespie, 1995) (*vide supra).* In this respect, genetically altered mouse models have again played a critical role in identifying stage-specific roles of PTHrP during osteoblast differentiation in regulating bone formation and resorption (Table 25.1, Fig. 25.3).

Major insights into the role of PTHrP in bone were obtained from further studies carried out in heterozygous $Pthlh^{+/-}$ mice. Although homozygous $Pthlh^{-/-}$ mice died soon after birth (Amizuka et al., 1994), heterozygous $Pthlh^{+/-}$ mice survived and, although phenotypically normal at birth, by 3 months of age exhibited a markedly lower trabecular thickness and connectivity, and histomorphometry revealed low bone formation rate and osteoclast surface (Amizuka et al., 1996). In $Pthlh^{+/-}$ mice the number of apoptotic osteoblasts was greater than in controls, and ex vivo culture of bone marrow cells

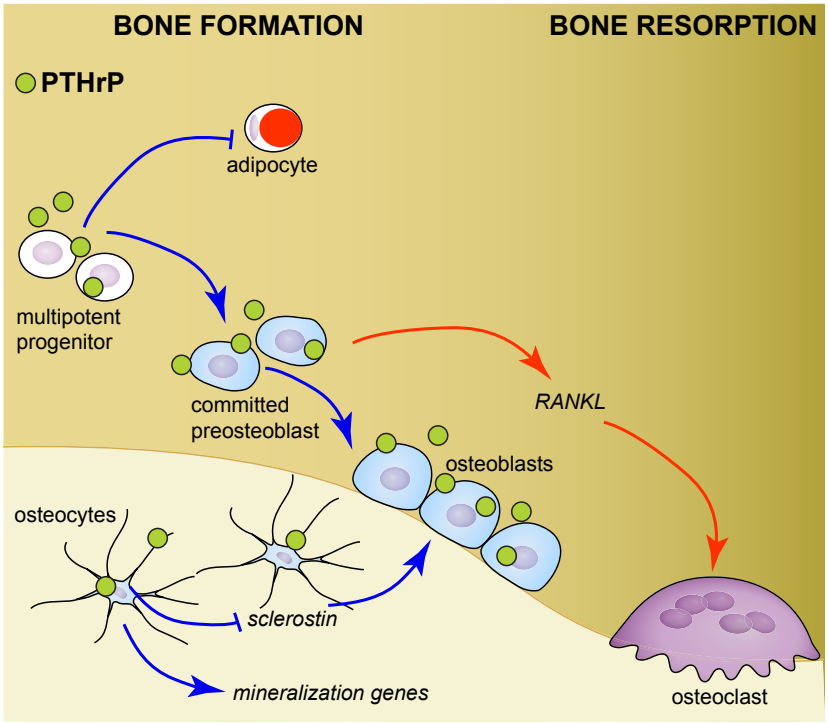

FIGURE 25.3 Stage-specific actions of parathyroid hormone–related protein (*PTHrP*) on the osteoblast and related cell lineages. (1) PTHrP is produced at all stages of osteoblast differentiation. (2) PTHrP acts on multipotent progenitors to inhibit adipogenic differentiation and promote osteoblast differentiation. (3) PTHrP acts on committed osteoblast precursors to promote their continued differentiation to osteoblasts, and promotes their expression of receptor activator of NF-κB ligand (*RANKL*), thereby indirectly stimulating the differentiation of osteoclast precursors to form bone-resorbing osteoclasts. (4) PTHrP acts on mature, bone-forming osteoblasts to promote their bone-forming activity and inhibit their apoptosis. (5) PTHrP acts on osteocytes, resulting in signals that promote bone formation by osteoblasts and signals that maintain mineralization of the bone matrix.

resulted in markedly fewer alkaline phosphatase−positive colonies, indicating impairment of osteogenic cell recruitment and survival. Moreover, *Pthlh*$^{+/-}$ bone marrow contained an abnormally high number of adipocytes. Since the same pluripotent stromal cells in the bone marrow compartment can give rise to adipocytes and osteoprogenitor cells (Owen, 1971), the increased number of adipocytes and osteopenia in these mice could be attributed to preferential development of adipocytes rather than osteoblasts as a consequence of PTHrP haploinsufficiency. Further investigations of the PTHrP mutant mice provided evidence that PTHrP is equally important for the orderly commitment of precursor cells toward the osteogenic lineage and their subsequent maturation and/or function (see Fig. 25.3). In the *Pthlh*$^{+/-}$ mice, osteoblastic progenitor cells (as with chondrocytes) were observed to contain inappropriate accumulations of glycogen, indicative of a defect in cells of the osteogenic lineage arising as a consequence of PTHrP deficiency (Amizuka et al., 1994). The overall conclusion was that PTHrP haploinsufficiency resulted in a low-bone-turnover state with low bone mass resulting from impaired bone formation.

The finding of an osteopenic phenotype in the *Pthlh*$^{+/-}$ mice was sufficiently intriguing to prompt the preparation of mice with osteoblast-specific knockout of *Pthlh* to determine whether it was locally derived PTHrP that was responsible for the low bone mass phenotype. *Col1(2.3kb).Cre* mice were crossed with *Pthlh* floxed mice, resulting in generation of mice that closely reproduced the low-bone-mass phenotype of the earlier *Pthlh*$^{+/-}$ (Miao et al., 2005). Higher levels of osteoblast apoptosis occurred in *Col1(2.3kb).Cre.Pthlh*$^{fl/fl}$ mice than in controls, and histomorphometry showed a low mineral apposition rate, osteoblast number, and osteoid volume, and few osteoclasts. Ex vivo studies showed that precursor cells from these mice were markedly less able to generate osteoblasts. Differences noted between the *Pthlh*$^{+/-}$ and the *Col1(2.3kb).Cre.Pthlh*$^{fl/fl}$ mice were that the latter lacked a marrow adiposity phenotype (Table 25.1). This difference could be explained by the fact that genetic deficiency in the *Pthlh*$^{+/-}$ mice was operative throughout cellular development, whereas in the targeted knockout it came into play at a later stage, after stromal cells had already committed to the osteoblast lineage. The findings in these genetic experiments gave much impetus to the view that locally derived PTHrP, produced by cells in the osteoblast lineage, acts within the lineage to inhibit apoptosis and promote differentiation of committed precursors to become osteoblasts capable of forming bone, and promotes support of osteoclastogenesis by the osteoblast lineage (Fig. 25.3).

The fact that PTHrP protein and mRNA had been noted in osteocytes (Suda et al., 1996; Kartsogiannis et al., 1997), together with the increased awareness of the importance of osteocytes, led to studies that revealed a role for osteocyte-derived PTHrP in bone remodeling, and confirmed suspicions that this might be achieved through autocrine/paracrine mechanisms. First, the effect of disruption of PTHR1 signaling was investigated in *Dmp1Cre.Pth1r*$^{fl/fl}$ mice. This was carried out using two different Cre models: *Dmp1(8kb)Cre* (Delgado-Calle et al., 2017) and *Dmp1(10kb)Cre* (Saini et al., 2013). In contrast to PTHrP deletion, both these PTHR1-deficient models had greater trabecular bone mass than control mice. This phenotype may result from a mild osteopetrosis since both osteoblast and osteoclast surfaces were slightly, but not significantly, lower in the *Dmp1(10kb)Cre.Pth1r* model, and the resorption marker Ctx1 was significantly lower in *Dmp1(8kb)Cre.Pth1r* mice; it does not appear to relate to a high level of bone formation. Furthermore, while both mice showed a blunted anabolic response to intermittent PTH treatment, induction of high circulating PTH levels in the *Dmp1(10kb)Cre.Pth1r* mice by dietary calcium restriction still markedly increased osteoclast formation despite the lack of PTH1R expression in osteocytes. This is consistent with a view that receptor activator of NF-κB ligand (RANKL) production induced through PTHR1 action in less mature osteoblast lineage cells, rather than mature osteoblasts or osteocytes, contributes to osteoclast formation.

The phenotype arising from the osteocyte-specific knockout of PTHrP was strikingly different from the receptor knockout. This was addressed using *Dmp1Cre.Pthlh*$^{f/f}$ mice prepared with the *Dmp1(10kb)Cre*. The mice with PTHrP-deficient osteocytes had low trabecular bone mass with low osteoblast numbers and mineralizing surface, as well as impaired cortical bone strength, indicating a material change in cortical bone matrix (Ansari et al., 2017). This phenotype differed in two important ways from that of *Col1(2.3kb).Cre.Pthlh*$^{fl/fl}$ (Table 25.1). First, the *Dmp1Cre.Pthlh*$^{f/f}$ phenotype was not evident at 6 weeks, but was so at 12 weeks of age, suggesting that while osteoblast-derived PTHrP may play a role in the development of the trabecular network, osteocyte-derived PTHrP is important later in life, when it has a role in remodeling the young adult skeleton. Second, the lack of osteoclast phenotype in the osteocyte-null mice indicated a lesser role for osteocytes in supporting osteoclastogenesis than that for cells earlier in the osteoblast lineage. In addition, the bones from the *Dmp1Cre.Pthlh*$^{f/f}$ mice had impaired bone material strength despite normal size, indicating a role for osteocyte-derived PTHrP in regulating bone composition. PTHrP knockdown, treatment, and overexpression studies in the Ocy454 osteocyte cell line showed that osteocyte-derived PTHrP suppresses sclerostin expression and modifies production of genes known to regulate bone mineralization (*Dmp1*, *Mepe)* (Ansari et al., 2017). This suggests that osteocyte-derived PTHrP not only is physiologically required to promote osteoblast differentiation, but also may regulate the process of bone mineralization, thereby controlling not only bone mass, but also bone strength (Fig. 25.3).

The difference in phenotypes between the high-bone-mass phenotype of the *Dmp1Cre*-driven PTH1R-deficient mice and the low-bone-mass phenotype in *Dmp1Cre*-driven PTHrP ligand−deficient mice suggests that PTHrP could have effects in the osteocyte that are mediated by non-PTH1R-mediated actions. Such noncanonical PTHrP signaling pathways acting in autocrine or paracrine ways have been noted in other cell types, as discussed earlier. The actions of these regions of PTHrP in bone remain poorly defined. Low bone mass, retarded growth, and early senescence (Miao et al., 2008; Toribio et al., 2010) have been reported in knock-in mice expressing PTHrP lacking both its NLS and its C-terminal regions, but retaining the PTHR1-activating N terminus. This provides evidence that these regions are physiologically important. However, the extreme defects in bone growth and development in that model make it difficult to discern their roles in the mature adult skeleton.

Parathyroid hormone−related protein and osteosarcoma

Given the evidence that PTHrP has important roles in osteoblast biology and bone formation, it might have been predicted that it would feature in the pathology of OS. This tumor of the osteoblast lineage is the fifth most common cancer in children and has become a focus of attention, since an improved understanding could lead to new pathways of treatment. We now have evidence from studies of genetically induced OS in the mouse that tumor-derived PTHrP acts in an autocrine/paracrine way in OS to drive its establishment and progression.

Induction of OS in rats with radio-phosphorus injection yielded transplantable tumors that exhibited sensitive dose responsiveness of adenylyl cyclase to PTH activation. PTH-responsive clonal cell lines from those tumors (UMR106 cells) (Partridge et al., 1981) and from a similar rat osteogenic sarcoma (Ros17.2/8 cells) (Majeska et al., 1980) have been used widely in studies of hormone and cytokine actions upon osteoblast-like cells. In that early work, removing the source of PTH by parathyroidectomy had no influence on the growth or on any other aspect of this transplantable OS (Ingleton et al., 1977). These findings came many years before PTHrP was discovered. Subsequent studies in OS cell lines from several species, including human, established that PTHR1 expression is a common, if not universal, feature of OS (e.g., Goerdeladze et al., 1993). Consistent with a pathogenic role for PTHR1 in OS, higher expression of PTHR1 mRNA was detected in metastatic or relapsed human OS samples compared with primary sites, and overexpression of PTHR1 in an OS cell line increased its proliferation and invasion (Yang et al., 2007b).

Although these findings suggested that activation of PTHR1 in OS may promote tumor invasion and proliferation, the role of the receptor signaling or of PTHrP has never been clearly defined. Studies in genetically induced mouse models of OS have pointed to an important pathogenetic role of activation of the cAMP/PKA/CREB pathway in osteoblast lineage cells, driven by autocrine PTHrP acting through the PTHR1 (Ho et al., 2014; Walia et al., 2016). Evidence obtained from human OS is also consistent with this possibility. Although a diverse mutational pattern of single-nucleotide variations has been reported in human OS (Chen et al., 2014), when we compared these proteins known to interact with the cAMP pathway the data suggested that recurrent and enriched changes in the cAMP/CREB pathway occur in osteogenic sarcoma (Walia et al., 2016).

Murine models have been long established for OS, developed from the knockout of genes associated with familial predisposition to OS (such as $p53^{-/-}$; Jacks et al., 1994) or from phenotyping in mutant or transgenic mice (Wang et al., 1995). However, not all cases of murine/rodent OS have proven to be applicable to human OS, with the murine OSs induced by *Nf2* and *Notch1* mutations being key examples (Engin et al., 2008; Mutsaers and Walkley, 2014; Tao et al., 2014; Walia et al., 2018). However, high-fidelity models recapitulating the mutational pattern and phenotypes of human OS have been developed by mesenchymal- and osteoblast-targeted conditional mutant alleles of *p53* and *Rb1,* the key genes implicated in familial OS (Berman et al., 2008; Walkley et al., 2008; Lin et al., 2009; Mutsaers et al., 2013; Quist et al., 2015). These murine models reproduce the cardinal features of the common forms of human OS, where osteoblastic OS is the most common clinical subtype (60%), with fibroblastic and chondroblastic OS comprising about 15% each (Walkley et al., 2008; Mutsaers et al., 2013). The *Osx*-Cre $p53^{fl/fl}pRb^{fl/fl}$ model (osteoblast lineage deletion of *p53*) yields a fibroblastic OS characterized by predominant areas of relatively poorly differentiated (Berman et al., 2008) histology with cells on the surface that appear to be immature osteoblasts (Walkley et al., 2008; Mutsaers et al., 2013). The *Osx*-Cre TRE_shp53.1224$pRb^{fl/fl}$ model (short hairpin RNA [shRNA] knockdown of *p53*) histologically resembles osteoblastic OS, with large mineralized areas and a cell surface phenotype of mature osteoblasts (Mutsaers et al., 2013). The early passage cells from both models have genetic and pharmacological sensitivities comparable to those of primary human patient-derived OS cultures (Baker et al., 2015; Gupte et al., 2015).

In these models of fibroblastic and osteoblastic OS, the primary and metastatic tumors from either subtype all express functional PTHR1. The cultures derived from those models all express PTHrP and PTHR1, and responded to treatment with either PTH or PTHrP with increased adenylyl cyclase activity and consequent increased expression of CREB pathway

genes (Mutsaers et al., 2013; Ho et al., 2014; Walia et al., 2016). Conversely, knockdown of PTHR1 in murine OS (fibroblastic) reduced PTHR1 activation, cAMP responses, and tumor cell invasion in vitro (Ho et al., 2014). Although PTHR1 knockdown resulted in greatly reduced proliferation, the tumor was more mineralized in vivo. PTHrP was present intracellularly in OS cells, but was very low as a secreted protein in culture media.

Osteoblastic OS cells expressed high levels of *Pthlh* transcript (Walia et al., 2016), consistent with our previous data identifying substantial levels of intracellular PTHrP in OS cells (Ho et al., 2014). We showed that PTHrP was an OS autocrine ligand by treating cells with phosphodiesterase inhibitor without adding exogenous PTHrP, thus assaying the cAMP induced by an endogenous ligand(s) of the OS cells. This was confirmed when neutralizing anti-PTHrP antibody reduced cAMP formation, and when shRNAs against *Pthlh* reduced cAMP accumulation by >50%. This indicated that OS-derived PTHrP is an endogenous ligand promoting cAMP accumulation in an autocrine/paracrine manner (Fig. 25.4).

An early consequence of p53 deletion in osteoblastic cells was increased cAMP levels, PTHrP production, and autocrine activation of cAMP signaling via PTHrP (Walia et al., 2016). Activation of the PTHrP/cAMP/CREB1 axis was required for the hyperproliferative phenotype of p53-deficient osteoblasts and the maintenance of established OS, identifying this as a tractable pathway for therapeutic inhibition in OS. In support of this, knockdown of *Pthlh* reduced cell proliferation, reduced CREB phosphorylation and transcription of known CREB target genes, and induced apoptosis (Walia et al., 2016). In vivo, two different fibroblastic OS lines infected with sh-*Pthlh* showed reduced tumor growth that

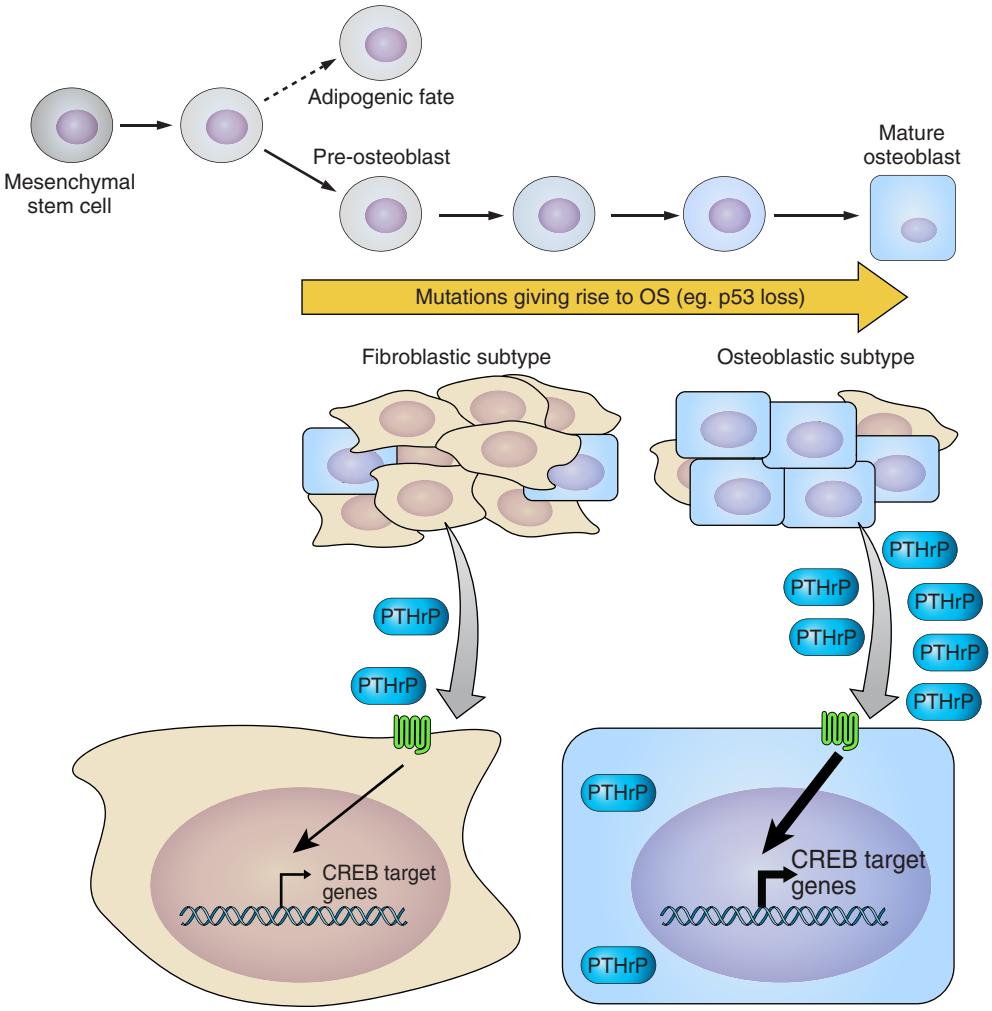

FIGURE 25.4 Actions of parathyroid hormone–related protein (*PTHrP*) in osteosarcoma (*OS*). Mutations giving rise to OS in committed pre-osteoblasts lead to the development of OS of a fibroblastic subtype, which expresses low levels of PTHrP that act through the PTH transmembrane receptor to promote low levels of cAMP-responsive element binding protein (*CREB*) target gene expression. When these mutations occur in more differentiated osteoblasts, this leads to an osteoblastic subtype of OS, which produces high levels of both secreted and intracellular PTHrP, acting in an autocrine/paracrine manner leading to higher levels of CREB target gene expression.

was comparable to the effects of *Pthr1* knockdown in the same OS lines (Ho et al., 2014), providing additional support for the concept that PTHrP is the tumor-derived ligand that promotes PTHR1-dependent OS growth (Fig. 25.4).

The identification of the PTHrP → PTHR1 → CREB-dependent mechanism for OS development may provide an explanation for data showing OS caused by enhanced PKA activity (Molyneux et al., 2010), and suggests that PTHrP → PTHR1 may be an upstream effector of such a pathway (Walia et al., 2016). Such a role extends the involvement of PTHrP in cancer, but in quite a different way compared with that in which it was discovered, as a bone-resorbing factor produced by certain cancers and resulting in hypercalcemia, and possibly also as a paracrine factor contributing to bone metastasis formation.

These data may also have relevance to the high incidence of OS in rats in long-term toxicology studies of any agonist of the PTHR1 (Tashjian and Chabner, 2002). This has resulted in a warning label accompanying these anabolic therapies for bone (Tashjian and Goltzman, 2008). The mechanism of tumor induction in these circumstances is not known. The toxicology study involved daily treatment of Fisher rats from soon after birth to 2 years of age. The high incidence of OS was obtained in rats treated with PTH(1−34) (Vahle et al., 2002), PTH(1−84) (Jolette et al., 2006), and abaloparatide (Jolette et al., 2017). It is conceivable that OS development is related to prolonged stimulation of the PKA/CREB pathway in an animal that might be susceptible to tumor development with such a treatment, but establishing this would require much further work.

Distinct roles of PTH and PTHrP in fetal and postnatal bone

All that has been available in anabolic therapy for the skeleton has been teriparatide (hPTH(1−34)), in use for some years, and now abaloparatide (Tymlos), which is a modified form of PTHrP(1−34) that has been approved by the US FDA. We might make better use of this anabolic pathway if we were to understand better how physiology and pharmacology meet.

A central question of the relative roles of PTH and PTHrP in the regulation of bone remodeling is: to what extent does the hormone PTH contribute to bone remodeling, either directly or indirectly? Further insights into this question came from a series of studies using *Pthlh*, *Pth*, and compound knockout mice.

When *Pth* was ablated in mice, trabecular bone mass in the fetal metaphysis was low compared with controls; in the postnatal state this phenotype reversed, and *Pth*-null mice exhibited high metaphyseal bone mass (Miao et al., 2002). Although this was at first puzzling, a low trabecular bone mass phenotype was then observed when the mice were rendered PTHrP deficient by crossing *Pth*-null mice with $Pthlh^{+/-}$ mice (Miao et al., 2004). In this case PTHrP deficiency prevented the high trabecular bone mass of postnatal PTH-deficient mice, even though the mice were still hypoparathyroid with low serum calcium and high serum phosphate. It was concluded that the PTH-null phenotype of high trabecular bone mass was caused by increased local production of PTHrP; this provided the first indication in vivo for a local role of PTHrP in promoting bone formation.

A comparable series of experiments in older mice provided further insights into the relative roles of PTH and PTHrP in osteogenesis. A model of bone marrow ablation was used (Zhu et al., 2013), in which de novo bone formation precedes resorption during recovery (Suva et al., 1993). When this was carried out in *Pth*-null mice, both osteogenesis and osteoclast formation were delayed and impaired, and *Pthlh* expression in osteoblasts was increased (Zhu et al., 2013). When a similar experiment was carried out in *Pth*-null mice crossed with *Pthlh*-haploinsufficient mice, the response to bone marrow ablation generated fewer osteoblasts, less bone formation, and fewer osteoclasts than in *Pth*-null mice (Zhu et al., 2013). These data suggest a role for PTH in recruiting osteoblast progenitor cells, with locally generated PTHrP being necessary both for further differentiation of osteoblast progenitors to bone-forming osteoblasts and for the generation of osteoclasts.

These genetic experiments point to specific roles for PTH and PTHrP that change between fetal and postnatal environments (Fig. 25.5). In the fetus, ambient calcium is dependent on maternal supply promoted by PTHrP placental action. In the fetus, when PTH promotes osteogenesis, the major function of PTHrP appears to be in directing the sequential controlled proliferation and differentiation of chondrocytes for growth plate development. In the immediate postnatal period, with the major environmental change and the source of nutrient calcium switching from the placenta to the diet, PTH secretion is regulated by extracellular fluid calcium levels, and its action on bone serves primarily to provide calcium to the body by promoting bone resorption. The aforementioned study provided evidence that the other major change in function after birth is that PTHrP becomes the major endogenous stimulus of bone formation, and it does this in a paracrine and possibly an autocrine manner. This is achieved at least partly by action through the PTHR1, but possibly also through actions promoted by other active domains within PTHrP (*vide supra*).

Thus, the anabolic physiological roles of PTH and PTHrP are development and environment dependent. PTH has not been shown to exert a direct physiological anabolic role in the adult animal, where its physiological function rather is the regulation of calcium homeostasis postnatally and in the fetus, and in the latter case is essential in providing calcium for

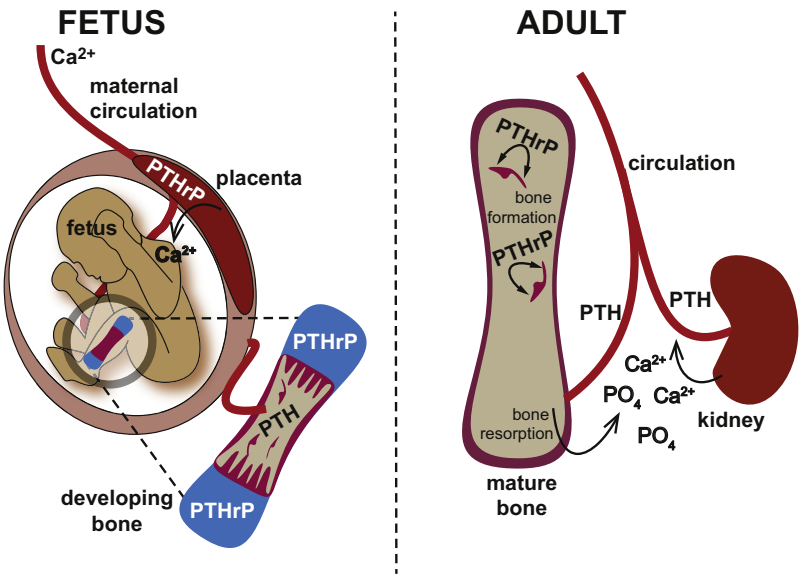

FIGURE 25.5 Roles of parathyroid hormone–related protein (*PTHrP*) and PTH in fetus and adult. Fetal calcium is predominantly provided by the placental action of PTHrP, which is also essential for chondrogenesis. PTH promotes osteogenesis. Postnatally, functions change, with the hormone PTH responsible for calcium homeostasis through actions on the kidney to restrict excretion and through generation of osteoclasts to provide calcium to the extracellular fluid. The bone-forming function is physiologically ascribed to locally generated PTHrP.

mineralization of bone. A hypothesis embracing the relative roles of PTH and PTHrP is that the hormone, PTH, governs osteogenesis through PTHR1 in the fetus and newborn, while PTHrP governs chondrocyte differentiation. The paracrine/autocrine action of PTHrP on bone becomes important when remodeling supervenes sometime after birth, and this role is maintained in the mature skeleton.

PTH and PTHrP in adult bone: PTHrP in physiology and PTH in pharmacology

The observation that physiological functions of PTHrP are carried out by local generation and action made it important to understand the nature of PTHrP released locally in bone and thus available for autocrine and paracrine actions. In discussing processing of PTHrP in an earlier section (*vide supra*) we reviewed early work in neuroendocrine cells that showed PTHrP is subject to the regulated secretory pathway, thereby generating PTHrP(1–36), midterminal peptides, and a C-terminal sequence. Although that might be true of cells that are capable of using the regulated secretory pathway, it would not be expected of mesenchymal cells such as those within the osteoblast lineage.

Accordingly, in studying the role of osteocyte-derived PTHrP, we used knockdown of PTHrP in the immortalized osteocyte cell line Ocy454 to show that PTHrP derived from those cells acts upon PTHR1 in the same cells in an autocrine/paracrine manner to activate adenylyl cyclase and modify gene expression (Ansari et al., 2017). In the same series of experiments full-length and mutant constructs of PTHrP were expressed in the osteocytes, secretion of biologically active PTHrP was established, and a combination of bioassay, radioimmunoassay, and chromatographic and electrophoretic separation methods was used to show that the only protein released from those cells and able to act through PTHR1 was PTHrP of full length. This might not be surprising, given the mesenchymal origin of cells of the osteoblast lineage, which would be expected to use the constitutive pathway of secretion, without the packaging and processing ability inherent in the regulated secretory pathway.

The importance of the observations, though, is that they identify full-length PTHrP as the most likely locally active material released in bone and available to act on the same or nearby cells. Among the questions that this leads to are: (1) does full-length PTHrP interact with the receptor PTHR1 in any unique way that distinguishes it from shorter forms used pharmacologically, (2) do other domains within the PTHrP molecule contribute to actions locally in bone, and (3) what significance might this have for the pharmacological use of peptide analogs that are based to some extent on PTHrP?

The discovery of the role of paracrine/autocrine PTHrP in bone remodeling underlies the thought that has been harbored for some time, that the anabolic action of intermittent (daily) treatment with PTH for osteoporosis mimics pharmacologically the physiological action of PTHrP. That anabolic action is predominantly remodeling based (Lindsay et al., 2006; Ma et al., 2006), with the effect of therapeutic PTH being to promote the recruitment of new basic multicellular units (BMUs) and enhance the activity of those already in progress (Fig. 25.6). Overfilling of BMUs (Compston, 2007), and perhaps also some effect on modeling through activation of lining cells (Kim et al., 2012), results in increased bone

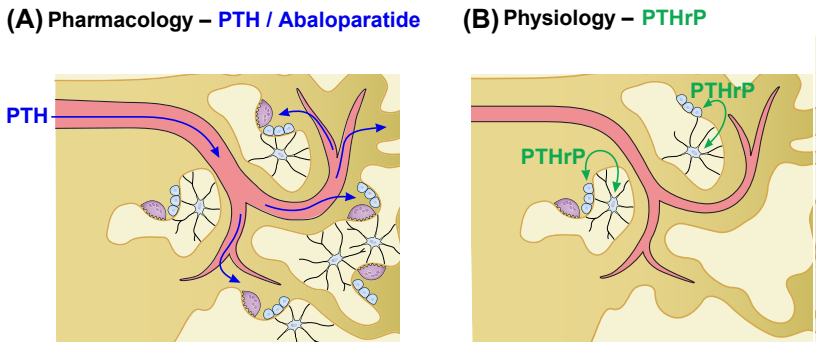

FIGURE 25.6 Physiological actions of parathyroid hormone–related protein (*PTHrP*) versus pharmacologic actions of PTH (teriparatide) and abaloparatide. (A) Pharmacologic administration of intermittent injections of PTH (teriparatide) or abaloparatide provide brief bursts of high systemic levels of these agents that act through the PTH receptor to stimulate bone remodeling at multiple basic multicellular units (BMUs) throughout the skeleton. (B) Physiologically, PTHrP is not provided through the bloodstream, but is provided locally, and stimulates active BMUs at those sites at which they are needed and active.

mass. The cellular actions of exogenous PTH administration are to promote osteoblast differentiation, prevent osteoblast and osteocyte apoptosis, and reduce osteocyte production of the bone formation inhibitor, sclerostin (Jilka, 2007; Martin, 2016). Although PTH promotes bone resorption by stimulating RANKL expression in osteoblasts, in the context of intermittent administration, PTH action on osteoclasts is probably confined to the recruitment of osteoclasts for the initiation of new BMUs, because of the brief exposure of cells to PTH. In contrast, prolonged activation of PTHR1 results in a net greater effect on osteoclast formation and activity. Early experimental evidence for this was obtained in rats using treatment with several different intermittent PTH(1−34) injection schedules and continuous infusion (Frolik et al., 2003). The pharmacokinetic profile and outcome data showed that an anabolic outcome required a short period of elevation of plasma PTH, whereas a catabolic outcome was associated with prolonged elevation of PTH levels.

It is easy to see how PTH given pharmacologically by intermittent injection can mimic the effects of local PTHrP to promote bone formation that take place through the PTH1R, since all these effects of anabolic PTH have been ascribed to locally generated PTHrP (Fig. 25.6). Nevertheless, if the anabolic action of PTHrP is modified in any way, or mediated in part by non-receptor-mediated actions in addition to PTHR1-mediated actions, some differences might be expected. In that case discovering how noncanonical actions might signal through osteoblastic cells could provide ways to optimize PTH-based therapies.

A question related to this concerns the interpretation of experimental data obtained by the treatment of cells in vitro with PTHR1 agonists. Over decades there have been very many published effects of treatment of cells in vitro with PTH, e.g., on gene expression and/or protein production. Although these are often taken to indicate that such pharmacological actions reflect physiological actions of PTH in vivo, evidence for such a physiological role is invariably lacking. In such circumstances, the possibility should be considered that such effects might reflect physiological roles of PTHrP. Some examples in which this might be considered are the PTH promotion of glycolysis in osteoblast lineage cells (Esen et al., 2015), PTH inhibition of salt-induced kinase in osteocytes (Wein et al., 2016), and the finding in osteoblast precursor lineage tracing experiments in mice that PTHR1 is required for the PTH-mediated increase and suppression of apoptosis in early osteoblast precursors without any effect on their rate of proliferation (Balani et al., 2017). If these effects are also induced by physiological PTHrP, this provides further information on how this protein functions in the normal adult skeleton.

Since bone remodeling takes place asynchronously throughout the skeleton at sites where it is needed to replace old or damaged bone and to respond to loading and unloading, it is obvious that the control of remodeling needs to be very local. It might be argued that local PTHrP release would need to be very tightly regulated so that in bone remodeling it is presented only briefly to its target cells so that bone formation is promoted, rather than stimulating both bone formation and resorption. Excessive osteoclast formation in response to PTHrP is unlikely in the context of normal physiological remodeling, where (1) BMUs are active at any one time only in those places in which they are required (Fig. 25.6) and (2) where only osteoblast-derived, and not osteocyte-derived, PTHrP promotes osteoclast formation, as evidenced by the comparison of the cell-specific PTHrP-null mice (see earlier and Table 25.1).

Can changes in the level of the circulating hormone, PTH, exert any fine controlling influence upon these processes that take place asynchronously, scattered throughout the skeleton in virtually a stochastic manner? There have been studies that suggest that circulating PTH levels vary in a circadian manner in human subjects. The changes in circulating levels of PTH in those studies were consistently at a maximum of about 40% and within the normal circulation range of 2−6 pmol/L (Fraser et al., 1998; Rejnmark et al., 2002; Joseph et al., 2007). In one such study (Logue et al., 1989) the late night/early morning increase in plasma PTH rose in parallel with nephrogenous cAMP, suggesting the change in PTH may be sufficient to produce an appropriate response in the kidney target. It remains difficult to envisage how such changes in

circulating PTH could bring about initiation of BMUs at sites of need scattered throughout the skeleton. These comments do not apply to situations of PTH excess. Persistent elevation of circulating PTH resulting from primary hyperparathyroidism, from prolonged PTH treatment, or from transgenic overexpression in mice results in a generalized activation of remodeling sites and therefore increased resorption.

PTHrP analogs in pharmacology: could this change the approach to skeletal anabolic therapy?

Studies of the anabolic effect of PTHrP(1−36) in human subjects had their origin in the view that amino-terminal PTHrP is the paracrine ligand for PTHR1 in bone (Wu et al., 1996). The susceptibility of full-length protein to proteolysis (Orloff et al., 1989; Diefenbach-Jagger et al., 1995) precluded its use for this application, so preclinical experiments tested several truncated forms as anabolic agents, including PTHrP(1−34), PTHrP(1−36), and PTHrP(1−74). From the earliest of these studies in the rat (Hock et al., 1989) it was evident that these PTHrP preparations exerted anabolic effects, but were significantly less potent in vivo than PTH, although the two are equally active in promoting cAMP production in vitro. Such a lesser potency in vivo could be anticipated because even these truncated forms of PTHrP have many target sequences that are susceptible to proteolysis (Fig. 25.1). The anabolic action of PTHrP(1−36) in human subjects has been investigated extensively by Stewart and colleagues (Horwitz et al. 2003, 2006, 2010, 2011, 2013; Augustine and Horwitz, 2013). The daily dose of PTHrP(1−36) in human subjects required to increase bone formation markers was manifold higher than the dose of teriparatide needed to achieve these marker levels (Augustine and Horwitz, 2013; Horwitz et al., 2013), probably due to the proteolytic cleavage described earlier. The higher dose requirements might be due to a difference in pharmacokinetics, with PTHrP(1−36) degraded more rapidly following injection, and thus not so widely distributed to activate BMUs. The result would be that lesser amounts of active agonist would be available to the receptor.

Early studies by Stewart and colleagues suggested that PTHrP(1−36) action was relatively free of a resorptive effect as determined by measuring serum biochemical markers of bone formation and resorption. Similar claims have been made for abaloparatide (Leder et al., 2015; Miller et al., 2016), which is a 34-amino-acid peptide in which the first 21 residues are identical with PTHrP. Abaloparatide also contains a number of substitutions that were planned to improve stability (Dong et al., 2001; Hattersley et al., 2016), though the most susceptible of the PTHrP cleavage sites ($-R_{19}R_{20}R_{21}-$) is located within both PTHrP(1−36) and abaloparatide. Abaloparatide (80 μg per day) and teriparatide (20 μg per day) have been reported to have comparable anti-fracture efficacy in the vertebrae, with claims based on biochemical marker data of a greater net bone formation due to a lesser effect on bone resorption marker with abaloparatide than with teriparatide (Dong et al., 2001; Leder et al., 2015; Hattersley et al., 2016). In the same data, the formation marker level was also less with abaloparatide (Dong et al., 2001), so the claim of a lesser effect on resorption might not be soundly based. There remains no information on the cellular basis by which PTHrP(1−36) or abaloparatide could have a lesser effect on bone resorption than formation.

The structural features of abaloparatide have led to it being called a PTHrP analog that is a selective activator of the PTHR1 receptor (Dong et al., 2001; Leder et al., 2015; Hattersley et al., 2016), with adenylyl cyclase assay data showing it to be equipotent with teriparatide. Despite this equivalence, when PTH(1−34) and PTHrP(1−36) were compared for their initial receptor interaction mechanisms, the action of PTHrP(1−36) was restricted to the cell surface, while PTHrP(1−34) was more readily internalized and brought about a somewhat more prolonged increase in cAMP in the target cells through continued endosomal signaling (Ferrandon et al., 2009) (Gardella and Vilardaga, 2015). Similar findings were obtained with abaloparatide (Hattersley et al., 2016), leading to this being suggested as a mechanism by which PTHrP(1−36) and abaloparatide might lead to a lesser resorption response than that with PTH(1−34). These in vitro findings of differing initial interactions of the peptides with receptor have not been taken beyond the stage of cAMP generation. It is difficult to extrapolate them to explain the purportedly different in vivo effects on bone resorption given the lack of evidence of differences in cellular effects beyond cAMP generation in vitro, e.g., on gene expression.

Without information to the contrary it might be assumed that any anabolic action of abaloparatide is through a mechanism shared with teriparatide—predominantly activation of remodeling sites. The possibility of either PTHrP(1−36) or abaloparatide being anabolic and resorption sparing would be an intriguing one, if very difficult to explain. Given that resorption is an inescapable first phase of BMU-based bone remodeling, it is not easy to see how an anabolic effect equivalent to that of teriparatide could be obtained while sparing resorption. The nature of the question is such that it could be resolved only by the use of histomorphometry such as that used to show the predominantly modeling effect of teriparatide when used as an anabolic agent (Lindsay et al., 2006; Ma et al., 2006). A more likely explanation might lie in the pharmacokinetics, with a lesser potency of abaloparatide in vivo because of proteolytic degradation, and less of the agonist being presented to the receptor.

Abaloparatide offers an interesting new approach to anabolic therapy that merits much further understanding of mechanisms. If it can be regarded as a "PTHrP analog," it might be instructive in revealing aspects of the actions of the PTHrP N-terminal domain on target bone cells. The findings indicating full-length PTHrP as the locally generated secreted product highlight the need to consider also the possibility of other PTHrP actions in bone, especially through noncanonical pathways. It has always been assumed that all that is required of PTHrP is that it exerts its activity through acting on the PTHR1. That might not be so, however, in light of the increasing awareness of noncanonical actions of PTHrP.

Conclusion

We have been learning since the 1980s how PTH and PTHrP share a common receptor in many tissues. The current concept is that the hormone PTH regulates calcium homeostasis in development and maturity. PTHrP provides calcium to the developing fetus through its placental calcium transport action, and its local expression directs growth plate development by controlling chondrocyte proliferation and differentiation. Postnatally, PTH assumes the role of supplying calcium by stimulating bone resorption, while PTHrP is the main factor generated locally in bone and controls bone remodeling, without normally contributing to the maintenance of serum calcium. In maturity calcium homeostasis is the sole domain of PTH. Whether PTH physiologically regulates bone formation in maturity remains to be established in human subjects. These views have developed largely as a result of the insights provided from mouse genetic experiments, but much is owed also to pharmacological studies in animals and to the therapeutic efficacy of PTH in the treatment of osteoporosis.

The susceptibility of PTHrP to posttranslational processing is a striking feature of the molecule that results in the generation of a number of peptide components, some of which have been shown to have biological activities that do not require the PTHR1, leading it to be considered as a polyfunctional cytokine. The search for the presumed receptors of these peptides and the identification of the circulating peptide isoforms obviously needs to continue. Such investigation provides attractive challenges, as does the aim of determining the function of nuclear PTHrP. The nuclear role(s) and the susceptibility of PTHrP to proteolysis, together with the lability of PTHrP mRNA and the multiple splice forms, may be the result of evolutionary pressures that equip PTHrP to function as a paracrine agent, as it does in so many tissues.

When used as a skeletal anabolic therapy, PTH appears simply to be reproducing the local physiologic action of PTHrP. The great susceptibility of PTHrP to proteolytic degradation makes it unsuitable as a therapy itself. The possibility is raised in this chapter that domains of PTHrP other than that acting through PTHR1 might contribute to the action on bone. If that were so, the signaling pathways involved could be of interest therapeutically. In the meantime, the use of analogs of PTH and PTHrP that act through PTHR1 are the subject of attention, and much can be learned of the anabolic process through their use.

Chapter 26

Cardiovascular actions of parathyroid hormone/parathyroid hormone–related protein signaling

Sasan Mirfakhraee and Dwight A. Towler

The University of Texas Southwestern Medical Center, Department of Internal Medicine, Endocrine Division, Dallas, TX, United Sates

Chapter outline

Introduction

All osteotropic hormones have vasculotropic actions (Thompson and Towler, 2012b; Towler, 2017a). This pithy statement of fact most certainly holds true for the prototypic bone anabolic polypeptides parathyroid hormone (PTH) and parathyroid hormone–related protein (PTHrP) (aka PTHLH). The cardiovascular actions of PTH were first identified in 1925, when Collip and Clark injected anesthetized Dog 164 with intravenous parathyroid extract and documented hypotensive actions (Collip and Clark, 1925; Rambausek et al., 1982). However, only since the end of the 20th century has the fundamental role of PTH/PTHrP receptor (PTH1R) signaling in cardiovascular development, physiology, and disease been fully vetted—but this is not yet widely appreciated (Bilezikian et al., 2015; Tomaschitz et al., 2013). For example, PTH1R signaling is required for normal aortic valve (Gray et al., 2013) and myocardial (Qian et al., 2003) development. Paracrine vascular smooth muscle PTHrP/PTH1R signaling has emerged as important in the homeostatic regulation of renovascular blood flow (Raison et al., 2013), while endothelial PTH1R actions convey the endocrine regulation of blood flow to bone in response to PTH (Benson et al., 2016). In addition to its bone anabolic actions, intermittent pharmacological dosing with PTH(1–34) mitigates the endothelial dysfunction associated with aging (Guers et al., 2017) and suppresses arteriosclerotic responses to dysmetabolic states such as diabetes (Cheng et al., 2010). These observations, among others, provide a second "bookend" that, with Collip and Clark's early observation, serves to brace the first century of PTH/PTHrP research—a century that has *continuously* pointed to cardiovascular actions of the PTH family of ligands. Thus, a fundamental understanding of PTH/PTHrP biology must encompass a better understanding of actions within and upon the cardiovascular system (Cheng et al., 2010).

In this chapter, we build upon our recent reviews (Bilezikian et al., 2015; Thompson and Towler, 2012b; Towler, 2014a) to help highlight once again the importance of PTH/PTHrP to cardiovascular biology and disease. While

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00026-9

mammalian PTHrP is a dedicated PTH1R ligand, PTH can activate both human PTH1R and human PTH2R (Hoare and Usdin, 2001). Therefore, we also briefly discuss PTH2R and tuberoinfundibular peptide of 39 residues (TIP39), the dedicated PTH2R ligand, as relevant to cardiovascular biology. Finally, we reflect upon chronic kidney disease−mineral and bone disorder (CKD−MBD) as a "perfect storm" of cardiometabolic risk arising in significant part from perturbed PTH1R signaling. We use this discussion as a framework to detail physiologically important interconnections of PTH/PTHrP signaling within the emerging bone−vascular axis (Fadini et al., 2012; Thompson and Towler, 2012a; Towler, 2011). The reader is referred to recent editions of *The Parathyroids* for a more comprehensive historical review (Bilezikian et al., 2015).

PTH/PTHrP in cardiovascular development

Some of the earliest evidence that PTH/PTHrP signaling might contribute to cardiovascular development arose in Buck Strewler's group; they identified expression of PTHrP in the chicken embryonic heart as well as in other mesodermally derived tissues (Schermer et al., 1991). Descriptive studies in the rat revealed that mesenchymal PTH1R expression lay adjacent to epithelial or endothelial sources of PTHrP (Lee et al., 1995). Inductive, paracrine epithelial-to-mesenchymal signals mediated by PTHrP were inferred from the spatial relationship between *PTHrP* ligand and *PTH1R* expression as revealed by these in situ hybridization studies. In dogs, PTH1R was also identified early on as being expressed in heart and aorta, albeit at levels much lower than those observed in kidney and bone (Smock et al., 2001). However, the important role of PTH/PTHrP in cardiovascular development was not truly appreciated until Hank Kronenberg, Tom Clemens, and colleagues began their systematic analyses as to why mice globally lacking the PTH1R exhibit prenatal lethality (Qian et al., 2003). They demonstrated that, as in other vertebrate species, the murine *PTH1R* gene was abundantly expressed in developing mouse cardiomyocytes, but then went on to show that mice genetically lacking PTH1R abruptly die between embryonic day (E) 11.5 and E12.5 due to massive cardiomyocyte apoptosis (Qian et al., 2003). The primary abnormalities in cardiomyocyte mitochondrial morphology and pump function that arise with myocardial PTH1R deficiency were followed by secondary hepatic injury and tissue necrosis (presumptively due to cardiogenic circulatory congestion). The mechanisms whereby PTH1R signaling regulates mitochondrial metabolism to prevent apoptotic cell death in the cardiomyocyte have yet to be fully explored, but based upon recent studies will probably converge on protein kinase A-dependent inhibition of the mitochondrial fission protein Drp1 (Monterisi et al., 2017). Skeletal PTH1R activation has been shown to inhibit apoptosis in several cell types, including in osteoblasts challenged with glucocorticoids (O'Brien et al., 2008) or chondrocytes treated with tumor necrosis factor (Okoumassoun et al., 2007). Thus, PTH1R expression and signaling represent a fundamental component of cardiomyocyte cell physiology. A better understanding of the prosurvival mechanisms afforded by PTH1R signaling in the heart may prove useful in therapeutic approaches to ischemic heart disease as well as cardiotoxicity associated with a subset of chemotherapeutics (Babiker et al., 2018).

Other vertebrate models have confirmed the important role of PTH/PTHrP signaling in cardiovascular development. In zebrafish, a total of three PTH receptors (*pth1r*, *pth2r*, *pth3r*) are expressed (Gray et al., 2013). Knockdown of either *pth1r* or the selective zebrafish *pth1r/pth2r* ligand *pthrp* results in morphants with aortic coarctation defects. Because of the important role for *notch* in mammalian aortic valve development (van den Akker et al., 2012), Chico and colleagues wondered whether *notch* signaling might be perturbed and, indeed, demonstrated that restoration of *notch* signaling in *pth1r*-targeted morphants prevented the aortic defects (Gray et al., 2013). Thus, the variable penetrance for preductal aortic coarctation in lethal Blomstrand chondrodysplasia—a rare disorder due to loss-of-function mutations in the human *PTH1R* (Hoogendam et al., 2007)—may in fact relate to variable compensatory changes in Notch coregulatory pathways that partially compensate for PTH1R deficiency during development. PTH1R and Notch play vital roles in both bone and vascular biology, including vascular endothelial growth factor (VEGF)-dependent processes such as tip-cell selection (Blanco and Gerhardt, 2013). Thus, the cross talk between these morphogenetic signaling systems is likely to help juxtaposition microvascular supply to sites of bone formation in the basic multicellular unit in response to PTH anabolic actions (Prisby et al., 2011).

PTH receptor signaling in arterial biology: vascular smooth muscle cell and endothelial responses to PTH and PTHrP

The acute vasodilatory actions of PTH administration were recognized in the very earliest studies of the hormone's physiological response (Collip and Clark, 1925). Following Collip and Clark's lead, Pang et al. confirmed that bovine PTH(1−34) reduced blood pressure in anesthetized dogs and rats (Pang et al., 1980). Imai and colleagues demonstrated

coronary vasodilation in response to PTH that same year (Hashimoto et al., 1981). Ex vivo, human and bovine middle cerebral arteries were identified to undergo vasodilatation as well (Suzuki et al., 1983). These observations prompted additional work that demonstrated vasodilatory PTH responses in multiple vertebrate tissue beds, but responses varied widely in potency and efficacy (Crass et al., 1987; Nickols et al., 1986). Tissue-specific expression of PDZ domain-containing coadapters markedly influences the capacity of the PTH1R to access protein kinase A, phospholipase C, and extracellular signal-regulated kinase (ERK) signaling mediators that shape these responses (Romero et al., 2011). As of this writing, the molecular mechanisms conveying temporal and spatial differences in PTH1R-dependent vasodilation have not been delineated. Of note, in 1986 the salutary actions of PTH in a preclinical model of myocardial ischemia were reported; enhanced collateral blood flow was thought to represent the primary mechanism of benefit (see later) (Feola and Crass, 1986). However, since PTH1R signaling exerts direct antiapoptotic actions within fetal cardiomyocytes (*vide supra*), this response may also contribute to postnatal PTH1R benefits in the setting of ischemia.

Nickols, Barthelmebs, Jean-Jacques Helwig, and colleagues went on to confirm a widespread vasodilatory reaction to PTHrP (Musso et al., 1989; Roca-Cusachs et al., 1991). Endothelial NO production in response to PTH1R activation certainly contributes to vasodilatory PTH/PTHrP actions, as Prisby and colleagues have elegantly demonstrated in bone (Benson et al., 2016) (Fig. 26.1). However, direct PTH1R signaling in arterial vascular smooth muscle cells (VSMC) conveys many beneficial functions in other large conduit vessels. Coronary artery vasodilation is only partly dependent upon endothelial NO release due to direct actions of PTHrP/PTH1R signaling in coronary VSMC that drive vasorelaxation; the latter is dependent upon cAMP-mediated reductions in cytosolic calcium (Ishikawa et al., 1994; Nyby et al., 1995). However, as discussed earlier, this varies with vascular venue. Rhonda Prisby and colleagues identified that the endothelium was vital to PTH actions enhancing blood flow to the skeleton in studies of the femoral principal nutrient artery (Prisby et al., 2013). Whether age-dependent increases in vascular sensitivity to pressors combine with altered nutrient artery endothelial PTH1R signaling to compromise bone health remains to be fully explored.

Bilezikian et al. first established that PTH exerts acute inotropic actions in the isolated perfused heart, dependent upon coronary vasodilatation and independent of direct chronotropy (Ogino et al., 1995). In mechanisms that resemble the epithelial−mesenchymal induction effects of paracrine PTHrP during development (*vide supra*), subsets of endothelial cells appear to provide important sources of PTHrP tone that maintains myocardial function and coronary blood flow. Schlüter determined that coronary endothelial cells produce PTHrP under ischemic conditions to enhance both myocardial inotropy (contraction velocity) and lusitropy (relaxation velocity) (Lutteke et al., 2005; Schluter et al., 2000). Consistent with this, Feola and Crass demonstrated that administration of PTH(1−34) 30 min after the initiation of myocardial ischemia preserved left ventricular function and prevented cardiogenic shock in a canine model of myocardial infarction

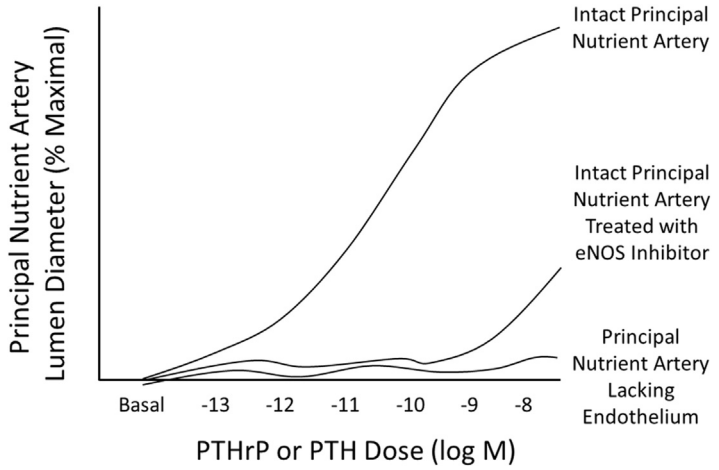

FIGURE 26.1 Parathyroid hormone (*PTH*) and parathyroid hormone−related protein (*PTHrP*) vasodilation of rat femoral nutrient arteries requires intact endothelial nitric oxide synthase (*eNOS*) signaling (Benson et al., 2016). Prisby and colleagues demonstrated that, in addition to aligning the marrow microvasculature closer to the bone multicellular unit as necessary for bone formation (Prisby et al., 2011), PTH/PTHrP signaling also increases blood flow to bone. In elegant ex vivo studies, they demonstrated that PTHrP and PTH induced vasodilation (increased lumen diameter) in the principal nutrient artery supplying rat femurs. This required an intact endothelium (Benson et al., 2016). Inhibition of eNOS with $_L N^G$-nitroarginine methyl ester (L-NAME) also significantly inhibited the vasodilatory responses to either PTH or PTHrP. Importantly, Gohin et al. (2016) have shown that L-NAME inhibits PTH-stimulated increases in bone formation as well. *Graphic representation/summary of results from Benson, T., Menezes, T., Campbell, J., Bice, A., Hood, B., Prisby, R., 2016. Mechanisms of vasodilation to PTH 1-84, PTH 1-34, and PTHrP 1-34 in rat bone resistance arteries. Osteoporos. Int. 27, 1817−1826.*

(Feola and Crass, 1986). However, others have reported direct inotropic effects of PTH(1−34) using isolated cardiomyocytes studied in culture (Tastan et al., 2009). This suggests that pharmacological mimicry of these PTHrP-mediated paracrine endothelial-to-mesenchymal (e.g., coronary smooth muscle, myocardium) signals may hold therapeutic potential in human cardiovascular disease.

Vascular smooth muscle-derived PTHrP has emerged as a stretch-inducible paracrine vasodilator, important for homeostatic roles of PTH1R signaling that control tissue perfusion via regional arterial tone (Noda et al., 1994; Pirola et al., 1994; Takahashi et al., 1995). Clemens's group first established that augmenting local PTHrP/PTH1R signaling has an impact on blood pressure and vascular contractility; sustained reductions in blood pressure and increases in volume-dependent renal tissue perfusion were obtained in novel VSMC-specific transgenic mice expressing either PTHrP or the PTH1R (Noonan et al., 2003). Moreover, pressor responses to angiotensin II were significantly reduced in transgenic animals versus nontransgenic siblings. Wild-type PTH1R activation is ligand dependent; thus, these data strongly suggest that endogenous paracrine PTHrP production—modulated by mechanical, inflammatory, and endocrine cues—locally regulates tissue perfusion (Noonan et al., 2003).

However, it was a seminal study published a decade later by Raison et al. that elegantly confirmed and refined this working model (Raison et al., 2013). Using mice possessing floxed PTHrP alleles and implementing a smooth muscle cell transgene driving tamoxifen-inducible Cre recombinase, postnatal conditional deletion of VSMC PTHrP was achieved in adult mice, thus permitting an assessment of effects on renal blood flow (Raison et al., 2013). Compared with control mice, mice lacking PTHrP in VSMCs (viz., transgenic smooth muscle ERT2-Cre;PTHrP(flox/flox) treated with tamoxifen) exhibited increased renal vascular resistance with concomitant reductions in kidney perfusion and glomerular filtration (Raison et al., 2013). Importantly, renovascular perfusion in response to mechanical stimulation with saline volume expansion (SVE) was also impaired. While normal mice increase renal plasma flow with subsequent diuresis in response to SVE—indices of renovascular vasodilation (see Fig. 26.2)—mice lacking VSMC PTHrP were unable to do so. Interestingly, no change in systemic blood pressure was noted in these VSMC-specific PTHrP-knockout mice even though *pharmacological* dosing with PTHrP simultaneously reduced blood pressure while increasing renal plasma flow (Raison et al., 2013). Thus, endogenous VSMC PTHrP production is required to enable regulated renal perfusion in response to hemodynamic challenge without overt changes in baseline blood pressure.

At first glance, this emerging physiology appears paradoxical when viewed against the backdrop of the cardiovascular disease burden that accrues with primary hyperparathyroidism (HPT) (Yu et al., 2010, 2011, 2013) or the secondary HPT of CKD. Hypertension, arteriosclerosis, valve and vascular calcification, and cardiovascular mortality are all increased with HPT (Carrelli et al., 2013; Fitzpatrick et al., 2008; Iwata et al., 2012; Rubin et al., 2005; Silverberg et al., 2009; Walker

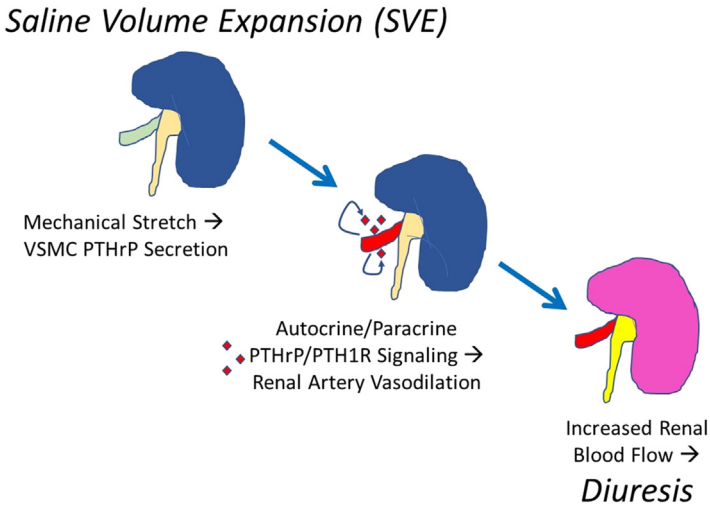

FIGURE 26.2 Saline volume expansion (*SVE*) activates vasodilatory vascular smooth muscle cell (*VSMC*) parathyroid hormone−related protein (*PTHrP*) actions that regulate renal blood flow. Barthelmebs and colleagues demonstrated that increases in renal blood flow in response to SVE require VSMC PTHrP expression (Raison et al., 2013). Unlike the model depicted for wild-type mice, conditional deletion of PTHrP in adult VSMCs abrogates physiological increases in renovascular perfusion and diuresis in response to SVE. Interestingly, no change in systemic blood pressure was noted with genetic VSMC PTHrP deficiency, even though *pharmacological* dosing with PTHrP simultaneously reduces blood pressure while increasing renal plasma flow (Raison et al., 2013). *Graphic representation/summary of results from Raison, D., Coquard, C., Hochane, M., Steger, J., Massfelder, T., Moulin, B., Karaplis, A.C., Metzger, D., Chambon, P., Helwig, J.J., et al. 2013. Knockdown of parathyroid hormone related protein in smooth muscle cells alters renal hemodynamics but not blood pressure. Am. J. Physiol. Renal. Physiol. 305, F333−F342.*

et al., 2009, 2010; Walker and Silverberg, 2008; Yu et al., 2010). Vascular desensitization to the aforementioned paracrine PTHrP cues is likely to be one explanation—arising from sustained elevation in circulating PTH with HPT and the inhibitory PTH fragments that accrue in CKD (Friedman and Goodman, 2006; Langub et al., 2003; Nyby et al., 1995). Vascular tissue PTH1R signaling exhibits tachyphylaxis, becoming rapidly refractory to PTH1R-dependent vasorelaxation in response to PTH or PTHrP exposure (Nyby et al., 1995). By studying rat femoral artery segments contracted with norepinephrine ex vivo, Brickman and colleagues demonstrated that vasodilatory responses to either PTHrP or PTH were markedly diminished, by >50%, following 40 min of prior exposure to either of these PTH1R ligands (Nyby et al., 1995) (Fig. 26.3). Similarly, isolated rat VSMCs exhibit tachyphylaxis within 30 min of exposure by using cAMP production as an assay of PTH1R activation (Nyby et al., 1995). Of note, renovascular tachyphylaxis to PTH has been independently documented in the isolated perfused rabbit kidney model (Massfelder et al., 1996). Finally, in otherwise healthy adult humans, while singular administration lowers blood pressure, sustained PTH administration over a period of 12 days actually increases blood pressure (Hulter et al., 1986)—consistent with data from these preclinical disease models (see also "PTH1R activation and the renin–angiotensin–aldosterone axis: a feed-forward vicious cycle"). The precise molecular mechanisms are poorly characterized with respect to the cardiovascular PTH1R; however, as observed in other tissues, modulation of PTH1R actions by PDZ adapter proteins, β-arrestins, and G-protein-receptor kinases certainly contributes to arterial responsivity (Dicker et al., 1999; Peterson and Luttrell, 2017; Romero et al., 2011; Smith and Rajagopal, 2016; Song et al., 2010). Thus, the vasculopathy of primary and secondary HPT will relate in part to arterial desensitization to the important paracrine, PTHrP-dependent regulation of vascular tone and cellular function (Nyby et al., 1995; Raison et al., 2013) (Figs. 26.2 and 26.3). In this model, sustained exposure to PTH and antagonistic PTH degradation fragments can downregulate PTH1R signals regulated by paracrine PTHrP actions that serve homeostatic roles in cardiovascular health (Fig. 26.4) (Friedman and Goodman, 2006; Thompson and Towler, 2012a).

No clinically useful test of *cardiovascular* PTH1R signaling has been developed or validated as of this writing—a clear shortcoming. However, by implementing histomorphometry to quantify the *skeletal* anabolic state (osteoblast surface, mineralizing surfaces) coupled with simultaneous measurements of the prevailing intact PTH level, London and colleagues (London et al., 2015) created an index that reflects an individual's *skeletal* responsiveness to PTH (Towler, 2015) (Fig. 26.5). The investigative team then demonstrated that as a cohort, those dialysis patients with lower ankle–brachial index (ABI)—an index of peripheral arterial disease—exhibit impaired skeletal PTH1R responsiveness (lower osteoblast surface, reduced bone mineralization) compared with dialysis patients with normal ABI (London et al., 2015) (Fig. 26.5). Vascular responses to PTH are important to bone physiology, increasing not only NO-dependent blood flow to bone, but also VEGF-dependent juxtaposition of microvasculature to bone-forming surfaces (Fig. 26.6) (Benson et al., 2016; Guers et al., 2017; Prisby et al., 2011, 2013; Prisby, 2017). Gohin demonstrated that PTH administration increases hindlimb

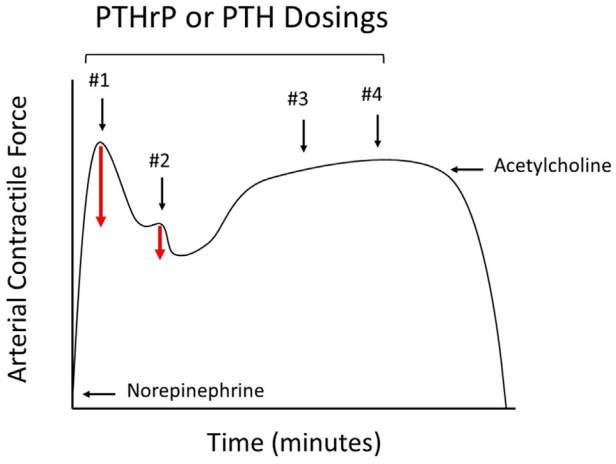

FIGURE 26.3 Arterial desensitization to the vasodilatory actions of parathyroid hormone–related protein (*PTHrP*) or parathyroid hormone (*PTH*). Brickman and colleagues established that following maximal contraction of isolated rat femoral artery segments with the pressor norepinephrine, the initial vasodilatory responses observed with PTH or PTHrP dosing are rapidly lost (Nyby et al., 1995). Compared with the first dose (#1) of either PTH or PTHrP, which resulted in vasorelaxation, subsequent dosing over the next tens of minutes exhibited either blunted (#2) or no (#3, #4) response, indicating tachyphylaxis. However, response to other vasodilators remained intact, as exhibited by preserved vasorelaxation to acetylcholine. *Downward red arrows*, magnitude of vasorelaxation in response to PTHrP or PTH dosing. See text for details. *Graphic representation/summary of results from Nyby, M.D., Hino, T., Berger, M.E., Ormsby, B.L., Golub, M.S., Brickman, A.S., 1995. Desensitization of vascular tissue to parathyroid hormone and parathyroid hormone-related protein. Endocrinology 136, 2497–2504.*

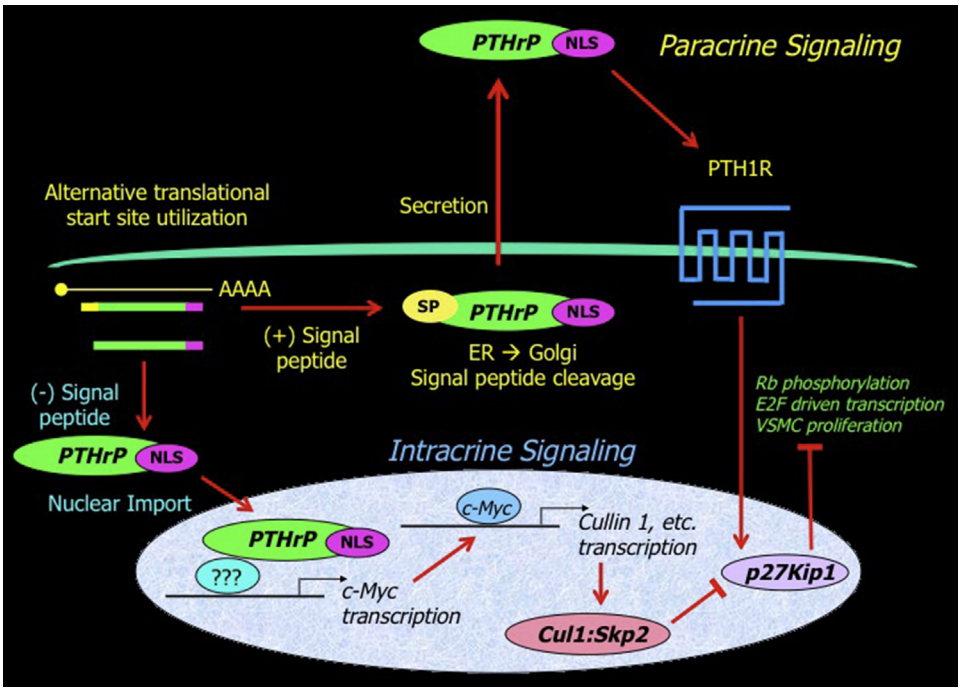

FIGURE 26.4 Paracrine versus intracrine parathyroid hormone–related protein (*PTHrP*) signaling. Translation of the full-length PTHrP protein results in signal peptide (*SP*)-dependent secretion of PTHrP(1–141). Paracrine PTHrP signaling in vascular smooth muscle cells (*VSMCs*), via the G-protein-coupled plasma membrane receptor *PTH1R*, reduces cellular proliferation, promotes vasodilation, and mitigates procalcific signals. Since prior exposure to PTH1R ligands impairs subsequent vasodilatory responses to agonists such as PTHrP (tachyphylaxis; see Fig. 26.3), primary or secondary hyperparathyroidism is predicted to impair the paracrine PTHrP signals important in the hemodynamic regulation of tissue perfusion (e.g., kidney, Fig. 26.2). The nuclear localization signal (*NLS*), although present, is not required for this paracrine activity. Of note, the initiation of PTHrP translation at an alternative internal start site results in a truncated PTHrP protein lacking the N-terminal SP. This nonsecreted PTHrP protein is directed to the nucleus via the NLS encoded at residues 88–106. Nuclear PTHrP activates the c-Myc promoter via this intracrine mechanism, directing expression of programs that enhance Skp2/Cul1-dependent p27Kip1 degradation and promote Cdk2-dependent cellular proliferation. The antagonistic paracrine versus intracrine PTHrP signals differentially regulate p27Kip1— and this emerges as a relevant nodal point in the reciprocal control of VSMC proliferation. Nullification of the paracrine PTHrP actions, as arises with desensitization to chronic PTH exposure (see Fig. 26.3), is predicted to result in unchecked intracrine PTHrP signaling. *ER*, endoplasmic reticulum; *???*, unidentified DNA-binding coregulators of nuclear PTHrP actions. *Reprinted with permission from Towler, D.A., 2014b. FIGURE 26.5 Histomorphometric evidence of skeletal resistance to parathyroid hormone (*PTH*) in chronic kidney disease patients with peripheral arterial disease (*PAD*). PAD can be identified using a measurement called the ankle–brachial index, or *ABI*. London and colleagues established that, compared with those patients without PAD, patients with PAD exhibit a regression relationship between osteoblast anabolic functions (*y* axis; double-labeled surface or osteoblast surface with bone surface referent) and intact PTH (*x* axis) that characterizes a reduced PTH sensitivity (London et al., 2015). *Graphic representation of the results of London, G.M., Marchais, S.J., Guerin, A.P., de Vernejoul, M.C. 2015. Ankle-brachial index and bone turnover in patients on dialysis. J. Am. Soc. Nephrol. 26, 476-483; Towler, D.A. 2015. FIGURE 26.6 Parathyroid hormone (*PTH*) actions on skeletal microvasculature are important contributors to anabolic responses. Prisby and colleagues have demonstrated that PTH enhances nutrient artery vasodilation and marrow blood flow in part via endothelial nitric oxide generation by endothelial NO synthase (Prisby et al., 2011) (see also Fig. 26.1). These PTH-induced increases in hindlimb blood flow are important in endocortical bone formation responses (Gohin et al., 2016). Moreover, PTH also increases osteoblast production of vascular endothelial growth factor (*VEGF*; depicted as *red dots*). The paracrine VEGF signaling promotes the juxtaposition of marrow microvasculature to active bone-forming surfaces (Prisby et al., 2011).

blood flow by ca. 30% within 10 min following dosing: a response that is required for PTH-stimulated cortical bone formation (Gohin et al., 2016). Perhaps not surprisingly, then, the vascular dysfunction of arteriosclerosis reduces hip bone mass in humans (Collins et al., 2009) and skeletal perfusion in mice (Shao et al., 2011). However, it remains to be shown that impaired *skeletal* PTH1R signaling is a reliable surrogate for impaired *cardiovascular* PTH1R signaling. Nevertheless, London's important paper (London et al., 2015) highlights that a human metabolic milieu associated with impaired PTH1R signaling exhibits simultaneous reductions in bone and vascular health.

Like CKD, type 2 diabetes and the metabolic syndrome increase the incidence and prevalence of arteriosclerosis, vascular calcification, and conduit vessel stiffness (Stabley and Towler, 2017; Towler, 2017a). This arteriosclerotic vascular stiffness conveys risk for cognitive impairment, stroke, myocardial infarction, heart failure, progression of CKD, and lower extremity amputation (Stabley and Towler, 2017; Thompson and Towler, 2012b; Towler, 2017a). In 2010, our group began to directly assess the potential benefits of cell-autonomous arterial smooth muscle PTH1R signaling in a preclinical model of diabetic arteriosclerosis. We did this by generating a transgenic mouse expressing a constitutively active PTH1R transgene, *PTH1R(H223R)*, in vascular smooth muscle of LDLR$^{-/-}$ mice using the SM22 promoter as a delivery module (Cheng et al., 2010). The PTH1R(H223R) Jansen metaphyseal chondrodysplasia variant is ligand-independent, constitutively active PTH1R that does not undergo homologous desensitization/tachyphylaxis (Schipani et al., 1995). In the LDLR-deficient mouse model of diet-induced diabetic arteriosclerosis, we showed that the VSMC *PTH1R(H223R)* transgene significantly reduced aortic calcification and fibrosis while maintaining arterial compliance (Cheng et al., 2010). This occurred in part via PTH1R-dependent inhibition of arterial prosclerotic Wnt signaling and arterial oxidative stress in VSMCs. Furthermore, intermittent dosing with PTH(1−34) was also shown to reduce vascular osteogenic programs, mineralization, and oxidative stress (Cheng et al., 2010; Shao et al., 2003, 2005). Of note, similar responses have been reported by Morii and colleagues in vitro using cultured primary VSMCs treated with PTHrP (Jono et al., 1997). In vivo, Friedman and coworkers subsequently showed that intermittent PTH(1−34) administration reduces vascular calcification in uremic rats (Sebastian et al., 2008). Likewise, Prisby, Lennon-Edwards, and colleagues showed that intermittent PTH(1−34) administration restores endothelial nitric oxide synthase (NOS) levels and endothelium-dependent arterial vasorelaxation impaired with advanced age in rats (Guers et al., 2017). In collaborative studies that are still ongoing at the time of writing, we have shown that conditional deletion of the PTH1R in VSMCs increases arterial fibrosis in diabetic LDLR$^{-/-}$ mice (Cheng et al., 2016). This confirms and extends our previous results demonstrating that enhancing vascular smooth muscle PTH1R actions reduces arteriosclerosis in this diet-induced murine arteriosclerotic disease model (Cheng et al., 2010). Thus, data from multiple laboratories converge to reveal that maintenance of vascular PTH1R signaling tone helps mitigate the arteriosclerotic responses to diabetes, dyslipidemia, uremia, and aging. However, the precise pharmacokinetic−pharmacodynamic (PK−PD) relationships, including the healthy homeostatic "set point" for cardiovascular PTH1R signaling, remain to be determined.

Of note, a novel intracellular signaling system has been identified for PTHrP actions in both VSMCs and the skeleton that differs dramatically from classical PTH1R activation, and actually antagonizes many of the latter's actions (Fig. 26.4) (Clemens et al., 2001; Miao et al., 2008; Towler, 2014b). This mechanism needs to be recognized in any detailed

understanding of PTHrP biology, molecular genetics, and perturbations in circulating PTH levels. The PTHrP gene can encode a transcript wherein translation generates an N-terminal truncation lacking the signal peptide for secretion (Nguyen et al., 2001; Wysolmerski, 2012). A nuclear localization sequence within PTHrP targets the protein to the nucleus where suppression of p27Kip1 expression promotes cell proliferation and neointima formation (Fiaschi-Taesch et al., 2004, 2006, 2009; Fiaschi-Taesch and Stewart, 2003; Massfelder et al., 1997). This intracrine PTHrP/p27Kip1 suppression pathway exerts actions in contradistinction to those elicited by paracrine (secreted) PTHrP/PTH1R signal transduction that suppress proliferation. Thus, when sensitization of the paracrine PTHrP/PTH1R pathway occurs from prior exogenous ligand exposure (Fig. 26.3), the intracrine VSMC PTHrP signaling remains unchecked (Fig. 26.4). The spectrum of nucleoprotein complexes mediating nuclear PTHrP responses involves retinoblastoma-regulated E2F transcriptional pathways (Fiaschi-Taesch et al., 2004; MacLean et al., 2004) and p53 expression (Zhang et al., 2018), but is incompletely characterized.

Thus, strategies that selectively preserve the *paracrine* PTHrP/PTH1R pathway are predicted to exert cardiovascular benefits with respect to enhanced tissue perfusion, reduced arteriosclerotic calcification and vascular stiffness, and restricted neointimal proliferation; these actions, in sum, help to preserve arterial structure, cardiac pump functions, and tissue perfusion. Therefore, in addition to alterations in circulating calcium phosphate levels, the physiology of direct cardiovascular PTH1R signaling and actions deserves full consideration. This concept is very important to embrace as we seek to better define medical and surgical strategies to combat cardiovascular disease in the settings of primary HPT and CKD (Shroff, 2011). As briefly mentioned earlier, no clinically validated metric yet exists to monitor the healthy cardiovascular PTH1R signaling set point. This is all the more difficult since beneficial actions of paracrine PTHrP signaling will be influenced by endocrine PTH tone and circulating inhibitory fragments that accumulate with CKD (Friedman and Goodman, 2006). Moreover, as highlighted (Bilezikian et al., 2015), because variable posttranslational oxidation occurs at residues Met-8 and Met-18 of intact PTH that alters bioactivity, establishing these relationships in certain disease states (CKD, diabetes) may require implementation of an even newer generation of PTH assays (Hocher et al., 2012).

PTH2R signaling in vascular pharmacology

PTH and TIP39 are both agonists for the human PTH2R, while TIP39 is selective for PTH2R and PTHrP is selective for PTH1R activation (Hoare and Usdin, 2001). Compared with PTH1R, far less is known concerning PTH2R signaling and cardiovascular physiology and function. At this early stage of investigation, available data suggest that endogenous TIP39 actions relevant to cardiovascular physiology are likely to be mediated through the central nervous system (CNS). Functional TIP39 protein in peripheral tissues has yet to be unambiguously established; however, since mice transgenic for chondrocyte-specific expression of its cognate receptor PTH2R exhibit skeletal defects, the *TIP39* expression noted in the hypertrophic zone is likely to be functional (Panda et al., 2012). Strategies that rigorously probe *endogenous* TIP39/PTH2R signaling in cardiovascular biology have not yet been pursued. Most relevant studies have pursued pharmacological approaches. In the CNS, intracerebroventricular injection of TIP39 causes a fall in blood pressure in rats (Sugimura et al., 2003). Presynaptic augmentation of glutamatergic autonomic outflow in the hypothalamus (Dimitrov et al., 2011; Dobolyi et al., 2012) and/or arginine vasopressin release may also be important. Of interest, though, TIP39 mRNA has been detected in intrarenal arteries and aorta by RT-PCR (Eichinger et al., 2002).

The *pharmacological* actions of TIP39 administration have been implemented as a strategy to explore contributions of the peripheral PTH2R to cardiovascular physiology. Like the PTH1R, the PTH2R is expressed in endothelial cells, smooth muscle cells, and cardiomyocytes (Potthoff et al., 2011; Ross et al., 2005). Coronary artery flow reserve as modulated by TIP39/PTH2R signaling has been studied in the Langendorff-perfusion isolated rat heart model (Ross et al., 2007). TIP39 treatment exerted little activity in vessels precontracted with phenylephrine. Curiously, precontraction followed by pretreatment with the PTH1R-selective agonist PTHrP enabled vasodilatory response to subsequent TIP39/PTH2R activation (Ross et al., 2007). In vivo, prior cardiac ischemia provided sufficient stimulus for sustained release of endogenous PTHrP from the heart (Monego et al., 2009), and thus potentially enabled the subsequent vasodilatory response to PTH2R ligands. The mechanisms and kinetics of PTH1R−PTH2R cross talk have yet to be fully elucidated, and while TIP39 expression has been detected in the heart and coronary endothelium (Papasani et al., 2004; Ross et al., 2005), endogenous role and regulation therein are virtually unexplored. However, because inducible NOS activity was required for TIP39-mediated dilatation, the coronary endothelium is likely to participate in this complex pharmacology (Ross et al., 2007). Of note, TIP39/PTH2R signaling profoundly reduces the contractility of *isolated* cardiomyocytes in culture (Ross et al., 2005). Thus, as Ross et al. note (Ross et al., 2007), as a dual PTH1R/PTH2R agonist, in some settings human PTH could theoretically exhibit direct negative inotropic actions in vivo via the PTH2R— actions that are countermanded by NOS

release via PTH1R. However, this notion contrasts profoundly with in vivo cardiac PTHrP/PTH1R responses; inotropy is augmented with a net positive impact dependent upon endothelial NO release in vivo (Ogino et al., 1995; Schreckenberg et al., 2009). Nevertheless, it remains possible that PTH1R-selective agonists, compared with dual PTH1R/PTH2R agonists, may differ substantially in any putative cardiovascular actions in human subjects.

By deploying newly available murine genetic models in studies of skin biology, TIP39/PTH2R receptor signaling has been shown to support expression of type I collagen and the small proteoglycan decorin as necessary for robust wound healing in the skin (Sato et al., 2017). Since these very same extracellular matrix molecules are also vital to the integrity of large conduit vessels such as aorta (Faarvang et al., 2016; Farb et al., 2004), PTH2R signaling may potentially play a role in cardiovascular tissue matrix remodeling and repair.

In humans, the complex interplay between actions of PTH as an agonist for both PTH1R and PTH2R has yet to be integrated with the kinetics of PTH1R versus PTH2R desensitization (Bisello et al., 2004); this integration will be necessary to provide a unifying model with respect to the PK−PD for PTH1R signaling in cardiovascular health and disease (Thompson and Towler, 2012a). Since PTH binds to both human PTH1R and human PTH2R and can induce tachyphylaxis in PTH1R—and PTH1R downregulation enables cardiovascular PTH2R vasodilation (Ross et al., 2007)—the kinetics of impaired PTH1R versus PTH2R signaling in HPT will matter. Based upon the current data, HPT is predicted to inhibit coronary flow reserve (CFR; discussed later) as supported by either PTH1R or PTH2R, with loss in PTH1R tone exerting the greater impact. Furthermore, the potential relationships between central actions of TIP39 with respect to peripheral PTH/PTHrP biology have yet to be vetted in detail. It is important to note that centrally administered PTHrP (Yamamoto et al., 1998) and TIP39 (Sugimura et al., 2003) differentially regulate arginine vasopressin release (increased by the former, decreased by the latter), which is relevant to cardiovascular pressor/volume homeostasis. Moreover, in contradistinction to peripheral actions, central actions of PTHrP provide a pressor response that is dependent upon CNS-regulated sympathetic outflow (Nagao et al., 1998), while CNS administration of TIP39 reduces blood pressure (Sugimura et al., 2003). Thus, pharmacology targeting the PTH family of ligands must be cognizant that any peripherally administered compounds that cross the blood−brain barrier may exhibit mixed cardiovascular responses.

Parathyroid hormone, hyperparathyroidism, and calcific aortic valve disease

Another vascular structure affected by PTH signaling is the aortic valve (Iwata et al., 2012). As of this writing, the role of PTH/PTHrP signaling in cardiac valve physiology is very poorly understood. As mentioned, knockdown in zebrafish of either *pth1r* or *pthrp* = *pthlh* ligand impairs aortic valve morphogenesis, dependent upon downstream *notch* actions (Gray et al., 2013). In humans, calcific aortic valve disease (CAVD) is prevalent, afflicting approximately 2% of our population over age 60, with up to half of these possessing previously unappreciated bicuspid aortic valves (Yutzey et al., 2014). By age 75 or older, 15% of individuals will have moderate to severe calcific aortic stenosis. Intriguingly, *NOTCH1* mutations in humans convey valve malformations, CAVD, and Notch1 expression inhibits aortic valve interstitial cell calcification in culture (Acharya et al., 2011). For those with valve stenosis and symptoms, surgical intervention is required to mitigate the very high cardiovascular mortality observed in this setting. Several epidemiological studies indicate that primary HPT is associated with CAVD (Iwata et al., 2012; Linhartova et al., 2008; Stefenelli et al., 1997), and genetic variation in the *PTH* gene has been suggested to be a contributor (Gaudreault et al., 2011; Schmitz et al., 2009). Moreover, elevated PTH and hypertension are both risk factors associated with accelerated clinical progression of CAVD in patients with CKD (Iwata et al., 2013). Because the annulus of the heart valve is rich in chondrocytes and chondrocyte progenitors (Lincoln et al., 2006)—cellular targets of PTH1R signaling in the endochondral skeleton (Hirai et al., 2011; Kronenberg, 2006)—the aortic valve response to PTH1R signaling is likely to be quite complex, and in some instances more akin to the tissue response of endochondral bone (Yutzey et al., 2014). With advanced CAVD, true ectopic woven bone formation—replete with marrow elements and osteoclast-dependent bone remodeling—is observed in 13% of specimens (Fuery et al., 2018; Mohler et al., 2001). Medical therapies targeting cholesterol metabolism have failed to have a significant impact on CAVD (Rajamannan et al., 2011), potentially because oxidized phospholipids and lysophosphatidic acid carried by Lp(a) appear much more important (briefly reviewed in Towler, 2017b). Once valve mineralization is advanced, surgical or endovascular strategies for aortic valve replacement are required (Unger et al., 2016). Should surgical treatment of asymptomatic primary HPT (Yu et al., 2010) prove to mitigate risk for future development of clinically significant CAVD (Iwata et al., 2012) in at-risk individuals (e.g., bicuspid valve, high Lp(a) levels, sclerosis without calcinosis on echocardiography), this would (1) provide additional rationale for integrating cardiovascular phenotyping into indications for surgical treatment and (2) potentially alter the age-specific cutoff for recommending surgery (e.g., to age < 60 in lieu of < 50) (Bilezikian, 2018)

Impaired vascular PTH1R signaling and cardiovascular disease: the impact of hyperparathyroidism on cardiovascular mortality, coronary flow reserve, and vascular stiffness

Numerous observational studies have supported the relationship between primary HPT and cardiovascular disease (Walker and Silverberg, 2008). However, one large study of 2.99 million person-years of follow-up in 5735 patients with mild primary HPT presents a clinically compelling epidemiological data set for this pathophysiological relationship (Yu et al., 2010). This study is called PEARS, the Parathyroid Epidemiology and Audits Research Study. PEARS is a retrospective, population-based outcomes study that investigated patients diagnosed with mild primary HPT in Tayside, Scotland, between 1997 and 2006 (Yu et al., 2010). In the 1683 subjects identified with mild primary HPT (2/3rd female), age- and gender-correlated cardiovascular mortality was increased 2.7-fold (Yu et al., 2010). Baseline PTH levels, not calcium, predict long-term outcomes in untreated primary HPT (Yu et al., 2013). The HEALTH ABC cohort, focused on individuals in Memphis and Pittsburgh, confirmed increases in cardiovascular mortality with elevated PTH; elevation conveyed a 1.8-fold increased risk, independent of serum calcium and 25-hydroxyvitamin D levels (Kritchevsky et al., 2012). As discussed before, preclinical models evaluating PTH/PTHrP actions have long indicated the role of the cardiovascular system as a physiologically relevant target, with mechanisms relevant to disease biology rapidly emerging from genetically and pharmacologically manipulated animals (Cheng et al., 2010, 2016; Qian et al., 2003; Raison et al., 2013). However, it is the physiological studies of human subjects that have confirmed and extended these observations in important ways that are likely to alter our recommendations for treatment of HPT in otherwise "asymptomatic" patients (Silverberg et al., 2009).

Macrovascular compliance and conduit functions, known as Windkessel physiology (Safar and Boudier, 2005; Westerhof et al., 2009), are impaired by HPT (Briet et al., 2012; Rubin et al., 2005; Walker et al., 2009). With every heartbeat, part of the energy of each systolic pulse is stored as potential energy within the rubbery elasticity of conduit vessels via systole-induced circumferential stretching of large arteries (Westerhof et al., 2009). During diastole, this energy is released to provide smooth perfusion of the coronary arteries, myocardium, and distal tissues (Thompson and Towler, 2012a). Moreover, with arterial stiffening, retrograde pulse wave reflections arising at vessel branch points travel faster; rather than supporting early diastole, these omnipresent reflections now sum with the orthograde pulse waves of late systole to increase systolic blood pressure (Safar and Boudier, 2005; Soldatos et al., 2011; Westerhof et al., 2009). Thus, with arterial stiffening, not only does perfusion during diastole become more erratically pulsatile, but the workload placed upon the heart increases due to systolic hypertension. Silverberg, Bilezikian, and colleagues established that arterial stiffening is increased in patients with mild HPT. Using the augmentation index (AIx), a measure of the retrograde wave reflection that characterizes vascular stiffening, they uncovered a positive linear relationship between PTH and AIx after adjusting for heart rate, height, gender, blood pressure, age, diabetes mellitus, smoking, and hyperlipidemia (Rubin et al., 2005). Smith and colleagues reported similar responses in their smaller patient cohort (Smith et al., 2000). Importantly, in patients with preexisting cardiovascular abnormalities, parathyroidectomy improves indices of cardiovascular/carotid stiffness (Walker et al., 2012), indicating reversibility. Of note, Prisby and colleagues noted a protective action of intermittent PTH administration on endothelial NOS expression and conduit vessel endothelial function with aging marrow in rodents (Lee et al., 2018). While not studied in great detail, a few small longitudinal studies of primary HPT patients pre− and post−curative parathyroidectomy have shown that the circadian, pulsatile nature of diurnal PTH secretion is normalized as well (Lobaugh et al., 1989).

CFR is a physiological index of epicardial conduit function. CFR assesses not only the significance of any coronary stenosis present, but also the presence of downstream microvascular dysfunction (Bianco and Alpert, 1997). When myocardial oxygen demand downstream of a conduit artery segment cannot be met by vasodilation, CFR is deemed to be compromised (Bianco and Alpert, 1997). Importantly, reduced CFR portends adverse cardiovascular outcomes in men and women (Cortigiani et al., 2012; Pepine et al., 2010). CFR was initially evaluated by angiography following intracoronary administration of vasodilators coupled with Doppler imaging (Pepine et al., 2010); however, transthoracic Doppler echocardiography (Cortigiani et al., 2012) has now been implemented, with peripheral adenosine vasodilator administration, as a mechanism for noninvasively assessing CFR (Caiati et al., 1999; Montisci et al., 2006).

In 2012, Osto and colleagues performed a highly important, longitudinal analysis of CFR in 100 primary HPT patients with solitary adenomas. These patients were studied before and after adenoma resection, comparing CFR results in that population to 50 gender- and age-matched controls (Osto et al., 2012). In this landmark study, they established that PTH, age, and heart rate were the only major variables altering CFR— and that CFR changes with HPT were independent of serum calcium. Moreover, in the 27 primary HPT patients with clearly abnormal CFR ($\leq$2.5 following adenosine

infusion), all of these individuals exhibited normal CFR (>2.5) following curative adenoma resection (Osto et al., 2012). Deploying an independent method for CFR measurement—viz., nuclear perfusion imaging—Marini and colleagues also demonstrated improvement of CFR in primary HPT undergoing surgical treatment (Marini et al., 2010). In a clinically important way, these two studies confirmed and extended the previous work of Kosch et al. (Kosch et al., 2000); they had shown that brachial artery flow-mediated vasodilation, an index of endothelial function and NOS activation, is impaired in primary HPT but reversed following surgical treatment (Kosch et al., 2000). The impaired flow-mediated dilation in patients with primary HPT undergoing medical observation has only recently been confirmed by others (Colak et al., 2017). Thus, primary HPT is consistently associated with reversible alterations in coronary and peripheral artery endothelial function that improve following surgical intervention. The improvements in CFR following surgery for HPT have significant implications as the risks versus benefits of parathyroidectomy in otherwise asymptomatic HPT are considered.

Chronic kidney disease–mineral and bone disorder: the metabolic "perfect storm" of cardiovascular risk

CKD is a highly significant cardiovascular risk factor, synergizing with diabetes to increase morbidity and mortality at least 5- to 10-fold (Chang et al., 2013; Debella et al., 2011). While cholesterol-lowering therapies have an impact, reducing nonfatal cardiovascular events by ca. 20% in predialysis CKD, no significant reduction in cardiovascular mortality has been achieved with this strategy in CKD patients on dialysis (Baigent et al., 2011; Baigent and Landry, 2003). This appears to be in large part due to the contributions of perturbed calcium phosphate metabolism to cardiovascular risk (Block et al., 2013) and the bone-derived hormone FGF23 (Moe et al., 2015). Indeed, the CKD–mineral and bone disorder designation was created as an imperfect mechanism meant to capture the implications of this clinical setting (Kidney Disease: Improving Global Outcomes, 2009; Moe et al., 2007).

In the setting of CKD, serum phosphate exerts a stepwise increase in cardiovascular mortality (Eddington et al., 2010). Vascular toxicity is mediated in part via arterial calcification (Shao et al., 2010), and cardiovascular mortality tracks the presence and extent of vascular mineralization (Blacher et al., 2001; London, 2003; London et al., 2003). Phosphate-dependent activation of sodium phosphate cotransporter signaling in VSMCs drives osteogenic mineralization programs (Liu et al., 2013) and proapoptotic responses that perturb mineralizing matrix vesicle clearance, thus augmenting vascular calcium load (Shroff et al., 2008, 2010, 2013). However, at every level of renal function, serum phosphate is a cardiovascular risk factor (Tonelli et al., 2005, 2009) and PTH is a key defense against hyperphosphatemia (Martin and Gonzalez, 2011). PTH directly induces renal phosphate excretion when renal function is intact, recruits osteoblast-derived FGF23 to assist in these phosphaturic actions, and maintains bone formation even in the setting of CKD—a state of variable skeletal resistance to PTH (London et al., 2004; Martin et al., 2012; Quarles, 2013). Thus, actions of PTH play an important role along with FGF23 in mitigating phosphate-dependent vascular toxicity when renal function is intact and normal bone turnover is maintained (London et al., 2004; Martin et al., 2012; Quarles, 2013). Extremes of bone turnover—too high or too low—are likely to negatively influence serum phosphate homeostasis in the setting of CKD (Barreto et al., 2008; Goodman, 2004; London et al., 2004). This may in part explain the bimodal relationship between PTH levels and mortality in dialysis patients (Durup et al., 2012). However, the specific relationship between bone formation (potentially functioning as a "buffer" mitigating vascular phosphate toxicity), changes in PTH tone with declining renal function, and maintaining healthy norms of serum phosphate homeostasis with respect to vascular physiology has not yet been established (Block et al., 2013; Maeda et al., 2007).

Gerard London and colleagues have provided the most important insights into the relationship between PTH, arterial calcification, and bone formation in the setting of CKD (London et al., 2004). Implementing an ultrasound-based method for scoring calcification in the common carotid arteries, the abdominal aorta, the iliofemoral axis, and the lower extremities, his group related the extent of arterial calcification with dynamic histomorphometric assessment of cellular bone functions to circulating PTH. In this important study, they established that patients with the lowest levels of PTH (with or without prior parathyroid surgery) exhibited low-turnover bone disease and the most extensive vascular calcification (London et al., 2004). The relationship between low PTH values and increased coronary artery calcification was subsequently confirmed by others (Kim et al., 2011). Interestingly, similar observations were made by Chertow and colleagues upon comparison of the relationships between bone mineral density, vascular calcium load, and PTH levels in patients treated with calcium-based phosphate binders versus sevelamer (does not contain calcium) (Raggi et al., 2005). Suppression of PTH levels in those subjects given calcium-based binders was associated with lower bone mass and increased vascular calcium load.

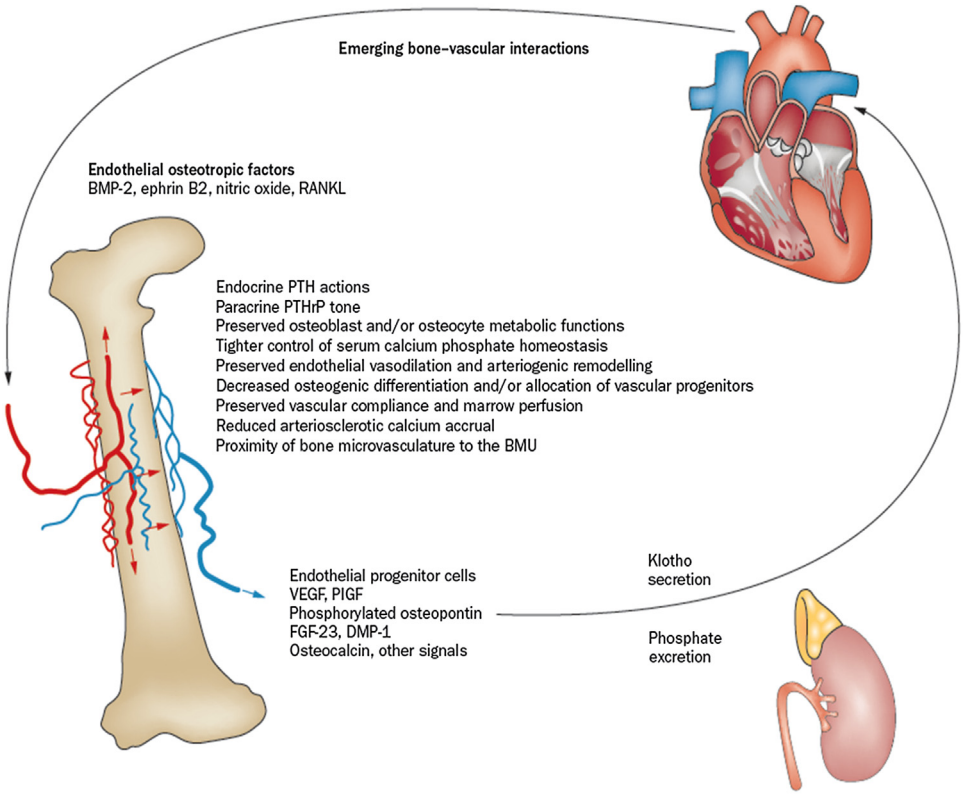

FIGURE 26.7 An emerging bone–vascular axis is connected by calcium, phosphate, hormonal, and cellular signals in cardiovascular health and disease. The skeleton is a parathyroid hormone (*PTH*) receptor 1 (PTH1R)-regulated source/repository of hormones, electrolytes, and cellular elements that profoundly influence cardiovascular health. The kidney plays a pivotal role in modulating this axis by mediating phosphate excretion and by providing additional hormonal relays. The vasculature is also a direct target of PTH actions via both PTH1R and PTH2R in humans. Perturbation of this axis creates the chronic kidney disease–mineral and bone disorder. *BMP-2*, bone morphogenetic protein; *BMU*, basic multicellular unit; *DMP-1*, dentin matrix protein 1; *FGF-23*, fibroblast growth factor 23; *PlGF*, placental growth factor; *PTHrP*, PTH-related protein; *RANKL*, receptor activator of NF-κB ligand; *VEGF*, vascular endothelial growth factor. *See text for details, reprinted with permission from Thompson, B., Towler, D.A. 2012a. Arterial calcification and bone physiology: role of the bone-vascular axis. Nat. Rev. Endocrinol.*

Basal PTH tone most likely exerts beneficial actions via maintenance of bone formation (London et al., 2004). As discussed (Demer and Tintut, 2010; Fadini et al., 2012; Thompson and Towler, 2012a; Zoppellaro et al., 2012), it has become increasingly clear that skeletal maintenance of hematopoiesis, regulation of calcium phosphate exchange, and skeletal production of phosphaturic hormones such as FGF23 play important roles in vascular health (Fig. 26.7; see also discussion of EVOLVE results later). Surgery is the standard of care for severe primary and severe secondary/tertiary HPT (Silverberg et al., 2009). However, surgery is not the first-line approach to the vast majority of patients with significant secondary HPT in CKD because of the clinical need to "titrate" PTH levels to maintain bone formation (London et al., 2004). In the setting of uremia, circulating fragments of PTH and uremic toxins give rise to a skeletal resistance to PTH (Friedman and Goodman, 2006). Based on dynamic histomorphometry performed in patients with CKD5 and on dialysis, PTH levels between 150 and 300 pg/mL were associated with maintenance of normal bone turnover in this setting. However, similar analyses have not been performed in CKD patients prior to the initiation of renal replacement therapy. Moreover, the specific PTH assay used to establish this treatment goal is no longer available, calling into question how one coregisters these prior guidelines with current-generation PTH assays. Hence, current KDIGO (Kidney Disease Improving Global Outcomes) guidelines recommend levels of PTH between two and nine times the upper limit of normal in any given assay, although not strictly coregistered with skeletal or cardiovascular indices of health (London et al., 2010).

Nevertheless, striving to achieve this skeletally defined set point also appears to improve cardiovascular disease risk; and the cardiovascular benefits of pharmacological management of HPT were first established in the setting of CKD5 on dialysis. Treatment with injectable calcitriol or paricalcitol to maintain PTH levels to approximately two to four times the upper limit of normal reduces cardiovascular mortality (Teng et al., 2003, 2005) and points once again to the importance of calciotropic hormones as key modulators of cardiovascular disease in this setting. This biology and pharmacology is likely

to be relevant to improving the care of the many aging individuals with CKD3 or worse who do not require renal replacement therapy (30 million individuals estimated in the United States alone). The Systolic Blood Pressure Intervention Trial (SPRINT) noted that predialysis patients with CKD3 or worse and high PTH levels accrued less cardiovascular benefit from intensive blood pressure therapy (Ginsberg et al., 2018). It will be important to determine if normalizing PTH levels in CKD3/CKD4 with novel oral extended-release formulations of calcifediol (Sprague et al., 2017) will restore the cardiovascular benefits of intensive blood pressure control (Ginsberg et al., 2018).

As a type II calcium-sensing receptor mimetic with a short half-life, cinacalcet successfully reduces circulating PTH levels and enables facile titration to goal. Cinacalcet is very effective in treating primary and secondary HPT, but its actions on cardiovascular and fracture risks are still emerging (Verheyen et al., 2013). A meta-analysis of four studies suggested reductions in both hip fracture and cardiovascular hospitalization rates with cinacalcet (Cunningham et al., 2005). In EVOLVE (Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events), a prospective study to treat secondary HPT in dialysis patients with CKD5, cinacalcet failed to achieve significant reductions in cardiovascular mortality ($P = .11$) in the unadjusted intention-to-treat analysis (Investigators et al., 2012). However, in a second prespecified analysis, older patients on hemodialysis with moderate to severe secondary HPT did accrue cardiovascular benefit with cinacalcet-mediated reductions in PTH (Parfrey et al., 2015). The milieu of CKD5 and dialysis represents a metabolic "perfect storm" for cardiovascular disease; in this setting, secondary HPT is but one important contributor that must be addressed (Towler, 2013). Moving forward, the multifactorial high-risk metabolic and genetic milieu of CKD must be prospectively embraced as strategies targeting PTH biology are evaluated for mitigating cardiovascular risk. Recall that PTH controls FGF23 release from the osteocyte (Rhee et al., 2011). Upon stratification of secondary reductions in FGF23 also achievable by cinacalcet dosing (64% vs. 28% placebo), the EVOLVE trial was able to demonstrate reduced cardiovascular mortality in those patients that exhibited a 30% or greater reduction in FGF23 (Moe et al., 2015). The improvement was achieved via reductions in nonatherosclerotic cardiovascular events, and mechanisms segregating responders from nonresponders have yet to be determined, but may reflect unknown features of the PTH-regulated bone−vascular axis (Fig. 26.7).

Of note, the relationship between bone turnover, PTH, and vascular risk may not hold with respect to the calciphylaxis syndrome, aka calcific uremic arteriolopathy (Shao et al., 2010). This distinct clinical entity involves fibroproliferative calcification of smaller-diameter arterioles in dermal adipose, lung, and mesentery. It is seen most frequently in obese diabetic patients with CKD on warfarin anticoagulation and can be associated with severe HPT (Matsuoka et al., 2005; Rogers et al., 2007). The pathobiology of this important and lethal entity is still poorly understood (Nigwekar et al., 2015).

PTH/PTHrP signaling and the bone−vascular axis

As Scadden, Kronenberg, and colleagues have established, the PTH1R controls the size of the bone marrow hematopoietic niche via its osteotropic actions (Adams et al., 2007; Calvi et al., 2003). This is a critically important concept to consider particularly in the setting of CKD−MBD; circulating hematopoietic progenitors and endothelial progenitor cells derived from the bone marrow niche contribute to both healthy and pathological injury responses in distant venues (Eghbali-Fatourechi et al., 2005, 2007; Fadini et al., 2012). Cognizant of this, Zaruba et al. (Brunner et al., 2008; Zaruba et al., 2008) and Napoli and colleagues (Napoli et al., 2008) examined the impact of PTH(1−34) in models of myocardial and critical limb ischemia, respectively. Zaruba demonstrated that survival following occlusion of the left anterior descending artery in mice was increased from 40% to 60% by postischemia dosing with PTH(1−34). While the relative contributions of vasodilation, angiogenesis, and apoptosis were not examined, survival tracked PTH(1−34)-induced increases in myocardial VEGF expression, neovascularization, and $CD31^+$ and $CD34^+/CD45^+$ cell populations (Zaruba et al., 2008). Border zone cardiomyocyte apoptosis was reduced, with concomitant improvement in cardiac output. Using unilateral femoral artery ligation to model critical limb ischemia, Napoli et al. demonstrated that preligation dosing with PTH(1−34) followed by postischemic granulocyte colony-stimulating factor mobilization of marrow progenitors simultaneously increased limb blood flow and viability and $CD34^+$ stem cell recruitment to and capillary density in ischemic limb skeletal muscle (Napoli et al., 2008).

Thus, an emerging bone−vascular axis has been proposed wherein circulating progenitor cells dependent upon PTH1R bioactivity can favorably influence cardiovascular health (Fig. 26.7). Since circulating endothelial progenitor cell subtypes are differentially altered in patients with peripheral arterial disease, coronary syndromes, or diabetes (Flammer et al., 2012a, 2012b, endothelial progenitor cell quality and character will be extremely important to consider (Gossl et al., 2010). Whether this axis can be productively harnessed with PTH/PTHrP signaling to have an impact on cardiovascular disease burden in humans remains to be explored.

PTH1R activation and the renin–angiotensin–aldosterone axis: a feed-forward vicious cycle

As mentioned before, the relationships between HPT and hypertension are well appreciated (Tomaschitz et al., 2012). In otherwise healthy adults, while singular administration lowers blood pressure, sustained PTH administration over a period of 12 days actually increases blood pressure in humans (Hulter et al., 1986). In addition to the aforementioned PTH1R desensitization mechanisms (Nyby et al., 1995) that impair paracrine PTHrP-mediated vasorelaxation (Maeda et al., 1999; Raison et al., 2013), PTH may have direct effects on aldosterone biosynthesis (Tomaschitz et al., 2012). However, PTH1R-dependent signals in the juxtaglomerular apparatus also support renin production (Saussine et al., 1993a, 1993b). Following surgery for HPT, renin and aldosterone levels fall (Kovacs et al., 1998), albeit with variable improvements in blood pressure and cardiac hypertrophy (Agarwal et al., 2013; Broulik et al., 2011; Ishay et al., 2011; Kovacs et al., 1998; Persson et al., 2011; Vazquez-Diaz et al., 2009). Conversely, it has become clear that angiotensin II augments circulating PTH levels in part via aldosterone/mineralocorticoid receptor signaling pathways in humans (Brown et al., 2013). Thus, a "feed-forward" vicious cycle may exist between dysregulated PTH and the renin–angiotensin–aldosterone (RAA) axis that promotes cardiovascular disease arising from the metabolic derangements of aging, declining renal function, and HPT (Tomaschitz et al., 2013). Of note, the risk for CAVD progression in the Japanese Aortic Stenosis Study tracked with absence of angiotensin receptor blocker therapy in early-stage disease (Yamamoto et al., 2010). While PTH levels were not assessed, it is intriguing to speculate that modulating both arms of the prosclerotic PTH–RAA cycle might help mitigate CAVD risk with aging and uremia (Rajamannan et al., 2011). This potential relationship has yet to be tested in either preclinical or clinical research settings. The use of RAA inhibitors does indeed reduce PTH levels in humans (Brown et al., 2015).

Summary, conclusions, and future directions

The cardiovascular actions of PTH have been known for almost a century (Collip and Clark, 1925). However, the clinical and pharmacological implications of altered PTH/PTHrP signaling with respect to cardiovascular endocrinology have been underappreciated except in the settings of extreme excess with severe hypercalcemia or calciphylaxis. In addition to mild primary HPT, secondary HPT associated with advancing age and/or declining renal function is increasingly prevalent. In addition to the uremic milieu of CKD (Friedman and Goodman, 2006), dyslipidemia also induces a state of PTH/PTHrP resistance (Li et al., 2014; Sage et al., 2011). As such, perturbations in PTH/PTHrP physiology are emerging as one of the most prevalent endocrinopathies affecting human health and health care today. Heart disease remains the No. 1 cause of mortality worldwide and is a growing burden (Gaziano et al., 2006). Given the contributions of PTH/PTHrP signaling in cardiovascular health and disease—and the prevalence of perturbed PTH endocrine physiology—it remains stunning that so very little is known about the fundamentals of PTH/PTHrP biology within the vasculature. The specific protein–protein interactions and signaling cascades conveying PTH1R/PTH2R actions in VSMCs, endothelial cells, and interstitial/adventitial cell populations need to be defined for each relevant vascular bed. Coronary, renal, and iliofemoral vessels may represent the most clinically relevant with respect to cardiovascular and metabolic bone diseases. The mechanisms controlling paracrine PTHrP bioactivities have yet to be identified and fully integrated with the mechanical and neuroendocrine cues that together coordinate tissue perfusion. Most importantly, tissue-specific biomarkers and functional imaging methods are required to quantify cardiovascular PTH/PTHrP actions as a first step toward establishing the healthy set point for signaling tone and dynamics. Because posttranslational modifications and dysmetabolic states induce PTH/PTHrP resistance in the very settings where this biology becomes most clinically significant (Demer and Tintut, 2010; Thompson and Towler, 2012a), titration to a single circulating PTH value range will probably prove to be inadequate. Moreover, whereas surgery is a standard of care in primary HPT that yields reductions in hip fracture risk, renal disease, and hypercalcemic crises (Silverberg et al., 2009; VanderWalde et al., 2006), the impact of parathyroid surgery on cardiovascular morbidity has yet to be firmly established for mild or asymptomatic disease. However, beneficial changes with curative surgery in important cardiovascular parameters, such as vascular stiffness (Walker et al., 2012) and CFR (Osto et al., 2012), are truly compelling. It remains unclear whether surgical and pharmacological interventions for treatment of HPT are functionally equivalent with respect to cardiovascular outcomes. As occurred during the history of the cholesterol controversy, discovery and implementation of clearly effective pharmacotherapy will be important (Steinberg, 2006). Clearly, detailed examination of cardiovascular physiology as regulated by the PTH superfamily will continue to yield important new insights, and will be necessary to devise novel therapeutic strategies that better treat our patients afflicted with cardiometabolic and mineral metabolism disorders.

Chapter 27

Parathyroid hormone and parathyroid hormone–related protein actions on bone and kidney

Alessandro Bisello and Peter A. Friedman

Department of Pharmacology and Chemical Biology, Laboratory for GPCR Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA, United States

Chapter outline

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00027-0

Introduction

Bone and kidney form a mineral-ion storage depot and regulatory axis that assures normal skeletal growth and development. Parathyroid hormone−related protein (PTHrP) is a major hormonal regulator of bone formation, while PTH (parathyroid hormone) contributes to postnatal skeletal integrity and extracellular mineral-ion homeostasis. PTHrP effects on the kidney are associated with controlling vascular tone, whereas PTH regulates phosphate and calcium absorption and the biosynthesis of vitamin D. Despite these distinct actions and tissue effects, PTH and the type I PTH/PTHrP receptor (PTHR) operate through a single canonical PTH/PTHrP receptor. This chapter reviews both well-accepted and recent advances in our understanding of PTH and PTHrP actions and considers controversial and unsettled elements of their effects.

Receptors and second-messenger systems for parathyroid hormone and parathyroid hormone−related protein

Most PTH and PTHrP effects in bone are mediated by the PTHR (Abou-Samra et al., 1992; Juppner et al., 1991). This family B G-protein-coupled receptor (GPCR) recognizes PTH and PTHrP as well as their biologically active N-terminal peptides PTH(1−34) and (1−36) and PTHrP(1−36). The PTHR binds PTH and PTHrP with equal affinity (although some differences in the affinity for G-protein-coupled and uncoupled states have been reported (Dean et al., 2008)), and in response, ligand binding signals through various cellular effector systems. Signal transduction by the PTHR is primarily mediated by G_s, $G_{q/11}$, G_i, and G_{12}/G_{13} heterotrimeric G proteins (Gardella and Vilardaga, 2015) (see alsoChapters 24, 25, and 28). The particular coupling mechanism for distinct G proteins depends on the cell type in a manner that remains incompletely understood (Abou-Samra et al., 1992; Civitelli et al., 1989, 1990; Juppner et al., 1991; Pines et al., 1996). Studies of the PDZ adapter protein Na^+/H^+ exchange-regulatory factor 1 (NHERF1) revealed that it serves as a switch to control signaling by G_s, $G_{q/11}$, and G_i (Mahon et al., 2002; Wang et al., 2010).

Important effects of the PTHR on mitogen-activated protein kinases (MAPKs), especially the extracellular signaling-related kinases (ERKs) ERK1 and ERK2, have been described (Cole, 1999; Miao et al., 2001; Sneddon et al., 2000, 2007; Swarthout et al., 2001; Syme et al., 2005). The mechanisms of activation of MAPK signaling by the PTHR are complex and involve Src. This nonreceptor tyrosine kinase interacts with the PTHR and its activity contributes to PTH-mediated ERK activation (Rey et al., 2006). In addition, ERK activation may arise from EGFR transactivation (Syme et al., 2005). Polyubiquitination of specific lysine residues in the C-terminal tail of the PTHR also regulates MAPK signaling, specifically activation of ERK1/2 and p38 (Zhang et al., 2018).

More recently, a newer paradigm of PTHR signaling via Gs/cAMP has emerged that differentiates the signaling activities of PTH and PTHrP (and related analogs) (Cheloha et al., 2015). Studies in cell systems show that in response to PTHrP, the PTHR at the cell membrane generates short-lived cAMP signals. PTH also elicits membrane signals via Gs. However, PTH also stimulates the recruitment of β-arrestins by the PTHR followed by its internalization in endosomes. Here, the PTHR assembles a functional complex with β-arrestin and Gs to produce sustained cAMP signaling (Ferrandon et al., 2009). In endosomes, β-arrestin promotes cAMP signaling, contrary to its typical function at the cell membrane, which terminates cAMP signaling. This action involves stimulation of ERK1/2 leading to inhibition of phosphodiesterases, in particular PDE4, and diminished cAMP degradation (Wehbi et al., 2013). Subsequent studies in animals show that this temporally discrete pattern of signaling by PTH and PTHrP results in markedly distinct calcemic responses (Shimizu et al., 2016). Thus, the induction of hypercalcemia by PTHrP is significantly lower than that elicited by PTH. These observations are consistent with studies in humans showing that PTHrP and its modified analog abaloparatide elicit significantly less hypercalcemia than does PTH (Horwitz et al., 2005, 2006; Leder et al., 2015).

The magnitude of physiological responses mediated by the PTHR is tightly linked to the balance between signal generation and termination. The receptor normally behaves in a cyclical pattern of activation and inactivation, where PTHR desensitization guards cells against excessive stimulation, and resensitization protects cells against prolonged hormone resistance. Rapid attenuation of PTHR signaling is mediated by receptor desensitization and internalization, while protracted reductions in responsiveness are due to downregulation and diminished receptor biosynthesis. Desensitization and internalization of the PTHR, as with other G-protein-coupled receptors, is generally thought to be regulated primarily by phosphorylation and arrestins. Ligand binding to the PTHR promotes receptor phosphorylation both by G protein receptor kinases (GRKs) and by two second-messenger-dependent protein kinases, protein kinase A (PKA) and protein kinase C (PKC) (Blind et al., 1996; Dicker et al., 1999; Flannery and Spurney, 2001). GRK2, and to a lesser extent by PKC, mediates phosphorylation of serine residues in the PTHR (Castro et al., 2002; Dicker et al., 1999; Malecz et al., 1998). GRK2 preferentially phosphorylates the distal sites of the intracellular PTHR tail, whereas PKC phosphorylates more

upstream residues (Blind et al., 1996). Mice harboring a phosphorylation-resistant PTHR, where serine residues at positions 489, 491, 492, 493, 495, 501, and 504 were mutated to alanine, exhibit essentially normal anabolic responses (Datta et al., 2012), suggesting that PTHR phosphorylation does not importantly affect PTHR internalization or bone anabolism.

Following activation, the PTHR rapidly recruits β-arrestins at the plasma membrane, an event that initiates dynamin-dependent endocytosis. Interestingly, PTHR phosphorylation is not required for the interaction of the receptor with β-arrestins or for receptor internalization (Dicker et al., 1999; Ferrari et al., 1999; Malecz et al., 1998; Sneddon et al., 2003). However, receptor phosphorylation may stabilize the receptor–arrestin complex. As described previously, although the interaction with β-arrestins dampens acute cAMP generation at the plasma membrane, the PTHR, in complex with β-arrestins, remains active in endosomes and induces prolonged cAMP signaling. Although the PTHR lacks a canonical NPXXY internalization motif, other endocytotic signals have been identified within the carboxy terminus. Detailed analysis of the intracellular tail of the PTHR revealed bipartite sequences that negatively or positively regulate receptor endocytosis (Huang et al., 1995). An endocytic signal was detected within residues 475–494 of the opossum kidney PTHR (corresponding to D482-S501 of the human PTHR). Mutations or deletions within this region result in diminished PTH-induced receptor endocytosis (Huang et al., 1995).

In addition to governing PTHR signaling, NHERF1 is importantly involved in determining receptor endocytosis. The interaction of NHERF1 with the PTHR is disrupted by mutating its carboxy-terminal PDZ-binding motif; mutating NHERF1; or depolymerizing the actin cytoskeleton, all of which cause important alterations in PTHR endocytosis (Sneddon et al., 2003). Notably, in the absence of NHERF1, both PTH(1–34) and PTH(7–34) (along with their corresponding full-length peptides) promoted efficient PTHR sequestration. In the presence of NHERF1, however, PTH(1–34)-induced receptor internalization was unaffected, whereas PTH(7–34)-initiated endocytosis was largely inhibited (Sneddon et al., 2003). NHERF1 contains two tandem PDZ domains and an ezrin-binding domain (EBD). PDZ core-binding domains and the NHERF1 EBD domain are required for the inhibition of endocytosis (Wang et al., 2007a).

Expression and actions of parathyroid hormone receptor in bone

The PTHR is expressed widely in cells of the osteoblast lineage. Receptor expression is greater in more differentiated cells such as mature osteoblasts on the trabecular, endosteal, and periosteal surfaces (Fermor and Skerry, 1995; Lee et al., 1993) and osteocytes (Fermor and Skerry, 1995; van der Plas et al., 1994). PTHRs are also expressed in marrow stromal cells near the bone surface (Amizuka et al., 1996), a putatively preosteoblast cell population shown to bind radiolabeled PTH (Rouleau et al., 1988, 1990). However, PTHR is virtually absent in STRO-1–positive alkaline phosphatase-negative marrow stromal cells (Gronthos et al., 1999; Stewart et al., 1999), which are thought to represent relatively early osteoblast precursors. Indeed, PTHR expression can be induced by the differentiation of stromal cells, MC3T3 cells, or C3H10T1/2 cells with dexamethasone, ascorbic acid, or bone morphogenetic proteins (Feuerbach et al., 1997; Hicok et al., 1998; Liang et al., 1999; Stewart et al., 1999; Wang et al., 1999; Yamaguchi et al., 1987). Other data suggest that PTH receptors are limited to a relatively mature population of osteoprogenitor cells that express the osteocalcin gene (Bos et al., 1996).

Whether receptors for PTH or PTHrP are expressed on the osteoclast is controversial. Initial studies using receptor autoradiography failed to demonstrate them (Rouleau et al., 1990; Silve et al., 1982), and other studies have not identified PTHR mRNA or protein on mature osteoclasts (Amizuka et al., 1996; Lee et al., 1993, 1995). However, PTHRs are reportedly present on normal human osteoclasts (Dempster et al., 2005) and osteoclasts from patients with renal failure (Langub et al., 2001). Also, relatively low-affinity binding of radiolabeled PTH peptides to osteoclasts or preosteoclasts has been reported (Teti et al., 1991). The functional importance of such putative receptors is unclear.

PTH and PTHrP have additional receptors besides the PTHR. The PTH2R, which recognizes the amino terminal domain of PTH but not of PTHrP, is a GPCR closely related to the PTHR (Usdin et al., 1995) (Chapter 28). The endogenous ligand for the PTH2R is likely to be tuberoinfundibular peptide of 39 amino acids (TIP39). The PTH2R and TIP39 are expressed predominantly in brain, vasculature, and pancreas (Dobolyi et al., 2003; Eichinger et al., 2002; Usdin et al., 1996, 1999). TIP39 and PTH2R are expressed in distinct areas of the growth plate of newborn mice. Whereas the PTH2R localizes to the resting zone, TIP39 is restricted to prehypertrophic and hypertrophic chondrocytes. In chondrocytes, the TIP39/PTH2R system inhibits proliferation and differentiation (Panda et al., 2009). These findings were expanded to postnatal mice with chondrocyte-specific expression of the PTH2R (Panda et al., 2012). Targeted PTH2R expression in chondrocytes resulted in delayed formation of the secondary ossification center and reduced trabecular bone. Consistent with the finding in cell systems, these mice have attenuated expression of numerous markers of chondrocyte proliferation and differentiation including Sox9, Gdf5, Wdr5, and β-catenin.

A large body of evidence exists for the presence of specific receptor(s) for carboxyl-terminal PTH peptides on osteoblasts (Divieti et al., 2005; Inomata et al., 1995; Nguyen-Yamamoto et al., 2001) and osteocytes (Divieti et al., 2001), and evidence for actions of carboxyl-terminal PTH peptides on bone has been presented (Murray et al., 1989, 1991; Nakamoto et al., 1993; Sutherland et al., 1994). Such a carboxyl-terminal PTHR has thus far eluded molecular cloning.

PTHrP is expressed and secreted by osteoblast-like osteosarcoma cells (Rodan et al., 1989; Suda et al., 1996) and by rat long-bone explants in vitro (Bergmann et al., 1990). Messenger RNA for PTHrP is detected in periosteal cells of fetal rat bones (Karmali et al., 1992). *In situ* hybridization and immunohistochemistry localized PTHrP mRNA and protein to mature osteoblasts on the bone surface of fetal and adult bones from mice and rats (Amizuka et al., 1996; Lee et al., 1995) and to flattened bone-lining cells and some superficial osteocytes (Amizuka et al., 1996) in postnatal mice. In addition, the PTHrP gene is expressed in preosteoblast cells in culture, and in some studies its expression is reduced as preosteoblasts undergo differentiation (Kartsogiannis et al., 1997; Oyajobi et al., 1999; Suda et al., 1996).

As discussed in Chapter 25, PTHrP is cleaved to produce a set of peptides: those that contain the amino terminus (such as PTHrP(1−36)) activate the PTHR, and additional peptides representing the midregion and carboxyl terminus of PTHrP appear to have distinct biological actions mediated by their own receptors (Philbrick et al., 1996; Wysolmerski and Stewart, 1998). Receptors that are specific for amino-terminal PTHrP and do not recognize PTH have been identified in brain (Yamamoto et al., 1997) and other tissues (Gaich et al., 1993; Orloff et al., 1992; Valin et al., 2001), and midregion peptides of PTHrP have actions on placental calcium transport that imply a distinct receptor (Care et al., 1990; Kovacs et al., 1996), but there is presently no evidence for either receptor in bone. Carboxyl-terminal PTHrP fragments [e.g., PTHrP(107−139)] reportedly inhibit bone resorption (Cornish et al., 1997; Fenton et al., 1991a, 1991b, 1993) and stimulate (Goltzman and Mitchell, 1985) or inhibit (Martinez et al., 1997) osteoblast growth and function (Esbrit et al., 2000; Gray et al., 1999), and it is thus likely that a specific receptor for this peptide is present on osteoblasts and conceivably also on osteoclasts.

Effects of parathyroid hormone and parathyroid hormone−related protein on bone cells

Molecular mechanisms of action in osteoblasts

Transcription factors

A major effect of PTH and PTHrP in osteoblasts is directed at modulating the expression and/or function of a number of transcription factors important in bone metabolism. Among these, the most prominent are the cAMP response element binding protein (CREB) (Brindle and Montminy, 1992; Papavassiliou, 1994), the immediate early gene of activator protein-1 (AP-1) family members *c-fos* (c-fos, fra-1, fra-2) and *c-jun* (c-jun, junD) (Clohisy et al., 1992; Lee et al., 1994; McCauley et al., 1997, 2001; Stanislaus et al., 2000a), and Runx2 (Komori, 2002).

PTH induces *c-fos* transcription in a fashion that does not require protein synthesis and is mediated by the transcription factor CREB. Binding and phosphorylation of CREB to cAMP responsive elements within the *c-fos* promoter (Evans et al., 1996; Pearman et al., 1996; Tyson et al., 1999) are required to activate transcription. These events are stimulated by PTH through its ability to activate PKA, whereas the PKC signaling pathway is not involved in this response (Evans et al., 1996; McCauley et al., 1997). Activation of AP-1 transcription factors is important for osteoblast function because the *collagenase-3* (MMP-13) promoter contains AP-1 binding sites (Pendas et al., 1997; Selvamurugan et al., 1998).

One member of the runt-domain transcription factor family, viz. Runx2 (also called cbfa1 and OSF2), is a specific osteoblast transcriptional activator and is required for determination of the osteoblast phenotype (Ducy et al., 1997; Komori, 2002). Runx2 stimulates transcription of a number of key osteoblastic genes such as osteocalcin, osteopontin, collagenase-3, and collagens α1 and α2 (Banerjee et al., 2001; Porte et al., 1999; Selvamurugan et al., 1998). The importance of Runx2 for osteoblast formation and bone metabolism has been established with in vitro and in vivo models (Ducy et al., 1997, 1999; Komori et al., 1997; Otto et al., 1997). Brief PTH treatment stimulates rapid and transient increases of Runx2 mRNA and protein both in osteoblastic cell cultures and in mice (Krishnan et al., 2003). In addition, PTH, likely via cAMP/PKA activation, stimulates Runx2 activity (Selvamurugan et al., 2000; Winchester et al., 2000). In contrast, long-term treatment with PTH reduces Runx2 levels (Bellido et al., 2003). The dual effect of PTH on Runx2 levels and activity is particularly interesting. As will be discussed later, PTH promotes osteoblast survival in part by increasing Runx2 activity and consequently inducing expression of the survival gene *Bcl2*. However, PTH also induces proteasomal degradation of Runx2 through a mechanism involving Smurf2. Therefore, the ability of PTH to either increase or decrease Runx2 levels in osteoblasts in a fashion dependent on the administration schedule may provide one of the possible (and likely many) mechanisms to explain the complex effect of PTH on bone formation and resorption.

Osterix is a zinc finger domain transcription factor expressed specifically in osteoblasts (Nakashima et al., 2002). Its function is necessary for full osteoblastic differentiation and maturation (Nakashima et al., 2002), and studies in cells (Nishio et al., 2006) and genetically modified mice (Nakashima et al., 2002) have established that osterix lies downstream of Runx2. Similar to Runx2, PTH rapidly stimulates expression of osterix both in cell cultures (Wang et al., 2006) and in vivo (Tanaka et al., 2004).

Finally, PTH injection stimulates rapid and transient increases in the expression of at least three members of the nerve growth factor-inducible factor B (NR4A/NGFI-B) family of orphan nuclear receptors: Nurr1, Nur77, and NOR-1 (Pirih et al., 2005). Nurr1 mediates PTH-stimulated activation of the *osteopontin* (Lammi et al., 2004) and *osteocalcin* (Nervina et al., 2006; Pirih et al., 2004) promoters.

Clearly, PTH has profound effects on gene expression during bone remodeling. The complexity of this regulation is further illustrated by studies showing that PTH induces epigenetic modifications via histone deacetylating enzymes (HDACs). These epigenetic events profoundly impact PTH-mediated regulation of important genes including MMP13, Runx2, RANKL, and sclerostin. In osteoblastic cells, PTH signaling induces PKA-dependent phosphorylation of HDAC4 that in turn regulates expression of MMP13 via Runx2 (Shimizu et al., 2014). In contrast, in calvarial cells PTH elicits polyubiquitylation and degradation of HDAC4, an event that promotes RANKL (Obri et al., 2014). Further understanding of the complex mechanisms by which PTH regulates HDACs comes from studies in osteocytes (Wein et al., 2016, 2017). In these cells, the salt-inducible kinases (SIKs) maintain HDAC4/5 phosphorylated and outside the nucleus. Activation of the PTHR induces PKA-mediated phosphorylation of SIK2, which inhibits its activity. This causes nuclear translocation of HDAC4/5, inhibition of sclerostin transcription, and bone formation. By a similar mechanism, PTH controls the localization of the cAMP-regulated transcriptional coactivators CRTC2. When dephosphorylated, CRTC2 translocates to the nucleus, where it potentiates CREB-dependent transcription of RANKL, thus inducing bone resorption. Collectively, these observations highlight the critical contribution of epigenetic modification to the dual actions of PTH on bone formation and resorption.

The HDAC Sirt1 inhibits PTH-induced MMP13 transcription (Fei et al., 2015) in osteoblastic cells. Other studies show that PTH induces nuclear translocation of HDAC5 with attendant reduction in sclerostin expression, whereas HDAC2 and HDAC3 appear to induce constitutive *SOST* transcription in osteoblastic cells (Baertschi et al., 2014).

Growth factors and cytokines

Insulin-like growth factors. PTH stimulates synthesis and secretion of insulin-like growth factors (IGFs) IGF-I and IGF-II in bone. IGF-I and IGF-II are expressed in the rat (McCarthy et al., 1989) and mouse (Linkhart and Mohan, 1989; Watson et al., 1995). A PTH-dependent increase of IGF requires activation of the cAMP/PKA pathway because its effects are mimicked by cAMP analogs or agents that increase cAMP but not by stimulation of calcium signals or PKC (McCarthy et al., 1990).

IGF-I exerts proliferative and antiapoptotic actions in osteoblasts (Gray et al., 2003), and a number of observations support the requirement of IGF-I as a mediator of the anabolic action of PTH. First, treatment with PTH under conditions where it has an anabolic effect on bone leads to an increase in IGF-I mRNA (Watson et al., 1995) and the bone matrix content of IGF-I. Second, daily PTH injection failed to stimulate bone formation in mice lacking IGF-I (Bikle et al., 2002). Third, a similar absence of an anabolic effect of PTH was observed in mice lacking insulin receptor substrate-1 (Yamaguchi et al., 2005), the key intracellular mediator of IGF-I receptor signaling.

Additionally, both PTH and PTHrP affect the secretion in bone of IGF-binding proteins (IGFBPs), in particular IGFBP-4 (LaTour et al., 1990) and IGFBP-5 (Conover et al., 1993). The role of IGFBPs on IGF function is complex, since they can exert both inhibitory (IGFBP-4) and stimulatory (IGFBP-5) effects on IGF action in a cell- and context-specific manner. Moreover, some IGFBPs have been proposed to have effects independent of IGF (Conover, 2008). Thus, the role of IGFBPs on PTH action remains mostly to be defined.

Fibroblast growth factor-2 (FGF-2). Like IGF-I, FGF-2 is a potent mitogen (Ling et al., 2006), induces differentiation (Woei Ng et al., 2007), and exerts antiapoptotic actions on osteoblasts (Chaudhary and Hruska, 2001; Debiais et al., 2004). PTH rapidly increases FGF-2 and FGF receptor expression in both primary and clonal osteoblastic cells (Hurley et al., 1999). Stimulation of bone formation by PTH is impaired in mice null for FGF-2 (Hurley et al., 2006), and bone marrow cultures from these mice produce fewer osteoclasts in response to PTH (Okada et al., 2003). Collectively, these observations provide evidence that FGF-2 participates in the skeletal actions of PTH in vivo.

Amphiregulin. Recent studies demonstrated an important role for amphiregulin (AR), a member of the epidermal growth factor (EGF) family, as a mediator of PTH action. PTH stimulates AR expression in osteoblastic cells in a cAMP/PKA-dependent manner (Qin and Partridge, 2005). The increase in AR mRNA is mediated by phosphorylation of CREB and binding to a conserved CRE site in the AR promoter. AR appears to be important for bone metabolism because mice

lacking AR have decreased trabecular bone (Qin et al., 2005b). In addition, AR stimulates rapid increases in *c-fos* and *c-jun* expression (Qin et al., 2005b). Treatment of primary calvarial cultures in vitro with AR stimulated cell proliferation and concomitant inhibition of osteoblastic differentiation, suggesting a role for AR on preosteoblastic mesenchymal stem cells (Qin and Partridge, 2005; Qin et al., 2005b). It is also notable that PTH stimulates the release of heparin-bound EGF, which belongs to the same family of membrane-bound and releasable EGF receptor agonists as AR, by activation of ADAM proteins in osteoblasts (Ahmed et al., 2003). This process leads to the activation of EGF receptor in an autocrine and paracrine fashion. It is therefore likely that PTH may induce not only the expression of AR in osteoblasts but also its release via a similar mechanism.

Transforming growth factor-β. All three TGF-β isoforms are detected in bone, with TGF-β1 being the most abundant (Hering et al., 2001; Seyedin et al., 1985). TGF-β1 is secreted by bone cells and stored in the extracellular matrix. TGF-β is a potent mitogen for osteoprogenitors (Hock et al., 1990) and has varied effects on differentiation and mineralization. Intermittent PTH treatment of rats increases the bone matrix content of TGF-β1 (Pfeilschifter et al., 1995; Watson et al., 1995) and the expression of TGF-β in osteoblasts (Oursler et al., 1991; Pfeilschifter and Mundy, 1987; Wu and Kumar, 2000). Moreover, PTH and PTHrP increase the secretion of TGF-β by osteoblast-like bone cells (Wu and Kumar, 2000), TGF-β1 activity (Pfeilschifter and Mundy, 1987; Sowa et al., 2003) and the release of TGF-β from bone matrix. Collectively, these observations suggest that TGF-β may contribute to the anabolic effects of intermittent PTH administration.

RANK ligand and osteoprotegerin. The regulation of these molecules by PTH and PTHrP is now recognized as the most prominent mechanism linking PTHR-mediated actions in osteoblasts (and possibly stromal cells) and osteoclastogenesis. RANK ligand (RANKL)[1] is a member of the TNF family of cytokines that is expressed on the osteoblast and stromal cell surface. Its receptor, called receptor activator of NFkB (RANK), is expressed in osteoclast precursors and mature osteoclasts, and its activation by RANKL stimulates osteoclast formation, activity, and survival (Burgess et al., 1999; Fuller et al., 1998; Hofbauer et al., 2000; Lacey et al., 1998). A second component of this system, expressed and secreted by osteoblasts, is osteoprotegerin (OPG) (Simonet et al., 1997; Yasuda et al., 1998), a released protein that binds and sequesters RANKL, preventing its actions on RANK. Therefore, it is the balance between RANKL and OPG (in other words the ratio RANKL:OPG) that ultimately determines the extent of osteoclast formation and function.

PTH and PTHrP regulate the expression of RANKL and OPG. It is interesting to note that the frequency of administration of PTH affects the RANKL:OPG ratio differently. Thus, prolonged exposure to PTH in rats causes sustained stimulation of RANKL expression while inhibiting OPG expression (Huang et al., 2004; Kondo et al., 2002; Lee and Lorenzo, 1999; Ma et al., 2001), with the final effect being an overall stimulation of osteoclast number and resorptive capacity. In contrast, intermittent PTH treatment affected RANKL and OPG only transiently (Ma et al., 2001). Exposure to PTH increases the expression of RANKL in murine bone marrow cultures, cultured osteoblasts, and mouse calvariae (Hofbauer et al., 2000; Lee and Lorenzo, 1999; Tsukii et al., 1998) as well as simultaneously decreasing the expression of OPG (Lee and Lorenzo, 1999). In addition, studies using primary cultures indicate that the effect of PTH on RANKL expression is more pronounced in differentiated osteoblasts, whereas the inhibition of OPG occurs at all differentiation stages (Huang et al., 2004). Notably, the stimulation of osteoclastic differentiation by RANKL requires the presence of macrophage-colony stimulating factor M-CSF, which is also upregulated by PTH (Horowitz et al., 1989; Weir et al., 1989).

Strong evidence supports the key role of the RANK/RANKL/OPG system in the activation of bone resorption upon prolonged exposure to PTH and PTHrP. Stimulation of osteoclastogenesis by PTH is blocked by antibodies to RANKL (Tsukii et al., 1998) or by OPG (Lacey et al., 1998; Yasuda et al., 1998), and OPG inhibits the hypercalcemic response to PTH and PTHrP (Morony et al., 1999; Oyajobi et al., 2001).

Wnt/β-catenin/sclerostin. The Wnt/β-catenin signaling pathway is recognized as an important regulator of bone mass. This is a complex signaling system comprising a number of members. Canonical Wnt signaling is mediated by a receptor complex formed by a Frizzled (a seven-transmembrane domain GPCR) and a lipoprotein-receptor-related protein 5 or 6 (LRP5/6) coreceptor. Upon engagement by Wnt, this complex activates the cytoplasmic protein disheveled (Dvl) followed by the accumulation of unphosphorylated β-catenin. As a result, β-catenin translocates to the nucleus and regulates gene transcription. Moreover, cells secrete proteins such as Dickkopf-1 that interact with the coreceptors LRP5/6 and inhibit Wnt signaling (Baron and Rawadi, 2007). All the key elements of this pathway are expressed in bone cells and osteoblastic cultures and regulated by PTH (Kulkarni et al., 2005). Treatment of rats with PTH increased Frizzled-1 and β-catenin levels and decreased DKK-1, with resulting activation of Wnt responses (Kulkarni et al., 2005). Sclerostin, the product of the *Sost* gene, is also a secreted Wnt inhibitor that binds LRP5 and LRP6 (Li et al., 2005; Semenov et al., 2005), and its

1. RANKL is also called osteoprotegerin ligand (OPGL), osteoclast differentiation factor (ODF), and TNF-related activation-induced cytokine (TRANCE).

level in osteocytes is dramatically reduced by continuous PTH treatment (Bellido, 2006; Bellido et al., 2005). It is interesting that sclerostin appears to inhibit osteoblast differentiation (van Bezooijen et al., 2004, 2007), thereby providing a functional link between osteocytes and osteoblasts. The profound effects of the Wnt signaling complex on bone metabolism are well described by a number of genetic studies in both human and animal models (Baron and Rawadi, 2007), and the observation that PTH engages this pathway in bone cells is indeed of great interest.

Adaptor proteins

G-protein-coupled receptor kinase 2 and β-arrestins. These two ubiquitously expressed proteins play important roles in the regulation of several G-protein-coupled receptors including the PTHR. It is not surprising that alterations in their expression or activity impact the function of osteoblasts and their responsiveness to PTH. G-protein-coupled receptor kinase 2 (GRK2) phosphorylates agonist-occupied PTHR and promotes the binding of β-arrestins (Dicker et al., 1999; Ferrari et al., 1999; Flannery and Spurney, 2001; Vilardaga et al., 2001). These combined actions result in decreased signaling at the cell membrane (Bisello et al., 2002; Dicker et al., 1999; Ferrari and Bisello, 2001). As mentioned earlier, prolonged PTHR signaling in endosomes is promoted by β-arrestins through the inhibition of PDE4 and reduction in cAMP degradation (Gardella, Vilardaga) (Cheloha et al., 2015).

Targeted overexpression of GRK2 in osteoblasts promotes bone loss (Wang et al., 2005a). In contrast, inhibition of GRK2 activity by expression of a dominant negative mutant increases PTH-stimulated cAMP, and mice overexpressing Grk2 have increased bone remodeling with a net gain in bone content (Spurney et al., 2002). Similarly, intermittent PTH increased the number of osteoblasts in mice null for β-arrestin2 (Ferrari et al., 2005). However, no net increase in bone mass was observed, likely due to the intense stimulation of osteoclastogenesis. Another regulator of G-protein-coupled receptor signaling, the regulator of G protein signaling-2 (RGS2), which increases the rate of hydrolysis of GTP bound to G proteins, thereby terminating signaling, has also been implicated in PTHR actions on bone cells. RGS2 mRNA is rapidly and transiently increased by PTH in rat bones as well as osteoblast cultures (Miles et al., 2000b), and its expression in bone cells resulted in decreased PTH-stimulated cAMP production (Thirunavukkarasu et al., 2002). Interestingly, RGS2 upregulation was also observed in cells overexpressing Runx2 (Thirunavukkarasu et al., 2002), suggesting the possibility that mechanisms limiting PTHR signaling by G proteins may be activated upon differentiation of cells along the osteoblastic lineage.

Na^+/H^+ exchange-regulatory factor 1 (NHERF1). NHERF1 is a PDZ-domain scaffolding protein that interacts with the PTHR and regulates various functions including preferential G-protein coupling, membrane retention, and trafficking. Little information exists concerning the role of NHERF1 in regulating the PTH-mediated effect in bone cells. NHERF1 is expressed in active mineralizing osteoblasts, where it regulates PTHR expression during differentiation (Liu et al., 2012). Indeed, when cultured in differentiating medium, mesenchymal stem cells from NHERF1$^{-/-}$ mice show a dramatic reduction in PTHR mRNA accompanied by preferential differentiation to adipocyte. NHERF1 is required for osteoblast differentiation and matrix synthesis, but whether this is directly due to alterations in PTHR signaling is yet unknown. NHERF1-null mice and humans with NHERF1 polymorphisms display osteopenia and increased skeletal fractures (Karim et al., 2008; Morales et al., 2004; Shenolikar et al., 2002). Proliferating osteoblasts express Npt2a and Npt2b, PTHR, and NHERF1 (Wang et al., 2013). In cells from wild-type mice, PTH inhibits phosphate uptake, but this effect was not observed in cells from NHERF1$^{-/-}$ mice. In contrast, PTH increases phosphate uptake in differentiated osteoblasts, and this effect depends on NHERF1 expression.

Effects on gap junctions

PTH increases intercellular communication of bone cells by increasing connexin-43 gene expression (Schiller et al., 1992) and opening gap junctions (Donahue et al., 1995; Schiller et al., 1992). The reduction of connexin-43 levels by transfection of antisense cDNA markedly inhibited the cAMP response to PTH (Vander Molen et al., 1996) and blocked the effect of PTH on mineralization by osteoblast-like cells (Schiller et al., 2001). These effects appear to significantly impair the anabolic action of PTH because increases in bone mineral content in response to intermittent PTH administration were significantly decreased in mice with targeted deletion of connexin43 in osteoblasts (Chung et al., 2006).

Effects on bone matrix proteins and alkaline phosphatase

PTH regulates the expression of a number of bone matrix proteins including type I collagen, osteocalcin, osteopontin, bone sialoprotein, osteonectin, and alkaline phosphatase. In most cases, these genes (with the exception of osteocalcin) are

downregulated by continuous exposure to PTH (Wang et al., 2005b), whereas intermittent administration of PTH has inhibitory and stimulatory effects on different genes.

Type I collagen is the most abundant bone matrix protein. PTH and PTHrP acutely inhibit collagen synthesis in vitro (Kream et al., 1980, 1986; Partridge et al., 1989; Pines et al., 1990). Similar inhibition is observed upon infusion of PTH in humans (Simon et al., 1988). However, anabolic PTH treatment can stimulate type I collagen expression (Canalis et al., 1990; Opas et al., 2000), an effect that is likely mediated by increases in IGF-I (Canalis et al., 1989). Intermittent treatment of mouse bone marrow cells with PTH modestly increased collagen expression (Locklin et al., 2003). Similarly, PTH treatment inhibits osteopontin (Noda et al., 1988) and osteonectin (Termine et al., 1981) expression.

The osteocalcin gene is also importantly regulated by PTH (Noda et al., 1988; Towler and Rodan, 1995; Yu and Chandrasekhar, 1997). However, in contrast to the effect on type I collagen, expression of osteocalcin is stimulated by chronic administration of PTH or PTHrP, whereas the acute effect of these hormones is inhibitory (Gundberg et al., 1995).

Finally, the effect of PTH on the expression of bone sialoprotein can be either stimulatory (Ogata et al., 2000; Yang and Gerstenfeld, 1997) or inhibitory (Ma et al., 2001; Wang et al., 2000).

The reported actions of PTH on the expression of alkaline phosphatase are inconsistent. PTH can either stimulate or inhibit secretion of alkaline phosphatase from bone cells (Jongen et al., 1993; Kano et al., 1994; Majeska and Rodan, 1982; McPartlin et al., 1978; Yee, 1985) and may not be particularly indicative of PTH-specific actions. Indeed, although anabolic therapy with PTH generally increases the circulating levels of alkaline phosphatase (Finkelstein et al., 1998), this effect is likely due to an increase in osteoblast number rather than an increase in protein expression.

Effects on bone proteases

PTH stimulates the secretion of a number of matrix metalloproteases (MMPs) in bone cells (see Chapter 16) that are involved in bone remodeling. These include collagenase-3 (MMP-13) (Partridge et al., 1987; Quinn et al., 1990; Scott et al., 1992; Winchester et al., 1999, 2000), stromelysin-1 (Meikle et al., 1992), gelatinase B (Meikle et al., 1992), and the disintegrin and metalloprotease with thrombospondin repeats (Miles et al., 2000a). Bone proteases, in particular collagenase-3 and gelatinase B, partially mediate the stimulation of bone resorption by PTH (Witty et al., 1996). As described above, stimulation of the MMP-13 promoter by PTH requires the combined action of AP-1 transcription factors and Runx2, effects that are mediated by cAMP-dependent activation of CREB (Porte et al., 1999; Selvamurugan et al., 1998, 2000). All of these events are stimulated by PTH. PTH treatment also increases secretion of the tissue inhibitor of matrix metalloproteins (TIMP-1) by osteoblasts (Meikle et al., 1992). This is relevant to the action of PTH because mice overexpressing TIMP-1 in osteoblasts responded to intermittent PTH with increases in bone mineral density higher than those in normal mice (Merciris et al., 2007). This was also accompanied by decreased osteoclastic differentiation (Geoffroy et al., 2004; Merciris et al., 2007).

Effects of parathyroid hormone and parathyroid hormone–related protein on bone cell proliferation

Continuous exposure to relatively high concentrations of PTH(1–34) or PTHrP(1–34) inhibits proliferation of virtually every osteoblastic cell line including UMR 106–01, MC3T3-E1, SaOS-2, and calvarial primary cultures (Civitelli et al., 1990; Kano et al., 1991; Onishi et al., 1997; Qin et al., 2005a). This effect is mediated by changes in the expression levels of several components of the cell cycle, ultimately resulting in arresting cells in the G1 phase. PTH treatment decreases expression of cyclin D1 while increasing the levels of $p21^{Cip1}$ and $p27^{Kipl}$ (Onishi et al., 1997; Qin et al., 2005a), with evident cell cycle arrest.

In contrast, some in vitro studies demonstrated that in certain circumstances PTH stimulates the proliferation of osteoblastic cells (Finkelman et al., 1992; Onishi et al., 1997; Somjen et al., 1990). In particular, very low concentrations of PTH (Swarthout et al., 2001) and brief exposure to PTH (Scutt et al., 1994) resulted in increased cell proliferation. In the preosteoblast cell line TE-85, PTH stimulated proliferation by increasing expression of the cyclin-dependent kinase cdc2 (Onishi et al., 1997).

The effects of PTH and PTHrP on the cell cycle in osteoblastic cells have important consequences in vivo. Several studies indicate that intermittent injections of PTH increase the number of osteoblasts (Kostenuik et al., 1999; Nishida et al., 1994), and this contributes to the stimulation of bone formation. However, this effect does not appear to be related to direct stimulation of osteoblast mitogenesis. Indeed, although intermittent PTH administration in rats greatly increased osteoblast number and function, osteoblast proliferation was not detected (Dobnig and Turner, 1995; Onyia et al., 1995, 1997). It is possible that the increase in osteoblast number produced by intermittent treatment with PTH is due to the

activation of bone-lining cells to osteoblasts (Dobnig and Turner, 1995), a process that does not require mitosis. These findings are compatible with the conclusion that PTH inhibits cell cycle progression of committed osteoprogenitors, thereby permitting their maturation.

Effects of parathyroid hormone and parathyroid hormone–related protein on bone cell differentiation

PTH and PTHrP profoundly influence the differentiation program of bone marrow cells to form osteoblasts (Fig. 27.1). Several studies indicate that anabolic administration of PTH stimulates rapid changes in histomorphometry and gene expression, which have been interpreted as resulting from cell differentiation (Hodsman and Steer, 1993; Onyia et al., 1995). The effects of PTH and PTHrP on cell differentiation in culture are also well documented and appear to depend on both the duration and the frequency of PTH exposure. Early, transient PTH treatment enhances the commitment of progenitor cells and increases osteoblast differentiation (Wang et al., 2007b). In vitro, primary osteoblasts briefly (1 h every 48 h) exposed to PTH showed inhibited expression of alkaline phosphatase activity and bone nodule formation (Ishizuya et al., 1997). In contrast, intermittent PTH treatment for 6 h every 2 days stimulated osteoblastic differentiation and formation of mineralized nodules (Ishizuya et al., 1997). Similarly, transient PTH treatment of calvarial osteoblasts inhibited initial osteoblast differentiation but ultimately resulted in increased mineralized nodules and osteoblastic differentiation (Wang et al., 2007b). In cultured murine marrow cells, intermittent PTH treatment increases the expression of osteoblast differentiation markers (such as Runx2, alkaline phosphatase, and type I collagen) (Locklin et al., 2003). In all cases, however, continuous exposure to PTH strongly inhibits osteoblast differentiation (Ishizuya et al., 1997; Wang et al., 2007b). In this respect, it is interesting to note that in humoral hypercalcemia of malignancy (HHM), PTHrP is continuously secreted by tumors and results in the virtual absence of mature osteoblasts (Stewart et al., 1982). In contrast, elevated PTH levels observed in hyperparathyroidism do not have the same effect: indeed, hyperparathyroidism is characterized by increased bone remodeling (i.e., higher formation and resorption) with complex effects on bone (Bilezikian, 2012) (Chapter 54). Although the mechanisms of this difference remain to be fully elucidated, one possible underlying basis is the pulsatile secretion of PTH by the parathyroids in hyperparathyroidism versus the continuous, unregulated secretion of PTHrP in HHM.

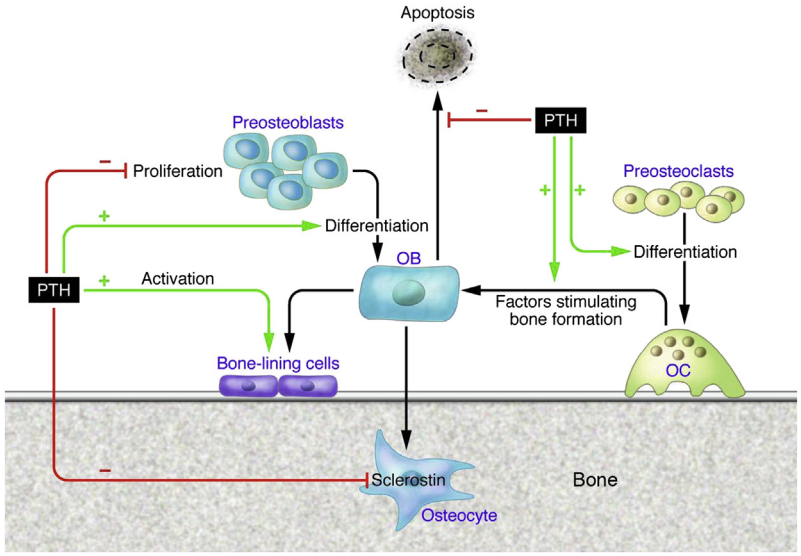

FIGURE 27.1 Cellular effects of PTH on bone. *Bone resorption*. PTH stimulates differentiation and activation of osteoclasts by increasing RANKL and possibly decreasing OPG production by stromal cells and osteoblasts. *Bone formation*. PTH decreases proliferation of preosteoblasts and stimulates their differentiation. PTH decreases osteoblast apoptosis and can activate bone-lining cells into functioning osteoblasts. These combined actions result in increased numbers of osteoblast. Moreover, PTH suppresses the production of the Wnt inhibitor sclerostin by osteocytes, thereby increasing β-catenin signaling in osteoblasts. *From Khosla, S., Westendorf, J.J., Oursler, M.J. 2008. Building bone to reverse osteoporosis and repair fractures. J. Clin. Investig. 118, 421–428.*

Effects of parathyroid hormone and parathyroid hormone–related protein on bone cells

Survival

Cell culture studies show that PTH rapidly stimulates transcription of the prosurvival gene *Bcl-2* while increasing the inactivation of the apoptotic protein Bad (Bellido et al., 2003; Jilka et al., 1998), suggesting that activation of the PTHR in osteoblasts may inhibit apoptosis. Indeed, various studies showed that PTH reduces the apoptotic effects of etoposide, dexamethasone, and serum deprivation in osteoblastic cultures (Bellido et al., 2003; Chen et al., 2002; Jilka et al., 1998). The effect of PTH on the expression of survival proteins appears to require the action of CREB and Runx2 (Bellido et al., 2003). Considering the disparate effects of PTH on Runx2 stability discussed previously, it is therefore possible that the timing and frequency of PTH stimulation may be key determinants for its prosurvival action. Thus, although some studies in mice demonstrated a significant decrease in apoptotic osteoblasts following daily PTH administration (Bellido et al., 2003; Jilka et al., 1999), a study in rats reported an actual increase in apoptotic osteoblasts by intermittent PTH (Stanislaus et al., 2000b). An additional complexity results from the observation that daily administration of PTH in post-menopausal women resulted in increased osteoblast apoptosis (Lindsay et al., 2007). Finally, it should be noted that differences have been observed in the effect of PTH on osteoblast apoptosis at different skeletal sites (cortical and trabecular) and possibly between primary and secondary spongiosa (Jilka et al., 1999; Stanislaus et al., 2000b).

Effects of parathyroid hormone and parathyroid hormone–related protein on bone

Bone resorption

Cellular basis of parathyroid hormone action

PTH and PTHrP increase bone resorption by stimulating osteoclastogenesis and activating the mature osteoclast. These effects require the participation of classical PTH target cells including stromal cells and osteoblasts (Akatsu et al., 1989; McSheehy and Chambers, 1986). Moreover, as described earlier, osteoclasts seemingly do not express high-affinity PTHR (Amizuka et al., 1996; Rouleau et al., 1990; Silve et al., 1982). The identification of the central role of the RANK/RANKL system in osteoclast formation and function, and the appreciation that PTH and PTHrP affect the expression of RANKL and OPG in stromal cells and osteoblasts, provide a molecular basis for understanding PTH-stimulated bone resorption. The precise target cell in the osteoblast lineage responsible for mediating the bone-resorbing effects of PTH and PTHrP, if any, has not been identified, but various marrow stromal cell lines suffice in vitro (Aubin and Bonnelye, 2000), and bone resorption is still active when mature osteoblasts have been ablated (Corral et al., 1998). By binding to its cognate receptor, RANK, on osteoclast precursors and mature osteoclasts, RANKL stimulates osteoclastogenesis and the activity of mature osteoclasts. Therefore, increased RANKL expression mediated the acute and chronic actions of PTH on bone resorption. The major difference in the two effects is likely related to the stronger suppression of the decoy receptor OPG upon prolonged exposure to PTH (Huang et al., 2004). Osteoclast activation by RANKL is apparently responsible for bone resorption at the cellular level and for hypercalcemia, as both are blocked by the decoy receptor OPG (Morony et al., 1999; Yamamoto et al., 1998).

The bone-resorbing effects of amino-terminal PTH and PTHrP are essentially indistinguishable when studied using isolated osteoclasts (Evely et al., 1991; Murrills et al., 1990), bone explant systems (Raisz et al., 1990; Yates et al., 1988), or infusion into the intact animal (Kitazawa et al., 1991; Thompson et al., 1988). In contrast, PTHrP is considerably less potent than PTH in inducing hypercalcemia in humans (Horwitz et al., 2006). This difference is most likely due to lower induction of renal $1.25(OH)_2D_3$ by PTHrP compared with PTH (Horwitz et al., 2003b), though recent findings regarding the persistent noncanonical signaling of cAMP by PTH but not PTHrP described earlier provide a compelling alternative explanation (Cheloha et al., 2015; Ferrandon et al., 2009). Notably, studies in humans showed that intermittent administration of PTHrP(1–36) over 3 months stimulated bone formation without attendant increases in markers of bone resorption (Horwitz et al., 2003b).

As discussed in Chapter 3, PTHrP is a polyhormone, the precursor of multiple biologically active peptides. Carboxy-terminal peptides predicted to arise from cleavage of PTHrP in the polybasic region PTHrP(102–106) have been synthesized and shown to inhibit bone resorption in several explant systems (Fenton et al., 1991a, 1993) and in vivo (Cornish et al., 1997). On this basis, the minimal peptide that inhibits bone resorption, PTHrP(107–111), has been identified and called osteostatin.

Effects of parathyroid hormone and parathyroid hormone–related protein on bone

Bone formation

The mechanisms by which PTH increases bone formation are complex. As described before, PTH and PTHrP exert a variety of effects on osteoblasts. The increase in bone formation in response to intermittent administration of PTH and PTHrP correlates with marked increases in the number of active osteoblasts (Boyce et al., 1996; Dempster et al., 1999; Shen et al., 1993).

It is evident from the previous discussion that every aspect of the osteoblast existence is affected by PTH, and all of these cellular actions may contribute to the increase in osteoblast number observed in the stimulation of bone formation. First, activation of the PTHR produces various actions on the cell cycle of osteoblasts and their precursors. It is clear that in most circumstances PTH and PTHrP cause cell cycle arrest in osteoblasts and preosteoblasts, and this may be a prerequisite to induce further differentiation and activation. Most in vivo evidence does not support a direct proliferative effect of PTH on mature osteoblasts (Dobnig and Turner, 1995; Onyia et al., 1995, 1997). However, PTH and PTHrP increase the expression and release of a number of potent mitogens including IGF-I, TGFβ, and amphiregulin, which may act in a paracrine fashion to expand the pool of osteoprogenitors (Gray et al., 2003; Hock et al., 1990; Qin and Partridge, 2005). Second, intermittent PTH administration stimulates transcription factors, such as Runx2 and osterix, which in turn stimulate differentiation. This effect is accompanied by increases in osteoblastic differentiation markers (Hodsman and Steer, 1993; Onyia et al., 1995; Wang et al., 2007b). Third, some rapid histomorphometric changes observed upon anabolic administration of PTH may derive from stimulation of bone-lining cells to become active osteoblasts (Dobnig and Turner, 1995). Fourth, intermittent PTH administration exerts antiapoptotic actions in osteoblasts and osteocytes (Bellido et al., 2003; Jilka et al., 1999). Obviously, prolonging the life span of osteoblasts would enhance the number of mature osteoblasts. It is interesting that Runx2, a key molecule mediating PTH effects on osteoblast survival, is also involved in the stimulation of osteoblastic differentiation.

The relative contribution of each of these mechanisms to the anabolic action of PTH has not been completely established. It seems likely that the remarkable increases of bone formation in response to intermittent administration of PTH and PTHrP arise from a combination of these effects. Moreover, it is possible that PTH and PTHrP may not have the same effect under all circumstances and in the presence of other treatments affecting bone metabolism.

Finally, it has long been thought that the anabolic actions of PTH and PTHrP are substantially equivalent because most of their cellular effects in vitro and activities in animal models are quite similar. However, it has recently become apparent that some basic differences exist in the action of these two hormones in humans. Intermittent administration of PTHrP(1–36) for 2 weeks (Plotkin et al., 1998) and 3 months (Horwitz et al., 2003a), for instance, leads to increases in biochemical markers of bone formation without changing markers of bone resorption, suggesting that PTHrP(1–36) may uncouple bone formation and resorption.

Parathyroid hormone actions on kidney

PTH regulates renal tubular absorption of phosphate and calcium and synthesis of $1.25(OH)_2D_3$, thereby controlling plasma levels and urinary excretion of these mineral ions and vitamin D (calcitriol) Fig. 27.2). Renal tubular responses to PTH deficiency, PTH or PTHrP excess, and defects in function of the PTHR lead to alterations in blood calcium, phosphate, or vitamin D that are the hallmarks of numerous clinical disorders described later in this volume. Here we review the mechanisms of PTH and PTHrP control of renal tubular calcium and phosphate absorption. The narrative focuses principally on PTH because distinct or unique PTHrP actions on tubular ion transport are not well delineated despite their displaying distinct signaling dynamics (Ferrandon et al., 2009). Because the amino termini of both ligands are similarly recognized by the PTHR, it is likely that PTHrP shares the effects of PTH, though the differences in signaling noted and described earlier may translate to different patterns of dynamic actions. Expression and specific renal actions of PTHrP are associated with regulation of renovascular hemodynamics and may have important effects on hypertension or preeclampsia (Massfelder et al., 1998; Massfelder and Helwig, 1999; Yadav et al., 2014).

Although biologically important, serum magnesium levels do not appear to be significantly regulated by PTH and PTHrP and therefore are not discussed here. Reviews of renal magnesium transport can be found elsewhere (Blaine et al., 2015; Houillier, 2014; Schaffers et al., 2018).

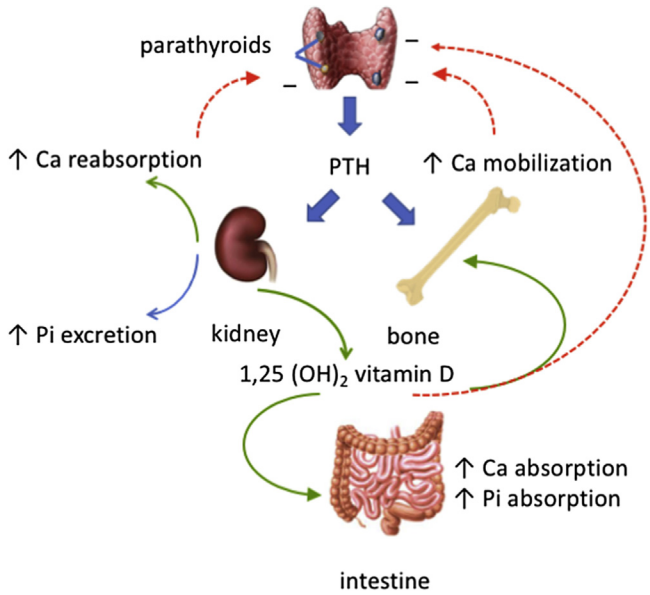

FIGURE 27.2 Parathyroid hormone (PTH) regulation of calcium homeostasis. PTH regulates extracellular calcium homeostasis through a negative feedback scheme. Decreases of extracellular calcium trigger PTH release. PTH in turn stimulates renal calcium reabsorption and mobilizes surface calcium from bone to inhibit further PTH release (dashed lines). PTH also promotes phosphate excretion and stimulates 1α-hydroxylase activity in kidney mitochondria leading to the production of 1,25-dihydroxyvitamin D (calcitriol). Calcitriol, the biologically active metabolite of vitamin D, increases intestinal calcium and phosphate absorption, and calcium mobilization in bone.

Calcium and phosphate homeostasis

Calcium chemistry

Calcium participates in a variety of structural and functional roles in animal cells and tissues. The physical qualities of the calcium ion are especially well suited to the tasks it performs. At first glance, calcium would seem to be an unlikely choice to subserve such diverse functions as an integral macromolecular constituent of bone and at the same time be a primary element in micromolecular signaling. Extracellular concentrations of unbound calcium are roughly 1 mM, whereas its intracellular free concentration under resting conditions is about 0.1 μM—i.e., four orders of magnitude lower. Such extreme differences between intra- and extracellular concentrations place severe constraints and demands on plasma membrane transport proteins to safeguard the integrity of the intracellular milieu. To extrude calcium from the cell, for instance, a prodigious adverse electrochemical gradient must be overcome. Simultaneously, extracellular calcium must be fastidiously regulated. What makes calcium so biologically apt that a variety of evolutionarily taxing developments emerged to accommodate its superior aspects? Some of these structural virtues have been summarized by Williams (1976). For example, calcium, in contrast to magnesium, exhibits a particularly adaptable coordination sphere that facilitates binding to the irregular geometry of proteins. The ability to cross-link two proteins requires an ion with a high coordination number (which dictates the number of electron pairs that can be formed) and is generally six to eight for calcium (Williams, 1976). Such cross-linking of osseous structural proteins is facilitated at the high calcium concentrations found in extracellular fluid. At the same time, the variable bond length of calcium permits formation of the more extensive cross-linking involved in membrane stabilization by facilitating lipid polymorphism and formation of hexagonal arrays. Moreover, unlike disulfide or sugar-peptide cross-links, calcium linking is readily reversible. Despite these virtues, if intracellular free calcium ($[Ca^{2+}]_i$) was similar to its extracellular concentration, the proper functioning of a variety of proteins and macromolecules would be impaired. Thus, there seems to be some evolutionary rationale for maintaining the intracellular concentration of calcium at rather low levels. What benefits, then, result from maintaining low intracellular calcium?

The corollary of the benefits of the physical characteristics of calcium at high extracellular concentrations defines a nearly ideal set of attributes that are desirable at submicromolar intracellular concentrations. By virtue of its low cytoplasmic levels, changes of calcium activity can function as first or second messengers to activate effector targets. The fact that calcium can be rapidly bound and released, together with the high affinity and selectivity of many proteins for calcium, would seem to enhance its ability to serve as a trigger or rapid on/off signaling switch. Another advantage of low free

intracellular calcium concentrations is that microcrystallization and precipitation of calcium phosphate is avoided. Circumventing these processes, it has been speculated (396), favors the evolution of high-energy phosphate compounds, which serve as the energy source for a host of biological reactions.

Serum calcium

Calcium may be measured in serum or plasma. As discussed later, this makes little practical difference. Clinical laboratories typically analyze and report results for total calcium; free calcium requires an additional order. Insofar as much circulating calcium is bound either to proteins or as small chemical complexes, the determination of free, or ionized, calcium is useful. Moreover, because pathological conditions including liver disease or kidney failure may change protein levels. Thus, discrepancies between total and ionized calcium may arise but can go undetected without knowing both total and free calcium.

Total calcium concentrations fluctuate with age (Fig. 27.3), averaging 9.5 mg/dL (2.4 mmol/L) (Table 27.1) in adults. Calcium in plasma is present to varying extents in protein-bound, complexed, and ionized forms. Approximately 45% percent of calcium is bound to plasma proteins, mostly to albumin. Smaller amounts of calcium are bound to globulins and a negligible portion to fibrin. Therefore, serum and plasma calcium concentrations are generally indistinguishable (Miles et al., 2004). Another 45% of calcium is ionized (or "free"). The remaining 10% of calcium is associated with small polyvalent anions such as bicarbonate, phosphate, and sulfate. Such ion pairs, e.g., calcium bicarbonate, that arise by electrostatic forces are called "calcium complexes." Together, ionized and complexed calcium are referred to as "diffusible" because only these forms are (1) filtered at the glomerulus and (2) able to cross cell membranes.

Ultrafilterable and ionized fractions of calcium are affected by changes in the total serum calcium concentration, blood pH, plasma protein concentration, and the abundance of complexing anions. Increases in total serum calcium are usually

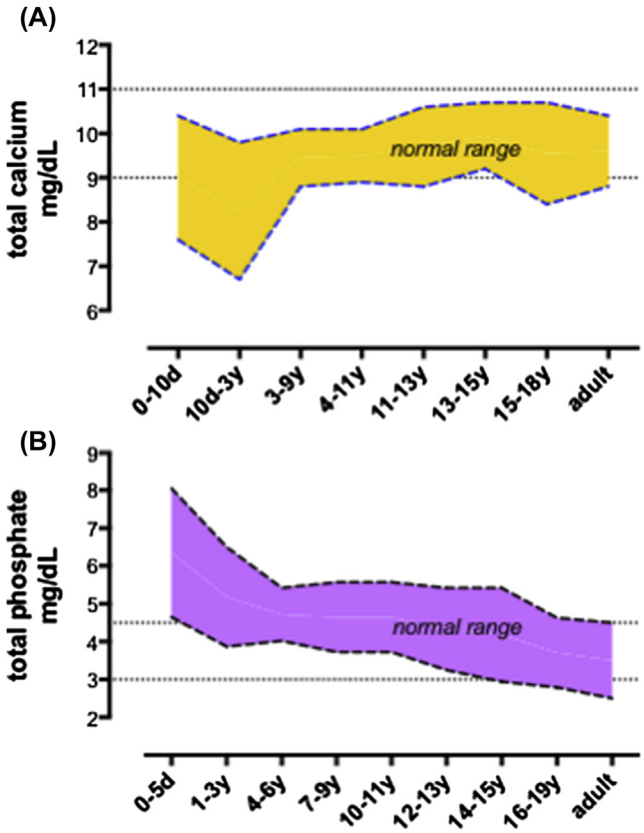

FIGURE 27.3 Total serum calcium (A) and phosphate (B) concentrations during growth and in adults. The normal ranges are highlighted. *Values compiled from various sources Fischbach, F.T., Dunning, M.B. 2015. A manual of laboratory and diagnostic tests. ninth ed. Wolters Kluwer Health, Philadelphia; Meites, S. 1989. Pediatric clinical chemistry: reference (Normal) values. third ed. AACC Press, Washington, DC.*

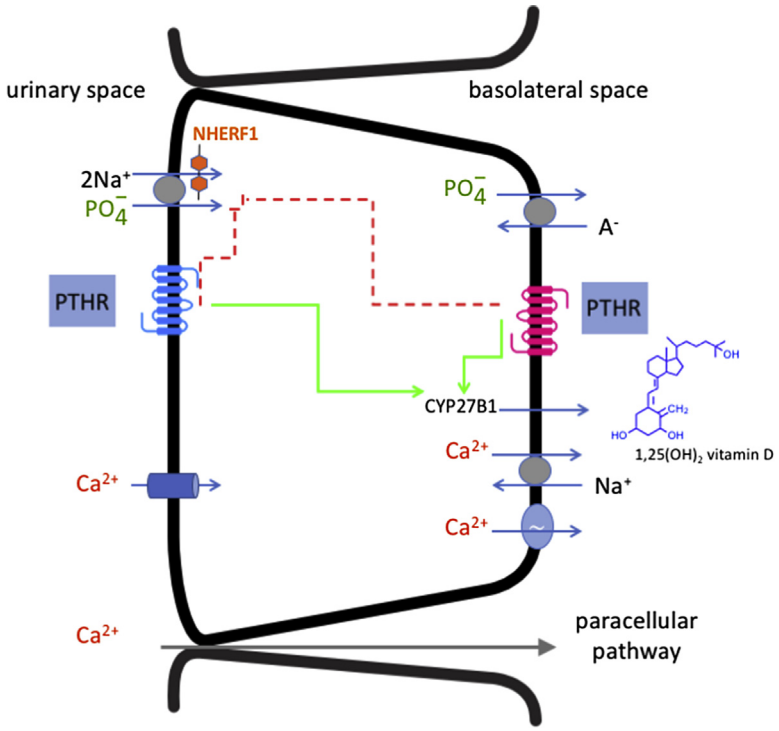

FIGURE 27.4 Phosphate and calcium transport in proximal tubules. Proximal tubule Na-Pi cotransport is mediated principally by apical membrane Npt2a. Two sodium ions are taken up together with a single phosphate molecule. Npt2a is inhibited by PTH as described in the accompanying text. NHERF1 is required for this activity. The mechanism of basolateral PO_4 extrusion is uncertain and is illustrated here as proceeding by a nonspecified anion (A^-) exchanger. Calcium absorption by proximal tubules is largely, if not entirely, a passive process that proceeds through the paracellular pathway of the lateral intercellular spaces (dashed line). Evidence for apical membrane Ca^{2+} entry and basolateral efflux has been described but it is uncertain whether these single processes contribute to transcellular calcium absorption or subserve intracellular calcium homeostasis. PTHR is shown on apical and basolateral cell membranes. Emerging evidence along with published findings suggest the preferential regulation of Npt2a by apical PTHR and induction of CYP27B1 and vitamin D formation by basolateral PTHR.

accompanied by concomitant elevations of ultrafilterable calcium to a total of about 4 mM (Edwards et al., 1974; Le Grimellec et al., 1974). This upper limit of calcium ultrafiltration with hypercalcemia has been postulated to result from the formation of insoluble $[Ca_3(PO_4)_2^-$ −protein] complexes. This idea is supported by the finding that the ultrafilterable phosphate concentration also declines (Cuche et al., 1976). Conversely, hypocalcemia is generally associated with a decline of calcium ultrafiltration (Terepka et al., 1957).

Changes in the concentration of serum proteins are accompanied by parallel alterations of total serum calcium concentration. However, the ultrafilterable fraction generally remains constant. In severe hypoproteinemia, however, the ultrafilterable fraction increases.

TABLE 27.1 Serum calcium (Fischbach and Dunning, 2015).

	mg/dL	mEq/L	mM
Adults			
Total calcium	8.8–10.4	4.4–5.2	2.2–2.6
Ionized calcium	4.6–5.3	2.3–2.6	1.16–1.32
Children			
Total calcium (10d–3yr)	6.7–9.8	3.4–4.9	4.80–5.52
Ionized calcium (1–18yr)	2.24–2.75	1.1–1.4	1.2–1.4

Normal ranges vary between laboratories and depend on applied measurement technology and assay conditions.

In contrast to the parallel relation between total calcium and serum protein, ionized Ca^{2+} levels vary inversely with blood pH. Acidosis increases ionized Ca^{2+} because H^+ ions displace Ca^{2+} from serum proteins. Conversely and for the same reason, alkalosis decreases Ca^{2+} (Hopkins et al., 1952; Loeb, 1926; Peterson et al., 1961). Thus, in these settings the fraction of ionized calcium changes without affecting total calcium. Ionized Ca^{2+} concentrations also change inversely with variations of serum anions. For instance, elevation of phosphate, citrate, sulfate, or bicarbonate increases the serum-free Ca^{2+} secondary to augmented formation of calcium complexes (Walser, 1973).

Symptoms of hypocalcemia vary in relation to the ionized serum calcium concentration. Mild reductions of plasma calcium are associated with paresthesia and muscle cramps; more severe decreases of calcium may induce seizures. Hypercalcemia, on the other hand, has been implicated in the attenuation of the renal effects of PTH, the antidiuretic action of vasopressin, and reduced renal concentrating capacity (Gill and Bartter, 1961; Takaichi and Kurokawa, 1986). The calcium concentration in the extracellular fluid represents a dynamic balance between intestinal absorption, renal reabsorption, and skeletal resorption. Assuming a daily dietary calcium intake of 1000 mg, net intestinal absorption amounts to about 200 mg with the remaining 800 mg excreted in the feces. When in balance, net intestinal absorption is matched by urinary excretion, while calcium accretion and loss from bone are equal. Thus, approximately 200 mg of calcium are excreted daily. In adults, net calcium balance is effectively zero, suggesting that in the absence of a calcium challenge such as lactation, the kidneys represent the dominant regulatory site of calcium metabolism (Peacock et al., 1969).

Phosphate chemistry

Terrestrial mammals are characterized by their avidity for calcium and equally keen mechanisms to eliminate phosphorous. Elemental phosphorous (P) exists in organic and inorganic (Pi) forms. Organic forms include phospholipids and various organic esters. The bulk of phosphate in extracellular fluid exists as the inorganic forms, Na_2HPO_4 and NaH_2PO_4. The Henderson relation determines the ratio of the two:

$$\frac{HPO_4^{2-}}{H_2PO_4^{-}} = 10^{pH-pKa} \tag{27.1}$$

The dissociation constant, pKa, for phosphate is 6.8. Thus, at pH 7.4, the ratio is essentially 4:1, and the plasma phosphate thus has an intermediate valence of 1.8.[2]

Serum phosphate

Serum phosphate is generally expressed as milligrams per deciliter because concentration in millimolar units can vary with acid–base status as outlined previously. Serum Pi averages between 3 and 4.5 mg/dL and decreases with age (Fig. 27.3B). As with calcium, serum Pi circulates in both free and protein-bound forms. However, some 90% of Pi, whether ionized or complexed with Ca, Mg, or Na, is filtered at the glomerulus. Although it is commonly stated that Pi is freely and completely filtered at the glomerulus, this is incorrect. Ten percent of plasma Pi is bound to protein and not filtered. However, the reduction in ultrafilterable Pi is counterbalanced by an opposite Gibbs–Donnan effect that raises the Pi concentration in the ultrafiltrate. Correcting the volume occupied by plasma proteins (7%) raises the ultrafiltrate Pi concentration by an additional 7.5%, mitigating the reduction of protein-bound Pi. Indeed, both in vivo and in vitro measurements show that the ratio of ultrafilterable Pi to total plasma Pi is close to unity (Harris et al., 1974). Ultrafilterable Pi decreases with the elevation of Ca or Pi, presumably because of formation of high-molecular-weight protein complexes.

Parathyroid hormone actions on mineral-ion homeostasis

By regulating renal tubular absorption of calcium and phosphate and the synthesis of $1.25(OH)_2D_3$, PTH controls the urinary excretion and intestinal absorption of these mineral ions and thereby plays a prominent role in setting their blood levels. Renal tubular responses to PTH deficiency, PTH or PTHrP excess, and defects in PTHR function lead to alterations in blood calcium, phosphate, or $1.25(OH)_2D_3$ that are the hallmarks of numerous clinical disorders, described later in this volume. This chapter reviews current understanding of the mechanisms whereby PTH and PTHrP control renal tubular epithelial function. Because PTH and PTHrP actions in kidney and bone are mediated by the PTHR, its expression, signaling, and trafficking are presented first as a foundation for understanding hormone actions. Although PTH and PTHrP

2. The net valence is calculated from the total number of negative charges, $2 \times 4 + 1$, divided by the number of molecules, $4 + 1$, as determined by the Henderson relation, viz., $9/5 = 1.8$. Thus, at pH 7.4, 1 mmol of phosphorous = 1.8 mEq.

receptors distinct from the PTHR have been described (see Chapter 28), their role, if any, in normal renal physiology is unknown. While not unequivocally proven in each case, it is likely that the effects of PTH and PTHrP described here are mediated by the canonical PTHR.

Parathyroid hormone receptor expression, signaling, and regulation in the kidney

Renal PTHR in is expressed on tubular epithelial cells and vascular endothelial cells. PTHR expression along the nephron is associated with regulatory actions on mineral-ion homeostasis, whereas expression on capillary endothelial cells and glomerular podocytes mediates PTH effects on vascular tone and GFR.

The response to PTHR activation observed in individual renal cells depends upon several factors including (1) receptor location and abundance; (2) the expression of cell-specific adapter proteins that modify PTHR signaling; (3) the array of PTHR-inducible genes; (4) effector proteins including enzymes, ion channels, and transporters; (5) the local concentration of PTH or PTHrP; (6) exposure to other agents that heterologously regulate PTHR function; and (7) the history of recent exposure to PTH or PTHrP, which affects the state of receptor desensitization.

Parathyroid hormone receptor expression

The prominent actions of infused PTH on phosphate and calcium absorption pointed to proximal and distal tubules, respectively, as the principal sites of PTHR expression. These deductions were confirmed as molecular biological tools and antibodies became available. We now recognize PTHR expression at the glomerulus, proximal convoluted and straight tubules, cortical ascending limbs, and distal convoluted tubules. Unexpectedly, detailed examination revealed PTHR localization in proximal tubules on both basolateral and apical cell membranes (Amizuka et al., 1997; Ba et al., 2003; Kaufmann et al., 1994). Possible roles of apical membrane PTHRs are discussed later.

Considerable evidence supports the bilateral expression of PTHR on apical and basolateral surfaces of proximal tubules. Moreover, PTH actions are asymmetrical (Quamme et al., 1989; Reshkin et al., 1990, 1991). Such biased actions suggest differential PTHR coupling to G proteins on apical and basolateral membranes; the presence of adapter proteins such as the PDZ proteins NHERF1 and SCRIBBLE; or A-kinase-anchoring proteins that modify or specify second messenger signaling. The possibility of differential G protein expression seems unlikely because G_s is abundant in brush border membrane vesicles (Brunskill et al., 1991; Stow et al., 1991; Zhou et al., 1990). Interestingly, inhibitory G_i isoforms are found only on apical and not basolateral proximal tubule cells (Stow et al., 1991). Nonetheless, PTH triggers greater cAMP formation when added to the serosal than to the mucosal compartment of cells grown on filter barriers (Reshkin et al., 1991). This finding is compatible with other results showing that apical membrane receptors appear not to be coupled tightly, if at all, to adenylyl cyclase (Kaufmann et al., 1994; Shlatz et al., 1975).

Apical membrane expression of PTHR in proximal tubules was unexpected. The conspicuous presence of apical PTHR raises the question of the nature and function of PTH peptides in the urine. Full-length PTH(1−84) has a molecular weight of 9.4 kDa, is filtered at the glomerulus, and is found in urine (Bethune and Turpin, 1968; Norden et al., 2001). The role of urinary PTH fragments has largely been ignored because of the absence of a conceptual framework meriting their examination, the attendant problems of bioassay and immunometric PTH determinations that have been applied to these assays, and the overriding view that PTHR functionality stems from its expression at basolateral surfaces facing the vasculature. The demonstrable effects of PTH peptides applied to the apical surface of isolated kidney tubules or cultured proximal tubule cells, however, supports the view that PTH may differentially regulate phosphate transport from apical and basolateral surfaces (Kaufmann et al., 1994; Reshkin et al., 1990; Traebert et al., 2000)}.

The *PTHR* gene harbors multiple promoters and 5′-untranslated exons and is thereby capable of generating various transcripts by alternative promoter usage and different RNA splicing patterns (Amizuka et al., 1997; Bettoun et al., 1998; Jobert et al., 1996; Joun et al., 1997; McCuaig et al., 1995). P1 promoters in mouse and P3 in human seem to be used exclusively in kidney cells, whereas the P2 promoter is employed to generate PTHR mRNAs that are widely expressed in extrarenal tissues and organs (Amizuka et al., 1997; Bettoun et al., 1998; Joun et al., 1997). It is presently unknown whether these differences simply reflect opportunities for tissue-specific gene regulation or lead to expression of structurally different forms of the PTHR (Jobert et al., 1996; Joun et al., 1997).

Parathyroid hormone receptor signal transduction in kidney tubular cells

PTH administration promptly increases urinary excretion of cAMP, referred to as nephrogenous cAMP. This effect has been employed clinically to distinguish between primary and secondary hyperparathyroidism, wherein nephrogenous

cAMP is elevated in primary but not secondary hyperparathyroidism due to impaired kidney function in the latter condition (Broadus, 1979; Llach and Massry, 1985). Practically speaking, cAMP formation in the nephron originates exclusively from proximal tubules because of the extensive mass of this portion of the nephron compared with other nephron segments. Further, although PTH-induced nephrogenous cAMP is a robust index of the phosphaturic action of PTH, it fails to disclose the effects of PTH on calcium absorption by distal tubules. This too stems from the profusion of proximal tubules compared with distal tubules, possible differences in receptor abundance on the two cell types, the presence of modifying proteins that alter the coupling of the PTHR to G_s, and the signaling array employed.

PTH stimulates adenylyl cyclase with attendant formation of cAMP and activation of PKA in kidney epithelial and vascular cells. PLC may also or alternatively be activated with consequent generation of inositol phosphates and diacylglycerol, release of intracellular calcium, and activation of PKCs, phospholipase A_2, and phospholipase D (PLD). Other signaling mechanisms may participate in mediating PTHR actions in renal cells. For example, PTH-induced stimulation of MAPKs in renal epithelial cells may be triggered by GPCRs, proceeding by activation of nonreceptor tyrosine kinases and transactivation of EGF receptors. MAPK, through PTHR and the FGFR1 fibroblast growth factor receptor, participates in mediating PTH and FGF23 effects, respectively, on phosphate transport (Sneddon et al., 2016). In heterologous cell expression systems, PTHR activation of MAPK occurs by transactivation and PTHR internalization (Syme et al., 2005).

Different patterns of PTHR signaling are present along the nephron. For example, PTH provokes rapid and transient elevations of Ca_i^{2+} in proximal tubule cells (Filburn and Harrison, 1990; Friedman et al., 1999; Hruska et al., 1986, 1987; Tanaka et al., 1995). This response is characteristic of PLC activation, as opposed to calcium influx that produces a more sustained increase of intracellular calcium, which results from the formation of inositol trisphosphate and calcium release from endoplasmic reticulum. Distal tubule cells, in contrast, exhibit a delayed and sustained elevation of Ca_i^{2+} in response to PTH. This effect is due to apical membrane Ca^{2+} entry (Bacskai and Friedman, 1990; Hoenderop et al., 1999). Furthermore, PTH-stimulated calcium transport in distal tubule cells involves PLC-independent PKC activation (Friedman et al., 1996), which is mediated by phospholipase D (Garrido et al., 2009).

More recent characterization of PTHR signaling offers additional and alternative interpretations of cAMP signaling and function. Refined analysis of PTHR activation in single cells using FRET revealed that PTH but not PTHrP promoted sustained elevation of cAMP. Similar findings subsequently were described for other GPCRs (Calebiro et al., 2009; Feinstein et al., 2013; Inda et al., 2016; Kuna et al., 2013; Merriam et al., 2013; Pavlos and Friedman, 2017). In the case of PTHR, sustained cAMP signaling originating at basolateral surfaces may induce 25-hydroxyvitamin D-hydroxylase (*CYP27B1)* transcription, CREB phosphorylation, and 1.25$(OH)_2$vitamin D_3 formation.

Regulation of parathyroid hormone receptor signaling in tubular epithelial cells

As described before, the expression of PTHRs on the surface of kidney cells is controlled by the interaction with adaptor proteins. However, PTHR expression is also controlled by the rate of PTHR gene transcription, though current understanding of this process is incomplete. Hypoparathyroidism, induced by parathyroidectomy or dietary phosphate depletion, upregulates PTHR mRNA levels in rat renal cortex (Kilav et al., 1995a). However, high concentrations of PTH have no detectable effect on PTHR mRNA (Kilav et al., 1995b; Ureña et al., 1994). Renal PTHR mRNA expression is reduced in rats with renal failure, but this apparently is due to some aspect of uremia or renal disease (Disthabanchong et al., 2004) other than secondary hyperparathyroidism per se, as it is not prevented by parathyroidectomy (Largo et al., 1999; Urena et al., 1994; Ureña et al., 1995). In rats with secondary hyperparathyroidism due to vitamin D deficiency, renal cortical PTHR mRNA levels were found to be twice as high as normal and could not be corrected by normalizing serum calcium (Turner et al., 1995). These results suggest that vitamin D impairs PTHR gene transcription in proximal tubules. However, in immortalized distal convoluted tubule cells, PTHR expression was upregulated severalfold by 1.25$(OH)_2D_3$ (Sneddon et al., 1998). In opossum kidney (OK) cells, TGFβ1 diminished PTHR mRNA expression (Law et al., 1994). The physiologic significance of this effect has not been clarified. PTHR mRNA expression was not affected by the mild secondary hypoparathyroidism induced by ovariectomy in rats nor by subsequent estrogen treatment (Cros et al., 1998).

A critical insight to PTHR regulation was achieved with the discovery that the receptor interacts with the cytoplasmic scaffolding proteins Na/H exchanger regulatory factors NHERF1 NHERF2 (NHERF1/2; known also as EBP50 and E3KARP, respectively), which govern certain aspects of signaling and trafficking (Mahon et al., 2002). NHERF1/2 consist of two tandem PSD95/Discs Large/ZO-1 (PDZ) domains and an EBD. The PTHR binds to either PDZ domain through a recognition sequence at its carboxy-terminus. This Glu-Thr-Val-Met sequence corresponds to a canonical PDZ ligand that takes the form D/E–S/T-X-Φ, where X is any amino acid and Φ is a hydrophobic residue—generally L/I/V, but it can also be M (Broadbent et al., 2017). Mutation of any residue of the PDZ sequence of the PTHR, other than the permissive

position, abrogates interaction with NHERF1/2 (Mahon et al., 2002; Sneddon et al., 2003). In pivotal work, Mahon and Segre found that NHERF1/2 switched PTHR signaling from adenylyl cyclase to PLC. NHERF1 also regulates mitogen-activated ERK signaling (Wang et al., 2008). NHERF1 is abundantly expressed on proximal tubule apical membranes (Wade et al., 2001). Mouse proximal tubules expresses both NHERF1 and NHERF2 (Wade et al., 2003). NHERF1 is strongly expressed in microvilli, whereas NHERF2 is detected only weakly in microvilli. However, it is expressed predominantly at the base of the microvilli in the vesicle-rich domain. Notably, neither NHERF1 nor NHERF2 is found in distal tubules. Human and mouse kidneys exhibit comparable NHERF1 localization (Shenolikar et al., 2002; Wade et al., 2001, 2003; Weinman et al., 2002). As will be discussed in greater detail later, NHERF1 is expressed in the proximal nephron, where it importantly regulates PTH-dependent phosphate absorption.

Calcium absorption and excretion

The kidneys are responsible for controlling extracellular calcium balance by controlling the amount of calcium retained by the nephron or excreted in the urine. Renal calcium regulation occurs by a series of sequential events as the incipient urine passes through the nephron. The bulk of the filtered calcium is absorbed by proximal tubules, with progressively smaller fractions recovered as the urine passes through downstream tubule segments. Most calcium absorption is not subject to hormone regulation because it proceeds in upstream sites through passive mechanisms that are not regulated by hormones. Hormonal and pharmacological regulation of calcium absorption is achieved by fine-tuning the final few percent of calcium transport in distal nephron segments.

PTH participates importantly in maintaining extracellular calcium homeostasis. Early observations in animals and patients with hypo- or hyperparathyroidism clearly implicated renal calcium handling in PTH abnormalities (Carney, 1996; Gley, 1893; Hackett and Kauffman, 2004; Sandström, 1879−1880).

Renal calcium absorption

PTH reduces renal calcium excretion. Although calcium is absorbed throughout the nephron, the calcium-sparing action of PTH occurs primarily in distal tubule (Friedman, 2008; Sutton and Dirks, 1975). The sites of renal calcium absorption and mechanism of PTH action are summarized here. Extensive descriptions of this older work are available elsewhere (Friedman, 2008; Ko, 2017).

Approximately 20%−25% of the calcium filtered at the glomerulus is absorbed by medullary and cortical thick ascending limbs. In contrast to proximal tubules, calcium movement in thick ascending limbs occurs by parallel transcellular and paracellular calcium transport pathways. Passive paracellular calcium absorption is driven by the favorable lumen-positive transepithelial voltage. In this setting, the rate and magnitude of calcium transport are parallel and proportional to those of sodium. Physiological responses and interventions that enhance sodium absorption increase voltage, thereby augmenting calcium absorption (Hoover et al., 2015). Conversely, maneuvers that decrease sodium absorption concomitantly reduce calcium absorption. Such interventions typically involve the use of diuretics such as furosemide or bumetanide that inhibit sodium absorption by thick ascending limbs and increase calcium excretion. Less commonly, mutations of the Na−K−2Cl cotransporter (*SLC12A1*), as well as the ROMK apical K^+ channel and basolateral ClC−K2 basolateral Cl^- channel associated with the different forms of Bartter's syndrome, are accompanied by hypercalciuria, underscoring the parallel nature of sodium and calcium absorption by thick ascending limbs. PTH stimulates active calcium absorption by cortical thick limbs (Friedman, 2000).

Distal convoluted tubules display a third pattern of transepithelial calcium recovery. Two important features characterize this process (Fig. 27.5). First, calcium transport occurs only by a transcellular mechanism and second, calcium and sodium movement are inversely related. Here, decreased sodium absorption enhances calcium recovery; likewise, increased sodium absorption is accompanied by diminished calcium transport. This inverse relationship has important consequences for calcium economy. For example, thiazide diuretics, which increase sodium excretion, diminish that of calcium. Patients with Gitelman's syndrome further exemplify the inverse association of sodium and calcium movement. This inherited disorder is due to inactivating mutations of the Na−Cl cotransporter (NCC; *SLC12A3*) that mediates sodium absorption by distal convoluted tubules. Patients (Bettinelli et al., 1992; Gitelman et al., 1966) and experimental animals (Schultheis et al., 1998) with Na−Cl cotransporter mutations exhibit characteristic natriuresis accompanied by hypocalciuria, thus exemplifying the inverse relations between sodium and calcium absorption in distal tubules.

Cortical and medullary collecting tubules contribute minimally if at all to renal calcium conservation, and PTH exerts no detectable action on calcium movement by these nephron sites (Bernardo and Friedman, 2013; Friedman, 2014).

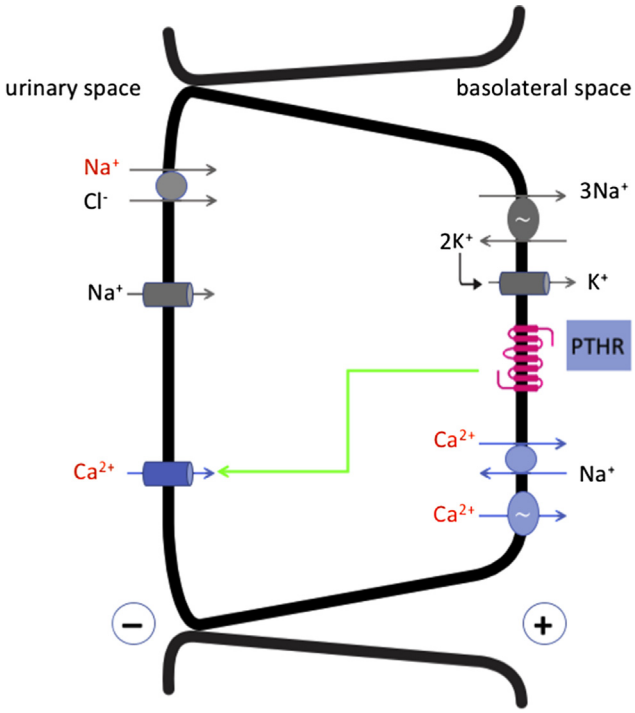

FIGURE 27.5 Calcium absorption by distal convoluted tubules. Two features distinguish distal tubule calcium absorption. First, calcium transport proceeds exclusively through a cellular pathway. Because of the substantial adverse electrochemical barrier, calcium movement is negligible in the absence of PTH (Costanzo and Windhager, 1980). Second, calcium and sodium movement in distal convoluted tubules are inversely related. Thus, thiazide diuretics, which block sodium transport, augment calcium absorption (Gesek and Friedman, 1992). The cell model shows two apical membrane sodium entry mechanisms, the thiazide-diuretic-inhibitable NaCl cotransporter and the amiloride-blockable epithelial Na channel, ENaC. Amiloride also stimulates calcium transport by distal tubule cells (Friedman and Gesek, 1995). Calcium enters the cell across apical membranes through dihydropyridine-sensitive calcium channels. PTHR expressed on basolateral membranes stimulates apical membrane calcium entry that is accompanied by efflux across basolateral membranes. Basolateral calcium efflux is mediated by the plasma membrane Ca^{2+}-ATPase (shown as the energy-dependent [∼] process), and the Na^{+}/Ca^{2+} exchanger as discussed in detail in the text and elsewhere (Ko, 2017; Moe, 2016).

Parathyroid hormone regulation of renal calcium absorption

PTH is the most important hormone regulating renal tubular calcium transport. PTH increases renal calcium reabsorption and lowers urinary calcium excretion. In the complete absence of the hormone or in PTH deficiency states, diminished tubular reabsorption is accompanied by frank hypercalciuria. The stimulatory effect of PTH on calcium transport is limited to distal nephron segments. Paradoxically, PTH decreases calcium absorption by proximal tubules; the calcium-sparing action is due to its effects on distal convoluted tubules, and to a limited extent actions on cortical thick ascending limbs. In some species, the calcium-sparing action proceeds in connecting tubules.

Parathyroid hormone effects on proximal tubule calcium transport

The primary action of PTH on proximal tubule mineral-ion transport is to inhibit Na^{+}-dependent phosphate (Na^{+}-Pi) absorption (see below). It is uncertain whether PTH exerts significant or even specific actions on proximal calcium transport. PTH has been reported to increase (234), decrease (5), or not change (150, 251) proximal tubule calcium absorption. Studies showing that PTH alters intracellular free calcium, $[Ca^{2+}]_i$, irrespective of whether it increased or decreased (123, 146, 179, 213, 214, 368), should not be construed as evidence for an effect of PTH on calcium entry, much less on net calcium absorption. Although the aforementioned findings may be associated with net calcium absorption, they may also represent the aggregate of intracellular calcium release, and perhaps individual calcium entry and exit steps that support constitutive cellular activities and intracellular homeostasis. The reason for this is that PTH exerts a host of biochemical effects on proximal tubules such as activation of 25-hydroxyvitamin D-1α-hydroxylase, gluconeogenesis, or ammoniagenesis as well as transport effects on Na^{+}-Pi absorption, Na^{+}/H^{+} exchange, and Na^{+}/Ca^{2+} exchange that may involve calcium signaling but do not entail effects on net calcium absorption.

Parathyroid hormone effects on distal tubule calcium transport

Substantial evidence supports the view that PTH increases active transcellular calcium absorption by distal convoluted tubules (Ko, 2017; Moe, 2016). The distal action of PTH may be accompanied by decreased sodium absorption and diuresis (Ko et al., 2011).

PTH potently induces apical calcium entry in distal convoluted tubule cells (165). PTH-stimulated calcium entry in distal convoluted tubules is mediated by the TRPV5/Trpv5 calcium channels (van Goor et al., 2017b). This action is mediated by PKA (de Groot et al., 2009). PKA-induced phosphorylation of TrpV5 Thr^{709} increases open-channel probability (de Groot et al., 2009). Other studies point to a role (Hoenderop et al., 1999) or requirement for combined PKA and PKC action (Friedman et al., 1994).

PTH may further dissociate calcium and sodium absorption by distal convoluted tubules. PTH depresses Slc12a3, the electroneutral NaCl cotransporter, and its surface expression (Ko et al., 2011). Thus, reducing Na^+ entry while enhancing calcium absorption supports the inverse relation between basal and hormone-stimulated calcium transport.

Phosphate excretion

Extracellular phosphate homeostasis is regulated primarily by controlling its renal excretion, where it is absorbed mostly by proximal tubules. The prompt phosphaturia caused by PTH was one of the earliest recognized and best studied actions of PTH (Albright et al., 1929; Greenwald and Gross, 1925). Fibroblast growth factor 23 (FGF23) plays an equally important role in phosphate balance. FGF23 is discussed in Chapter 65 and its renal actions reviewed elsewhere (Erben, 2017; Hu et al., 2013). One point worth emphasizing here is that although PTH and FGF23 exert parallel inhibitory actions on renal phosphate absorption, they display opposing effects on vitamin D metabolism, with PTH increasing vitamin D levels and FGF23 lowering them. The underlying basis for these diverse actions is not known.

NPT2a (SLC9A3R1) and NPT2c (SLC9A3R3) mediate renal Na-Pi cotransport[3] (Table 27.2). Npt2a is found throughout the proximal tubule, with expression decreasing from S1 to S2 and then to S3 segments (Picard et al., 2010; Segawa et al., 2007). Npt2c is found only in the S1 portion of proximal tubules. NPT2b is expressed by intestines, where it participates in phosphate absorption.

Mechanisms of proximal tubular phosphate absorption

Apical phosphate entry is rate-limiting for cellular phosphate absorption and is the major site of its regulation. Phosphate enters the cell across apical brush border membranes against a steep electrochemical gradient established primarily by the strongly negative intracellular voltage. This electrochemical barrier is overcome by NaP_i cotransporters that couple phosphate influx to the favorable dissipative entry of Na^+ (Fig. 27.4).

Type I and type IIa NaP_i cotransporters are localized on apical brush border membranes of proximal convoluted tubule cells. Nonspecific type I transporters exert a variety of functions unrelated to phosphate absorption and are not regulated by PTH or FGF23. Type II cotransporters are structurally and genetically distinct from type I transporters, sharing only 20% identity. As alluded to above, NPT2a and NPT2c are expressed in kidney proximal tubules, whereas NPT2b, an isoform of Npt2a, is expressed exclusively in intestine (Hilfiker et al., 1998). Type III NaP_i cotransporters, originally identified as cell surface virus receptors Glvr-1 and Ram-1, are widely expressed within and outside the kidney (Kavanaugh and Kabat, 1996). Type III cotransporters, found on basolateral cell membranes, are regulated by extracellular phosphate deprivation and PTH (Ohkido et al., 2003; Segawa et al., 2007). Type II cotransporters may also be expressed by distal convoluted tubule cells and may thus be involved in phosphate absorption by both proximal and distal nephrons (Collins et al., 2004; Tenenhouse et al., 1998). Npt1, Npt2a, and Npt3 account for 15%, 84%, and 0.5% of Na-Pi-cotransporter mRNAs (Murer et al., 2003). Type II cotransporters are 80−90-kDa glycoproteins predicted to span the membrane eight times with both their amino and carboxyl termini in the cytoplasm (Murer and Biber, 1997). Recent work shows two variant transcripts of the mouse Npt2a gene, Npt2a-v1 and Npt2a-v2 (Yamamoto et al., 2005). These are characterized by the presence of alternative first exons (either exon 1A or exon 1B). Npt2a-v2 is important for $1.25(OH)_2D_3$-dependent renal cell-specific activation. Npt2a cotransporters are electrogenic and transport Na^+ and $H_2PO^-_4$ at a molar ratio of 3:1 (Murer and Biber, 1997). Expression and activity of NPT2a/Npt2a are strongly regulated by parathyroid status and dietary phosphate (and FGF23) (Keusch et al., 1998; Lotscher et al., 1999; Pfister et al., 1997; Ritthaler et al., 1999; Takahashi et al., 1998). PTH regulation of serum phosphate and tubular NaP_i absorption is lost in mice lacking Npt2a (Zhao and Tenenhouse, 2000).

3. Human genes and gene products are designated by uppercase italics, whereas nonhuman forms are shown in lowercase.

TABLE 27.2 Sodium phosphate transporter family.

Type	GenBank	Function	Reference
NPT1	*SLC17A1*	Modulator of organic and inorganic anion transport	Busch et al. (1996)
NPT2A	*SLC34A1*	3:1 electrogenic BBM proximal tubule Pi uptake	Murer et al. (2000)
NPT2B	*SLC34A2*	Intestinal Pi transport	Hilfiker et al. (1998)
NPT2C	*SLC34A3*	2:1 electroneutral BBM proximal tubule Pi uptake	Bacconi et al. (2005); Bergwitz et al. (2006); Madjdpour et al. (2004); Segawa et al. (2002); Tenenhouse et al. (2003)
NPT3	*SLC20A1*, *SLC20A2*	Pi transporter in bone. Broadly expressed.	Suzuki et al. (2001, 2006)

Npt2c/NPT2c is expressed in rat and human kidneys (Ohkido et al., 2003). Npt2c accounts for approximately 30% of Na/Pi cotransport in kidneys of phosphate-deprived adult mice (Ohkido et al., 2003). Npt2a activity is the principal mechanism whereby PTH controls phosphate absorption in proximal convoluted tubules, at least in rodents. In humans, however, NPT2c plays an important role in phosphate economy. NPT2c mutations are associated with hereditary hypophosphatemic rickets with hypercalciuria, kidney stones, and nephrocalcinosis (Christov and Juppner, 2013; Dasgupta et al., 2014).

Parathyroid hormone regulation of renal phosphate absorption

PTH promptly elevates urinary phosphate elimination. Early studies revealed that this action is involved reduction of Na-Pi cotransport and that restoration of maximal phosphate absorption required microtubules and new protein synthesis (Dousa et al., 1976; Malmström and Murer, 1987).

Functional and immunohistochemical analyses of Npt2 in intact kidneys and cultured cells revealed that PTH induces rapid (15 min) removal of Npt2 from the apical membrane into the subapical endocytic apparatus, followed by microtubule-dependent delivery to lysosomes and proteolytic degradation (Bacic et al., 2006; Kempson et al., 1995; Keusch et al., 1998; Lötscher et al., 1999; Pfister et al., 1997; Zhang et al., 1999). It had been assumed that PTH inhibited Na-Pi cotransport through phosphorylation or other action that would control the kinetics or driving force. This turned out not to be the case. Instead, PTH and FGF23 inhibit Na-Pi cotransport by initiating internalization and downregulation of Npt2a. Though Npt2a phosphorylation apparently is not involved, PTH and FGF23 lead to phosphorylation of NHERF1 (Andrukhova et al., 2012; Deliot et al., 2005; Weinman et al., 2007). It is also worth noting that PTH and FGF23 maximally inhibit only 50%–60% of phosphate transport. It is not known if the balance is subject to hormonal or other regulatory control.

Hypoparathyroidism and hypophosphatemia increase PTHR, Npt2a mRNA, and protein, showing the proteins mediating PTH effects on renal phosphate transport that are coordinately regulated (Kilav et al., 1995a). PTH does not acutely reduce Npt2 mRNA expression, although parathyroidectomy leads to a severalfold increase of apical Npt2a protein and mRNA (Kilav et al., 1995a; Saxena et al., 1995; Takahashi et al., 1998).

Parathyroid hormone receptor signal transduction in the regulation of calcium and phosphate excretion

As described earlier and discussed in Chapter 28, the PTHR mediates its actions through multiple signaling pathways. Signaling is both ligand- and cell type-specific. PTH exerts physiologically distinct and temporospatially separated effects on the kidney. In proximal tubules, PTH inhibits Na-Pi cotransport and Na/H exchange, increases Na^+/Ca^{2+} exchange (Fig. 27.4), and activates CYP27B1 while suppressing 24-hydroxylase activity to increase circulating vitamin D levels. PTH also inhibits Na^+,K^+-ATPase activity, stimulates gluconeogenesis and ammoniagenesis. Complex but precise individual control over these multiple physiological activities assures that all are not simultaneously engaged in response to changing levels of PTH. Just how this is accomplished is far from understood. However, important insights have been gained into PTH-dependent regulation of renal calcium and phosphate transport by identifying cytoplasmic scaffolding proteins that specifically modulate individual PTH actions (Mahon, 2012; Pavlos and Friedman, 2017).

Parathyroid hormone signaling of renal calcium transport

The primary action of PTH is to stimulate renal calcium conservation. This related process proceeds principally in distal tubules. The portion of the distal tubule where this occurs differs somewhat between species. In most species including humans, the rat, the mouse, and the dog, distal convoluted tubules are the primary site of PTH-dependent calcium absorption. This has been demonstrated directly or can be inferred from the localization of the PTHR or the presence of PTH-stimulated adenylyl cyclase activity (Chabardès et al., 1980; Friedman and Gesek, 1993). In the rabbit, connecting tubules are the site of PTH-stimulated calcium transport (Shimizu et al., 1990).

Ca^{2+} entry across apical cell membranes of distal convoluted tubule cells is mediated by TrpV5/TRPV5 calcium channels (Mensenkamp et al., 2007; Na and Peng, 2014). Although activating PKA purportedly accounts for PTH actions on calcium absorption (de Groot et al., 2009), we think it likely that this action involves both PKA and PKC insofar as activation of omnipresent β_2-adrenergic receptors, which are well expressed by distal tubules, fails to augment calcium recovery (Gesek and White, 1997). This suggests that PTH-sensitive calcium transport requires activating both PKA and PKC. Such effects have been reported (Cha et al., 2008; de Groot et al., 2009; Hoover et al., 2015). Some interspecies differences of PKA-sensitive PTH activation of TRPV5 have been noted between rabbit and rodent and human, which behave similarly (van Goor et al., 2017a).

Cellular calcium efflux is mediated by the NCX1 Na^+/Ca^{2+} exchanger and PMCA1 and PMCA4 plasma membrane Ca^{2+}-ATPases (van der Hagen et al., 2014; van Loon et al., 2016), which are expressed on distal tubule cell basolateral membranes (Magyar et al., 2002; White et al., 1997). Although opinions differ regarding the relative contribution of NCX1 and PMCA1/4 to net calcium absorption, we think it likely that Ca^{2+}-ATPase mediates the bulk of Ca^{2+} efflux because the electrochemical driving force for Ca^{2+} extrusion by Na^+/Ca^{2+} exchange is insufficient to account for more than basal calcium transport levels (Friedman, 1998). How these two processes are regulated and synchronized so as to coordinate apical calcium entry with basolateral extrusion is unknown.

Parathyroid hormone signaling of renal phosphate transport

Early experiments in vivo or with isolated renal membranes indicated that regulation of phosphate absorption was mediated by cAMP. The evidence marshaled in support of this conclusion was based, inter alia, on the observation that cAMP analogs and phosphodiesterase inhibitors mimicked the phosphaturic action of PTH (Agus et al., 1973; Coulson and Scheinman, 1989; Gmaj and Murer, 1986; Hammerman, 1986). Indeed, the excretion of urinary cAMP in response to PTH administration, so-called nephrogenic cAMP, reflects virtually exclusively the action of PTH on proximal tubule phosphate absorption (and not distal tubule Ca absorption) and is a direct index of PTHR sensitivity or refractoriness (Besarab and Swanson, 1984). Although these conclusions are solid, the mechanisms by which PTH inhibits renal phosphate transport are complex and incompletely resolved. The intricacy stems from the recognition that the PTHR activates multiple signaling paths. The possibility that differentially expressed PTHR types (Pun et al., 1988) or isoforms account for the heterogeneity of action can be excluded. The first studies profiling the effect of PTH on inositol phosphate and Ca^{2+}-signaling, in fact, preceded the cloning of the PTHR (Bidot-López et al., 1981; Meltzer et al., 1982). PTH stimulation of inositol phosphate and diacylglycerol accumulation is independent of cAMP formation (Hruska et al., 1987) and occurs in parallel (Friedman et al., 1996).

The involvement of specific PTHR-generated signals in regulating Na-P_i cotransport has been pursued extensively in vitro using immortalized OK cells, which exhibit a proximal tubule-like phenotype that includes expression of the Npt2a NaP_i cotransporter and the PTHR (Jüppner et al., 1991; Rabito, 1986). Considerable evidence supports cAMP/PKA-mediated signaling, while other observations point to an important contribution of inositol phosphates/PKC. The extensive body of work on this subject has been reviewed elsewhere (Muff et al., 1992; Murer et al., 2000; Pfister et al., 1999) and described in the previous edition of this text (Bringhurst and Strewler, 2002). Recent incisive work and the discovery of cytoplasmic binding partners for the PTHR and Npt2a have largely reconciled the apparently disparate views. The salient features of PTHR signaling of proximal tubule phosphate transport can be summarized as follows.

PTHRs, as noted earlier, are expressed at both apical and basolateral surfaces of proximal tubule cell membranes (Amizuka et al., 1997; Ba et al., 2003; Traebert et al., 2000). Both PTH(1−34) and PTH(3−34), thought to be a relatively PKC-selective agonist, induced rapid removal of apical NaP_i proteins when selectively applied to apical surfaces of perfused murine proximal tubules or proximal-like OK cells (Pfister et al., 1999; Traebert et al., 2000). Only PTH(1−34) promoted Npt2a endocytosis when added at basolateral surfaces. Two conclusions can be drawn from these findings. First, they are consistent with the expression of PTHRs at both membrane domains. Second, they are compatible with the view that apical PTHR activates both PKA and PKC, whereas basolateral PTHRs couple primarily to PKA. The biological

significance of these findings may relate to the dynamics of PTHR signaling and the duration of the phosphaturic action of PTH. Short-term, acute regulation of phosphate absorption is mediated mainly by the PKA pathway, whereas long-term, persistent actions are signaled by PKC (Guo et al., 2013; Nagai et al., 2011).

Independent studies uncovered a likely molecular basis for the polarized PTH action and asymmetric effects and signaling of PKC and PKA. The explanation stems from the localized expression of the adapter protein NHERF1. NHERF1 is a PDZ protein that binds to both the PTHR and Npt2a (Hernando et al., 2002; Mahon et al., 2002; Wade et al., 2003). In the absence of NHERF1, mice exhibit a phosphate-wasting phenotype (Shenolikar et al., 2002). NHERF1 is abundantly expressed at proximal tubule brush border membranes in the rat, and is also detected in the cytoplasm and on basolateral membranes (Wade et al., 2001). In mice, NHERF1 is found exclusively on proximal tubule brush border microvilli (Wade et al., 2003). In OK/H cells, which lack NHERF1, PTH fails to inhibit Na-Pi cotransport, and this defect can be surmounted by overexpressing NHERF1 (Mahon et al., 2003).

According to presently accepted views, PTHR signals through PKA in the absence of NHERF1 and by means of PKC in its presence (Mahon et al., 2002). Thus, at basolateral membranes, where NHERF1 is absent, PTH would be expected to signal through adenylyl cyclase and PKA. At apical (i.e., luminal or mucosal) cell membranes, signaling would be predicted to be mediated by PLC and PKC because of the coupling between the PTHR and PLC (Mahon and Segre, 2004). These predictions are compatible with the observations that PTH(1–34) evoked Npt2a sequestration when added to either cell surface, whereas PTH(3–34), which activates PKC but not PKA, induced Npt2a internalization only when applied to the luminal surface (Traebert et al., 2000). Consistent with this scheme, more recent studies reveal that PTH(3–34) was unable to promote Npt2a internalization from proximal tubule brush border membranes prepared from NHERF1-null mice (Capuano et al., 2006). Activation of PLC by PTH was impaired; bypassing this defect by directly activating PKC with a diacylglycerol analog caused Npt2a internalization in proximal tubules of both wild-type and NHERF1-null mice. Although these are elegant and compelling observations, their relevance to the regulation of phosphate transport under physiological and pathophysiological conditions is unsettled. Complicating this picture, metabolism of cAMP involves nucleotide degradation to adenosine by brush border membrane ectoenzymes such as ecto-5′-nucleotidase. PTH(1–34) augmented ecto-5′-nucleotidase activity in apical membranes of OK cells (Siegfried et al., 1995). This effect was mimicked by PTH(3–34) but not by forskolin. Both PTH fragments increased cytoplasmic Ca^{2+} and stimulated PKC activity. Conversely, stimulation of ecto-5′-nucleotidase activity was blocked by inhibitors of PKC. Thus, PKC-mediated stimulation of 5′-nucleotidase thereby bolsters the effects transduced by PKA.

PTHRs present on proximal tubule luminal membranes are presumably activated by PTH peptides that are filtered at the glomerulus and appear in the luminal fluid. Most of these peptides or smaller fragments are absorbed (Kau and Maack, 1977), internalized (Hilpert et al., 1999), and metabolized (Brown et al., 1991; Daugaard et al., 1994; Yamaguchi et al., 1994) during their passage through the nephron. However, given the increased generation and accumulation of amino-truncated PTH peptides during kidney disease and other pathological settings, it is likely that significant amounts of biologically active PTH reach luminal brush border membranes and would be expected to elicit Npt2a/NPT2a internalization with attendant elevation of urinary phosphate excretion. Such actions might represent an adaptive response to the elevation of plasma phosphate in chronic kidney disease. By contrast, in distal tubules, which lack NHERF1, no such effect would be anticipated.

Not covered here and only partially understood are the convergent actions of PTH and FGF23 on NPT2A and phosphate transport. PTHR and FGFR1, through distinct signaling pathways, both require NHERF1 for their inhibitory effects (Sneddon et al., 2016). The details of how a G-protein-coupled receptor and a receptor tyrosine kinase produce convergent effects to phosphorylate the same critical residue on NHERF1 remains to be defined.

Sodium and hydrogen excretion

Beyond its effects on mineral-ion metabolism, PTH is involved in acid–base balance through its actions on Na/H exchange in proximal tubules. Acute (Ellsworth and Nicholson, 1935; Hellman et al., 1965; Kleeman and Cooke, 1951; Nordin, 1960) or chronic (Hulter and Peterson, 1985) increases in PTH exert a prompt alkalotic response attended by elevated bicarbonate excretion. This action stems from PKA-dependent acute inhibition of NHE3. Chronic exposure to elevated PTH downregulates NHE3 expression (Lee et al., 2017). PTH actions on NHE3 involve and require NHERF1 (Cunningham et al., 2010). Sporadic case reports notwithstanding, primary hyperparathyroidism is generally not attended by consistent or remarkable changes in serum pH and is largely asymptomatic (Bilezikian, 2012; Coe, 1974).

PTH inhibits acidification by suppressing the NHE3, the Na^+/H^+ exchanger. This involves activating adenylyl cyclase, NHERF1, which serves as a scaffold to assemble PKA and NHE3, followed by phosphorylation and inhibition of NHE3

(Moe et al., 1995; Weinman et al., 1998, 2005). Notably, the inhibitory effect of PTH on proximal tubules does not necessarily result in increased bicarbonate excretion (Bank and Aynedjian, 1976; Puschett et al., 1976) and is not accompanied by appreciable reductions in serum bicarbonate (Hulter, 1985). These results suggest that distal tubule compensatory bicarbonate absorption (Bichara et al., 1986) and acidification by downstream tubule segments in response to PTH (Paillard and Bichara, 1989) mitigate the upstream actions of PTH. Secondary actions of PTH to mobilize bicarbonate from bone also contribute to the absence of an effect on systemic pH (Hulter and Peterson, 1985). More important than its modest effects on net bicarbonate balance or pH homeostasis, however, is the permissive action of bicarbonate to facilitate PTH-dependent distal tubule calcium absorption (Marone et al., 1983; Mori et al., 1992; Sutton et al., 1979), a primary function of PTH.

Na^+/H^+ exchange mediates most proximal tubule sodium absorption (Palmer and Schnermann, 2015). Although PTH inhibits Na^+/H^+ exchange and proximal sodium absorption, PTH has a negligible effect on net sodium excretion because of compensatory absorption by downstream tubule segments (Harris et al., 1979). Natriuretic actions of PTH, however, have been described in experimental animals (Bichara et al., 1986; Hellman et al., 1965) and humans (Jespersen et al., 1997).

The fundamental mechanism whereby PTH inhibits Na^+/H^+ exchange differs from its action on Na-Pi cotransport. Whereas PTH decreases Na-Pi cotransport by sequestering Npt2a from brush border membranes, PTH acutely regulates Na^+/H^+ exchange by PKA-dependent NHE3 phosphorylation (Hamm et al., 2008). Decreased NHE3 activity is followed several hours later by reduced brush border membrane NHE3 abundance (Fan et al., 1999). Details of this process and the involvement of NHERF1 are detailed in the next section.

Na^+/H^+ exchange is a dissipative—i.e., secondary active—transport process that depends on the continuous extrusion of Na across basolateral cell membranes. This is accomplished by the ATP-dependent Na^+,K^+-ATPase. Data showing that PTH inhibits the Na^+,K^+-ATPase have been published (Ribeiro and Mandel, 1992; Zhang et al., 1999). An inhibitory action of PTH on Na^+,K^+-ATPase would certainly contribute to, or explain, reduced Na^+/H^+ exchange. However, such an action would be expected to have profound effects on proximal tubule ion transport and all Na-coupled transport processes such as those mediating glucose (Na-glucose) and amino acid (Na-amino acid) cotransport, and perhaps Na-Pi cotransport. Moreover, the inhibitory action of PTH should extend to virtually all cells expressing PTHR including the distal tubule. In this setting, blockade of the Na^+,K^+-ATPase would be expected to reduce Na^+/Ca^{2+} exchange and decrease net calcium absorption, when in fact just the opposite occurs. The described actions of PTH seem remarkably specific for the proximal tubule Na^+,K^+-ATPase and for Na^+/H^+ exchange. A rational explication of these findings awaits further clarification.

Parathyroid hormone regulation of proximal tubular sodium and hydrogen excretion

Efficient bicarbonate absorption by proximal tubules requires NHERF1. Targeted disruption of NHERF1 virtually eliminates PTH- and forskolin-inhibited Na^+/H^+ exchange in proximal tubule cells (Cunningham et al., 2004). This defect could be restored by infecting the cells with an adenovirus containing NHERF1. Interestingly, cAMP generation and PKC activation were equivalent in proximal tubule cells from wild-type mice and NHERF1-null animals. This result seemingly contrasts with the paradigm of the PTH "signaling switch" advanced by Mahon and Segre (Mahon et al., 2002), where PTHR signaling proceeds through cAMP in the presence of NHERF1 but by PKC in its absence. However, mouse proximal tubules express both NHERF1 and NHERF2, and NHERF2 expression is normal in NHERF1-null mice (Cunningham et al., 2008; Shenolikar et al., 2002). Alternate PDZ proteins such as PDZK1 could also compensate for the lack of NHERF1 (Ardura and Friedman, 2011; Yeruva et al., 2015). Thus, it is entirely possible that NHERF2 compensates for the absence of NHERF1, binds the PTH receptor and directs appropriate signaling and cell functions. Notably, OK cells express NHERF1 but not NHERF2 (Wade et al., 2001). Rats too express only NHERF1 on proximal tubule brush border membranes. Thus, OK cells are more of a model for the rat proximal tubule than for that of humans or mice, where both NHERF1 and NHERF2 are expressed (Wade et al., 2003). Thus, results of studies conducted with OK cells demonstrating an absolute role of NHERF1 in PTHR mediated inhibition of Na-Pi cotransport (Mahon et al., 2003) may have fortuitously benefited from the absence of NHERF2.

The majority of PTH effects appear to be mediated by PKA, and to a lesser extent by PKC. However, recent evidence uncovered an alternative pathway that involves cAMP but utilizes exchange protein directly activated by cAMP (EPAC) rather than PKA as an effector (Fujita et al., 2002). Studies employing proximal tubule cells derived from wild-type and NHERF1-null mice revealed a role for EPAC in mediating Na^+/H^+ exchange (Murtazina et al., 2007).

Following secretion of H^+ in exchange for one Na^+ ion by the apical cell membrane Na^+/H^+ exchanger, OH^- is generated within the cell. This is converted to HCO_3^- which is extruded across basolateral cell membranes. This is accomplished by Na^+-dependent-HCO_3^- (NBC1-4, SLC4A4) cotransporters (Boron, 2006; Romero et al., 2004; Soleimani

and Burnham, 2001). The possibility that PTH inhibits bicarbonate absorption by an action on basolateral HCO_3^- exit was uncertain and this action was attributed to an effect on the Na^+,K^+-ATPase. More recent studies reveal direct effects of PTH on NBC activity through multiple signaling pathways (Ruiz et al., 1996). This action requires NHERF1 (Bernardo et al., 1999; Weinman et al., 2001). NHE3 is a target for PKA-mediated phosphorylation (Zhao et al., 1999). A role for PKC on PTH-regulated NHE3 is uncertain. Apical PTHR stimulation preferentially activates PKC. PTH induces phosphorylation of multiple serine residues within the cytoplasmic tail of NHE3 (Collazo et al., 2000). Phosphorylation is maximal within 5 min and associated with a reduction in NHE3 activity but not surface expression.

By way of summary, PTH regulates Na^+/H^+ exchange primarily by an immediate inhibitory action that depends upon phosphorylation and requires the presence of NHERF1. PKA and PKC phosphorylate NHE3 (Lee et al., 2017). Following the initial inhibition of membrane-associated NHE3, the protein is withdrawn from the membrane but unlike NPT2A is not degraded or downregulated. Thus, following dephosphorylation the transporter likely is recycled to the plasma membrane.

Vitamin D metabolism

The biologically active form of vitamin D, $1.25(OH)_2D_3$, is synthesized by a cascade of multiorgan processes, the penultimate step of which is 1α hydroxylation that proceeds in proximal renal tubules and is regulated by PTH and the CaSR calcium-sensing receptor (Nolin and Friedman, 2018).

Parathyroidectomy reduces $1.25(OH)_2D_3$ synthesis, whereas PTH administration increases renal 1α-hydroxylase activity (Armbrecht et al., 2003; Fraser and Kodicek, 1973; Walker et al., 1990). Increased synthesis of *CYP27B1*, the $25(OH)D_3$ 1α-hydroxylase gene, results from kidney-specific regulated expression, where the promoter is rapidly induced in response to PTH (Christakos, 2017; Meyer et al., 2017)}. Positive actions of PTH on 1α-hydroxylase expression and $1.25(OH)_2D_3$ biosynthesis are counterregulated by the CaSR (Maiti and Beckman, 2007; Maiti et al., 2008).

PTH not only promotes $1.25(OH)_2D_3$ synthesis but also regulates its degradation. 24-hydroxylation of $1.25(OH)_2D_3$ is the first step in the catabolic inactivation of $1.25(OH)_2D_3$ (Carpenter, 2017; Zierold et al., 2003). It was thought that only proximal renal tubules expressed 24-hydroxylase. Distal tubules, however, take up $1.25(OH)_2D_3$, express the vitamin D receptor, and possess vitamin D-dependent calcium-binding proteins. 24-hydroxylase message, protein, and activity have been demonstrated in distal tubule cells (Yang et al., 1999) and human distal tubules (Blomberg Jensen et al., 2010). Whereas PTH reduces 24-hydroxylase activity in proximal tubule cells, PTH and cAMP augment 24-hydroxylase activity in murine distal tubule cells (Yang et al., 1999). Oppositely oriented actions of PTH on 24-hydroxylase activity suggest differential regulation of 24-hydroxylase expression in proximal and distal tubules.

The signaling pathways employed by the PTHR to increase $1.25(OH)_2D_3$ synthesis have been examined extensively in vivo and in vitro. Involvement of cAMP is suggested by the fact that the PTH effect can be mimicked by cAMP analogs, forskolin, and phosphodiesterase inhibitors (Armbrecht et al., 1984; Henry, 1985; Horiuchi et al., 1977; Korkor et al., 1987; Larkins et al., 1974; Rost et al., 1981; Shigematsu et al., 1986). PTH- or forskolin-stimulated transcriptional induction of 1α-hydroxylase occurred and was blocked by the PKA inhibitor H89 (Murayama et al., 1999). A role for PKC in regulating 1α-hydroxylation has been identified from studies of the effects of PTH on isolated proximal tubules (Janulis et al., 1992, 1993). PKC activation produced rapid (30–60 min) increases of $1.25(OH)_2D_3$ synthesis (PKC and $1.25(OH)_2D_3$ synthesis correlated with PTH concentrations 100-fold to 1000-fold lower than those required for the activation of PKA). Moreover, inhibition of PKC blocked $1.25(OH)_2D_3$ synthesis, and amino-truncated PTH fragments that stimulate PKC but not PKA likewise enhanced $1.25(OH)_2D_3$ formation. Taken together, the results suggest a predominant effect of PKA on transcriptional regulation of *CYP27B1* gene expression and a more rapid posttranscriptional action of PKC on 1α-hydroxylase enzymatic activity.

Other renal effects of parathyroid hormone

PTH exerts a variety of additional described, but far less well understood, effects on ion transport, such as activation of apical Cl^- channels (Suzuki et al., 1991) and metabolism.

The kidney contributes importantly to systemic gluconeogenesis (Friedman and Torretti, 1978; Schoolwerth et al., 1988), although this is not normally apparent because of balancing by renal medullary glycolysis. PTH-dependent renal gluconeogenesis is attended by segmental and internephron heterogeneity. PTH increases gluconeogenesis (Chobanian and Hammerman, 1988), ammoniagenesis (Wang and Kurokawa, 1984), and phosphoenolpyruvate carboxykinase (Watford and Mapes, 1990) mRNA expression in proximal tubules. PTH primarily stimulates gluconeogenesis in cortical S1 and S2

proximal tubules (Wang and Kurokawa, 1984). Although juxtamedullary S1 proximal tubules exhibit the highest rate of gluconeogenesis, it is unaffected by PTH.

Gluconeogenesis is linked to ammoniagenesis because both are stimulated by acidosis and by PTH. Moreover, L-glutamine, which is the major gluconeogenic precursor, is also a substrate for ammoniagenesis. Thus, there may be some metabolic interdependence of PTH actions on gluconeogenesis and ammoniagenesis.

PTH also exerts conspicuous morphological effects causing rapid microvillus shortening (Hruska et al., 1986). This action appears to be specific for proximal tubule cells. Emerging observations suggest that this cell-specific effect may be due to prominent brush border expression of NHERF1 in proximal tubule cells and its absence from distal tubule cells.

It is not known if PTH regulation of Na-Pi cotransport, Na^+/H^+ exchange or Na^+/Ca^{2+} exchange, or its metabolic actions on 25-hydroxyvitamin D-1α-hydroxylase, gluconeogenesis, and ammoniagenesis, involves more complicated second messenger signaling. Notably, PTH receptors activate additional signaling pathways involving phospholipase A_2 (Mandel and Derrickson, 1997; Ribeiro et al., 1994), PLD (Garrido et al., 2009; Somermeyer et al., 1983), and MAPK (Quamme et al., 1994; Swarthout et al., 1997; Verheijen and Defize, 1997). Thus, subtle differences in regulatory control or changes in signaling may arise in pathological settings.

Renal expression and actions of parathyroid hormone–related protein

PTHrP is expressed by glomeruli, distal tubules, and collecting ducts of fetal kidneys and by proximal convoluted tubules, distal convoluted tubules, and glomeruli of adult kidneys (Aya et al., 1999; Philbrick et al., 1996). In rat kidneys, PTHrP mRNA is found in glomeruli, proximal convoluted tubules, and macula densa but not in cortical ascending limbs, medullary ascending limbs, distal convoluted tubules, or collecting ducts (Yang et al., 1997), whereas other studies reported PTHrP transcripts in glomerular mesangial cells and proximal and distal tubules (Soifer et al., 1993). Although PTHrP is critical for normal cardiovascular and bone development, the kidneys of PTHrP-null mice appear histologically normal (Karmali et al., 1992) and a physiological role for PTHrP on the kidney is uncertain (Mundy and Edwards, 2008).

Amino-terminal fragments of PTHrP exhibit renal actions including stimulation of cAMP production, regulation of Na-Pi cotransport, and calcium excretion that are largely indistinguishable from those of PTH (Everhart-Caye et al., 1996; Horiuchi et al., 1987; Horwitz et al., 2003b; Pizurki et al., 1988; Scheinman et al., 1990; Yates et al., 1988). Some differences may be discerned. In distal tubule cells, for instance, PTHrP(1–34) and PTHrP(1–74) were more potent than equimolar concentrations of PTH(1–34) and PTH(1–84) in stimulating adenylyl cyclase (Friedman et al., 1989). In contrast, PTHrP(1–36) has a markedly lower effect at raising serum $1.25(OH)_2D_3$ levels (a consequence of its action on proximal tubules) in human volunteers than does comparable administration of PTH(1–34) (Horwitz et al., 2003b).

PTHrP possesses mid- and carboxy-terminal regions that have distinct biological actions (Clemens et al., 2001; Philbrick et al., 1996). Longer PTHrP fragments may exhibit unique renal properties. For example, bicarbonate excretion in perfused rat kidneys was enhanced equivalently by PTHrP(1–34) and PTH(1–34), whereas PTHrP(1–84), PTHrP(1–108), and PTHrP(1–141) were each less active than PTH(1–34) (Ellis et al., 1990). As discussed in Chapter 25, the PTHrP gene can generate multiple transcripts and protein products, some of which may undergo unique nuclear localization. It is therefore possible that locally expressed PTHrP exerts actions in the kidney that are not shared with PTH.

A possible role for locally produced PTHrP in the renal response to insufficient vascular perfusion has been suggested by findings that PTHrP expression is induced by ischemia or following recovery from ATP depletion (García-Ocaña et al., 1999; Largo et al., 1999; Soifer et al., 1993). PTHrP is expressed by the intima and media of human renal microvessels and in the macula densa (Massfelder et al., 1996). PTHrP (like PTH) increases renin release from the juxtaglomerular apparatus and also stimulates cAMP in renal afferent and efferent arterioles, leading to vasodilation and enhanced renal blood flow (Endlich et al., 1995; Helwig et al., 1991; Musso et al., 1989; Saussine et al., 1993). Both cAMP and nitric oxide have been implicated in PTHrP-induced in vitro vasorelaxation (Massfelder et al., 1996). Thus, enhanced local PTHrP production induced by inadequate renal perfusion or ischemia may be involved in local and systemic autoregulatory mechanisms. According to this view, direct local vasodilatory actions are supplemented by the systemic activation of angiotensinogen, which increases arterial pressure and further sustains renal blood flow.

PTHrP promotes fibrogenesis and is upregulated in experimental nephropathy (Funk, 2001; Ortega et al., 2005, 2006). Locally produced PTHrP may contribute to the proinflammatory effect by activating NF-KB and ERKs (Ramila et al., 2008). The incidence of renal hypertrophy is greater in diabetic mice overexpressing PTHrP than in control animals, suggesting that constitutive PTHrP overexpression may elicit adaptive responses such as nitric oxide production to mitigate against renal damage (Izquierdo et al., 2006).

Chapter outline

Introduction

Parathyroid hormone (PTH) and PTH-related protein (PTHrP) mediate their principal biological actions by acting on a single cell-surface receptor, the type-1 PTH/PTHrP receptor, or PTHR1. The PTHR1 thus stands as a key regulatory molecule that is essential for normal physiology at all stages of life. The biological situation is somewhat unique in that the one receptor responds to two endogenous ligands to thereby control two disparate physiological processes: the maintenance of blood calcium and phosphate homeostasis via PTH and the timing of cell differentiation events in the developing skeleton and other tissues via PTHrP. The PTHR1 also holds interest as a prospective drug target, as pharmacologic agents that specifically modulate its activity can potentially be used to treat disturbances of bone and calcium metabolism that occur in a variety of pathologic conditions, such as osteoporosis.

The endogenous PTH and PTHrP ligands are polypeptide chains of 84 and 141 amino acids, respectively, with the first 34 amino acids containing sufficient information for high-affinity binding to the PTHR1 and potent activation of downstream signaling responses. Thus synthetic PTH(1–34) and PTHrP(1–34) peptides can generally mimic most of the biological actions of the full-length molecules. Nevertheless, certain functional activities have been reported for peptides derived from the C-terminal portions of PTH and PTHrP, which has led to the notion that other receptors, distinct from the PTHR1, might exist that bind the C-terminal portion of the ligands, although no such receptor has so far been identified. For the PTHR1, much effort has been directed at elucidating the mechanisms by which the ligands PTH and PTHrP engage the receptor and stimulate signal transduction. These studies generally reveal that PTH(1–34) and PTHrP(1–34) interact

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00028-2

with the PTHR1 in highly similar, yet not identical, fashions. Consistent with this, the primary structures of the ligands exhibit considerable amino acid sequence homology in the amino-terminal region, particularly at the N-terminal 1−14 portion, which is critical for receptor activation, with eight amino acid identities, while the 15−34 portion, which contributes to binding affinity, shows only a moderate level of homology, with three identities. As discussed later in this chapter, studies suggest that differences can indeed be discerned in the binding modes utilized by PTH(1−34) and PTHrP(1−34) and that such differences can lead to differences in functional effects, particularly in the duration of the signaling responses induced. Such findings further support the notion that the capacity of the PTHR1 to regulate the aforementioned two disparate types of physiological processes—the endocrine control of mineral ion homeostasis and the paracrine control of tissue development—is at least partly based on differences in the mechanisms by which the two respective ligands engage the receptor.

Early work conducted prior to the cloning of the PTHR1 in 1991 and which used canine or bovine renal membrane preparations or cell lines derived from bone or kidney gave initial clues as to the basic pharmacology of PTH ligand binding to endogenous receptor binding sites and the downstream signaling responses that could be activated. This work was made possible in large part by the development of peptide synthesis technology and its early application to PTH (Potts et al., 1971), which yielded most notably the PTH(1−34) peptide, as well as radioiodinated derivatives that enabled direct characterization of the binding sites used (Segre et al., 1979). Such studies further revealed that residues in both the N- and the C-terminal region were important for overall binding affinity (Nussbaum et al., 1980). Parallel studies revealed that PTH peptides induced rapid and robust increases in intracellular cAMP, and that the N-terminal residues of the ligand were critical for activating this response. That this response was mediated by a cell-surface G-protein-coupled receptor (GPCR) was indeed borne out in 1991 by the cloning of the cDNA encoding the PTHR1 from kidney- and bone-derived cell lines (Juppner et al., 1991), which revealed the seven membrane-spanning-domain protein architecture that defines all 800 or so members of the GPCR superfamily. A key goal now is to elucidate the specific mechanisms by which the PTHR1 uniquely recognizes its two specific ligands, PTH and PTHrP, and activates selected intracellular effectors in different target cells. Progress toward this goal has been made via the application of a number of molecular and pharmacological approaches, such as the use of receptor mutagenesis coupled with peptide analog design strategies to reveal sites of specific intermolecular contact and clues about conformational changes involved in activation. The use of genetically modified mice engineered so as to have a specific alteration in a selected component of the ligand−receptor response system have also helped make possible a level of analysis at the whole-animal physiological level. These experimental systems ultimately help reveal the involvement of the PTHR1 and its ligands in skeletal and mineral ion physiology as well in diseases, such that they could lead to the development of new forms of therapy targeted to the PTHR1. Broader views of the roles that the PTHR1 and its ligands play in the systemic control of metabolic processes in bone and kidney, and developing tissue, as well as the downstream processes that the receptor controls within target cells, are discussed in detail in other chapters (see Chapters 24−27, 32, and 52). This chapter then focuses on the molecular properties of the PTHR1 per se, and principally on the mechanisms by which PTH and PTHrP ligands, via their N-terminal portions, interact with this receptor and induce signal transduction processes. It will also discuss findings on the so-called type-2 PTH receptor, or PTHR2, and its endogenous ligand, tuberoinfundibular peptide of 39 residues (TIP39), as well as the possibility that other, as yet unidentified, receptors exist that can bind and potentially respond to the carboxy-terminal portion of the endogenous PTH and PTHrP ligands, which appear not to be contributing to interactions with the PTHR1.

The PTHR1 is a class B G-protein-coupled receptor

The PTHR1 exhibits the general protein architecture seen in each of the class B GPCRs and thus is a single-chain integral membrane protein containing a relatively long amino-terminal extracellular domain (ECD) of ∼170 amino acids (after removal of residues 1−22, which act as the signal sequence), a transmembrane domain (TMD) or core region comprising the seven membrane-spanning α helices (TMs 1−7) and their interconnecting extracellular and intracellular loops (ECLs 1−3 and ICLs 1−3), and a C-terminal tail extending from the base of TM7 (∼Cys452) to the C terminus (Met593) (Fig. 28.1A). As a class B GPCR, the PTHR1 contains none of the hallmark amino acid residues and sequence motifs that define the three other main classes of GPCRs: the class A receptors represented by the β_2Ar, the class C GPCRs represented by the calcium-sensing receptor, and class F receptors, as represented by the Frizzled receptors (Fredriksson et al., 2003). Instead, the PTHR1 exhibits a distinct pattern of amino acids that is conserved in each of the 14 or so other class B GPCRs, which include the receptors for calcitonin, secretin, glucagon, glucagon-like peptide-1 (GLP1), corticotropin-releasing factor (CRF), and several other peptide hormone ligands (Segre and Goldring, 1993). Nevertheless, comparison of the three-dimensional structures obtained for GPCR representatives from each of the main GPCR families reveals

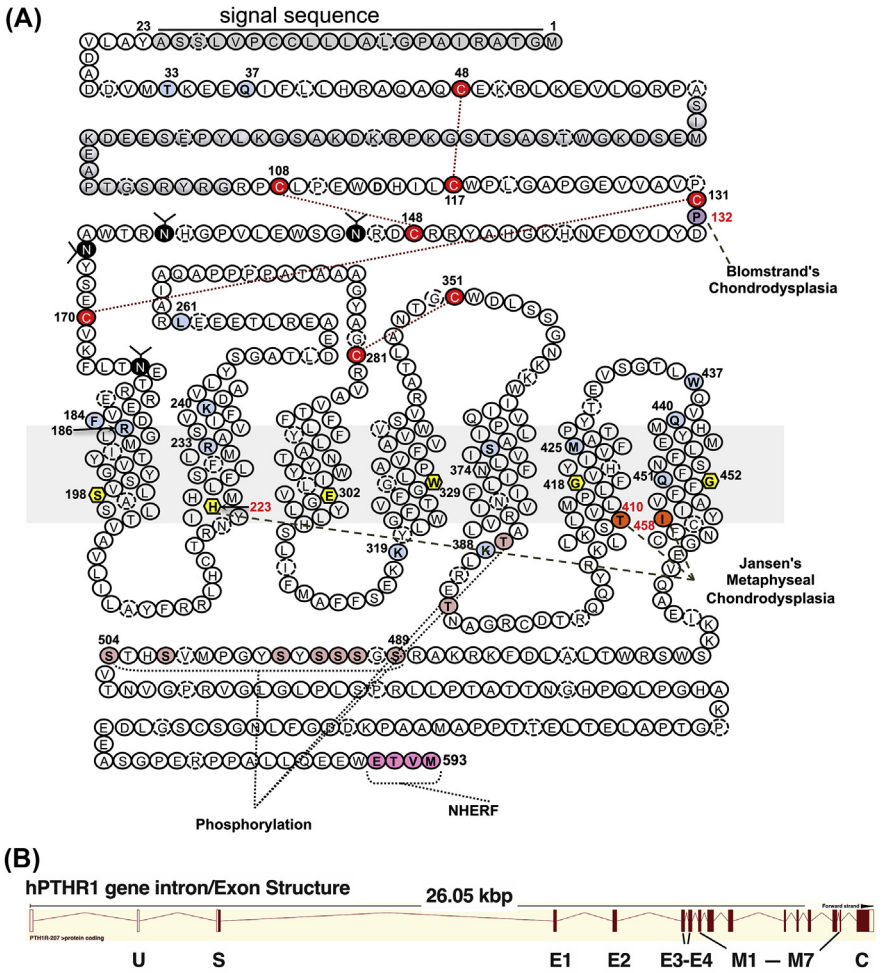

FIGURE 28.1 Primary structure of the human parathyroid hormone receptor type 1 protein and corresponding gene organization. (A) The human parathyroid hormone receptor type 1 (*hPTHR1*) protein is displayed to illustrate the domain organization and locations of selected key residues, including the eight extracellular cysteines involved in a disulfide bond network (*connecting dotted lines*); the four glycosylated extracellular asparagines; Pro132, at which loss-of-function mutations occur in Blomstrand's chondrodysplasia (compound homozygous) and in failed tooth eruption (heterozygous); His223, Thr410, and Ile458, at which activating mutations occur in Jansen's metaphyseal chondrodysplasia; cytoplasmic sites of serine and threonine phosphorylation; the four C-terminal residues involved in PDZ-domain interactions with Na^+/H^+ exchange regulatory factor 1 (*NHERF*) proteins; and a number of residues shown by mutagenesis and/or cross-linking studies to be involved in ligand interaction (*filled shaded circles* with position numbers). Also shown is the residue in each transmembrane domain helix that is the most conserved among the class B G-protein-coupled receptors (*filled hexagons*). (B) The intron/exon structure of the hPTHR1 gene with coding and noncoding exons indicated as *filled* and *open boxes*, respectively.

similarities not only in the basic seven-TMD protein fold that is shared across all GPCR classes, but also in some of the key interhelical contact points that occur within the hepta-helical bundle and are thought to mediate key mechanistic steps of activation (Cvicek et al., 2016). At least some aspects of function are thus likely preserved, at least topologically, between the PTHR1 and perhaps most of the 800 or so other GPCRs encoded in the human genome.

While each class B GPCR responds to a peptide ligand of moderate size—about 30–40 amino acids in length—the PTHR1 is the only class B GPCR for which the endogenous ligands extend more C-terminally, as PTH is 84 amino acids in length and PTHrP is 141 amino acids. Such C-terminal extensions are absent in the ligands identified in the genomes of fish and other nonmammalian species (Rubin and Jüppner, 1999; Mirabeau and Joly, 2013), and thus appear to be modifications that occurred later in vertebrate evolution. In any event, most if not all of the available data indicate that only the first 34 amino acids or so of PTH and PTHrP participate in binding to the PTHR1, such that PTH(1–34) and PTHrP(1–34) peptides exhibit nearly the same affinities and signaling potencies on the PTHR1 as the corresponding full-length polypeptides (Li et al., 2012; Dong et al., 2012).

Parathyroid hormone receptor gene structure and evolution

Structure of the PTHR1 gene

The gene encoding the human PTHR1 resides on chromosome 3 (locus 3p22−p21.1) and spans ∼26 kb of DNA (Fig. 28.1B) (McCuaig et al., 1994; Kong et al., 1994). The predicted transcript consists of 14 coding exons and 2 noncoding exons, ranging in size from 42 bp for exon M7 encoding a portion of transmembrane helix 7 to more than 400 bp for exon T encoding the C-terminal tail. The introns vary in size from 81 bp between exons M6 and M6/7 to more than 10 kb between exon S encoding the signal sequence and exon E1 encoding the N-terminal portion of the mature receptor. Three promoter regions have been identified for the gene and shown to be active at different levels in different tissues (Minagawa et al., 2001; Bettoun et al., 1997; Amizuka et al., 1997). Expression of PTHR1 mRNA can be detected in a variety of fetal and adult tissues, including the adrenals, placenta, fat, brain, spleen, liver, lung, and cardiac muscle, with strongest signals observed in adult bone and kidney (Urena et al., 1993; Tian et al., 1993; Uhlen et al., 2015). The genes for the other class B GPCRs generally exhibit a similar intron/exon organization, which is consistent with their evolution from a common ancestor gene and utilization of a similar protein design for engaging their cognate peptide ligands (Hwang et al., 2013).

Evolution of the parathyroid hormone receptor−ligand system

Bioinformatics-based investigations of PTH receptor as well as PTH and PTHrP ligand coding sequences present in the genomes of species representing various stages of evolution have yielded clues about how the PTH ligand and receptor system first emerged and evolved over time to provide the complex developmental and adaptive capacities established in the mammalian species. These studies suggest that PTH receptors and ligands emerged before the evolution of the first vertebrates, as apparent orthologs of the receptor as well as PTH-like ligands have been detected in the genomes of early vertebrates, such as the elephant shark and sea lamprey, as well as some invertebrates, such as the tunicate *Ciona intestinalis* and the amphioxus *Branchiostoma floridae*, which are thought to be representative of early chordates (Fig. 28.2) (Kamesh et al., 2008; Pinheiro et al., 2012; Mirabeau and Joly, 2013; On et al., 2015; Cardoso et al., 2006; Hwang et al., 2013). Sequences with at least some homology (∼69% amino acid similarity) have also been identified in the genomes of several insects, such as the red flour beetle (*Tribolium castaneum*) and honeybee (*Apis mellifera*), but not in the fruit fly (*Drosophila melanogaster*) (Li et al., 2013; Cardoso et al., 2014). The biological function of any such invertebrate PTH receptor−like sequence remains unknown.

Genome studies also suggest that chromosomal rearrangements contributed to the diversification of the PTH ligand−receptor system. At least two copies of a PTH receptor gene family member are thus found in the haploid genomes of most vertebrate species, and these can be attributed, in part, to two rounds of whole-genome duplication that are thought to have occurred during the early phases of vertebrate evolution (Fig. 28.2) (Hwang et al., 2013; On et al., 2015; Pinheiro et al., 2012; Cardoso et al., 2006, 2014). These early duplications were followed by other gene duplications as well as deletion events that occurred at different points along the evolutionary paths leading to the divergent animal groups. The genomes of teleost fish, as represented by the zebrafish, *Danio rerio*, thus encode three receptors, the PTHR1, PTHR2, and PTHR3, but lack a PTHR4 gene as a putative partner to the PTHR2, apparently due to a deletion event that happened in early fish evolution (Rubin and Juppner, 1999; Hwang et al., 2013). Bird genomes encode PTHR1 and PTHR3, and lack PTHR2 and PTHR4, while mammals encode PTHR1 and PTHR2, and lack PTHR3 and PTHR4. The absence of a PTHR2 in birds and a PTHR3 in primates apparently reflects separate gene deletion events that occurred at distinct times during the evolution of these two vertebrate groups. The peptide ligands, as represented in humans by PTH, PTHrP, and TIP39, the last a ligand for the PTHR2 as discussed further in a later section, are presumed to have evolved in parallel with their receptors, and thus to have stemmed from some precursor peptide ligand that emerged at or about the time that the first chordates appeared, as indeed, PTH- and/or TIP39-like coding sequences are found in the genomes of early fish, as well as amphioxus and *C. intestinalis* (Rubin and Juppner, 1999, Yan et al., 2012; Pinheiro et al., 2012; Trivett et al., 2005; Liu et al., 2010). These findings are consistent with the notion that the PTH ligand−receptor system is an evolutionarily ancient adaption that emerged in some precursor form before the appearance of the first vertebrates and evolved over time so as to contribute importantly not only to the successful adaption of the animal to changing environments but also to the development of higher-order organ systems, such as the skeleton (Hogan et al., 2005; Suzuki et al., 2011; Trivett et al., 2005).

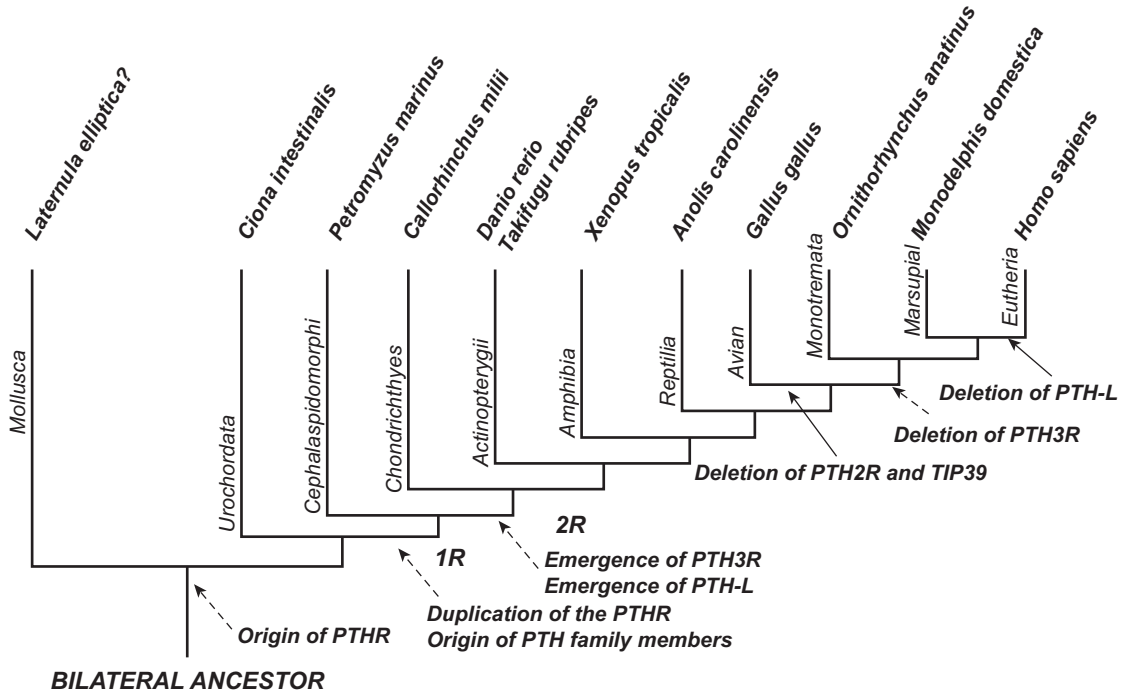

FIGURE 28.2 Evolutionary model for parathyroid hormone receptors. Shown is a tree diagram to depict that the ancestral parathyroid hormone receptor (*PTHR*) sequence probably originated before the appearance of the first chordates, as represented by the tunicate *Ciona intestinalis*, and that two rounds of whole-genome duplication (*1*R and *2R*) occurred before the emergence of the terrestrial vertebrates to result in three receptor subtypes—PTHR1, PTHR2, and PTHR3—with the expected fourth subtype lost by an early gene deletion event. The PTHR2 and PTHR3 subtypes were probably lost by later gene deletion events occurring with the radiations leading to birds and mammals, respectively. *Reproduced pending permission from Pinheiro, P. L., Cardoso, J. C., Power, D. M., Canario, A. V. 2012. Functional characterization and evolution of PTH/PTHrP receptors: insights from the chicken. BMC Evol. Biol. 12, 110.*

Mechanisms of ligand recognition and activation by parathyroid hormone receptors

Basic structural properties of the PTHR1

As in all class B GPCRs, the ECD contains six highly conserved cysteine residues that form a disulfide network (Fig. 28.1A) that maintains the tertiary fold of the ECD, which follows a tripartite helix–β sheet–helix pattern (Pioszak et al., 2008). The ECD contains four asparagines that are glycosylated during intracellular processing and transported to the plasma membrane. A feature of the ECD that is seen only in the mammalian PTHR1s, and not in the mammalian PTHR2s or any other class B GPCR, is a 44-amino-acid segment—Ser61–Gly105 in the human PTHR1—located between the first and the second cysteine. This segment is encoded by a separate exon, called E2, and appears not to contribute to function, as assessed by site-directed mutagenesis strategies and pharmacological analyses in transfected cells (Lee et al., 1994).

Other than the general seven membrane-spanning helical architecture, the class B receptors share no obvious homology with receptors from the other main GPCR subgroups, including the class A GPCRs, which comprise the largest GPCR subgroup and include the β-adrenergic receptor and rhodopsin as well-studied representatives. Nevertheless, the high-resolution structures now available for a number of GPCRs from each main class, including several class B GPCRs, suggest that certain relationships of structure and function might be preserved in all GPCRs, particularly in the intramolecular interaction networks that are located within the TMD bundle and mediate processes of receptor activation and G protein coupling (Bortolato et al., 2014; Cvicek et al., 2016). Within the class B GPCRs there are about 45 amino acid residues that are strongly conserved. These conserved residues are dispersed in the seven TM helices and in the ECD and probably help define the basic three-dimensional scaffold structure of the receptor and as well may participate more directly in basic mechanisms of activation, while other more divergent residues are likely to provide the specific recognition determinants used for selective binding of the appropriate peptide ligand.

Binding of a PTH agonist peptide ligand, such as PTH(1–34), to the extracellular surface of the PTHR1 induces a conformational change in the receptor that leads to G protein coupling and activation of downstream signaling responses (see Chapters 32 and 52 for an in-depth discussion of downstream signaling responses). In most target cells the PTHR1

couples strongly to G proteins containing the GαS subunit, and thus activates the adenylyl cyclase/cAMP/protein kinase A (PKA) signaling system. The agonist-stimulated PTHR1 can also activate other signaling systems, including the Gαq/phospholipase C (PLC)/IP3/iCa^{2+} pathway, the Gα12/DAG/PLD pathway, and the arrestin/ERK1/2 pathway, depending potentially on the type of target cell and PTH or PTHrP ligand analog used (Gesty-Palmer et al., 2006, 2013). PTHR1 signaling is generally thought to be a highly regulated process and thus to terminate relatively soon after initial binding via mechanisms involving receptor phosphorylation and internalization (Bisello et al., 2002; Malecz et al., 1998; Qian et al., 1998), but variations on this theme now seem possible, as discussed in a later section. It is now becoming clear that ligands with different structures can bind to a receptor in different modalities so as to induce different biological outcomes in target cells, in terms of type of pathway activated as well as the duration of the response, a concept generally referred to as biased agonism (Luttrell et al., 2015). This concept has particular relevance for the PTHR1, as it may help explain, at least in part, certain differences in biological actions that have been observed for PTH and PTHrP peptides (Horwitz et al., 2003) and, moreover, could provide a strategic basis for developing new ligand analogs for the PTHR1 that have therapeutic utility.

Two-site model of ligand binding to the PTHR1

Clues regarding the overall mechanism of ligand binding and agonist-induced activation used by the PTHR1 were initially obtained from receptor mutagenesis and photoaffinity cross-linking studies, but more recently have come from the successful application of X-ray crystallography and cryo-electron microscopy (cryo-EM) approaches to the analysis of several other class B GPCRs, either as intact receptors or as the isolated ECD or TMD. Such structural information for the PTHR1, however, is so far reported only for the isolated ECD in complex with PTH(15−34) or PTHrP(12−34) peptides (Pioszak et al., 2008, 2009). The emerging structural data combined are providing valuable insights into the basic mechanisms by which the class B GPCRs engage their cognate peptide ligand and activate signal transduction. The earlier studies on binding mechanisms for the PTHR1 performed in parallel by several groups led to the so-called "two-site" model of ligand−receptor interaction. According to the model, the ligand, such as PTH(1−34), first docks to the receptor via the binding of the C-terminal domain of the ligand, approximately residues 15−34, to the ECD of the receptor. Then the amino-terminal portion of the ligand, approximately residues 1−14, engages the extracellular surface of the TMD portion of the receptor to yield the intact ligand−receptor complex (Fig. 28.3). The ECD component of the interaction contributes predominantly to the overall binding affinity of the complex, while the TMD component mediates the process of receptor activation and G protein coupling. The experimental findings that led to this model came from studies employing, often in parallel, the two complementary approaches of receptor mutagenesis and photoaffinity cross-linking. By the former approach, receptors altered at specific residues or defined regions were generated and analyzed in pharmacologic binding and signaling assays for interaction with various peptide ligand analogs with defined structural modifications such that they could be used as functional probes of specific contact sites or regions. For example, a receptor chimera strategy based on the weaker binding of PTH(7−34) to the rat versus the human PTH receptor was used to establish that the ECD of the receptor was the major site of binding for the C-terminal portion of the ligand (Juppner et al., 1994). A similar chimera strategy based on the capacity of the analog Arg2-PTH(1−34), in which the highly conserved valine-2 is replaced by a bulky arginine, to function as an antagonist on the rat PTHR1 and an agonist on the opossum PTHR1 led to the finding that residue 370 at the extracellular end of TM5, alanine and serine in the opossum and rat receptors, respectively, is a key determinant of ligand-induced activation (Goltzman et al., 1975). Other such mutagenesis studies that followed, extending also to the PTHR2, further supported the two-domain model (Bergwitz et al., 1996, 1997; Turner et al., 1998). The second approach involving the use of photoaffinity cross-linking strategies provided more direct biophysical analyses of ligand and receptor sites in close intermolecular proximity. The method involved ligands modified at a selected position with an amino acid analog containing a photolabile side chain, typically benzophenylalanine (BPA) (Zhou et al., 1997). After binding to the receptor, the complex is UV irradiated, causing the BPA group to covalently link to a site in the target protein chain within a radius of a few angstroms. Initially BPA was thought to react rather nonselectively, but was later discovered to have a propensity to react with methionines (Wittelsberger et al., 2006b). In any event, the strategy resulted in the identification of a number of cross-links that could be mapped to specific receptor residues, including between positions 1 and 2 in the ligand and Met425 at the extracellular end of TM6 (Bisello et al., 1998; Gensure et al., 2001a), between ligand residue 13 and Arg186 at the extracellular end of TM1 (Adams et al., 1998), and between ligand position 23 and Thr33 and/or Gln27 at the N-terminal end of the receptor (Mannstadt et al., 1998). A number of other contacts involving residues in the middle or C-terminal region of PTH(1−34) or PTHrP(1−36) and various sites in the receptor were also mapped, although not always to specific receptor residues (Gensure et al., 2001b, 2003; Greenberg et al., 2000; Wittelsberger et al., 2006a). The information gained from these cross-linking studies provided distance constraints that enabled development of initial molecular models of the PTHR1·PTH ligand complex (Greenberg et al., 2000; Gensure

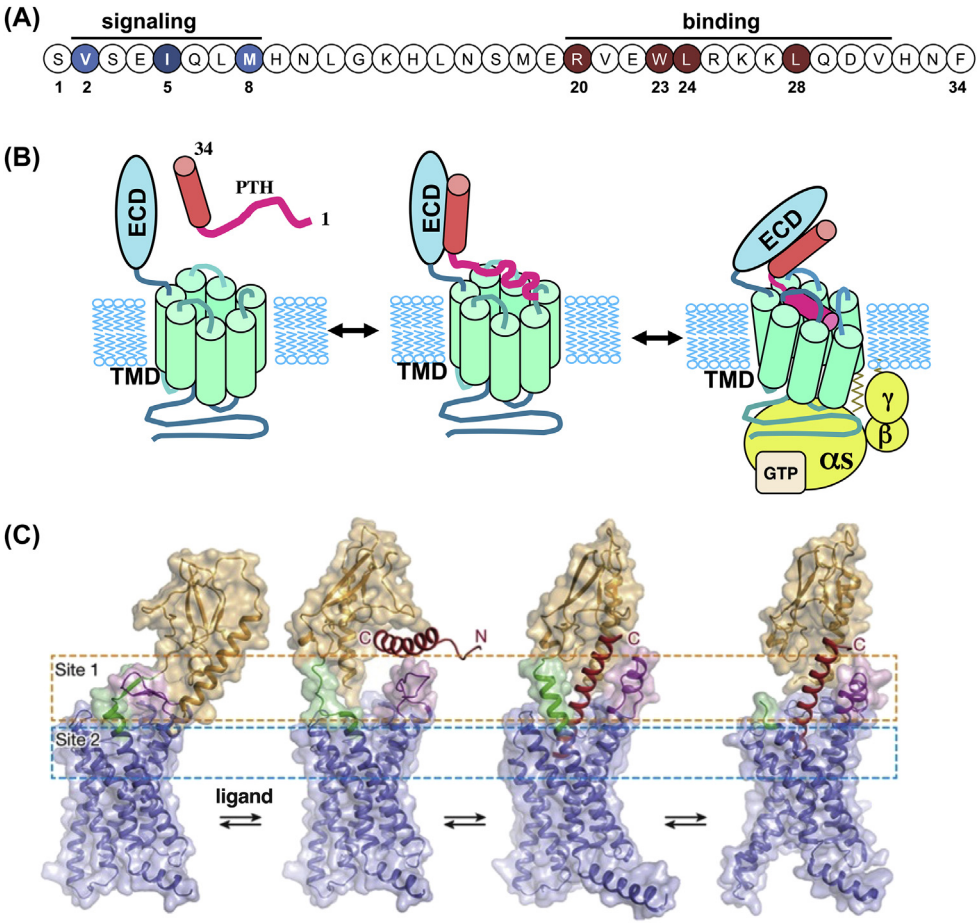

FIGURE 28.3 Ligand binding mechanisms at the parathyroid hormone receptor 1. (A) Sequence of PTH(1−34) highlighting the N-terminal residues Val2, Ile5, and Met8, which play critical roles in receptor activation, and the C-terminal residues Arg20, Trp23, Leu24, and Leu28, which play critical roles in receptor binding. (B) The two-domain model of ligand binding and activation at the PTHR1, as developed by cross-linking and mutagenesis data obtained for the parathyroid hormone receptor 1 (PTHR1): the C-terminal portion of PTH(1−34) first docks to the amino-terminal extracellular domain (*ECD*) of the receptor to provide affinity interactions, and then the amino-terminal portion of the ligand engages the transmembrane domain (*TMD*) of the receptor to induce conformational changes that enable G protein coupling. (C) Refinement of the two-domain model based on high-resolution X-ray crystal and cryo-electron microscopy structures of the glucagon receptor and GLP1 receptor, which are class B GPCRs structurally related to the PTHR1. The ligand, shown in *red*, binds as a nearly linear α helix and makes extensive contacts with exposed extracellular surfaces in both the ECD and the TMD receptor regions. Ligand binding results in an outward movement of the cytoplasmic termini of several of the TM helices, particularly TM6, to thus open a cavity that will accommodate the G protein. *(C) Reproduced pending permission from Zhang, H., Qiao, A., Yang, L., Van Eps, N., Frederiksen, K. S., Yang, D., Dai, A., Cai, X., Zhang, H., Yi, C., Cao, C., He, L., Yang, H., Lau, J., Ernst, O. P., Hanson, M. A., Stevens, R. C., Wang, M. W., Reedtz-Runge, S., Jiang, H., Zhao, Q., Wu, B. 2018a. Structure of the glucagon receptor in complex with a glucagon analogue. Nature 553, 106−110.*

et al., 2003; Wittelsberger et al., 2006a; Piserchio et al., 2002), although the incomplete nature of the input data left a fair amount of uncertainty.

The two-site model was also found to be relevant for most if not all of the other class B GPCRs and their cognate peptide ligands, as elucidated using similar functional and cross-linking-based approaches by other groups (Parthier et al., 2009). This basic model has now been confirmed and refined by high-resolution structural data that have been obtained using X-ray crystallography or cryo-EM approaches for several of the other class B GPCRs, including the CRFR1, the glucagon receptor, and the GLP1 receptor, although not yet for the PTHR1 (de Graaf et al., 2017). A key modification used in the crystallography work, and a potential limitation in terms of data interpretation, is the introduction of thermostabilizing point mutations and insertions of heterologous protein segments known to promote crystallization at dispersed positions in the receptor TMD, which generally tends to be conformationally dynamic. One set of findings from the functional studies that helped define the TMD component of the two-domain model for the PTHR1 was that short amino-terminal PTH fragment peptides, such as PTH(1−14) and PTH(1−11), which as unmodified peptides are inert for binding

and signaling due to a lack of stabilizing interactions with the ECD, could act as potent agonists when modified with certain helix-stabilizing and affinity enhancing substitutions. Furthermore, they could stimulate signaling via a PTHR1 construct that lacks most of the ECD (up to Glu182), about as potently as PTH(1−34) does on the intact PTHR1 (Shimizu et al., 2001). These findings highlight the functional autonomy of the N-terminal region of the ligand and the TMD of the receptor, and also suggested that ligands much smaller than PTH(1−34) that target the functionally critical TMD and thus act as potent PTH mimetics could be developed. Native PTH and PTHrP peptides are thought to bind to the PTHR1 via a sequential process that involves initial ligand interactions with the ECD followed by interactions with the TMD and the conformational rearrangements involved in activation (Fig. 28.3) (Hoare and Usdin, 2001). The nature of these conformational changes and the extent to which they may involve a higher-order folding of the complex, for example, a movement of the ECD relative to the TMD, remains an area of uncertainty, but the new class B GPCR structures now available provide clues as to the types of changes that might be possible for the PTHR1−PTH complex.

The crystal structures of the isolated ECD protein in complex with the PTH(15−34) or PTHrP(12−34) fragment suggest that the two ligands bind to the ECD via similar, though not identical, mechanisms (Pioszak et al., 2009). Each peptide thus is bound to the ECD as an α helix and fits into a groove that runs along the center of the ECD. Key hydrophobic interactions occur between Trp23, Leu24, and Leu 28 in the ligand, which align along an apolar face of the helix, and complementary apolar surfaces in the receptor-binding groove. The side chain of Arg20 in the ligand makes extensive interactions with a ring of polar residues located at one end of the ECD. Residues Arg20, Trp23, Leu24, and Leu28 are well conserved in PTH and PTHrP ligands, while residues on the opposite helix face are less well conserved, are mostly polar in character, and can be mutated with relatively little effect on binding. Compared with the PTH(15−34)·ECD structure, the PTHrP helix bends modestly at about Leu24 such that the C-terminal portions of the two helices make distinct contacts, and the C-terminal residue is offset by a few angstroms in the two structures (Pioszak et al., 2009).

Interactions that occur between the N-terminal portion of the ligand, as contained in the PTH(1−14) segment, and the receptor's TMD are of key interest as they are critically involved in receptor activation. There is no direct structural data available for the PTHR1 TMD. The aforementioned mutagenesis and cross-linking data are consistent with the ligand making multiple contacts with an extensive, solvent-exposed surface area that involves the extracellular ends of the TMD helices and the extracellular loops. In the crystal and cryo-EM structures of the TMDs of the other class B GPCRs, the extracellularly exposed surface of the TMD bundle forms a relatively large pocket that accommodates the N-terminal portion of the ligand (Liang et al., 2017; de Graaf et al., 2017). In the intact GLP1R−GLP1 (Zhang et al., 2017, 2018a) and CTR−calcitonin structures, the full-length peptides are bound as linear α helices that extend along the ECD, which is positioned above the TMD, and enter into the TMD bundle such that the N-terminal residues of the ligand helix project into the bundle such that they can trigger the conformational rearrangements involved in receptor activation (Zhang et al., 2018a) (Fig. 28.3C). It is reasonable to suggest that PTH(1−34) binds to the PTHR1 in a fashion similar to that seen for glucagon and calcitonin, but direct confirmation of any such interaction mode for PTH and the PTHR1 remains to be established by direct high-resolution methods.

Mechanism of ligand-induced activation at the PTHR1

Previous mutagenesis and biophysical cross-linking data suggest that substantial conformational changes occur within the TMD bundle of the PTHR1 during agonist-induced activation (Gardella et al., 1996; Gensure et al., 2001a; Thomas et al., 2008). Insights into the types of specific changes that might occur can be inferred by comparing the active- versus inactive-state structures obtained for the several other class B GPCRs. Such comparisons suggest that during the agonist binding and receptor activation process, the ECD of the complex rotates in a counterclockwise direction, relative to the vertical axis of the TMD bundle, by nearly 90 degrees (Zhang et al., 2018a). In addition, two segments at the extracellular ends of the TM1 and TM2 helices isomerize from β-strand conformations to α-helical conformations. Interestingly, whereas the two β strands in the inactive state receptor pair together to form a cover over the ligand-binding pocket of the TMD bundle, the induced α-helical segments extend upward and contact the midregion of the bound ligand helix to thus help stabilize the ligand and guide the N-terminal segment into the TMD pocket (Zhang et al., 2018a). The structural studies on the class B GPCRs also reveal a cluster of highly conserved polar residues within the core of the TMD bundle that form a network of H-bond and electrostatic interactions and thus act to constrain the bundle in a closed, inactive conformation. Agonist interactions within the TMD core trigger a rearrangement of this network to release the constraints and promote the outward movement of the cytoplasmic ends of several of the TM helices, particularly TM6. These movements result in a cavity on the cytoplasmic surface of the receptor that accommodates the G protein (Fig. 28.3C) (Zhang et al., 2017; Yin et al., 2017).

While any such mechanism remains to be assessed for the PTHR1, the studies provide clues as to the types of conformational changes that are likely to occur during the PTHR1 activation process. It is worth noting that several PTHR1 residues that are located at least in the vicinity of the predicted cytoplasmic cavity used by G proteins have been implicated by mutagenesis methods to be involved in G protein interaction. These include Lys319, Val384, and Leu385 for Gαq coupling; Thr387 for Gαs coupling; and Lys388 for Gαs and Gαq coupling (Iida-Klein et al., 1997; Huang et al., 1996). Of further note, these studies led to the generation of the "DSEL" knock-in mouse in which the normal PTH receptor allele is replaced by a PTHR1 mutant having the Glu–Lys–Lys–Tyr sequence at positions 317–320 replaced by Asp–Ser–Glu–Leu and which is thus selectively impaired for Gαq/PLC signaling; the relatively modest effect of the mutant allele on the skeletons of these mice suggests that the Gαq/PLC signaling pathway does not play a critical role in PTH receptor–mediated control of endochondral bone formation (Guo et al., 2002).

Conformational selectivity and temporal bias at the PTHR1

Two high-affinity PTH receptor conformational states, R^0 and RG

The aforementioned structural models are consistent with the notion that structurally distinct ligands for the PTHR1 can stabilize or induce different receptor conformations so as to result in different types of signal transduction responses. The notion that variation in receptor conformation could play an important role in determining the affinity with which certain ligands bind to the PTHR1 emerged from a series of PTH radioligand binding studies that utilized membranes from cells transfected to express the PTHR1 and were performed under conditions to favor either the G-protein-uncoupled receptor conformation or the G-protein-coupled conformation (Hoare et al., 1999b). To promote the G-protein-uncoupled state, the binding reactions were conducted in the presence of GTPγS, which binds to the G protein α subunit and causes it to dissociate from the receptor. To promote the G-protein-coupled state, the binding reactions were conducted using membranes from cells transfected to express excess Gαs, typically a mutant form that binds the receptor with high affinity. The conceptual basis came from early pharmacologic studies performed on the β_2-adrenergic receptor and other such prototypic GPCRs that bind small catecholamine ligands. These studies led to the classical ternary complex model of GPCR action that posits that G protein coupling promotes a high-affinity receptor conformation, while G protein uncoupling, which occurs upon GDP–GTP exchange or GTPγS binding, causes the receptor to relax to a low-affinity state and thus release the bound agonist (De Lean et al., 1980). It was thus surprisingly found that certain ligands for the PTHR1, including PTH(1–34), bound with high affinity even in the presence of GTPγS, while others, such as PTHrP(1–36) and the modified N-terminal PTH fragment M-PTH(1–14), behaved in a fashion more consistent with the classical model and dissociated rapidly upon addition of GTPγS (Hoare et al., 2001; Dean et al., 2006, 2008). The findings thus suggested that the PTHR1 could exist in two distinct high-affinity conformations, depending on the type of ligand bound: one high-affinity conformation, as bound by PTH(1–34), could exist even in the absence of a bound G protein, while the other conformation, as bound by PTHrP(1–36) and M-PTH(1–14), required G protein coupling. Consequently, the two high-affinity states, G protein uncoupled and G protein coupled, were termed R^0 and RG, respectively.

Conformation-based differences in signaling responses to PTH and PTHrP ligands

While the initial findings on distinct affinity PTHR1 conformations came from biochemical studies performed in cell membranes, subsequent studies in intact cells as well as animals supported a biological significance. Thus, cAMP time-course studies performed in PTHR1-expressing cells, in which various ligands were allowed to bind to the receptor typically for 15–30 min and then all unbound ligand was removed by washout, revealed that Gαs/cAMP signaling as induced by R^0-selective ligands such as PTH(1–34) persisted for extended durations after washout. In contrast, cAMP signaling induced by RG-selective ligands such as PTHrP(1–36) or M-PTH(1–14) terminated more rapidly after washout (Okazaki et al., 2007; Dean et al., 2008). The results thus revealed a difference in the mode of binding and hence biological action for the structurally distinct ligands, including for PTH(1–34) and PTHrP(1–36), which until then were thought to bind to and activate the PTHR1 in similar if not identical fashions (Nissenson et al., 1988; Jüppner et al., 1988). However, an intriguing deficiency for stimulation of vitamin D synthesis was suggested for PTHrP(1–36) relative to PTH(1–34) in a human infusion study (Horwitz et al., 2003). The kinetic washout approaches thus enabled differences in modes of binding and signaling to be revealed for different PTH and PTHrP ligands. The kinetic assays initially used were performed in multiwell plate formats and involved measurement of cAMP either by radioimmunoassay of cell lysates or by a luciferase-based Glo sensor reporter that enables the nearly continuous detection of intracellular cAMP in live cells over time (Okazaki et al., 2007; Dean et al., 2008; Maeda et al., 2013). Such studies were subsequently complemented by highly

sensitive optical methods of fluorescence resonance energy transfer (FRET) microscopy, which enabled assessment of near-instantaneous changes in intracellular cAMP production at the single-cell level (Ferrandon et al., 2009; Feinstein et al., 2011). The findings also suggest a possible mechanistic basis for the distinct biological roles that PTH and PTHrP play in biology. Thus, a sustained mode of action, as occurs with PTH, would provide a suitable means to maintain blood calcium at the levels needed for normal physiological processes, while a more transient mode of signaling, as occurs with PTHrP, would provide a more suitable means to achieve the precise temporal control of cell differentiation that is required during tissue development, as for example in the skeletal growth plates, in which a precisely timed program of chondrocyte differentiation is required for proper elongation and shape formation of the long bones (Chagin and Kronenberg, 2014; Kronenberg, 2003).

The structural basis for the different modes of binding and hence signaling observed for PTH and PTHrP ligands in these studies is not completely known, but several amino acids that differ in the two ligands have been implicated. Most notably is the divergence at position 5, which is Ile in PTH and His in PTHrP, as it was thus found that the Ile5-PTHrP(1−36) analog binds with higher affinity to the R^0 conformation and exhibits more prolonged cAMP responses after washout than does PTHrP(1−36) (Dean et al., 2008). The divergences in the C-terminal (15−34) regions of the two ligands, which probably result in moderately altered modes of binding to the ECD (Pioszak et al., 2009), could also contribute to the differences in binding modes detected for the two ligands in the functional assays. The PTHrP(12−34) fragment was in fact shown to bind to the isolated ECD of the PTHR1 with an affinity about twofold higher than that of PTH(15−34), which supports an altered mode of binding, although the difference in affinity is opposite to that seen for the N-terminally intact ligands and the intact receptor (Dean et al., 2008). In any case, the findings on conformational selectivity for the PTHR1 provide insights into the mechanisms controlling the duration of ligand-induced signaling at the PTHR1, and furthermore have potential implications for the development of new PTHR1-based therapeutics. These two aspects are discussed in the following sections.

Endosomal signaling and signal termination at the PTHR1

Termination of G protein signaling at most GPCRs has generally been thought to occur relatively soon after initial binding of the agonist ligand and coincident with internalization of the receptor into endosomes (Drake et al., 2006). Findings on the PTHR1, as well as several other GPCRs, however, indicate that G-protein-mediated signaling can continue after most if not all of the receptor has moved into the endosomal domain. According to classical GPCR models, the process of signal termination involves a sequence of biochemical steps that include the phosphorylation of the receptor at serine and threonine residues located on exposed portions of the receptor's C-terminal tail and intracellular loops, the recruitment of β-arrestin proteins to the phosphorylated receptor with a coincident displacement of the G protein, the assembly of the β-arrestin-associated receptor into clathrin-coated pits that then pinch off from the membrane to form vesicles, and the trafficking of the vesicles containing the receptor and ligand as cargo through the endosomal sorting system. The last step directs the cargo to pathways of degradation as mediated by lysosomes and/or the proteasome system or recycles the receptor back to the cell surface (Drake et al., 2006). Many studies provide data generally consistent with this general scenario for the PTHR1. Thus, the agonist-activated PTHR1 is indeed rapidly phosphorylated on at least seven serine and two threonine residues, as well as being ubiquitinated on at least two lysines in the C-terminal tail and intracellular loops; β-arrestin proteins are recruited, the receptor moves into endosomal vesicles and internalizes, and it can be at least partially recycled back to the cell surface (Rey et al., 2006; Tawfeek et al., 2002; Vilardaga et al., 2002; Chauvin et al., 2002; Zhang et al., 2018b). The PTHR1 also engages with certain intracellular scaffolding proteins, particularly members of the Na^+/H^+ exchange regulatory factor family of proteins via PDZ-domain-based anchoring to the receptor's C-terminal tail (Mahon et al., 2003; Mamonova et al., 2012), which further are thought to contribute to the trafficking and signal termination events that occur following agonist binding and activation (see Chapter 27 for further information on PTHR1 trafficking events related to actions in the kidney).

The initial evidence suggesting that PTHR1 could deviate from the classical model of GPCR signal termination came from studies on M-PTH(1−34) and M-PTH(1−28) analogs that contained the same set of affinity- and potency-enhancing modifications as contained in the M-PTH(1−14) analogs mentioned earlier (Okazaki et al., 2008). These M-PTH(1−34) analogs were thus found to mediate cAMP responses in PTHR1-expressing cells that lasted for as long as several hours after washout, and thus for much longer times than those induced by PTH(1−34). Microscopy studies using fluorescent PTH analogs, typically modified with tetramethylrhodamine attached to the ε-amino function of lysine-13, revealed that within 15 min of initial binding, most, if not all, of the ligand was located in cytoplasmic vessels and not on the cell surface. There was thus a spatiotemporal correlation between persistent signaling and location in vesicles, which raised the novel possibility that the agonist-activated PTHR1, at least when bound by certain modified ligands, could mediate

prolonged Gαs-mediated cAMP responses from the endosomal compartment. It was further observed that upon injection into mice, such M-PTH(1–34) and related analogs induced elevations in blood calcium that persisted for much longer durations than those induced by PTH(1–34). Importantly, the prolonged calcium responses could not be explained by a simple plasma pharmacokinetic effect, as the modified ligands disappeared from the blood, if anything, more rapidly than did PTH(1–34). The results thus suggested that the modified ligands were rapidly sequestered by binding to receptors in target cells of bone and kidney and thus continued to signal from the endosomal compartment (Okazaki et al., 2008).

Parallel studies by Vilardaga and colleagues using fluorescence microscopy and FRET-based kinetic approaches to track ligand–receptor complexes in real-time in live HEK293 cells supported a novel mechanism, and also identified some of the key cytoplasmic effector proteins involved. These data thus confirmed that the ligand–receptor complexes were translocated rapidly from the plasma membrane to internalized endosomes where they remained associated with the G protein as well as adenylyl cyclase (Ferrandon et al., 2009). Prolonged signaling at the PTHR1 thus clearly correlated not only with binding to a distinct high-affinity state of the receptor, R^0, but also with the formation of signaling complexes that remained stable and presumably active in endosomes. Evidence of such endosomal signaling has now been reported for a number of other GPCRs, including the calcitonin receptor (Andreassen et al., 2014), the calcium-sensing receptor, a class C GPCR (Gorvin et al., 2018), and a number of class A receptors (Godbole et al., 2017; Thomsen et al., 2016).

The concept of endosomal signaling could have implications for understanding the basic processes for how these receptors function. PTHrP(1–36) was found to bind more selectively to the RG conformation of the PTHR1 and thus induces more transient cAMP responses compared with PTH(1–34) or the more strongly R^0-selective analogs, such as M-PTH(1–34) (Dean et al., 2008). Live-cell fluorescence tracking studies in HEK293 cells revealed that PTHrP(1–36) did not colocalize with the PTHR1 in intracellular vesicles (Ferrandon et al., 2009). The findings thus suggested that PTHrP and presumably other RG-selective ligands follow a subcellular trafficking path distinct from that used by PTH(1–34) and the longer-acting analogs and which thus involves differences in processes of signal termination. A key step in the signal termination process for the PTHR1, as induced by PTH(1–34), was thus found to be the association of the internalized receptor with a macromolecular assembly called the retromer complex (Feinstein et al., 2011), which acts at the later stages of endosomal maturation to sort vesicle cargo along pathways of either recycling or degradation. Retromer-mediated signal termination for the PTHR1 was found to be dependent on the constituent proteins, VPS26, VPS35, and SNX27, the last of which binds to the PTHR1 C tail via a PDZ-domain-directed interaction (McGarvey et al., 2016; Chan et al., 2016; Feinstein et al., 2011). The biological relevance for this PTHR1–retromer interaction, initially revealed in HEK293 cells, is supported by studies showing that targeted reduction of VP35 expression in osteoblastic MC3T3 cells prolongs the cAMP signaling response to PTH(1–34), and that mice genetically ablated for VPS35 in osteoblasts exhibit a mild osteoporotic phenotype and an enhanced anabolic response to intermittent PTH(1–34) (Xiong et al., 2016). These studies also revealed that PPP1R14C, which acts to inhibit the PP1 phosphatase, can associate with VPS35 or the internalized PTHR1 to thus result in changes in the phosphorylation status of downstream effectors, including phosphorylated cAMP-responsive element binding protein (CREB). It is thus intriguing to consider that endosomal signaling provides a means for the PTHR1 to activate specific target effectors in defined subcellular compartments so as to achieve efficient control of downstream responses; for example, the phosphorylation of a transcriptional activator such as CREB in the immediate vicinity of the nucleus to thus facilitate its access to the genome.

A second mechanistic aspect of subcellular trafficking and signal termination for the PTHR1 revealed in these studies concerns the role of endosomal acidification. In general, the endosomal interior progressively acidifies from an initial pH of ~7.4 to a low pH of ~4.5, at which most biological ligand–receptor complexes dissociate. This acidification is mediated by the vacuolar ATPase proton pumps, which are activated by cAMP/PKA-dependent phosphorylation. PTH(1–34)-induced cAMP/PKA signaling was thus found to promote vesicle acidification and hence the dissociation of the PTH·PTHR1 complexes, leading to signal termination. Thus PTHR1 signaling appears to be regulated at the level of the endosome by a negative feedback system of acidification (Gidon et al., 2014). These findings further suggest the possibility that structurally distinct ligands might bind to the PTHR1 in different fashions so as to form complexes that have differential sensitivities to endosomal acidification and hence can signal for different durations.

Ligand-directed temporal bias and therapeutic implications

The profound differences in the duration of signaling now seen to be clearly possible for structurally distinct ligand analogs via binding to distinct PTHR1 conformations are consistent with the emerging GPCR concept of ligand-directed temporal bias (Grundmann and Kostenis, 2017). Thus, for the PTHR1, ligands that bind mainly to the G-protein-dependent conformation, RG, mediate transient signaling responses because the ligand–receptor complexes dissociate soon after the first round of G protein activation, hastened by endosomal acidification, whereas ligands that bind with high affinity to the

G-protein-independent conformation, R^0, mediate prolonged signaling responses as the ligand−receptor complexes remain intact upon G protein uncoupling and endosomal acidification and hence can activate multiple G protein coupling cycles (Okazaki et al., 2008). Such temporal bias for the PTHR1, as it relates to distinct PTH and PTHrP analog ligands, has relevance to strategies aimed at the development of new PTHR1-based therapeutics, as the duration of signaling at the PTHR1 can have a profound impact on physiological outcomes, particularly those relating to the balanced processed of bone anabolism and catabolism (Martin et al., 2006).

Ligand-dependent temporal bias at the PTHR1 holds relevance for two key diseases that are treatable with PTHR1-targeted ligands: osteoporosis and hypoparathyroidism. Because of the distinct pathophysiological mechanisms underlying these two diseases—an imbalance in the coupled processes of bone formation bone and resorption leading to an inadequate bone structure in osteoporosis, and a deficiency of PTH production by the parathyroid glands leading to a condition of chronic hypocalcemia in hypoparathyroidism—distinct PTH ligand modes of action and hence pharmacodynamic profiles are needed to achieve effective treatment. Thus, a pulsatile mode of action is needed for osteoporosis, while a more sustained mode of action is needed for hypoparathyroidism (see Chapters 10, 23, and 70 for more detailed information on underlying mechanisms and modes of treatment for these diseases). The concept of temporal bias thus suggests that a short-acting RG-selective ligand, such as PTHrP(1−36), could have utility for osteoporosis, whereas a longer-acting R^0-selective ligand, such as those in the M-PTH(1−34) series of peptides and the long-acting analog LA-PTH, discussed in the next section, could have utility for hypoparathyroidism (Okazaki et al., 2008).

LA-PTH, a long-acting PTH/PTHrP analog for hypoparathyroidism

Based on the initial findings with M-PTH(1−34), efforts were made to develop even longer-acting analogs that could potentially be useful for hypoparathyroidism. One new long-acting analog derived, called LA-PTH, is a hybrid peptide in which the M-PTH(1−14) portion also present in the M-PTH(1−34) is joined to a modified C-terminal 15−36 portion of PTHrP(1−36). This unique structure results in high-affinity binding to the PTHR1 R^0 conformation, and hence markedly prolonged calcemic responses (Fig. 28.4A−D) (Maeda et al., 2013). The functional properties of LA-PTH suggested that it could have therapeutic utility for hypoparathyroidism, a disease for which PTH(1−34) as delivered especially by pump (Winer et al., 2014) and PTH(1−84) by subcutaneous injection by which it exhibits a prolonged pharmacokinetic profile (Mannstadt et al., 2013) have proven to be efficacious, with the latter now available as the drug Natpara. As a potentially improved form of therapy, LA-PTH was tested in several rodent models of the disease in which the parathyroid glands were either surgically removed or, in mice, ablated by diphtheria toxin treatment (Fig. 28.4D), and the results revealed that indeed the analog could normalize blood calcium levels more effectively and for longer periods of time after a single injection than could at least severalfold higher doses of PTH(1−34) or PTH(1−84) (Shimizu et al., 2016; Bi et al., 2016). The observed prolonged pharmacodynamic effects were again not explained by a prolonged pharmacokinetic profile, as the analog was cleared from the circulation if anything more rapidly than PTH(1−34). LA-PTH thus stands as a promising preclinical candidate as a new therapeutic option for hypoparathyroidism.

It should be noted that several other PTH(1−34)-based analogs have been reported to induce sustained pharmacodynamic actions in animals via distinct mechanisms. These mechanisms include the prolongation of the pharmacokinetic profile, as is achieved via fusion of the C terminus of the PTH(1−34) peptide to either the fragment crystallizable (Fc) portion of IgG (Kostenuik et al., 2007) or a 20-kDa polyethylene glycol (PEG) chain (Guo et al., 2017), each of which acts to impede the rate of glomerular filtration, or, in a third analog, via a combination of modifications (Nle8, Lys27, and a C-terminal 2-kDa PEG group) that results apparently in a prolonged retention of the peptide on the cell surface due to impairment of β-arrestin-mediated receptor internalization (Krishnan et al., 2018). Such analogs could also lead to new modes of treatment for hypoparathyroidism. Whether such analogs designed to induce prolonged actions in vivo via distinct mechanisms elicit different types of downstream responses, as, for example, in the specific gene sets regulated, remains to be determined.

Abaloparatide: a PTHrP analog for osteoporosis

Based on the dogma that a pulsatile administration and hence action of PTH is required to achieve an optimal increase in bone structure and strength while avoiding an excess of bone resorption, which typically occurs with a more continuous administration and action of the peptide, it was postulated that a PTHR1 ligand analog that binds selectively to the RG PTHR1 conformation, and thus induces signaling responses of short duration, would be more effective at building new

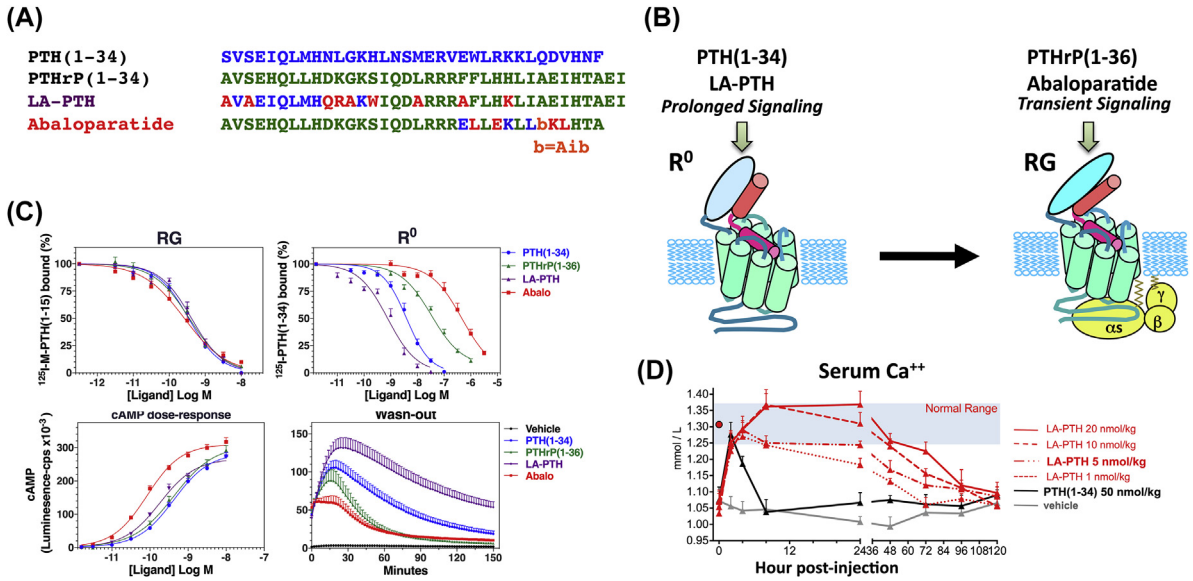

FIGURE 28.4 Conformational selectivity and temporal bias at the parathyroid hormone receptor 1. (A) Ligands that exhibit altered modes of conformational selectivity and temporal bias at the parathyroid hormone receptor 1 (PTHR1). (B) Proposed mechanism of temporal bias. A ligand that binds with high affinity to the G-protein-independent conformation, R^0, mediates prolonged signaling since the complex is stable and can interconvert over time to the biologically active G-protein-coupled conformation, RG; a ligand that binds selectively to RG induces only transient signaling since the ligand dissociates after G protein activation. (C) In HEK293 membranes and cells expressing the human PTHR1, LA-PTH binds with high affinity to R^0 and thus mediates prolonged cAMP signaling responses after washout, whereas abaloparatide binds preferentially to RG and induces more transient cAMP responses. PTH(1–34) and PTHrP(1–36) exhibit intermediate selectivity profiles. (D) In a parathyroidectomized mouse model of hypoparathyroidism, a single injection of LA-PTH, assessed at several doses, results in an extended elevation in serum calcium, whereas PTH(1–34) at an even higher dose results in a more transient elevation. *(C) Reproduced pending permission from Hattersley, G., Dean, T., Corbin, B. A., Bahar, H. & Gardella, T. J. 2016. Binding selectivity of abaloparatide for PTH-type-1-receptor conformations and effects on downstream signaling. Diphtheria toxin- and GFP-based mouse models of acquired hypoparathyroidism and treatment with a long-acting parathyroid hormone analog. J. Bone Miner. Res. 31, 975–984.*

bone than would an analog that binds selectively to the R^0 conformation and thus induces prolonged responses. Moreover, because excess bone resorption, as occurs with continuous PTHR1 signaling, gives rise to hypercalcemia, an RG-selective analog might provide a reduced risk of this adverse event, which probably was a factor that limited the final dose approved by the US FDA to 20 μg per day rather than 40 μg, even though the latter was more effective at reducing fracture risk (Neer et al., 2001). The newer PTHrP(1–34) analog, called abaloparatide, formerly called BA058, which was approved by the FDA in 2016 as an alternative anabolic treatment for osteoporosis, is thus of interest as data from preclinical and human clinical studies suggest that it increases bone mass at least as effectively as PTH(1–34) but causes less bone resorption and hence hypercalcemia (Miller et al., 2016). Abaloparatide is administered by subcutaneous injection at a dose of 80 μg per day. As both peptide drugs act by binding to the same target PTHR1, the differences in clinical outcomes suggested the possibility that their modes of action on the receptor might not be equivalent. Abaloparatide was found to bind with relatively high selectively to the RG PTHR1 conformation and thus induce more transient cAMP signaling responses in PTHR1-expressing HEK293 cells than PTH(1–34) (Hattersley et al., 2016) (Fig. 28.4A–C). These studies thus revealed a conformation-based mode of temporal bias for abaloparatide that was distinct from that of PTH(1–34), and hence provided at least a plausible mechanism to help explain the distinct effects that the two ligands have on bone metabolism, as seen in the clinical and preclinical testing (Makino et al., 2018).

PTHR1 mutations in disease

The full spectrum of diseases associated with PTHR1 mutations and their biological and clinical aspects are discussed in Chapter 58. The following sections focus on how the disease-associated mutations relate to the structure and functional properties of the receptor, particularly as they are assessed in cell and mouse model systems.

Jansen's metaphyseal chondrodysplasia

Jansen's metaphyseal chondrodysplasia (JMC) is a rare disease associated with skeletal abnormalities, dwarfism, and hypercalcemia, and is caused by heterozygous dominant activating mutations in the PTHR1 (Ohishi et al., 2012; Schipani et al., 1995). Five different PTHR1-activating mutations have been identified in patients with JMC. These mutations occur at the cytoplasmic termini of TM2 (Arg233 → His), TM6 (Thr410 → Pro/Arg), and TM7 (Ile458 → Arg/Lys) (Fig. 28.1A), and each results in agonist-independent cAMP signaling. Strikingly, the mutations each occur at or, in the case of the Ile458 mutations, adjacent to a residue that is involved in the conserved polar network that is present in all class B GPCRs and operates to control receptor activation and deactivation processes and particularly the outward movements of the TMD helices that allow G protein coupling (Yin et al., 2017). Several PTH and PTHrP antagonist ligand analogs, such as [Leu^{11}, D-Trp^{12}]PTHrP(7−34), behave as inverse agonists on the mutant receptors and thus depress their basal signaling activities (Carter et al., 2001, 2015). The mechanism by which these ligands achieve their inverse effect on the receptor's conformational status is unknown, although the Gly12 → D-Trp substitution is required for the effect. In any case, the functional properties of the analogs suggest possible paths toward therapy for JMC, which potentially can be tested in the transgenic models of JMC that have been developed to express the PTHR1-H223R allele in osteoblasts or osteocytes, which leads to marked increases in bone mass (O'Brien et al., 2008; Calvi et al., 2001).

Other diseases linked to PTHR1 mutations

Enchondromatosis (Ollier disease/Maffucci syndrome) is a rare disease characterized by cartilage tumors of the bone, and has been associated with four PTHR1 mutations, Gly121 → Glu, Ala122 → Thr, Arg150 → Cys, and Arg255 → His, each located in the ECD or ECL1 portion of the receptor. One study on the Arg150 → His mutant expressed in COS-7 cells intriguingly suggested a moderately elevated rate of basal cAMP signaling when corrected for a reduced cell-surface expression level (Hopyan et al., 2002), while another study suggested that each of the four mutations causes a loss-of-function phenotype due to effects on expression and/or binding affinity (Couvineau et al., 2008). The mechanism by which these mutations result in cartilage tumors in bone thus remains unclear, but certainly effects on the extracellular scaffold structure seem possible. Blomstrand's chondrodysplasia is a neonatal lethal condition of markedly accelerated bone mineralization that is caused by homozygous loss-of-function mutations in the PTHR1. One coding mutation has been identified, Pro132 → Leu, which affects a conserved site in the core ECD scaffold (Zhang et al., 1998; Karaplis et al., 1998). Eiken syndrome is a very rare skeletal dysplasia that has been associated with a homozygous recessive nonsense mutation in the PTHR1, Arg485 → Stop, that leads to a shortened C-terminal tail (Duchatelet et al., 2005). The phenotype is markedly delayed ossification of the skeleton, which is opposite that of Blomstrand's disease and seems consistent with a gain-of-function effect, albeit a mild one, since the heterozygous mutation is not associated with disease and the homozygous phenotype is distinct from that of JMC. In any case, it seems possible that the mutation leads to altered interactions with cytoplasmic effectors or scaffolding proteins, and hence diversions in subcellular trafficking and signaling, but this remains to be determined. A number of heterozygous loss-of-function mutations have been identified in individuals with defects in tooth eruption (Roth et al., 2014), which is consistent with studies in mice that show that PTHR1 signaling, as induced by PTHrP, is required for proper tooth formation (Ono et al., 2016). Among the mutations found in patients with tooth eruption defects is the Pro132 → Leu also found in Blomstrand's disease, but in that disease the mutation is in a compound-heterozygous arrangement.

Nonpeptide mimetic ligands for the PTHR1

The capacity for PTH agonists to effectively treat osteoporosis and hypoparathyroidism raises interest in the goal of developing orally available nonpeptide mimetics for this receptor. So far two such small-molecule PTHR1 agonists have been reported. The first, AH3960, was tested only in cells and shown to stimulate cAMP formation at doses of about 10 μM or higher (Rickard et al., 2006). More recently, PCO371 was reported and shown to stimulate cAMP formation in cells at concentrations in the low-micromolar range and, moreover, to effectively raise blood calcium levels in TPTX rats (Tamura et al., 2016). Due to an unexpectedly prolonged calcium response, possibly attributable to a prolonged pharmacokinetic profile, PCO371 is under development for hypoparathyroidism, rather than osteoporosis, as treatment of the latter disease requires a transient pharmacodynamic response to avoid excess bone catabolism, whereas treatment of the former disease requires a more sustained pharmacodynamic profile to mimic the effects of the missing hormone. Several nonpeptide antagonist compounds have also been identified for the PTHR1. SW106, discovered by screening a compound library for agents that could inhibit the binding of a radiolabeled PTH(1−14) peptide analog, binds to the PTHR1 with

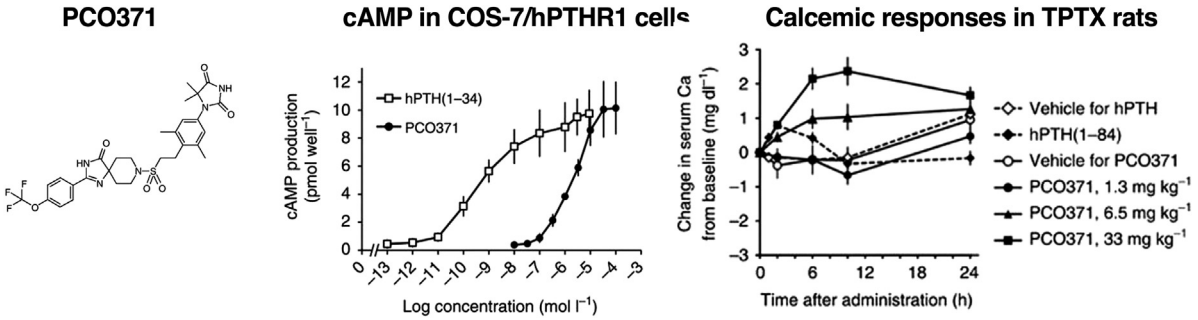

FIGURE 28.5 Small-molecule agonist for the PTHR1. The compound PCO371 was developed from a lead compound identified in a high-throughput screen for parathyroid hormone receptor 1 (*PTHR1*) agonist ligands. In COS-7 cells expressing the human PTHR1, PCO371 is a full agonist for cAMP signaling, albeit its potency is about 3 log-orders weaker than that of PTH(1−34). In TPTX rats, PCO371 induces elevations in serum calcium that are sustained, relative to the effects of PTH(1−34), presumably because of a prolonged pharmacokinetic profile. Consequently, PCO371 is reported to be in development for hypoparathyroidism. *Reproduced pending permission from Tamura, T., Noda, H., Joyashiki, E., Hoshino, M., Watanabe, T., Kinosaki, M., Nishimura, Y., Esaki, T., Ogawa, K., Miyake, T., Arai, S., Shimizu, M., Kitamura, H., Sato, H. & Kawabe, Y. 2016. Identification of an orally active small-molecule PTHR1 agonist for the treatment of hypoparathyroidism. Nat. Commun. 7, 13384.*

micromolar affinity and behaves as a competitive antagonist (Carter et al., 2007, 2015). A broad set of antagonist compounds was reported by a different group, and the most effective of these antagonized the cAMP-stimulating actions of PTH(1−34) in HEK293 cells transfected with the human PTHR1, with inhibitory constants in the 10 nM range, although studies in vivo were not reported (McDonald et al., 2007). Mechanistic studies performed on SW106 and AH3960 (Carter et al., 2015), as well as on PCO371 (Tamura et al., 2016), show that each of these compounds interacts with the TMD region of the receptor, as they exhibit the same effectiveness on the PTHR1 construct that lacks the ECD as they do on the intact PTHR1. Moreover, PCO371 was found to be inactive on the human PTHR2, specifically due to a single divergent residue corresponding to proline-415 in the PTHR1, which is replaced by leucine in the PTHR2. Pro415 is otherwise highly conserved in the class B GPCRs and is located in the middle of TM6, where it is predicted to play a pivotal role in receptor activation (Zhang et al., 2017). Whether PCO371 directly binds to Pro415 or to a site within the extracellularly exposed orthosteric pocket used by the peptide ligand remains to be determined. In any event, it is now clear that small-molecule ligands, both agonists and antagonists, can be developed for the PTHR1, and ultimately might lead to more effective therapies for PTHR1-related diseases (Fig. 28.5).

Other receptors for parathyroid hormone and related ligands

PTHR2 and PTHR3 subtypes

There continues to be appropriate interest in other receptors for the PTH family of ligands. Two apparent receptor subtypes distinct from the PTHR1 have been identified, as discussed in the earlier section on the evolution of this receptor/ligand family. The PTHR3 is present in vertebrate evolution as late as the avian radiation, but its function is not yet clarified or studied extensively, partly because it has been lost from the genome of higher mammals, including humans. Some cell-based tests suggest that it can function in a fashion similar to that of the PTHR1, at least in terms of ligand recognition and response properties (Rubin and Juppner, 1999; Pinheiro et al., 2012). The apparent absence of the PTHR3 in the higher vertebrates leaves open the question of biological importance. On the other hand, the PTHR2 is present in humans and other mammals, and has been characterized sufficiently to suggest a distinct ligand and biological role profile (Dimitrov et al., 2013), although it has been apparently lost in the avian lineage (Pinheiro et al., 2012).

The PTHR2 was initially identified through hybridization-based screening of a human brain cDNA library for PTHR1-related sequences. The identified receptor was thus found to share 51% amino acid identity with the human PTHR1 (Usdin et al., 1995), but to respond weakly to PTH and not at all to PTHrP, while the rat PTHR2 responded to neither (Hoare et al., 1999a). The search for a cognate ligand in bovine hypothalamic extracts yielded the new bioactive peptide called TIP39 (Usdin et al., 1999). TIP39 binds only weakly to the PTHR1 and lacks agonist activity. Nevertheless, TIP39 exhibits some structural homology with PTH and PTHrP (Piserchio et al., 2000), and N-terminally truncated analogs such as TIP9(7−39) bind with improved affinity such that they act as PTHR1 inhibitors (Hoare and Usdin, 2000; Jonsson et al., 2001). Continuing studies with the PTHR2 and TIP39 system since the initial discovery have emphasized its principal role in the central nervous system, with evidence suggesting that it functions to modify behavior, such as combating excessive fear

reactions, modifying pain sensations, and playing a role in positive maternal behavior, as studied in suckling rodents, perhaps by stimulating oxytocin release (Cservenak et al., 2017; Usdin et al., 2003). Distinctive other functions include a critical role in spermatid production and fertility through receptors in testicular tissue (Usdin et al., 2008). Other studies indicate the presence of TIP39 and the PTHR2 in skin with a role for keratinocyte differentiation and regulation of extracellular matrix formation and wound repair (Sato et al., 2016). There is no/little evidence to suggest a role in calcium or bone metabolism.

Possible receptors for C-terminal PTH and PTHrP

Other receptors with actions on bone and calcium have been postulated to interact with the carboxyl regions of PTH and PTHrP that lie beyond the amino-terminal (1−34) segment. Indirect evidence for such a possibility is suggested by the moderate degree of sequence homology maintained in the middle and carboxy-terminal regions of ligands from human and related mammalian species and even in chicken for the PTHrP molecule and also, but to a slightly lesser, extent for PTH. Added to this is the awareness that the overall peptide length of these two molecules is considerably greater than that noted for the ligands that activate other members of the class B receptor class, raising the possibility that the C-terminal extensions of PTH and PTHrP were acquired or preserved biologically during evolution. Experimental support for a C-terminal receptor for PTH comes from the capacity of the PTH(39−84) fragment to bind and cross-link to a 90-kDa protein on the surface of ROS17-2.8 cells (Inomata et al., 1995; Takasu et al., 1996), and that the fragment also induced apoptosis in a mouse osteocytic cell line ablated for the PTHR1 (Divieti et al., 2001). For PTHrP, there is evidence from in vivo studies that the mid- or C-terminal region contributes to effects on placental calcium transport as well as tissue development, the latter involving a nuclear localization mechanism (Kovacs et al., 1996; Wu et al., 1996; Gu et al., 2012; Toribio et al., 2010; Lam et al., 1999). On the other hand, genetic data support the view that the actions of PTH and PTHrP on bone are largely attributable to actions through the PTHR1. Thus, homozygous ablation of the PTHR1 in mice gives rise to a neonatal lethal skeletal dysplasia similar to that seen with homozygous ablation of PTHrP (Lanske et al., 1996). In addition, in the very rare human disorder Blomstrand's chondrodysplasia with homozygous loss-of-function PTHR1 alleles there is a similar lethal skeletal chondrodysplasia. Heterozygous loss-of-function mutations of PTHrP in humans give rise to brachydactyly type E (Bae et al., 2018), and such mutations of the PTHR1 give rise to failures in tooth eruption (Ono et al., 2016; Roth et al., 2014), both of which are consistent with a defect in bone development as controlled by the PTHR1. For PTH, conditions of hypoparathyroidism can be sufficiently corrected with PTH(1−34) administration (Winer et al., 2012), while the related condition of pseudohypoparathyroidism results from deficiencies in Gαs (Juppner, 2015), the primary mediator of PTHR1 signaling. In any event, there remains considerable interest in the possibility of such C-terminal receptors, as potential roles in calcium and bone biology have been supported by biological data in studies extending back several decades. However, despite much effort, such putative receptors have not been cloned and therefore the molecular identities not characterized.

Conclusions

Mechanisms of ligand binding and signal transduction at the PTHR1 are becoming increasingly better understood, with the high-resolution X-ray crystal and cryo-EM structures obtained for several related class B GPCRs providing particularly valuable new information. Ligand binding is thus seen to occur via the basic two-site model initially revealed by mutagenesis and cross-linking studies, but to further involve significant conformational rearrangements and molecular movements that ultimately lead to G protein coupling and activation. Structurally distinct PTH and PTHrP ligand analogs can induce or stabilize different PTHR1 conformations to thereby mediate different modes of signaling, with some ligands inducing particularly prolonged cAMP signaling responses, probably from within endosomes, while others induce more transient responses, presumably from the cell surface. Such conformation-based temporal bias for the PTHR1 suggests new approaches for the development of therapies for diseases such as hypoparathyroidism and osteoporosis. Insights into key sites in the receptor involved in function are also provided by PTHR1 mutations identified in certain skeletal disorders, including loss-of-function mutations in cases of failed tooth eruption and gain-of-function mutations in JMC. Mutations of the latter disease reveal the importance of a conserved polar network located at the base of the TMD helical bundle in controlling receptor activation and deactivation. As the views provided by such insights continue to deepen and refine, so should the capacity to design new ligand analogs for the PTHR1 that offer improved efficacy as treatments for diseases of bone and mineral metabolism.

Chapter 29

Structure and function of the vitamin D-binding proteins

Daniel D. Bikle

VA Medical Center and University of California San Francisco, San Francisco, California, United States

Chapter outline

Introduction

Vitamin D is obtained by the body either from its production in the skin or through absorption from the intestine. In either case vitamin D must be transported to tissues such as the liver where it is metabolized to its major circulating form, 25-hydroxyvitamin D (25(OH)D), by a number of 25-hydroxylases, the most important of which is Cyp2r1. 25(OH)D is then transported to tissues such as the kidney where it undergoes further metabolism to its major hormonal form 1,25-dihydroxyvitamin D ($1,25(OH)_2D$) by the mitochondrial-based Cyp27b1. Vitamin D-binding protein (DBP) is the key transport protein and, at least in some cells such as the kidney, participates in the transport of 25(OH)D into the cell. However, as will be discussed, DBP has a number of functions independent of its role as a vitamin D transport protein. Within at least some cells the 25(OH)D entering from the blood appears to be shuttled to mitochondria for this enzymatic reaction by what was originally called intracellular vitamin D-binding protein, later identified as the heat shock protein Hsp70, a known chaperone. Hsp70 in some cells may also facilitate the movement of $1,25(OH)_2D$ into the nucleus where it provides the activating ligand for the vitamin D receptor (VDR). The VDR is responsible for all the known genomic actions of vitamin D, most of which require $1,25(OH)_2D$ and its heterodimer partner RXR. However, VDR also has a nongenomic role in the membrane where it responds to a different conformation of ligands in activating a different set of signaling pathways. The membrane VDR shares this role with another protein initially called membrane-associated rapid response steroid (MARRS)-binding protein, more recently known as thioredoxin-like protein (GRP58), endoplasmic reticulum protein 57/60 (ERp57 or 60), or protein disulfide isomerase family A, member 3 (Pdia3). Thus, there is a series of vitamin D-binding proteins that sequentially provide for the transport of vitamin D from its point of origin (skin or gut) to tissues involved with its metabolism to its hormonal form, which mediate the handling of these metabolites within the cells

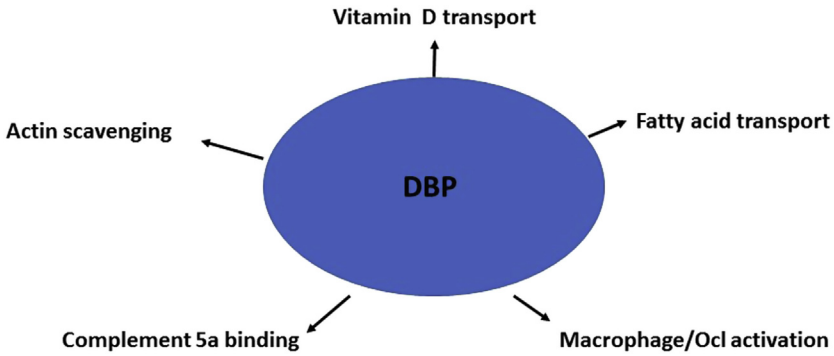

FIGURE 29.1 The multiple functions of vitamin D-binding protein. In addition to being the major transport protein for the vitamin D metabolites, vitamin D-binding protein (*DBP*) along with gelsolin participates in actin scavenging, fatty acid transport, and binding of complement 5a to neutrophils regulating their chemotaxis, and when the Gc1F and Gc1S variants are deglycosylated to form macrophage-activating factor, *DBP*—MAF can activate macrophages and osteoclasts (*Ocl*).

and ultimately to the proteins that initiate the biologic response, genomic and nongenomic. In this chapter aspects of the structures of these proteins relevant to their function and the mechanisms by which these proteins function will be reviewed. Given that vitamin D signaling affects nearly all if not all cells in the body, specific cellular responses will not be reviewed except as they illustrate these mechanisms.

Vitamin D-binding protein

Although the best known function of DBP is the transport of vitamin D metabolites from their source of production to their target tissues, DBP has a number of other functions, including actin scavenging, fatty acid binding, complement 5a (C5a)-binding regulation of neutrophil migration and chemotaxis, and, by way of its conversion to DBP—macrophage-activating factor (DBP—MAF), the regulation of osteoclast activity, immune function, and cancer growth (Fig. 29.1). These functions will be discussed in turn, including their clinical significance and the influence of the different polymorphisms on these functions.

Genomic regulation

The human *DBP* gene is located on chromosome 4q12—q13. It is 35 kb in length and comprises 13 exons encoding 474 amino acids, including a 16-amino-acid leader sequence, which is cleaved before release. The region of the chromosome where *DBP* is located also contains the homologous genes for albumin, α-fetoprotein, and afamin, with which it shares some properties, leading to speculation that this gene cluster arose from gene duplications. However, the transcription of *DBP* goes in the direction opposite that of the other genes in this cluster and it is separated by about 1500 kb (White and Cooke, 2000; Song et al., 1999). Expression of DBP is widespread, but the vast majority originates from the liver (Cooke et al., 1991). The proximal promoter of the *DBP* gene contains three hepatocyte nuclear factor 1 (HNF1) binding sites within 2 kb of the transcription start site (TSS). HNF1 is expressed as the α or β isoform and binds to its response element as a dimer. HNF1α is an activator, whereas HNF1β is inhibitory. In the liver, levels of HNF1α are high, resulting in increased expression of DBP, whereas in the kidney the β form exists, thus suppressing expression, and in the brain, little HNF1 is present (White and Cooke, 2000). The expression of DBP is increased by estrogen (Hagenfeldt et al., 1991) as is well illustrated with the rise in DBP during pregnancy (Moller et al., 2012; Zhang et al., 2014) and with oral contraceptive utilization (Moller et al., 2013). However, whether this is a direct action on the *DBP* gene via the estrogen receptor is not clear. Androgens, on the other hand, do not appear to affect DBP expression (Hagenfeldt et al., 1991). Dexamethasone and certain cytokines such as interleukin-6 (IL-6) also increase DBP production, whereas transforming growth factor β is inhibitory (Guha et al., 1995). As for estrogen, the mechanism underlying such regulation is unclear. However, from a clinical perspective these factors are likely to contribute to the increase in DBP production following trauma (Dahl et al., 2001a) and acute liver failure (Schiodt, 2008), which will be discussed subsequently. Primary hyperparathyroidism, on the other hand, is associated with a reduction in DBP levels, probably contributing to the lower 25(OH)D levels in these patients, as the free 25(OH)D is not reduced (Wang et al., 2017). Vitamin D itself or any of its metabolites does not regulate DBP production.

Structure and polymorphisms

The mature human DBP is 58 kDa in size, although differences in glycosylation of the protein alter the actual size. DBP is composed of three structurally similar domains. The first domain has an α-helical arrangement and is the binding site for the vitamin D metabolites (aa 35−49). Fatty acid binding demonstrates a single high-affinity site for both palmitic acid and arachidonic acid, but only arachidonic acid competes with 25(OH)D for binding, suggesting that the binding of fatty acids is not competitive for the vitamin D binding site in domain 1, but is due to alterations in DBP conformation (Calvo and Ena, 1989; Bouillon et al., 1992). The actin binding site is located in aa 373−403, spanning parts of domains 2 and 3, but part of domain 1 is also involved (Haddad et al., 1992; Head et al., 2002). The C5a/C5a des Arg binding site is to aa 130−149 (Zhang and Kew, 2004). Membrane binding sites have been identified in aa 150−172 and 379−402 (Wilson et al., 2015). DBP is the most polymorphic gene known. Over 120 variants have been described based on electrophoretic properties (Cleve and Constans, 1988), with 1242 polymorphisms listed in the NCBI database as of this writing (Chun, 2012). Of these variants, the Gc1F and Gc1S (rs7041) and Gc2 (rs4588) are the most common (Fig. 29.2). Gc1F and Gc1S involve two polymorphisms, one at aa 432 (416 in the mature DBP) and one at aa 436 (420 in the mature DBP). The 1F allele encodes the sequence of amino acids between 432 and 436 as **D**ATPT; the 1S allele encodes the sequence **E**ATPT. This subtle difference in charge makes GcF run faster and GcS slower during electrophoresis. The Gc2 allele encodes DATP**K**, which runs slower still**.** Glycosylation further distinguishes the Gc1 variants from the Gc2 variant. The threonine (T) in Gc1 binds *N*-acetylgalactosamine to which galactose and sialic acid bind in tandem. The lysine (K) in the comparable position in Gc2 does not bind these residues (Malik et al., 2013; Nagasawa et al., 2005). This affects the conversion of DBP to DBP−MAF, which involves a partial deglycosylation, removing the galactose and sialic acid by the sequential action of sialidase and β-galactosidase, by T and B cells (Uto et al., 2012).

Biologic function

Binding to and transport of vitamin D metabolites

DBP was discovered by Hirschfeld in 1959 (Hirschfeld, 1959), and was originally called group-specific component (Gc-globulin), and not until 1975 was its function as a carrier of vitamin D metabolites realized (Daiger et al., 1975). This is the function that gives DBP its name, although only about 5% of DBP is required for this purpose. In serum samples from normal individuals, ∼85% of circulating vitamin D metabolites are bound to DBP, whereas albumin with its substantially lower binding affinity binds only ∼15% of these metabolites despite its 10-fold higher concentration compared with DBP. Approximately 0.4% of total $1,25(OH)_2D_3$ and 0.03% of total $25(OH)D_3$ is free in serum from normal nonpregnant individuals. The affinity of DBP for the vitamin D_2 metabolites is lower (Armas et al., 2004), such that the free fraction would be expected to be higher, but this has not been directly determined. The "bioavailable" vitamin D metabolite comprises the free vitamin D metabolite and the amount bound to albumin, thus measuring around 15% in normal individuals (reviewed in Bikle et al., 2017a). At this point there is little evidence that the albumin fraction is truly bioavailable, and several studies indicate that albumin-bound vitamin D metabolites are not available to cells, at least under static conditions (Bikle and Gee, 1989). However, because the albumin−hormone complexes generally dissociate rapidly this fraction may be more bioavailable in a dynamically perfused tissue (Mendel, 1990). The free hormone hypothesis postulates that only the unbound fraction (the free fraction) of hormones that otherwise circulate in blood bound to their carrier proteins is able to enter cells and exert its biologic effects (Fig. 29.3). Examples include the vitamin D metabolites, about which we are concerned in this chapter; sex steroids; cortisol; and thyroid hormone. These are lipophilic hormones assumed to cross the plasma membrane by diffusion and not by an active transport mechanism. However, at least for some tissues, a transport system has been identified that takes up the 25(OH)D (and presumably other vitamin D metabolites) attached to DBP. That system involves megalin and cubilin. The importance of megalin for vitamin D metabolism was first

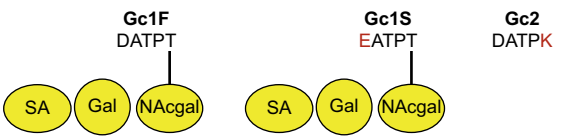

FIGURE 29.2 Major vitamin D-binding protein variants. Gc1F, Gc1S, and Gc2 are the major vitamin D-binding protein (DBP) variants. They differ in the sequence of amino acids from 432 to 436 as shown. DATPT of Gc1F represents Asp−Ala−Thr−Pro−Thr. In Gc1S the aspartate is mutated to glutamate. In Gc2, the threonine is mutated to lysine. The glycosylation at the threonine in Gc1F and Gc1S enables these forms to be converted to DBP−macrophage-activating factor by removal of the *N*-acetylgalactosamine (*NAcgal*) and galactose (*Gal*), leaving sialic acid (*SA*).

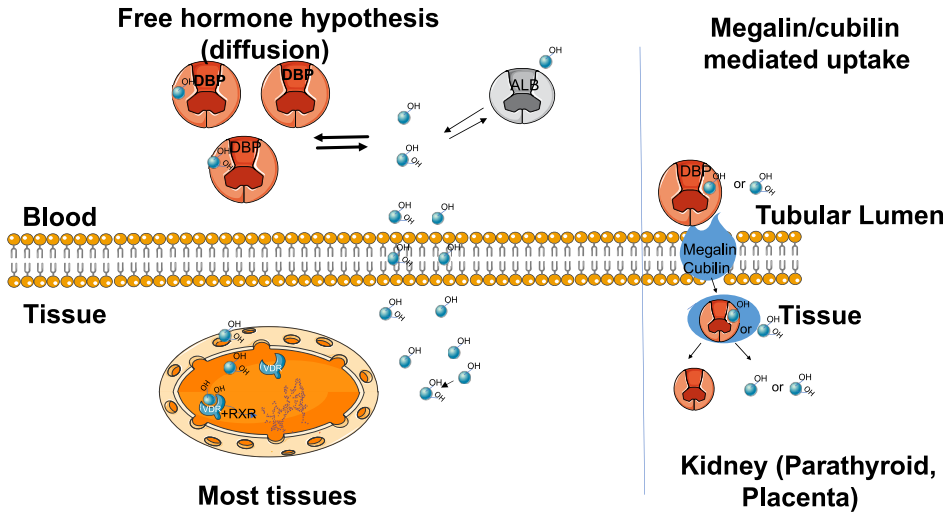

FIGURE 29.3 Free hormone hypothesis. For most cells the vitamin D metabolites are thought to diffuse into the cells in the unbound or free form. However, for some cells, such as the kidney, megalin and cubilin transport the vitamin D into the cell bound to vitamin D-binding protein (*DBP*).

noted by Nykjaer et al. (Nykjaer et al., 1999), who found in the megalin-knockout mouse extensive loss of DBP and 25(OH)D in the urine with the development of bone disease. These mice have very poor survival, but subsequently a kidney-specific knockout of megalin was developed with good survival, enabling the clear demonstration of decreased levels of the vitamin D metabolites, hypocalcemia, and osteomalacia in these mice (Leheste et al., 2003). While megalin has a transcellular domain that is necessary for its endocytosis, cubilin does not, but associates directly with megalin to enable the uptake of DBP and other ligands into the cell (reviewed in Christensen and Birn, 2002). A substantial number of tissues express the megalin/cubilin complex, including the parathyroid gland, choroid plexus, placenta, thyroid, type II pneumocytes, and endometrium, but the role of this complex with respect to its importance for vitamin D metabolism has been best studied in the kidney (Christensen and Birn, 2002), and its role in other tissues with respect to vitamin D metabolite transport into cells is unclear. Although the megalin/cubilin transport system is the best understood mechanism by which DBP-bound 25(OH)D is transported into cells, activated monocytes and the Raji cell line (human B cell lymphoma cell line) have also been reported to accumulate DBP by a mechanism apparently independent of megalin (Chun et al., 2010; Esteban et al., 1992). This mechanism has received little further study.

The knockout of megalin is fruitfully compared with the knockout of DBP in attempting to distinguish the respective roles of DBP and megalin/cubilin with respect to vitamin D entry into cells. In DBP-knockout mice the vitamin D metabolites are presumably all free and/or bioavailable. Unlike the megalin-knockout mice, mice lacking DBP do not show evidence of vitamin D deficiency unless placed on a vitamin D-deficient diet, despite having very low levels of serum 25(OH)D and $1,25(OH)_2D$ and losses of these metabolites in the urine (Safadi et al., 1999). However, on a vitamin D deficient-diet they rapidly develop hyperparathyroidism indicative of vitamin D deficiency. On the other hand, the DBP-knockout mice resisted the development of vitamin D toxicity (renal calcifications) when large doses of vitamin D were administered. In subsequent studies tissue levels of $1,25(OH)_2D$ were found to be normal in the DBP-knockout mice, as was the expression of markers of vitamin D action, such as intestinal transient receptor potential cation channel subfamily V member 6 (TRPV6), calbindin 9k, PMCA1b, and renal TRPV5. Moreover, injection of $1,25(OH)_2D$ into these DBP knockouts showed a more rapid increase in the expression of cytochrome P450 family 24 subfamily A member 1 (Cyp24A1), TRPV5, and TRPV6 (Zella et al., 2008). These studies support the concept that although the megalin/cubilin complex is critical for transporting 25(OH)D−DBP into some tissues such as the kidney, DBP is not necessary for getting the vitamin D metabolites into other cells, thus supporting the free hormone hypothesis for those cells. However, DBP clearly serves as a critical reservoir for the vitamin D metabolites, reducing the risk of vitamin D deficiency when intake or epidermal production is transiently reduced. Further support for this concept comes from studies in cell culture. In keratinocytes, only the free fraction of $1,25(OH)_2D$ was capable of inducing Cyp24A1 under varying conditions of DBP and albumin (Bikle and Gee, 1989). These results were subsequently supported by the observation that serum from DBP-knockout mice enabled the induction of Cyp24A1 by $1,25(OH_2)D$ in MC3T3 cells (Zella et al., 2008) and the induction by 25(OH)D and $1,25(OH)_2D$ of both Cyp24A1 and cathelicidin in monocytes (Chun et al., 2010) better than serum from control mice. These results indicate that DBP and albumin restricted the entry of the vitamin D metabolites into these cells.

To address the free hormone hypothesis, a method to measure the free concentration needed to be developed. This was originally performed by centrifugal ultrafiltration developed by the author to directly determine the free levels of 25(OH)D and 1,25$(OH)_2$D (Bikle et al., 1984, 1986a) in various clinical situations. However, this method is quite labor intensive and has been replaced, at least for free 25(OH)D, by a two-step enzyme-linked immunosorbent assay (ELISA) that directly measures free 25(OH)D (Future Diagnostics Solutions B.V., Wijchen, The Netherlands) using monoclonal antibodies from DIAsource ImmunoAssays (Louvain-la-Neuve, Belgium). This newer assay is dependent on the quality of the antibody used to bind the free 25(OH)D. The antibody in the current assay does not recognize 25$(OH)D_2$ as well as 25$(OH)D_3$ (77% of the 25$(OH)D_3$ value) so it underestimates the free 25$(OH)D_2$. However, in most situations where the predominant vitamin D metabolite is 25$(OH)D_3$, the data compare quite well with those obtained from similar populations using the centrifugal ultrafiltration assay (Bikle et al., 2017b; Schwartz et al., 2014a).

The centrifugal ultrafiltration method was utilized for the determination of the affinity constants for DBP and albumin binding to 25(OH)D and 1,25$(OH)_2$D. These affinity constants were measured in serum from a healthy young adult (the author) and demonstrated an affinity constant (K_a) of DBP for 1,25$(OH)_2$D of $3.7-4.2 \times 10^7\ M^{-1}$ and for 25(OH)D of $7-9 \times 10^8\ M^{-1}$, with a K_a of albumin for 1,25$(OH)_2$D of $5.4 \times 10^4\ M^{-1}$ and for 25(OH)D of $6 \times 10^5\ M^{-1}$ (Bikle et al., 1985, 1986b). Using these affinity constants along with measurements of DBP, albumin, and total vitamin D metabolite of interest permitted the free concentration to be calculated according to the following formula:

$$\text{free vitamin D metabolite} = \frac{\text{total vitamin D metabolite}}{1 + (\text{Ka}_{\text{alb}} * \text{albumin}) + (\text{Ka}_{\text{DBP}} * \text{DBP})}.$$

In sera from normal healthy younger individuals, the calculated values using DBP measured with polyclonal antibodies and the calculated values of free 25(OH)D and 1,25$(OH)_2$D correlate well with the directly measured free levels.

When applied to clinical populations with altered DBP levels during either physiologic (e.g., pregnancy) or pathologic (e.g., liver disease) conditions, however, the calculated values no longer are consistent with those measured directly by either centrifugal ultrafiltration or the newly developed ELISA (Schwartz et al., 2014b). There are a number of reasons for this. As noted earlier, calculation of free vitamin D metabolite levels depends on the accurate measurement of total vitamin D metabolite, DBP, and albumin and the affinity constants between DBP and albumin for the vitamin D metabolite whose free concentration is being measured. Although measurement of albumin is considered well standardized, that of the vitamin D metabolites is less so (Fuleihan Gel et al., 2015); although with major efforts to encourage laboratories to use well-defined standards and more advanced technology such as mass spectroscopy, this is improving (Muller and Volmer, 2015; Binkley and Carter, 2017). However, the measurement of DBP has not been standardized, and the results vary substantially between laboratories. One widely used monoclonal assay underestimates the Gc1F allele of DBP, leading to the conclusion that individuals expressing this allele, primarily African Americans, had lower DBP levels than Caucasians (Powe et al., 2013). On the other hand, Nielson et al. (Nielson et al., 2016a,b) subsequently reported their results measuring DBP levels with four different assays, three of which involved polyclonal assays and one the aforementioned monoclonal assay used by Powe et al. (Powe et al., 2013). The monoclonal antibody-based assay resulted in a 54% lower concentration of DBP in African Americans expressing the Gc1F allele, compared with Caucasians, with minimal differences in DBP levels among these groups using the three polyclonal assays. Similarly, mass spectrometry measurements of DBP by Hoofnagle et al. (Hoofnagle et al., 2015) failed to show a major difference in DBP levels with the various alleles, although the results with mass spectroscopy tended to be lower than those with the polyclonal assays. That said, assays using polyclonal assays or mass spectroscopy have consistently demonstrated a modest reduction in the Gc2 variant of DBP compared with the Gc1 variants (Hoofnagle et al., 2015; Lauridsen et al., 2001; Carpenter et al., 2013; Santos et al., 2013). A 2010 genome-wide association study demonstrated that rs2282679, an intronic polymorphism in the DBP gene, was likewise associated with lower 25(OH)D and DBP levels (Wang et al., 2010). This observation has been confirmed in several other populations (Leong et al., 2014; Cheung et al., 2013).

The clinical significance of these allelic differences is unclear. Individuals with the Gc2 variant have been shown to respond to vitamin D supplementation with a more robust increase in 25(OH)D (Fu et al., 2009).

Nevertheless, differences in these alleles were not found to contribute to a difference in fracture rate in a large study including African Americans and Caucasians (Takiar et al., 2015) or in other calcemic and cardiometabolic diseases in the Canadian Multicentre Osteoporosis Study (Leong et al., 2014). However, as reviewed by Malik et al. (Malik et al., 2013) and Speeckaert et al (Speeckaert et al., 2006), a large number of chronic diseases, including types 1 and 2 diabetes (Hirai et al., 1998; Baier et al., 1998; Ye et al., 2001), osteoporosis (Lauridsen et al., 2004; Papiha et al., 1999; Ezura et al., 2003), chronic obstructive lung disease (Chishimba et al., 2010), endometriosis (Faserl et al., 2011), inflammatory bowel disease (Eloranta et al., 2011), some cancers (Abbas et al., 2008; Dimopoulos et al., 1984; Zhou et al., 2012; Poynter et al., 2010)

(although see Poynter et al., 2010; McCullough et al., 2007; Ahn et al., 2009), and tuberculosis (Martineau et al., 2010) have been associated with various DBP variants.

A third major problem in attempting to calculate the free fraction of vitamin D metabolites is the assumption that all DBP alleles have the same affinity for the vitamin D metabolites, and that this is invariant under varying clinical conditions. Although differences in the affinity constants for the different DBP alleles have been reported, with Gc1F having the highest affinity and Gc2 the lowest among the common alleles (Arnaud and Constans, 1993), results from other laboratories have not confirmed these differences (Bouillon et al., 1980; Boutin et al., 1989). However, in a more recent study evaluating the half-life of 25(OH)D in serum, subjects homozygous for the Gc1F allele were found to have the shortest half-life, indicating reduced affinity (Jones et al., 2014). On the other hand, serum containing the Gc1F variant of DBP reduced the ability of 25(OH)D and $1,25(OH)_2D$ to induce cathelicidin in monocytes more than serum with the Gc2 allele, suggesting the opposite order of affinity (Chun et al., 2010). Regardless, these potential differences in measured affinity do not begin to explain the large differences between the calculated and the directly measured free metabolite levels in various disease states. Although there are statistically significant correlations between calculated and directly measured free 25(OH)D, the relationship accounts for only 13% of the variation. Calculated free 25(OH)D concentrations are consistently higher than directly measured concentrations in a variety of studies, such as those performed during the third trimester of pregnancy and in patients with liver disease and cystic fibrosis (Schwartz et al., 2014b; Nielson et al., 2016a,b; Lee et al., 2015; Sollid et al., 2016). These studies suggest changes in the affinity of 25(OH)D to DBP independent of allelic variations in at least these clinical conditions.

Studies of normal populations using direct methods of determining free 25(OH)D concentrations have shown good correlations with total 25(OH)D concentrations. The free levels have been reported to be between 0.02% and 0.09% of total 25(OH)D concentrations. Concentrations generally range from 1.2 to 7.9 pg/mL. However, in a study of normal individuals in which DBP alleles and total and free 25(OH)D were measured, those with the Gc2/2 variant had lower DBP and lower total 25(OH)D levels than those with Gc1 alleles, but the differences in directly measured free 25(OH)D levels were nearly the same, unlike the calculated free 25(OH)D levels (Sollid et al., 2016). Parathyroid hormone (PTH) is generally found to be negatively correlated with free 25(OH)D as well as total 25(OH)D, whereas serum C-terminal telopeptide of type I collagen has been reported to have a moderate positive correlation with total and free 25(OH)D (Aloia et al., 2015).

Thus in normal individuals, total 25(OH)D provides a reasonable assessment of vitamin D status. However, this is not the case in conditions in which DBP levels and/or affinities for the vitamin D metabolites are altered. Obesity is associated with reductions in total and free 25(OH)D but not DBP or half-life measurements of 25(OH)D (Walsh et al., 2016). On the other hand, bioavailable 25(OH)D correlated with bone mineral density but total 25(OH)D did not in one study (Powe et al., 2011). Similarly, in hemodialysis patients bioavailable 25(OH)D correlated negatively with PTH and positively with serum calcium, unlike total 25(OH)D. In the nephrotic syndrome, DBP is lost in the urine along with 25(OH)D, reducing the levels of both total and bioavailable 25(OH)D. However, like in the hemodialysis patients, bone mineral density correlated positively and PTH negatively with bioavailable 25(OH)D but not with total 25(OH)D (Aggarwal et al., 2016). In a study of patients with acute kidney injury, bioavailable 25(OH)D but not total 25(OH)D correlated inversely with mortality (Leaf et al., 2013). In acromegaly, DBP levels were observed to be increased, whereas 25(OH)D levels were not, resulting in a reduction in the calculated free 25(OH)D (Altinova et al., 2016) that may contribute to some of the alterations in bone and mineral metabolism in this condition. In a study of HIV^+ patients on triple antiviral therapy, the DBP levels were increased but not the total 25(OH)D, and these changes were associated with an increase in bone turnover markers and PTH, suggesting a fall in free 25(OH)D (which was not measured) (Hsieh et al., 2016). With vitamin D or 25(OH)D supplementation, free 25(OH)D concentrations rise in concert with total 25(OH)D concentrations (Sollid et al., 2016; Aloia et al., 2015; Alzaman et al., 2016; Schwartz et al., 2016; Liu et al., 2006), rising more steeply with D_3 supplementation compared with D_2 (Shieh et al., 2016) and even faster with $25(OH)D_3$ (Shieh et al., 2017). With high-dose D supplementation the changes in PTH were significantly related to changes in free 25(OH)D but not to changes in total 25(OH)D or changes in total $1,25(OH)_2D$ (Shieh et al., 2016), suggesting that free 25(OH)D might be a better marker of the biologically available fraction. In the third trimester of pregnancy, directly measured free 25(OH)D tends to be higher, and free $1,25(OH)_2D$ is substantially higher in pregnant women versus comparator groups of women (Bikle et al., 1984; Schwartz et al., 2014b). These results suggest that the affinity of DBP for the vitamin D metabolites is decreased during pregnancy, perhaps compensating for increased DBP concentrations and the needs of both the mother and the fetus for calcium. Directly measured free 25(OH)D and $1,25(OH)_2D$ tend to be higher in outpatients with cirrhosis compared with other groups (Bikle et al., 1986a; Schwartz et al., 2014b), despite lower total vitamin D metabolite concentrations. The relationship between free 25(OH)D and total 25(OH)D is both steeper and more variable in patients with liver disease than in healthy people, indicating altered affinity of DBP for 25(OH)D in these patients. Those with the most severe cirrhosis

and protein synthesis dysfunction have a higher percentage of free 25(OH)D compared with cirrhotics without protein synthesis dysfunction, but free 25(OH)D concentrations are similar due to the presence of both lower total 25(OH)D concentrations and lower DBP. In a vitamin D dose-titration study (Schwartz et al., 2016) of nursing home residents, who are older and likely to have more medical problems and receive more medications than younger people or community-dwelling elderly, free 25(OH)D levels rose along with increases in total 25(OH)D, but responses appeared to be steeper than those of normal subjects, younger outpatients, diabetics, or HIV-infected patients, suggesting altered affinity of 25(OH)D for DBP in this group of individuals. Additional support for the free hormone hypothesis comes from animal studies comparing the effects of vitamin D_2 with vitamin D_3 on calcium metabolism. In one such study mice were raised on a diet containing only vitamin D_2 or vitamin D_3 postweaning. These mice had comparable 25(OH)D levels 8 weeks later, but the D_2-raised mice had higher free 25(OH)D levels with increased numbers of osteoclasts and increased indices of both bone resorption and formation (Chun et al., 2016). These studies, clinical and translational, support the free hormone hypothesis and argue that measurement of the free vitamin D metabolite concentration provides information concerning the vitamin D status of the individual over and above that of the total vitamin D metabolite measurements.

Actin scavenging

A major function of DBP that has received considerably less study than that of vitamin D metabolite binding is its role in actin scavenging. Following trauma (Dahl et al., 2001a), sepsis (Wang et al., 2008; Dahl et al., 2003; Kempker et al., 2012), liver trauma (Schiodt, 2008; Gressner et al., 2009; Schiodt et al., 1997), acute lung injury (Lind et al., 1988), preeclampsia (Tannetta et al., 2014), surgery (Speeckaert et al., 2010; Dahl et al., 2001b), and burn injuries (Koike et al., 2002), large amounts of actin are released from the damaged cells, forming polymerized filamentous F-actin that in combination with coagulation factor Va can lead to disseminated intravascular coagulation and multiorgan failure unless cleared (Meier et al., 2006). The actin scavenging system consists of gelsolin and DBP. Gelsolin depolymerizes F-actin to G (globular)-actin. DBP with its high affinity for G-actin ($K_d = 10$ nM) prevents repolymerization and clears it from the blood (Vasconcellos and Lind, 1993; Mc Leod et al., 1989). There does not appear to be a difference among the major DBP variants for binding to G-actin (Speeckaert et al., 2006). The DBP−actin complexes are rapidly cleared (half-life in blood approximately 30 min) (Dahl et al., 2001b), primarily by the liver, lungs, and spleen, which express receptors for the DBP−actin complexes (Dueland et al., 1991). The immediate result is a drop in DBP levels, potentially altering the bioavailability of the vitamin D metabolites (Schiodt, 2008; Madden et al., 2015; Waldron et al., 2013), but a rise in the DBP−actin complexes (Dahl et al., 2001a; Wang et al., 2008; Schiodt et al., 1997; Lind et al., 1988). The ability of the organism to respond to the insult by increasing DBP production is correlated to survival (Dahl et al., 2001a; Schiodt, 2008; Leaf et al., 2013), and has led to consideration of the use of DBP therapeutically (Pihl et al., 2010; Gomme and Bertolini, 2004).

Neutrophil recruitment and migration with complement 5a binding

Neutrophil activation during inflammation increases their binding sites for DBP (DiMartino et al., 2007), and DBP binding to these sites facilitates C5a-induced chemotaxis (Binder et al., 1999). This role of DBP is not limited to C5a but includes other chemoattractants such as CXCL1 during inflammation (Trujillo et al., 2013). DBP by itself does not promote chemotaxis, nor does the DBP−actin complex discussed before (Ge et al., 2014). The interaction with C5a involves residues 130−149 of DBP, a region that is common to all major DBP alleles (Zhang and Kew, 2004), and no difference in these alleles has been found with respect to their promotion of C5a-mediated chemotaxis (Binder et al., 1999). Binding of $1,25(OH)_2D$ blocks the promotion by DBP of the C5a activity, although 25(OH)D does not (Shah et al., 2006). CD44 and annexin A2 are thought to be part of the DBP cell surface binding site, which also appears to involve cell surface ligands such as chondroitin sulfate proteoglycans, and are involved in C5a chemotaxis (DiMartino et al., 2001; DiMartino and Kew, 1999; McVoy and Kew, 2005). The binding of DBP to its receptor is not altered by and does not alter the affinity of C5a for its receptor (Zhang et al., 2010; Perez, 1994), but does increase the amount of binding of C5a des Arg to the C5a receptor (Perez, 1994).

Fatty acid binding

Like albumin, DBP binds fatty acids but with lower affinity ($K_a = 10^5-10^6 M^{-1}$) and a single binding site (Calvo and Ena, 1989; Swamy and Ray, 2008). Most of the fatty acids binding to DBP are monounsaturated or saturated, with only 5% polyunsaturated. However, only polyunsaturated fatty acids such as arachidonic acid and linoleic acid compete with vitamin D metabolites for DBP binding (Bouillon et al., 1992; Ena et al., 1989), suggesting that the different fatty acids

alter the configuration of DBP, which influences binding of the vitamin D metabolites, rather than directly competing with the vitamin D metabolites for their binding site. The role of DBP in fatty acid transport is not clear given its relatively minor participation in fatty acid transport in blood.

Formation of vitamin D-binding protein–macrophage-activating factor and its functions

DBP–MAF is formed from certain alleles of DBP by removal of galactose by membrane-bound β-galactosidase induced in B cells during inflammation by lysophosphatidylcholine, followed by removal of sialic acid by membrane-bound sialidase on T cells (Yamamoto and Homma, 1991). These deglycosylation steps are required for its role in macrophage activation (Uto et al., 2012), but further removal of the *N*-acetylgalactosamine (NAcgal) reduces this activity (Yamamoto et al., 1991). Swamy et al. (Swamy et al., 2001) demonstrated the ability of DBP–MAF to activate osteoclasts, and this activity was independent of its 25(OH)D-binding function. The presence of the NAcgal moiety on DBP–MAF is essential for its ability to activate osteoclasts. DBP–MAF has been shown to stimulate bone resorption in two models of osteopetrosis (Schneider et al., 1995): the osteopetrosis (OP) and the incisor absent (IA) rat. The OP rat lacks osteoclasts, whereas the IA rat has nonfunctional osteoclasts. When given DBP–MAF the OP rats showed increased numbers of osteoclasts, whereas the IA rats showed improved osteoclast function. DBP–MAF has shown efficacy in a number of tumor models. The mouse SCCVII tumor model of squamous cell carcinoma was used to demonstrate that DBP–MAF enhanced the curative effect of photodynamic treatment (Korbelik et al., 1997). The survival time of mice bearing Ehrlich ascites tumors was prolonged by DBP–MAF (Koga et al., 1999). Kister et al. (Kisker et al., 2003) showed that DBP–MAF had antiangiogenic activity and inhibited the growth of pancreatic cancer in SCID mice, which on histologic exam also showed an increase in macrophages with decreased vascularity. Removal of NAcgal by α-NAcgalase blocks DBP–MAF formation, contributing to the loss of immunosuppression in cancer patients (Yamamoto et al., 1996). α-NAcgalase is produced in the liver, and appears to be directly related to tumor burden (Yamamoto et al., 1997). Preparations of DBP–MAF may have therapeutic potential (Nagasawa et al., 2005).

Intracellular trafficking of vitamin D metabolites: role of heat shock protein 70 and hnRNPC1/C2

The role of DBP is to get the vitamin D metabolites to and, for some cells, into the cell. However, a protein originally called intracellular DBP, identified subsequently as Hsp70 (Gacad et al., 1997), was found to promote the intracellular uptake and distribution of the vitamin D metabolites within the cell (Wu et al., 2000). This observation was originally made in New World monkeys, which were resistant to $1,25(OH)_2D$ (Gacad and Adams, 1993), but expressed a lot of this protein compared with Old World monkeys. Overexpression of this protein in cells from Old World monkeys increased the amount of 25(OH)D in these cells, promoted synthesis of $1,25(OH)_2D$, and increased the genomic actions of $1,25(OH)_2D$, such as the induction of Cyp24A1 (Adams et al., 2004). Antisense constructs to Hsp70 blocked these actions. The concept is that Hsp70 functions to transport 25(OH)D to the mitochondria where Cyp27B1 (the 1-hydroxylase) is located, and then transport the product of Cyp27B1, $1,25(OH)_2D$, to the nucleus where it binds the VDR for its genomic actions. The affinities of these proteins favor this trafficking, with higher affinity of Hsp70 for 25(OH)D than DBP and lower affinity of Hsp70 for $1,25(OH)_2D$ than VDR. However, there is an additional intracellular protein that was discovered in New World monkeys that better explains their hormone resistance (Arbelle et al., 1996), and that was subsequently found in a human with vitamin D resistance (Hewison et al., 1993; Chen et al., 2003). This protein, originally called VDRE-BP, is now known to be hnRPC1/C2 protein (Chen et al., 2006). Its overexpression blocks $1,25(OH)_2D$ transcriptional activity. This protein normally sits on the VDRE (vitamin D response element), but is displaced by $1,25(OH)_2D$, allowing the liganded VDR to initiate transcription (Chen et al., 2006).

The vitamin D receptor

The VDR was first discovered as a chromatin-associated $1,25(OH)_2D$-binding protein in 1974 (Brumbaugh & Haussler, 1974, 1975). Although initially identified in the intestine, the site of the best studied actions of vitamin D at the time and the tissue from which it was originally cloned and sequenced (McDonnell et al., 1987), the VDR has subsequently been found in essentially all tissues in which it has been sought (Stumpf et al., 1979; Berger et al., 1988). Even in tissues such as the liver and muscle, low levels of the VDR have been identified. In the liver VDR is primarily expressed in the stellate cells, and not in the more abundant parenchymal cells (Ding et al., 2013). In skeletal muscle the VDR is more highly expressed during development such that in adult tissue the levels are quite low, making it difficult to detect by standard

methods (Girgis et al., 2014). Moreover, vitamin D has an impact on many cellular processes. In a 2015 ontology analysis 11,031 putative VDR target genes were identified, of which 43% were involved with metabolism, 19% with cell and tissue morphology, 10% with cell junction and adhesion, 10% with differentiation and development, 9% with angiogenesis, and 5% with epithelial-to-mesenchymal transition (Saccone et al., 2015). Furthermore, VDR can regulate various microRNAs and long noncoding RNAs, regulating the expression of numerous other proteins indirectly (Khanim et al., 2004; Wang et al., 2009; Jiang and Bikle, 2014). As a result of the appreciation that the VDR has such universal distribution and that vitamin D-metabolizing enzymes such as Cyp27B1 (that produces the active metabolite $1,25(OH)_2D$) and Cyp24A1 (that catabolizes 25(OH)D and $1,25(OH)_2D$ to less active forms) are also widely distributed (Bikle, 2014), interest in understanding the role of vitamin D and the VDR in tissues not obviously participating in the classic target tissues regulating calcium and phosphate homeostasis has been substantial. Over 4000 publications regarding vitamin D have appeared each year since 2014, most focused on the nonclassical actions of vitamin D. The remarkable aspect of this widespread distribution of the VDR is how many and yet how specific the actions of VDR are for any given cell. Although we have clues on how this specificity comes about, and these clues will be discussed in this chapter, we have much more to discover. Moreover, although most actions of VDR involve its role as a transcription factor within the nucleus (Carlberg, 2017; Pike et al., 2017), the VDR has also been shown to have nongenomic actions via its location in the membrane (Haussler et al., 2011) and perhaps even in mitochondria (Silvagno and Pescarmona, 2017). In this chapter I will not be dealing with actions of VDR signaling in specific tissues except as they illustrate more general points regarding VDR function, as tissue-specific aspects of VDR function have been well covered in several reviews (Bikle, 2014, 2016; Christakos et al., 2016).

Genomic location, protein structure, and regulation

The human *VDR* is located on chromosome 12. It spans 75 kb of DNA, and comprises nine exons, although the 5′ end is complex, with a number of potential minor TSSs 5′ of the major start site immediately upstream of exon 1a, resulting in alternatively spliced forms (Baker et al., 1988; Crofts et al., 1998; Sunn et al., 2001). Exon 2 contains the translation start site and the nucleotide sequence encoding the short A/B domain (24 aa), to which transcription factors such as TFIIB bind, and the first zinc finger of the DNA-binding domain (DBD) (65 aa). Exon 3 encodes the second zinc finger of the DBD. Exons 4–6 encode the hinge region (143 aa). Exons 7–9 encode part of the hinge region, the entire ligand-binding domain (LBD; E/F) (195 aa) including the AF2 domain, and the extensive 3′ untranslated region (UTR) (Fig. 29.4). A polymorphism (FokI restriction site) is found in the human *VDR*, changing an ATG to an ACG and shifting the translation start site by 3 aa, shifting the total length from 427 to 424 aa. The shorter form may be more transcriptionally active (Jurutka et al., 2000). Numerous other polymorphisms have been described in untranslated regions of the *VDR* gene, to which associations with various diseases have been made, but generally such studies suffer from small numbers and/or lack of reproducibility (Iqbal and Khan, 2017; Bizzaro et al., 2017; Rai et al., 2017) and will not be discussed further. Amino acids 49 and 50 between the two zinc fingers and 102–104 C terminal to the zinc fingers appear to provide the nuclear localization signal (Hsieh et al., 1998; Luo et al., 1994).

The DBD is composed of two zinc fingers held in a tetrahedral configuration by four cysteine residues. The first zinc finger directs DNA binding in the major groove of the DNA binding site. The second zinc finger provides a dimerization interface for its primary partner RXR. A short C-terminal extension from the second zinc finger participates in this dimerization interface (Wan et al., 2015a). The LBD is composed of 12 α helices (H1–H12) as shown in the original crystal structures (Rochel et al., 2000). The terminal H12 provides the essence of the mousetrap model for binding of

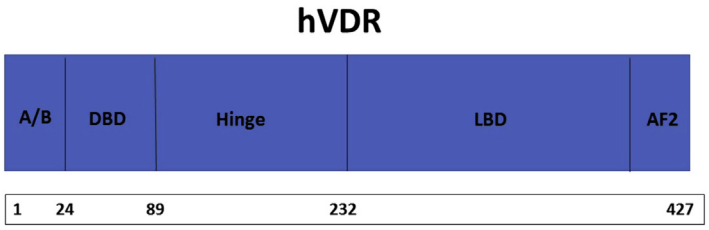

FIGURE 29.4 The structure of the human vitamin D receptor. The major domains of the human vitamin D receptor (*hVDR*) are depicted. The N-terminal A/B or AF2 domain is short in the VDR. It plays a role in TFII binding. The DNA-binding domain (*DBD*) comes next and is the site of the two zinc fingers that directly bind to DNA. The second zinc finger participates in binding to RXR, the major heterodimer partner for VDR. The hinge region also participates in RXR binding. The ligand-binding domain (*LBD*) is the site of binding for $1,25(OH)_2D$ and other ligands, as well as corepressors. When VDR binds to its ligand, AF2 on the C-terminal end undergoes a major conformational change to both enclose the ligand and provide docking for coactivators such as steroid receptor coactivators and Med1 of the Mediator complex.

$1,25(OH)_2D$ to the VDR in that in the nonliganded VDR H12 is open, but with ligand binding H12 moves over the ligand, enclosing it in the ligand-binding pocket (Rochel et al., 2000). This results in very tight binding (K_d approximately 10^{-10} M) (Mellon and DeLuca, 1979). In the closed position H12 along with H3 and H4 provides the interface for coactivators such as the steroid receptor coactivators (SRCs) and mediator complexes, which bind to H12 via their NR boxes containing the LxxLL sequence of amino acids (L for leucine, x any amino acid) (McInerney et al., 1998). The ligand-binding pocket is actually quite large and accommodates a number of ligands, including lithocholic acid. $1,25(OH)_2D$ fits into this pocket in an extended configuration, with its A ring in the β-chair configuration and the 1α group in an equatorial position (6-S *trans* conformation). Thirty-six residues line the ligand pocket, of which six make direct hydrogen bonds with the ligand (Wan et al., 2015b). H9 and H10 along with the second zinc finger provide the heterodimerization site for RXR (Whitfield et al., 1996). The structure of the full human RXR/VDR heterodimer complex with its DR3 DNA binding site has been revealed by cryo-electron microscopy (Orlov et al., 2012). This structure confirms the binding of the DBDs of both RXR and VDR to its major binding site on DNA (a direct repeat element with two hexanucleotide DNA sequences separated by a three-nucleotide spacer) with the RXR DBD binding to the 5′ half-site and the VDR to the 3′ half-site. Their LBDs project perpendicular to the DNA in an open confirmation, enabling binding by coregulators. The membrane VDR accepts a different configuration (6-S *cis* conformation), which led Mizwicki et al. (Mizwicki et al., 2004) to propose an alternative pocket for ligand binding, but this structure has not been confirmed by crystallography.

Amino acid residues critical for the structure/function of the VDR have been well demonstrated by mutations in the VDR in either the human or the mouse gene (reviewed in Malloy and Feldman, 2012). Approximately 45 different mutations in 100 patients have been described as of this writing. Mutations in the DBD block all functions of the VDR. Mutations at aa 274 in the LBD alter the affinity of the VDR for $1,25(OH)_2D$ by affecting the amino acid forming a hydrogen bond with the 1α group. Similarly, mutation at aa 305 alters the hydrogen bond with the 25(OH) group, likewise reducing affinity for the ligand. Mutation of 391 affects the dimerization domain at H9 and H10, reducing transactivation. Mutations of aa 420 in H12 alter coactivator binding. Mutations in the DBD and dimerization domain lead to alopecia as well as rickets, whereas those in the LBD that affect only the affinity for $1,25(OH)_2D$ or the coactivators result in rickets, but not alopecia, indicating that ligand binding is not essential for hair follicle cycling.

The regulation of VDR expression is quite cell specific. For example, $1,25(OH)_2D$ autoregulates VDR expression in bone cells but not in the intestine (Lee et al., 2014; Wood et al., 1998). Moreover, ligand binding to VDR stabilizes it, increasing its levels (Wiese et al., 1992). Many factors, including $1,25(OH)_2D$ itself, have been shown to regulate VDR expression. These include growth factors such as fibroblast growth factor, epidermal growth factor, insulin-like growth factor, and insulin, as well as PTH, glucocorticoids, estrogen, and retinoic acid. A variety of transcription factors have been identified that may mediate their regulation of VDR expression, including activator protein-1 (AP-1), specificity protein-1, CCAAT/enhancer binding protein (C/EBP), and caudal-type homeobox 2 (CDX2). For example, several enhancer elements have been found in the *VDR* gene that bind VDR. These enhancer elements are associated with binding sites for other transcription factors such as C/EBPβ, Runx2, cyclic AMP response element binding protein (CREB), retinoic acid receptor (RAR), and glucocorticoid receptor (Zella et al., 2010). Similarly, calcium upregulates VDR expression in the parathyroid gland presumably through its calcium-sensing receptor (Canadillas et al., 2010). On the other hand, SNAIL1 and SNAIL2 (SLUG) downregulate VDR expression in a number of cancer cell lines (Palmer et al., 2004; Mittal et al., 2008). MicroRNAs have also been shown to regulate VDR levels. miR-125b binds to the 3′ UTR to decrease VDR levels (Mohri et al., 2009; Gu et al., 2011), in the latter study in response to UVB treatment of psoriatic epidermis (Gu et al., 2011). Similarly miR-298 and miR-27b have been shown to bind to the 3′ UTR of VDR to reduce its expression (Pan et al., 2009). In addition the *VDR* promoter may also be hypermethylated by various methylases and methyltransferases, reducing its expression (Chandel et al., 2013).

Vitamin D receptor mechanism of action: genomic

Vitamin D binding sites in the genome

Combining data from chromatin immunoprecipitation sequencing studies of the entire genome from several different cell lines, Carlberg (Carlberg, 2017) reported that the human genome contained over 23,000 VDR binding sites, 70% of which occurred in only one cell type (Tuoresmaki et al., 2014). Only a small percentage of these binding sites can be clearly identified with a target gene (Ramagopalan et al., 2010). Moreover, within a given genome, the number of binding sites varied with the duration of exposure to ligand. Most of these binding sites were ligand dependent, but a substantial number of sites did not require $1,25(OH)_2D$ for VDR binding to occur, although the addition of ligand altered the location of these

sites (Heikkinen et al., 2011). For example, in LS180 colon cancer cells 262 VDR binding sites were identified without ligand, but following $1,25(OH)_2D$ 2209 binding sites were found, 71% in intergenic regions, 27% in introns, and only a small number near the TSS (Meyer et al., 2012). Similarly the addition of $1,25(OH)_2D$ also markedly enhances the number of RXR binding sites, a substantial percentage of which colocalized with the VDR binding sites (Meyer et al., 2010). Although the DR3 was the most common binding sequence, it occurred in only a minority of binding sites, albeit the ones with the highest affinity for VDR. An ER9 VDRE (everted repeats with nine spacing nucleotides) has been documented in a number of genes (Schrader et al., 1995, 1997), and a DR6, which incorporated RAR rather than RXR as the heterodimer partner with VDR, was identified in the phospholipase Cγ (PLCγ) promoter (Xie and Bikle, 1997). However, no obvious consensus DNA sequences have emerged for most other binding sites. The DR3, as noted earlier, refers to a DNA sequence with two hexanucleotide half-sites separated by a three-nucleotide spacer. Other nuclear hormone receptors have a similar DNA binding site, but the half-sites are separated by different numbers of nucleotides (Kliewer et al., 1992; Perlmann et al., 1993). The consensus sequence of the half sites is A/G G G/T T C/G A.

The VDR binding sites can be thousands of bases away from the TSS of the genes they regulate, and genes generally have multiple VDR binding sites, the activity of which may vary in different cells and different species. The likely explanation is that the DNA can be looped to bring the relevant regulatory elements adjacent to the TSS. This function is performed by CCCTC-binding factors (CTCFs), which define genomic insulator regions, although not all CTCF sites are involved in insulator actions. Genomic loops of hundreds to thousands of bases can be looped into topologically associating domains (TADs), organizing the genome into several thousand such domains (Dixon et al., 2012). In human monocytes $1,25(OH)_2D$ stimulated CTCF binding to approximately 1300 sites, 50% of which marked the anchors for TADs containing at least one VDR binding site and a $1,25(OH)_2D$ target gene (Neme et al., 2016). An informative example of how this might work in different cells is the regulation of the receptor activator of NF-κB ligand (RANKL) gene (*Tnfsf11*) (Fig. 29.5). This gene is regulated by PTH and $1,25(OH)_2D$ in osteoblasts, but by activators of c-fos in activated T cells. The Pike laboratory identified seven VDR binding sites in this gene up to 88 kb upstream of the TSS, of which the −75 kb site proved most active in the mouse gene (Kim et al., 2006; Martowicz et al., 2011), whereas the proximal site was most active in the human gene (Nerenz et al., 2008). However, in activated T cells, three additional sites even farther

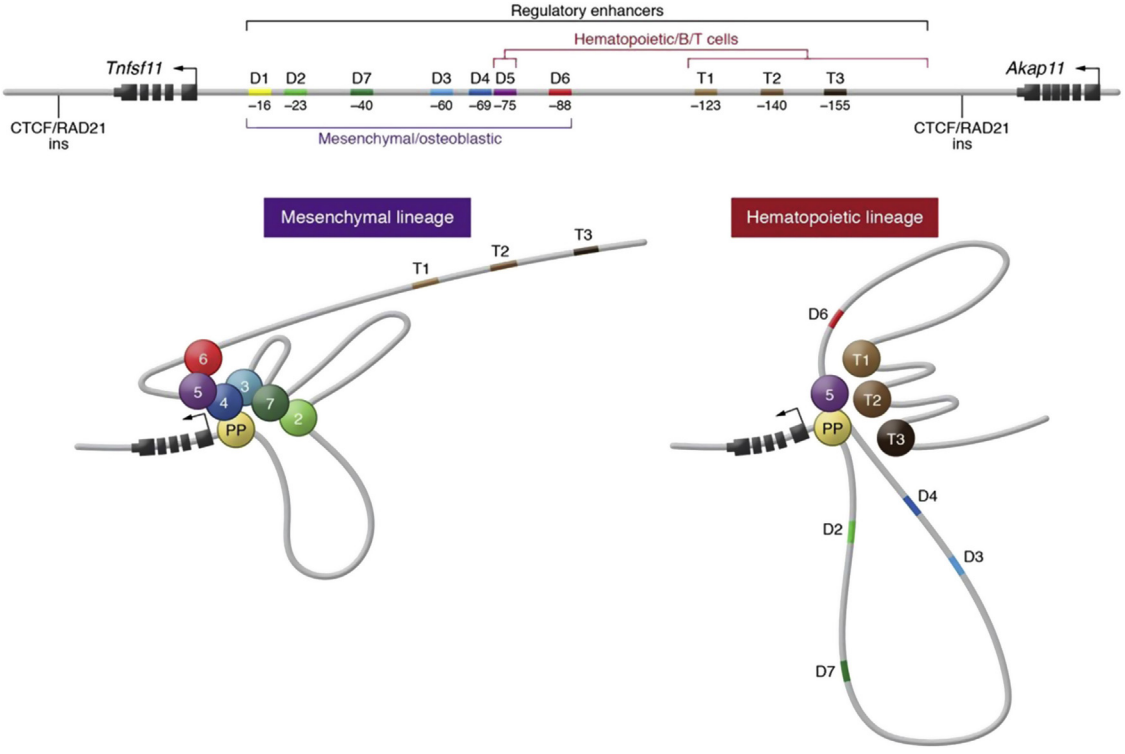

FIGURE 29.5 Theoretical schematic of the *Tnfsf11* (RANKL) gene as it might be configured in osteoblasts or T cells. These two configurations of the gene bring different response elements to the transcription site by alternate forms of looping, illustrating the potential for different means of regulating the same gene in different cellular contexts. The CCCTC-binding factor (*CTCF*) sites demarcate the gene. *Reproduced from Pike et al. Fig. 29.2, J Clin Invest 127:1148, 2017 permission pending.*

upstream of the TSS have been identified as sites of RANKL induction by c-fos (Bishop et al., 2011). CTCF binding sites separate the RANKL gene from adjacent genes, but also separate the VDR binding sites from the more upstream c-fos binding site active in T cells, potentially enabling different looping in these two types of cells (Pike et al., 2017; Bishop et al., 2011). A similar example can be found for Cyp27B1, the enzyme that produces $1,25(OH)_2D$. This gene is negatively regulated by its product in the kidney, as will be discussed later, but not in other tissues (Bikle, 2016b). Pike et al. demonstrated tissue-specific binding of VDR to response elements for this gene, showing differences between that in the kidney and that in other tissues (Meyer et al., 2017).

The VDR binding sites are generally situated in a region with other transcription factors that may share regulation of that gene. The RANKL gene is again a good example, as the −75 kb VDR binding region contains several CREB sites responsible for PTH regulation of this gene (Fu et al., 2006; Kim et al., 2007). Many genes regulated by $1,25(OH)_2D$ in bone cells also have Runx2 and C/EBPβ binding sites in the same regions as the VDR binding sites and influence VDR activity (Meyer et al., 2014). In intestinal cells the VDR binding sites have been colocalized with C/EBPβ, AP-1, CDX2, and T cell factor-4 (TCF4) (Meyer et al., 2012). Other transcription factors found in the vicinity of VDR binding sites that affect its transcriptional activity include ras-activated Ets transcription factors (Dwivedi et al., 2000) and YY1 (Guo et al., 1997; Raval-Pandya et al., 2001). Pu.1 has been hypothesized to serve as a pioneer factor preceding VDR binding, and has been found associated with a number of VDR binding sites in monocytes (Seuter et al., 2017). Changes in VDR binding sites as can occur during differentiation of the cell can affect the binding of these other transcription factors in similar fashion (Meyer et al., 2015, 2016). In osteoblasts such changes probably account for the ability of $1,25(OH)_2D$ to inhibit the early stages of osteoblast differentiation while promoting the later stages (Bikle, 2012a).

Coregulators and epigenetic changes regulating VDR function

The sites of active transcription are marked by epigenetic changes in both the gene itself and the histones that regulate access of the transcriptional machinery to the gene (reviewed in Long et al., 2015). For example, H3K4me3 (histone 3 in which lysine 4 is triply methylated) is found in sites of active transcription, whereas H3K9 is associated with silent promoter regions. H3K27me is associated with active enhancers, whereas H3K27me is associated with gene suppression. $1,25(OH)_2D$ can increase or decrease the expression of these methylases (Pereira et al., 2012). Sites of epigenetic gene suppression are also generally marked by methylation of cytosine in CpG islands (reviewed in Fetahu et al., 2014) in association with the epigenetic changes in the aforementioned histones (Esteller, 2008). The *VDR* promoter has three CpG islands in its promoter in exon 1a, which in breast cancer are hypermethylated, reducing VDR expression (Marik et al., 2010). Similar effects are seen in HIV-infected T cells (Chandel et al., 2013). $1,25(OH)_2D$ reduces the methylation of the E-cadherin promoter (Lopes et al., 2012), increasing its expression, but may promote methylation of other promoters (Doig et al., 2013). Methylases (amine oxidases or jumonji C domain-containing proteins JmJC) can be activators or suppressors. $1,25(OH)_2D$ regulates these epigenetic changes by affecting the binding of coregulators to the VDR, whether coactivators with histone acetyltransferase activity (HATs) or cosuppressors with histone deacetylase activity (HDACs).

There are over 250 published coregulators interacting with nuclear hormone receptors (McKenna et al., 2009). The best studied coactivators with respect to the VDR are the steroid hormone receptor coactivators (SRCs 1−3) (Xu and O'Malley, 2002) and the Mediator complex (Rachez and Freedman, 2001). Phosphorylation of serine 208 in the VDR following dimerization with RXR enhances their binding (Barletta et al., 2002; Arriagada et al., 2007) The SRCs have three NR boxes containing the LxxLL motif described earlier to which they bind the nuclear hormone receptors (Heery et al., 1997), but VDR binding is primarily to the third NR box (Teichert et al., 2009). Med1, the principal component of the Mediator complex binding to VDR and other nuclear hormone receptors, has two NR boxes, the second NR box being the one binding to VDR (Teichert et al., 2009). SRCs recruit HATs to the VDR, in particular CREB binding protein, CBP/p300 (Ogryzko et al., 1996) and the CBP/p300-associated factor p/CAF (Yang et al., 1996). The Med complex does not contain HAT activity but binds directly to RNA polymerase II to help form the preinitiation complex along with basal transcription factors such as TFIIB and several TAT-binding proteins (Yin and Wang, 2014). The peroxisome proliferator-activated γ coactivator-1α interacts with VDR to regulate genes involved in muscle development and energy metabolism (Narvaez et al., 2009). The VDR also binds histone methyltransferases that can synergize with SRCs in terms of regulation (Koh et al., 2001). These coactivators all bind to the AF2 domain (H12). NCoA62/SKIP does not bind to the AF2 domain but binds to the VDR/RXR heterodimer to increase transcription with SRC, but could also coordinate with corepressors NCoR/SMRT to suppress transcription (Baudino et al., 1998; Leong et al., 2004). WINAC is a member of the SWI/SNF subfamily which is an ATP-dependent chromatin remodeling complex involved in DNA replication and transcriptional elongation (Kitagawa et al., 2003). This complex includes the Williams syndrome transcription factor (WSTF) that when mutated results in Williams syndrome, a developmental disorder manifesting as hypercalcemia and disordered vitamin D

metabolism (Morris and Mervis, 2000). This complex plays a central role in the suppression by $1,25(OH)_2D$ of its own production by Cyp27B1, at least in the kidney as will be discussed further (Kim et al., 2007). Meningioma-1 is expressed in osteoblasts, where it enhances $1,25(OH)_2D$/VDR transcription (Sutton et al., 2005).

The best studied corepressors are the SMRT and NCoR complexes (Perissi et al., 1999; Tagami et al., 1998). They have HDAC activity. These corepressors bind to nuclear hormone receptors via their CoRNR boxes, analogous to the NR boxes of the SRC family but with the sequence LxxH/IxxxI/L (Hu and Lazar, 1999). These corepressors do not bind to the AF2 domain (H12) but to H3−H5 in the absence of ligand. In the presence of $1,25(OH)_2D$ and the conformational change with H12, these corepressors are displaced, enabling the coactivators to bind to their sites on H12. Hairless is a corepressor of VDR expressed primarily in the brain and skin (Xie et al., 2006). It binds to the central region of the LBD of VDR, as do NCoR/SMRT to two ϕxxϕϕ hydrophobic sites (ϕ = hydrophobic amino acid) (Hsieh et al., 2003), but also to H12 via its LxxLL motif, similar to SRC and Med1 (Teichert et al., 2009). The role of Hairless is complex in that it represses ligand-dependent VDR functions with respect to epidermal differentiation (Xie et al., 2006) but appears to be required for ligand-independent VDR regulation of hair follicle cycling (Wang et al., 2007). Alien binds to VDR and inhibits transcription by increasing HDAC activity and nucleosome assembly (Polly et al., 2000; Eckey et al., 2007). SUG1 is a proteasomal component that binds to the AF2 domain of VDR and may be involved in VDR degradation (Masuyama and MacDonald, 1998).

Negative vitamin D response elements

The general (and oversimplified) cycling model for the mechanism by which these coregulators control VDR transcription is that $1,25(OH)_2D$, by enhancing the conformational change in VDR, enhances its dimerization to RXR, strengthening the affinity of the complex for specific sites (e.g., DR3) in the DNA, displacing corepressors, and enabling the binding of the VDR/RXR heterodimer to coactivators. SRCs with their HAT activity are hypothesized to be the first to bind to the VDR, enzymatically altering the histones to open up the site for access to transcription factors. Med1 binding follows, which, by recruiting RNA polymerase II to the gene, facilitates the transcription process (Kim et al., 2005). This cycling model (Carlberg, 2010) does not explain situations such as the differentiation process in the epidermis where Med1 predominates in the early stages of differentiation, whereas SRCs 2 and 3 predominate in the more differentiated keratinocytes, each regulating a different profile of genes (Bikle, 2012b; Oda et al., 2003, 2009; Hawker et al., 2007). Moreover, this model does not explain the role of $1,25(OH)_2D$/VDR as an inhibitor of transcription. In microarray analyses genes downregulated by $1,25(OH)_2D$ are nearly as numerous as upregulated genes (White, 2004), but the mechanisms by which such inhibition takes place are unclear, as the VDR binding sites generally demonstrate no clear nucleotide sequence and may not involve direct binding of the VDR to the DNA. In the PTH and PTH-related protein genes inhibition has been reported to involve either half-sites of a DR3 (Demay et al., 1992) or a full DR3-like sequence (Falzon, 1996), but may also involve the binding of VDR to a vitamin D-interacting repressor (VDIR) that binds to DNA at E-box-like motifs (CANNTG, where N can be any nucleotide) (Kim et al., 2007; Murayama et al., 2004). The Kato lab (Kitagawa et al., 2003; Kato et al., 2004) has studied how $1,25(OH)_2D$ represses its own production in kidney cells through this mechanism. Such suppression appears to be restricted to kidney cells as Cyp27B1 expression in other cells does not show this suppression by $1,25(OH)_2D$ (Xie et al., 2002)). Their studies led them to propose that WSTF in the WINAC complex recruits the ligand-bound VDR to the VDIR sitting on the E-box-like negative VDRE, recruiting corepressors with HDAC activity as well as DNA methyltransferases and a methyl-CpG-binding protein (MBD4) that silences the Cyp27B1 promoter (Kim et al., 2009). PTH stimulated the phosphorylation of MBD4, which promoted demethylation by the glycosylase activity of MBD4, relieving the suppression, thus activating gene expression.

Interaction of VDR with β-catenin signaling

The interaction between VDR and β-catenin in terms of their complementary and opposing transcriptional activities has been well studied in the skin, bone, and intestine. β-Catenin binds to VDR in the AF2 domain (Shah et al., 2006) in a $1,25(OH)_2D$-dependent fashion. Such binding can promote ligand-dependent VDR transcriptional activity and promote cell fate determination (Shah et al., 2006; Palmer et al., 2008), but can also result in inhibition of β-catenin's transcriptional activity with respect to cell proliferation by preventing its interaction with T cell factors/lymphoid enhancer factors (TCFs/LEFs) in the nucleus and increasing its binding to the E-cadherin complex in the membrane (Palmer et al., 2001). VDR and calcium are essential for the formation of the E-cadherin complex (Bikle et al., 2012; Bikle, 2011). Palmer et al. (Palmer et al., 2008) evaluated the interaction between VDR and β-catenin in transcriptional regulation, and identified putative response elements for VDR and β-catenin/LEF in a number of genes, including *Shh*, *Ptch1* and *Ptch2*, and *Gli1* and *Gli2*,

members of the Hedgehog signaling pathway. For some genes the interaction is positive. An example of this was shown in TE-85 osteosarcoma cells in a ligand-independent fashion (Haussler et al., 2010). For other genes such as c-myc (where the region showing colocalization of VDR/RXR and β-cateninTCF4 is 335 kb away from the TSS) (Meyer et al., 2012) and cyclin D, $1,25(OH)_2D$/VDR suppresses β-catenin transcriptional activity (Sancho et al., 2004; Salehi-Tabar et al., 2012). The type of β-catenin transcriptional complex also plays a role in that β-catenin/LEF1 increases VDR induction of osteopontin, whereas β-catenin/TCF4 reduces the induction (Xu et al., 2009). Furthermore, the ability of β-catenin overexpression to induce trichofolliculomas (a benign tumor of the hair follicle) was blocked by an analog of $1,25(OH)_2D$, but in the absence of VDR, basal cell carcinomas were induced rather than trichofolliculomas. In the hair follicle and intestinal crypt cells, β-catenin signaling is essential for stem cell activation and their proliferation through a process that, at least in hair follicle stem cells, is dependent on the presence of the VDR (Sancho et al., 2004; Lisse et al., 2014; Cianferotti et al., 2007). In the epidermis β-catenin plays a critical role in cell migration and differentiation during wound repair as part of the E-cadherin/catenin complex in the membrane, which as noted is regulated by vitamin D signaling.

Vitamin D receptor mechanism of action: nongenomic

$1,25(OH)_2D$ exerts rapid effects on cells that cannot readily be explained by its better understood genomic actions. The first description of such rapid actions was that of rapid increases in intestinal calcium transport following $1,25(OH)_2D$ administration, called transcaltachia (Nemere et al., 1984). However, these rapid actions have subsequently been identified in a number of other cells, including chondrocytes, osteoblasts, keratinocytes, and fibroblasts as well as intestinal cells. A variety of signaling pathways are regulated by these rapid effects of $1,25(OH)_2D$, including PLC, phospholipase A_2 ,the tyrosine kinase Src, phosphatidylinositol-3-kinase (PI3K), Wnt5a, and p21ras, opening up calcium and chloride channels, with the generation of second messengers such as calcium, cyclic AMP, fatty acids, phosphatidylinositol 3,4,5-triphosphate activating downstream protein kinases A and C, src, mitogen-activated protein kinases, and calmodulin kinase II (reviewed in Hii and Ferrante, 2016; Doroudi et al., 2015). Two receptors for $1,25(OH)_2D$, both in the membrane, have been identified as mediating these rapid actions. The first receptor isolated from the chick intestinal membrane was initially called MARRS-binding protein (Nemere et al., 1994), which was subsequently shown to be the same protein as GRP58, ERp57 or 60, and Pdia3 (Khanal and Nemere, 2007). The second receptor is the VDR itself, but in its membrane location it is activated by $1,25(OH)_2D$ analogs with a different configuration (6-S *cis*) compared with those that activate the genomic actions of VDR (6-S *trans*), as mentioned earlier (Dormanen et al., 1994; Norman, 2006). In osteoblasts and epidermal fibroblasts both receptors have been shown to be involved in selected nongenomic actions of $1,25(OH)_2D$ (Chen et al., 2013; Sequeira et al., 2012). Moreover, these receptors can be found together with caveolin-1 in caveolae (Chen et al., 2013), where at least in skin fibroblasts they physically interact (Sequeira et al., 2012). Caveolin can provide a scaffold for other signaling molecules with which these nongenomic receptors may interact (Doroudi et al., 2015).

The interaction between the membrane VDR and the nuclear VDR has been suggested, but the mechanism is not totally clear. In kidney cells and the intestinal cell line Caco2 the rapid activation of extracellular signal-regulated kinase 1/2 (ERK1/2), JNK1/2, PKC, PI3K, and p21ras all has been shown to regulate $1,25(OH)_2D$ induction of Cyp24A1, a genomic action of VDR (Dwivedi et al., 2002; Nutchey et al., 2005; Cui et al., 2009). These studies indicated that the rapid activation of ERK1/2 and ERK5 affected $1,25(OH)_2D$ induction of Cyp24A1 by phosphorylating RXRα and Ets-1, respectively, thus modulating the environment of the VDREs in the Cyp24A1 promoter (Dwivedi et al., 2002). In Caco2 cells ERK1/2 activation did not alter VDR binding to its VDRE in the Cyp24A1 promoter but enhanced its transcription by helping recruit the coregulator Med1. On the other hand ERK1/2 activation did not influence another $1,25(OH)_2D$-induced gene, TRPV6, and did not alter the recruitment of Med1 to the VDR in the TRPV6 promoter (Cui et al., 2009). In human embryonic kidney 293T cells, JNK but not ERK1/2 activation facilitated $1,25(OH)_2D$ induction of Cyp24A1 (Nutchey et al., 2005). Rapid activation of PI3K by $1,25(OH)_2D$ also appears to enhance $1,25(OH)_2D$ induction of Cyp24A1 by mediating $1,25(OH)_2D$ activation of PKCζ and its phosphorylation of SP1, influencing its binding to the GC box in the Cyp24A1 promoter region (Dwivedi et al., 2010). In keratinocytes, activation of ERK1/2 promotes the ability of liganded VDR to induce the antimicrobial peptide cathelicidin (Peric et al., 2009).

VDR also alters the actions of other transcription factors in a nongenomic fashion. For example, the liganded VDR interacts directly with IκB kinase to block NF-κB signaling (Chen et al., 2013), and the liganded MARRS/ERp57/PIA3 has been shown to interact directly with NF-κB, with translocation of the complex into the nucleus where it appears to participate in the differentiation of NB4 leukemia cells (Wu et al., 2010). In T cells VDR/RXR prevents the formation of the NFATc1/AP-1 complex, suppressing the induction of IL-2 and IL-17A (reviewed in Wei and Christakos, 2015).VDR in the absence of $1,25(OH)_2D$ bound Stat1, inhibiting its action (Lange et al., 2014). $1,25(OH)_2D$ plus interferon-α (IFN-α) released this binding, enabling the binding of phosphorylated Stat1 to IFN-α DNA target genes, increasing their expression

(Lange et al., 2014). In some cancer cells nonliganded VDR can block arsenite-induced cell death by binding to and blocking c-jun (Li et al., 2007).

Conclusions

In this chapter I have reviewed three vitamin D-binding proteins: DBP, the protein that transports the vitamin D metabolites between and, in some cases, into cells; the intracellular DBP, otherwise known as Hsp70, that ferries the vitamin D metabolites between the relevant intracellular organelles; and VDR, which mediates the actions of the active vitamin D metabolite, $1,25(OH)_2D$, both in the nucleus for its genomic actions and in the membrane for its nongenomic actions. However, these proteins serve other functions that are not dependent on their binding to the vitamin D metabolites. DBP is an important actin scavenger, binds fatty acids, fixes C5a to neutrophils regulating chemotaxis, and when deglycosylated forms the DBP−MAF, which plays a role in osteoclast activation, macrophage function, and anticancer activity. Hsp70 serves as a chaperone role for other proteins. VDR has functions both genomic and nongenomic that do not require and may be inhibited by its binding to $1,25(OH)_2D$. Regulation of hair follicle cycling is one clear example of this ligand-independent action. Although we have learned much about the structure and function of these vitamin D-binding proteins, there is much more to learn. That said, the huge surge in vitamin D-related publications since 2008 indicates that research in this area will continue to produce new knowledge by which the roles of these proteins in both physiology and pathophysiology will be better understood.

Chapter 30

Vitamin D gene regulation

Sylvia Christakos[1] and J. Wesley Pike[2]

[1]Department of Microbiology, Biochemistry and Molecular Genetics, Rutgers, New Jersey Medical School, Newark, NJ, United States; [2]Department of Biochemistry, University of Wisconsin—Madison, Madison, WI, United States

Chapter outline

Vitamin D metabolism

Vitamin D is a principal factor required for the development and maintenance of bone as well as for maintaining normal calcium and phosphorus homeostasis. In addition, evidence has indicated the involvement of vitamin D in a number of diverse cellular processes, including effects on differentiation and cell proliferation, cancer progression, and the immune system (DeLuca, 2016; Christakos et al., 2016). For vitamin D to affect mineral metabolism as well as numerous other systems, it must first be metabolized to its active form. Vitamin D, which is taken in from the diet or is synthesized in the skin from 7-dehydrocholesterol in a reaction catalyzed by ultraviolet irradiation, is transported in the blood by the vitamin D-binding protein (DBP) to the liver. In the liver, vitamin D is hydroxylated at the carbon 25 position, resulting in the formation of 25-hydroxyvitamin D$_3$ (25(OH)D$_3$), the major circulating form of vitamin D, which is one of the most reliable biomarkers of vitamin D status (Bikle et al., 2013). The synthesis of 25(OH)D$_3$ has not been reported to be highly regulated (DeLuca, 2008). Cytochrome P450 2R1 (CYP2R1) is probably the key vitamin D 25-hydroxylase responsible for the conversion of vitamin D to 25(OH)D$_3$ based in part on genetic evidence that patients with a mutation in *CYP2R1* have vitamin D dysfunction (Cheng et al., 2004). However, in studies in *Cyp2r1*-null mice, 25(OH)D$_3$ levels were markedly reduced but not abolished, suggesting that other hydroxylases may also be involved (Zhu et al., 2013). 25-Hydroxyvitamin D proceeds to the kidney via the serum DBP. Megalin, a member of the low-density lipoprotein receptor superfamily, plays an essential role in the renal uptake of 25(OH)D$_3$ (Nykjaer et al., 1999). Cubilin and disabled 2 also work in conjunction with megalin for the cellular uptake of DBP/25(OH)D$_3$ (Nykjaer et al., 2001; Morris et al., 2002). In the proximal convoluted and straight tubules of the kidney nephron, 25(OH)D$_3$ is hydroxylated at the position of carbon 1 of the A ring

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00030-0

through the action of mitochondrial 25(OH)D 1α-hydroxylase (CYP27B1), resulting in the formation of the hormonally active form of vitamin D, 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) (Fig. 30.1). Mutations in the *CY27B1* gene result in vitamin D-dependent rickets (VDDR) type I, indicating the importance of the *CYP27B1* enzyme (Kitanaka et al., 1998). *Cyp27b1*-null mice have provided a model of VDDR type I (undetectable $1,25(OH)_2D_3$, low serum calcium, and secondary hyperparathyroidism) (Panda et al., 2001; Dardenne et al., 2001). The kidney can also produce 24,25-dihydroxyvitamin D_3 ($24,25(OH)_2D_3$). CYP24A1 has been reported to be capable of hydroxylating the 24 position of both $25(OH)D_3$ and $1,25(OH)_2D_3$ (Omdahl et al., 2003; Jones et al., 2014; Veldurthy et al., 2016) (see Fig. 30.1). It has been suggested that the preferred substrate for CYP24A1 in vivo is $1,25(OH)_2D_3$ rather than $25(OH)D_3$ (Shinki et al., 1992). Studies using mice with a targeted inactivating mutation of the *Cyp24a1* gene (*Cyp24a1*-null-mutant mice) provided the first direct in vivo evidence for a role for CYP24A1 in the catabolism of $1,25(OH)_2D_3$ (St-Arnaud et al., 2000). Both chronic and acute treatment with $1,25(OH)_2D_3$ resulted in an inability of *Cyp24a1*-deficient mice to clear $1,25(OH)_2D_3$ from their bloodstream. CYP24A1 limits the amount of $1,25(OH)_2D_3$ by catalyzing the conversion of $1,25(OH)_2D_3$ into 24-hydroxylated products targeted for excretion. In addition, production of $24,25(OH)_2D_3$ by CYP24A1 decreases the pool of $25(OH)D_3$ available for 1-hydroxylation. CYP24A1 can also catalyze the C23 oxidation pathway, resulting in the formation of $1,25(OH)_2D_3$ 26,23-lactone from $1,25(OH)_2D_3$ and $25(OH)D_3$ 26,23-lactone from $25(OH)D_3$ (Jones et al., 2014). CYP24A1 is present not only in kidney but also in all cells that contain the vitamin D receptor (VDR). Thus CYP24A1 not only regulates circulating $1,25(OH)_2D_3$ concentrations, but may also modulate the amount of $1,25(OH)_2D_3$ in target tissues, resulting in an appropriate cellular response. Inactivating mutations in CYP24A1 have been found in young children with idiopathic infantile hypercalcemia and in adults (Schlingmann et al., 2011; Dinour et al., 2013). In adults, patients were characterized by hypercalcemia, hypercalciuria, and recurring kidney stones (Dinour et al., 2013). These findings provide evidence for a critical role of CYP24A1 in the regulation of $1,25(OH)_2D_3$ in humans.

The production of $1,25(OH)_2D_3$ and $24,25(OH)_2D_3$ is under stringent control. Calcium and phosphorus deprivation results in enhanced production of $1,25(OH)_2D_3$ (Omdahl et al., 2003; Jones et al., 2014). Elevated parathyroid hormone (PTH) resulting from calcium deprivation may be the primary signal mediating the calcium regulation of $1,25(OH)_2D_3$ synthesis (Boyle et al., 1971; Henry, 1985). PTH has been reported to stimulate *CYP27B1* (Brezna and DeLuca, 2000; Meyer et al., 2017). $1,25(OH)_2D_3$ also regulates its own production by inhibiting *CYP27B1* (Brenza and DeLuca, 2000; Meyer et al., 2017). The synthesis of $24,25(OH)_2D_3$ has been reported to be reciprocally regulated compared with the synthesis of $1,25(OH)_2D_3$ (stimulated by $1,25(OH)_2D_3$, and inhibited by low calcium and PTH) (Shinki et al., 1992; Omdahl et al., 2003; Jones et al., 2014) (Fig. 30.1). Fibroblast growth factor 23 (FGF23), which promotes renal phosphate excretion and requires klotho, a transmembrane protein, has also been identified as a physiological regulator of vitamin D metabolism, which suppresses the expression of *CYP27B1* (Shimada et al., 2004; Hu et al., 2013) (Fig. 30.1). Low dietary phosphate intake results in decreased FGF23 levels and a corresponding increase in *CYP27B1* activity (Perwad et al.,

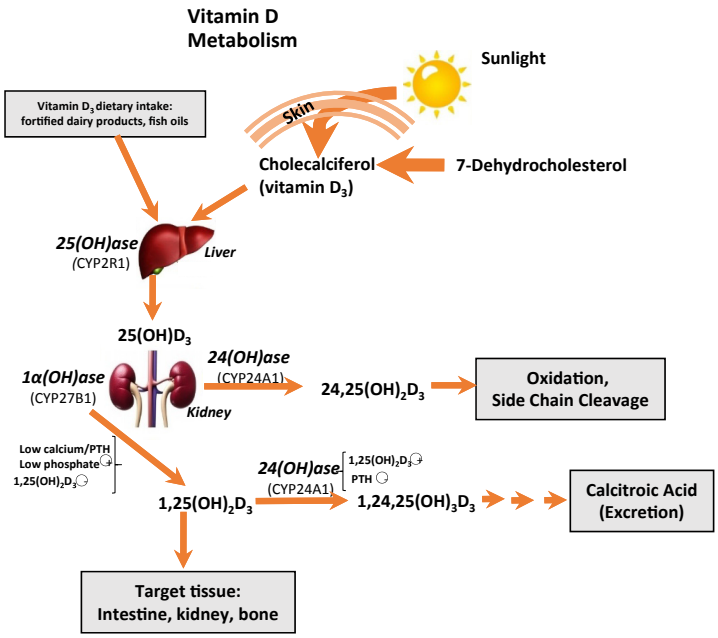

FIGURE 30.1 The pathway of vitamin D metabolism. Cytochrome P450 2R1 (*CYP2R1*) has been identified as a key vitamin D 25-hydroxylase. Parathyroid hormone (*PTH*), fibroblast growth factor 23/α-klotho, and serum calcium and phosphate act together to maintain optimal $1,25(OH)_2D_3$ levels (Dhawan et al., 2017).

2005). FGF23 requires the transmembrane receptor α-klotho (a multifunctional protein involved in phosphate and calcium homeostasis and in aging that binds to FGF receptors) to activate FGF signaling (Hu et al., 2013). Studies by Meyer et al. (2017) identified a kidney-specific control module generated by a renal cell−specific chromatin structure located distal to *Cyp27b1* that mediates PTH, FGF23, and $1,25(OH)_2D_3$ regulation of *Cyp27b1* expression, which will be discussed later in this chapter. In addition to the kidney, *CYP27B1* is also expressed during pregnancy in placenta (Zehnder et al., 2002). Extrarenal production by macrophages of CYP27B1 has also been convincingly demonstrated in patients with sarcoidosis (Barbour et al., 1981; Adams et al., 1983). Other immune cells also can produce $1,25(OH)_2D_3$ (Ooi et al., 2014). In addition, cancer cells have been shown to express *CYP27B1* (Hobaus et al., 2013). Although *CYP27B1* expression has been noted in a number of tissues (Bikle, 2009), whether there is a functional impact of *CYP27B1* activity in vivo in tissues other than the kidney and placenta under normal physiological conditions remains to be determined.

Serum $1,25(OH)_2D_3$ levels and the capacity of the kidney to hydroxylate $25(OH)D_3$ to $1,25(OH)_2D_3$ have been reported to decline with age (Armbrecht et al., 1980). In addition, an increase in renal *CYP24A1* gene expression and an increase in the clearance of $1,25(OH)_2D_3$ with aging have been reported (Matkovits and Christakos, 1995; Wada et al., 1992). These findings have implications concerning the etiology of osteoporosis and suggest that the combined effect of a decline in the ability of the kidney to synthesize $1,25(OH)_2D_3$ and an increase in the renal metabolism of $1,25(OH)_2D_3$ may contribute to age-related bone loss. Whether there is an interrelationship between the decline of sex steroids with age and age-related changes in *CYP27B1* and *CYP24A1* remains to be determined.

Role of $1,25(OH)_2D_3$ in classical target tissues

Bone

Exactly how $1,25(OH)_2D_3$ affects mineral homeostasis is a subject of continuing investigation. It has been suggested that the antirachitic action of $1,25(OH)_2D_3$ is indirect and the result of increased intestinal absorption of calcium and phosphorus by $1,25(OH)_2D_3$, thus resulting in their increased availability for incorporation into bone (Underwood and DeLuca, 1984; Weinstein et al., 1984). Studies using VDR-ablated mice (VDR-null mice) also suggest that a principal role of the VDR in skeletal homeostasis is its role in intestinal calcium absorption (Li et al., 1997; Yoshizawa et al., 1997; Amling et al., 1999). When VDR-null mice were fed a calcium/phosphorus/lactose-enriched diet, serum-ionized calcium levels were normalized, the development of hyperparathyroidism was prevented, and the animals did not develop rickets or osteomalacia, although alopecia was still observed. In addition, transgenic expression of VDR in the intestine of VDR-null mice results in normalization of serum calcium, bone density, and bone volume (Xue and Fleet, 2009). Thus, it was suggested that skeletal consequences of VDR ablation are due primarily to impaired intestinal calcium absorption. In vitro studies, however, have shown that $1,25(OH)_2D_3$ can resorb bone (Raisz et al., 1972). Although $1,25(OH)_2D_3$ stimulates the formation of bone-resorbing osteoclasts, receptors for $1,25(OH)_2D_3$ are not present in osteoclasts but rather in osteoblasts (Wang et al., 2014). Stimulation of osteoclast formation by $1,25(OH)_2D_3$ requires cell-to-cell contact between osteoblastic cells and osteoclast precursors and involves upregulation by $1,25(OH)_2D_3$ in osteoblastic cells of osteoprotegerin ligand or receptor activator of nuclear factor-κB ligand (RANKL; Takeda et al., 1999; Yasuda et al., 1998a, 1998b). RANKL is induced by $1,25(OH)_2D_3$ (Kim et al., 2007; Nerenz et al., 2008) as well as by PTH in osteoblasts/stromal cells. In *Cyp27a1*-null mice and in VDR-null mice, although PTH levels are markedly elevated, osteoclast numbers are not increased, indicating that both $1,25(OH)_2D_3$ and VDR are necessary for PTH production of osteoclasts (Amling et al., 1999; Panda et al., 2001). RANKL is a member of the membrane-associated tumor necrosis factor ligand family that enhances osteoclast formation by mediating direct interactions between osteoblasts/stromal cells and osteoclast precursor cells. Osteoclastogenesis-inhibitory factor/osteoprotegerin, a member of the tumor necrosis factor receptor family, is a soluble decoy receptor for RANKL that antagonizes RANKL function, thus blocking osteoclastogenesis. Osteoprotegerin is downregulated by $1,25(OH)_2D_3$ (Yasuda et al., 1998a).

In addition to increasing the availability of calcium and phosphorus for incorporation into bone and stimulating osteoclast formation, direct effects of $1,25(OH)_2D_3$ on bone cells have also been demonstrated (Bikle, 2012). For example, $1,25(OH)_2D_3$ has been reported to stimulate the synthesis of the calcium-binding proteins osteocalcin (OC) (Price and Baukol, 1980; Demay et al., 1990; Kerner et al., 1989) and osteopontin (OPN) (Prince and Butler, 1987; Noda et al., 1990; Shen and Christakos, 2005) in osteoblastic cells. OPN, a major noncollagenous bone protein, has been reported to inhibit bone matrix mineralization (Boskey et al., 1993). $1,25(OH)_2D_3$ suppresses mineralization by increasing the expression of mineralization inhibitors in osteoblasts in addition to OPN, including *Ennp1* and *Ennp3* (ectonucleotide pyrophosphastase phosphodiesterase 1 and 3) (Lieben et al., 2012). Thus during a negative calcium balance $1,25(OH)_2D_3$ can promote increased bone resorption and reduced matrix mineralization to maintain normal serum calcium levels at the expense of

skeletal integrity (Lieben et al., 2012). Direct effects of $1,25(OH)_2D_3$ on bone cells have also been demonstrated in osteocytes. $1,25(OH)_2D_3$ stimulates FGF23 production from osteocytes, resulting in renal modulation of phosphate levels (Lanske et al., 2014). Collectively these studies support a direct effect of $1,25(OH)_2D_3$ on bone as well as an indirect role through stimulation of intestinal calcium absorption.

Intestine

The major defect in VDR-null mice is in intestinal calcium absorption indicating that a principal action of $1,25(OH)_2D_3$ is to maintain calcium homeostasis via increasing efficiency of intestinal calcium absorption (Li et al., 1997; Yoshizawa et al., 1997; Amling et al., 1999). In addition, when patients with hereditary $1,25(OH)_2D_3$-resistant rickets (HVDRR) are treated with intravenous or high-dose oral calcium the skeletal phenotype of the patients is reversed (Hochberg et al., 1992). Although these studies indicate the importance of the intestine in $1,25(OH)_2D_3$ regulation of intestinal calcium absorption, the mechanisms involved are still incompletely understood. When the demand for calcium increases due to a diet deficient in calcium, demand for skeletal growth, or pregnancy or lactation, synthesis of $1,25(OH)_2D_3$ increases and intestinal calcium absorption occurs predominantly by an active transcellular process (Wasserman and Fullmer, 1995). In the transcellular process $1,25(OH)_2D_3$ has been reported to act by regulating (1) calcium entry through the apical calcium channel transient receptor potential cation channel subfamily V member 6 (TRPV6), (2) transcellular movement of calcium by binding to the calcium-binding protein calbindin, and (3) extrusion of calcium from the cell by the plasma membrane calcium ATPase (PMCA1b). Studies in TRPV6-null and calbindin-D-null mice have challenged this traditional view. There are no phenotypic differences between calbindin-D_{9k}-null mice and TRPV6-null mice and wild-type mice when dietary calcium is normal (Benn et al., 2008; Kutuzova et al., 2006; Kutuzova et al., 2008). However, studies in TRPV6/calbindin-D_{9k} double-null mice under conditions of low dietary calcium have shown that intestinal calcium absorption is least efficient in the absence of both proteins (compared with single-null mice and wild-type mice), suggesting that TRPV6 and calbindin can act together in certain aspects of the absorptive process (Benn et al., 2008). Findings in the single-null mice under adequate calcium conditions suggest that calbindin-D_{9k} and TRPV6 are redundant for intestinal calcium absorption and suggest compensation by other channels or proteins yet to be identified (Benn et al., 2008; Kutuzova et al, 2006, 2008; Christakos, 2012). Although other apical membrane transporters may compensate for the loss of TRPV6, intestine-specific transgenic expression of TRPV6 has been shown to result in a marked increase in intestinal calcium absorption and bone density in VDR-null mice, indicating a direct role for TRPV6 in the calcium absorptive process and that a primary defect in VDR-null mice is low apical membrane calcium uptake (Cui et al., 2012). It should also be noted that although the duodenum has been the focus of research related to $1,25(OH)_2D_3$ regulation of calcium absorption, it is the distal intestine where most of the ingested calcium is absorbed. Studies have shown that transgenic expression of VDR specifically in ileum, cecum, and colon can prevent abnormal calcium homeostasis and rickets in VDR-null mice (Dhawan et al., 2017a, 2017b). These findings indicate that, although calcium is absorbed more rapidly in the duodenum, the distal segments of the intestine contribute significantly to vitamin D regulation of calcium homeostasis. Studies related to mechanisms involved in $1,25(OH)_2D_3$ regulation of calcium absorption in the distal intestine may suggest new strategies to increase the efficiency of calcium absorption in individuals at risk for bone loss due to aging, bariatric surgery, or inflammatory bowel disease.

Kidney

In addition to bone and intestine, a third target tissue involved in the regulation by $1,25(OH)_2D_3$ of mineral homeostasis is the kidney. Although most of the filtered calcium is reabsorbed by a passive, paracellular path in the proximal renal tubule that is independent of $1,25(OH)_2D_3$, 10%−15% of the filtered calcium is reabsorbed in the distal convoluted tubule and connecting tubule and is regulated by PTH and $1,25(OH)_2D_3$ (Boros et al., 2009). $1,25(OH)_2D_3$ has been reported to enhance the stimulatory effect of PTH on calcium transport in the distal nephron in part by increasing PTH receptor mRNA and binding activity in distal tubule cells (Sneddon et al., 1998). Similar to studies in the intestine, $1,25(OH)_2D_3$ regulates an active transcellular process in the distal portion of the nephron by inducing the apical calcium channel TRPV5 (which shows 73.4% sequence homology with TPRV6) and by inducing the calbindins (both calbindin-D_{9k} [9000 M_r] and calbindin-D_{28k} [28,000 M_r] are present in mouse kidney and only calbindin-D_{28k} is present in rat and human kidney) (Boros et al., 2009; Rhoten et al., 1985; Christakos et al., 1989; Christakos, 1995). Calcium is extruded via PMCA1b and the Na^+/Ca^{2+} exchanger (Boros et al., 2009). Mice lacking TRPV5 display diminished calcium reabsorption in the distal tubule, hypercalciuria, and disturbances in bone structure, supporting the suggested role for TRPV5 in renal calcium handling (Hoenderop et al., 2003). Another important effect of $1,25(OH)_2D_3$ in the kidney is inhibition of *CYP27B1* and

stimulation of *CYP24A1* (Ohyama et al., 1996; Shinki et al., 1992; Kerry et al., 1996; Zierold et al., 1995; Meyer et al., 2010a, 2010b). In addition to effects on calcium transport in the distal nephron and modulation of the hydroxylases, effects of $1,25(OH)_2D_3$ on renal phosphate reabsorption have also been suggested. $1,25(OH)_2D_3$ may regulate phosphate homeostasis by increasing FGF23 expression in osteocytes and by inducing klotho expression in the distal tubule (Lanske et al., 2014; Forster et al., 2011).

Parathyroid glands

$1,25(OH)_2D_3$ and its analogs markedly decrease parathyroid hormone expression (Zella et al., 2014). $1,25(OH)_2D_3$ upregulates the calcium receptor, which is a major regulator of PTH (Canaff and Hendy, 2002). Parathyroid-specific VDR-null mice showed only a modest increase in PTH levels (Mier et al., 2009). In contrast, deletion of the calcium receptor in parathyroid resulted in severe hyperparathyroidism and the condition was lethal (Wettschureck et al., 2007). These findings suggest that a principal function of $1,25(OH)_2D_3$ is to sensitize the parathyroid gland to calcium inhibition by upregulating the calcium receptor. Direct action of $1,25(OH)_2D_3$ on the prepro-PTH gene has also been reported (Demay et al., 1992).

Nonclassical actions of $1,25(OH)_2D_3$

In addition to the regulation of calcium homeostasis, many additional biological processes are regulated by $1,25(OH)_2D_3$, including cellular proliferation and differentiation, inhibition of cancer progression, regulation of adaptive and innate immunity, and effects on cardiovascular function (for review see Christakos et al., 2016; Christakos and DeLuca, 2011). Convincing evidence for extraskeletal effects of $1,25(OH)_2D_3$ has been obtained through studies in cells and animal models. Understanding $1,25(OH)_2D_3$ extraskeletal biological responses may suggest similar pathways in humans that could lead to the development of new therapies to prevent and treat disease.

Transcriptional regulation by $1,25(OH)_2D_3$

The vitamin D receptor

The VDR mediates the genomic mechanism of action of $1,25(OH)_2D_3$ and was first discovered in the chicken intestine in 1974 and shortly thereafter in other tissues, including the parathyroid glands, kidney, and bone (Brumbaugh and Haussler, 1974a, 1974b; Brumbaugh et al., 1975). The protein's biochemical features, including its retention in chromatin (Haussler et al., 1968) and its ability to bind to DNA (Pike and Haussler, 1979), suggested that it was similar to other receptors for known steroid hormones and that it probably played a role in transcriptional regulation. However, it was the cloning of the chicken *VDR* gene (McDonnell et al., 1987) and then the human (Baker et al., 1988) and rat (Burmester et al., 1988) versions that ushered in a new era of defining the mechanisms through which vitamin D operated to control gene expression. Aside from the development of unique experimental probes, the cloning of the VDR enabled studies of the domain structure of the receptor that confirmed that it was a bona fide member of the steroid receptor gene family (Evans, 1988; Jin et al., 1996; McDonnell et al., 1989). Equally important, the cloning and structural analysis of the VDR's human chromosomal gene that followed (Hughes et al., 1988; Miyamoto et al., 1997) led ultimately to the identification of a series of mutations within the gene itself that were responsible for the syndrome of HVDRR (Brooks et al., 1978; Hughes et al., 1991; Malloy et al., 1990; Ritchie et al., 1989; Sone et al., 1989). This syndrome had been identified in 1978 (Brooks et al., 1978) and its etiology suggested at the time that it could be due to a defect(s) in the mechanism through which vitamin D exerted its actions (Eil et al., 1981; Lin et al., 1996; Pike et al., 1984; Sone et al., 1990), a hypothesis that was extended during the intervening years (Malloy et al., 2014). The discovery of mutations in the *VDR* gene solidified the essential role of the VDR as the sole mediator of the activities of the vitamin D hormone. This conclusion was eventually confirmed and extended through studies that recapitulated features of the disease phenotype through deletion of the VDR from the mouse genome.

General features of VDR action

Sites of DNA binding

Initial studies suggested that $1,25(OH)_2D_3$ activated gene expression programs in a wide variety of cell types and identified numerous gene candidates for further investigation. Most prominent among these were tissues that expressed the vitamin D-dependent calcium-binding proteins (calbindins) (Christakos et al., 1989; Gill and Christakos, 1993), OC (Lian et al.,

1989; Price and Baukol, 1980), OPN (Prince and Butler, 1987), and CYP24A1 (Haussler et al., 1980), although numerous others emerged during the following several decades as well. The cloning of many of the genes for these proteins and identification of their structural organization also prompted exploration of the mechanisms through which $1,25(OH)_2D_3$ and its receptor promoted their regulation. These studies, first with human *BGLP* (OC) (Kerner et al., 1989; Ozono et al., 1990) and subsequently with *Spp1* (OPN) (Noda et al., 1990), *Cyp24a1* (Ohyama et al., 1994, 1996; Zierold et al., 1994, 1995) and others (Carlberg, 2003), suggested that the VDR bound to a 15-bp vitamin D-responsive DNA element (VDRE) comprising two directly repeated consensus AGGTCA hexanucleotide half-sites separated by 3 bp that was generally located within a kilobase or so of the promoters for these genes (Ozono et al., 1990). These features were similar, but not identical, to those for other nuclear receptors. $1,25(OH)_2D_3$ also strongly suppressed the expression of numerous genes, most notably that of *PTH* and *CYP27B1*, but also in more recent studies that of the interleukin-17 (*IL-17*) gene. Repression of IL-17 transcription by $1,25(OH)_2D_3$ is thought to involve, in part, dissociation of histone acetylase activity, recruitment of deacetylase, and VDR/retinoid X receptor (RXR) binding to NFAT sites (Joshi et al., 2011). While some progress has been made, additional details of the mechanisms of suppression for these and other downregulated genes have yet to be fully understood but are almost certain to be highly diverse. Nevertheless, some progress has been made relative to the suppression of *Cyp27b1* by $1,25(OH)_2D_3$, and will be considered in specific detail later in this chapter. Although the presence of unique "negative VDREs" has been suggested at negatively regulated genes such as the PTH gene, this type of mechanism has yet to be substantiated (Demay et al., 1992).

Heterodimer formation with retinoid X receptors

The discovery of the first VDREs enabled the important subsequent finding that VDR binding to these specific DNA sequences was dependent upon an unknown nuclear factor (Liao et al., 1990; Sone et al., 1991a, 1991b). The identity of this protein was revealed shortly thereafter when it was found that RXRs, also members of the steroid receptor family, were capable of forming heterodimeric complexes with the VDR as well as other members of the steroid receptor class (Mangelsdorf and Evans, 1995). Importantly, $1,25(OH)_2D_3$ was found to promote heterodimer formation between VDR and RXR, although the precise cellular location where this interaction occurs between the two remains unclear (Kliewer et al., 1992). It has been suggested that in addition to its contribution to DNA binding, RXR may participate in the transcriptional activation process (Pathrose et al., 2002; Thompson et al., 2001); structural studies suggest otherwise (Orlov et al., 2012).

The vitamin D receptor functions to recruit coregulatory complexes that mediate gene regulation

Early studies revealed that transcription factor binding near promoters leads to an interaction with basal transcriptional machinery that enhances gene output. It is now known, however, that the activity of most DNA-binding transactivators involves the recruitment of additional coregulatory complexes by this protein class that function to modulate chromatin in a highly specific fashion. Overcoming and/or restoring the inherent repressive state of chromatin requires the presence of this complex regulatory machinery, which is able to shift and/or displace nucleosomes (chromatin remodeling), alter the condensation state and therefore the local architecture of chromatin (histone modifications), create or restrict novel binding sites for additional coregulatory complexes (epigenetic sites), and/or facilitate the entry of RNA polymerase II (RNA pol II) at appropriate times and sites. Three complexes that participate in these activities that are known to be recruited by the VDR include (1) vertebrate ATPase-containing homologs of the yeast SWI/SNF complex that utilize the energy of ATP to remodel and reposition nucleosomes (Carlson and Laurent, 1994); (2) complexes that contain either histone acetyltransferases (HATs) or methyltransferases and deacetyltransferases (HDACs) or histone demethylases, which function to modify the lysine- or arginine-containing tails of histone 3 and/or histone 4 at specific locations (Rachez and Freedman, 2000; Smith and O'Malley, 2004); and (3) the Mediator complex, believed to facilitate the entry of RNA pol II into the general transcriptional apparatus and perhaps to play a role in transcriptional reinitiation (Lewis and Reinberg, 2003) (Fig. 30.2). The activities of each of these complexes may be essential for the downstream activity of almost all DNA-binding proteins. Several classes of regulatory transferase complexes comprise components of dynamic and highly active mechanisms that are epigenetic in nature, and involve the coordinated integration of expression of gene networks (Arrowsmith et al., 2012). These programs are widely responsible for development, differentiation, and mature cell function (Gifford et al., 2013; Xie et al., 2013). HATs and their reciprocal HDACs, for example, regulate the level of epigenetic histone H3 and H4 marks, controlling the degree to which chromatin is condensed and therefore the DNA accessible for transcription factor binding (Ho and Crabtree, 2010). The recruitment of these large chromatin regulatory complexes is frequently coordinated by factors such as the p160 family steroid receptor coactivator 1 (SRC1), SRC2, and

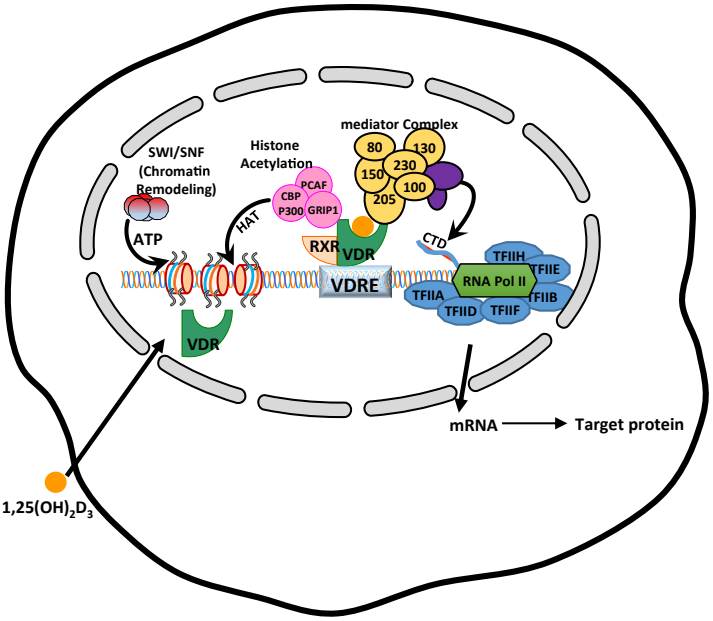

FIGURE 30.2 Mechanism of action of $1,25(OH)_2D_3$ in target cells. $1,25(OH)_2D_3$ regulates gene transcription in target cells by binding to its nuclear receptor, *VDR*. Activated VDR heterodimerizes with retinoid X receptor (*RXR*) and binds to vitamin D-response elements (*VDREs*) in and around target genes. In addition to basal transcription factors, VDR interacts with steroid receptor coactivator 2 (SRC2; also known as *GRIP1*), which has histone acetylase (HAT) activity as a primary coactivator. SRC2 can recruit proteins as secondary coactivators, such as CBP/P300 (which also have HAT activity). VDR also interacts with the Mediator complex, which facilitates the activation of the RNA polymerase II (*RNA Pol II*) holoenzyme through its C-terminal domain (*CTD*), thus promoting the formation of the preinitiation complex. The SWI/SNF complex, which remodels chromatin using the energy of ATP hydrolysis, also contributes to activation by VDR (Dhawan et al., 2017).

SRC3; the HATs CBP and p300; and the corepressor SMRT or NCoR, as well as any one of the many HDACs that interact directly with transcription factors such as the VDR to suppress activity (Smith and O'Malley, 2004). Importantly, activation of the VDR with $1,25(OH)_2D_3$ leads to the creation of a binding site on the VDR protein that mediates the link between the receptor and these coregulatory complexes (McInerney et al., 1998; Perissi et al., 1999; Westin et al., 1998). It is important to note, however, that many of these coregulatory factors are frequently prebound to sites of regulatory action by $1,25(OH)_2D_3$ as a result of their prior recruitment through additional DNA-binding proteins that co-interact at sites of VDR binding. Studies show that the ability of the VDR to recruit several of these coregulatory factors results in striking changes in epigenetic histone marks that facilitate altered gene output (Martowicz et al., 2011; Meyer et al., 2007; Zella et al., 2010). Thus, it is clear that, like other DNA-binding proteins, the function of the VDR is simply to focus and/or modulate the recruitment of transcriptionally active complexes to gene subsets that are then responsible for vitamin D hormone response. Considerable crystallographic information has now accrued to support not only the structural organization of the VDR/RXR heterodimer, but also its association with DNA and its recruitment of coregulators (Orlov et al., 2012). Many of these interactions are prompted by $1,25(OH)_2D_3$, and may well be differentially affected in the present of analogs of the vitamin D hormone. These differential interactions are proposed to account for the concept of analog selectivity in vivo, although this remains unproven and is highly controversial at this writing.

Applying emerging methodologies to study vitamin D receptor action on a genome-wide scale

The study of transcription has been revitalized since 2010, in part as a result of the coupling of chromatin immunoprecipitation (ChIP) to next-generation DNA sequence (ChIP-seq) analysis, providing new methodologies that are now capable of revealing unprecedented mechanistic detail on a genome-wide scale (Ernst and Kellis, 2010; Ernst et al., 2011; Hoffman et al., 2013). Using these methodologies many new principles have emerged, particularly when paired with transcriptomic measurements using RNA-sequencing analysis (Wang et al., 2009). In the following we will highlight the results of some of these collective studies, which have provided important new insights into the transcriptional mechanism of action of $1,25(OH)_2D_3$.

Overarching principles of VDR interaction at target cell genomes in bone cells

A compelling advantage of ChIP-seq analysis is the ability of this approach to identify VDR binding sites and other features of gene regulation in an unbiased manner on a genome-wide scale. Thus, although studies using traditional methods correctly pinpointed the regulatory regions of a few vitamin D target genes located near promoters, including *OC*,

OPN, *Cyp24a1*, and others (Kim et al., 2005), subsequent studies using ChIP-chip and ChIP-seq analyses not only confirmed many of these findings but also provided a broader overarching, genome-wide perspective on binding sites for the VDR in cells in general (see Table 30.1). In osteoblasts, we could detect approximately 1000 residual binding sites for the VDR in the absence of $1,25(OH)_2D_3$ using ChIP-chip analysis, which was increased to approximately 7000−8000 in the presence of $1,25(OH)_2D_3$ (Meyer et al., 2010b). This collection of binding sites has been termed a cellular cistrome and supports the idea that VDR DNA binding is largely hormone dependent (Meyer et al., 2014a). Importantly, similar analyses of binding sites for RXR revealed a more extensive collection of sites that was only modestly increased through $1,25(OH)_2D_3$ activation, emphasizing that RXR is a heterodimer partner not only for the VDR but also for several additional nuclear receptors (Mangelsdorf and Evans, 1995). Interestingly, RXR was frequently prebound at potential VDR binding sites in the absence of $1,25(OH)_2D_3$, suggesting that it might mark potential sites of VDR interaction on DNA. Each of these findings was confirmed in additional studies in mesenchymal stem cells, osteoblasts, osteocytes, and adipocytes, and revealed that while overlap was present, DNA sites for the VDR differed significantly across the genome depending on the cell type and stage examined (Meyer et al., 2014b, 2016; St John et al., 2014). Studies of VDR binding in EB-immortalized human B cells, primary B cells and monocytes (Ramagopalan et al., 2010), and THP-1 monocytes (Heikkinen et al., 2011) confirmed these conclusions. Importantly, although genome-wide ChIP-seq analyses demonstrate binding sites for the VDR near the promoters of genes such as OC, OPN, *Cyp24a1*, and a few others (Meyer et al., 2014b), this technique was unable to confirm a promoter-proximal VDR element for many genes, suggesting that regulatory elements were likely to be located elsewhere. Despite this, however, de novo motif finding analyses of the most common DNA sequence elements found in thousands of identified VDR binding sites confirm that most contain the originally postulated VDRE motif composed of AGGTCA xxg AGGTCA (Meyer et al., 2012, 2014b). Thus, the consensus VDRE initially identified in the human OC gene (Kerner et al., 1989; Ozono et al., 1990) remains the most representative of the DNA sequences with which the VDR interacts in mammalian genomes.

Interestingly, the unbiased and distance-unrestricted nature of ChIP-seq analysis also provided a number of surprising and unexpected insights of major significance (Ong and Corces, 2011). Perhaps most important, although traditional studies of $1,25(OH)_2D_3$ action identified regions immediately upstream of transcriptional start sites as indicated earlier, unbiased ChIP-seq analyses revealed that regulatory regions for the vitamin D hormone and its receptor are more commonly located in clusters within introns or in intergenic regions tens if not hundreds of kilobases upstream or downstream of regulated genes (Meyer et al., 2012, 2014b, 2016). Examples of such distal elements for the VDR abound, but can be found in many of the genes whose putative promoter proximal elements were undetectable by ChIP-seq analysis. They include the mouse *Tnfsf11* (RANKL) gene in bone cells, where at least five intergenic regulatory regions for the VDR are located (Kim et al., 2006); the *Cyp24a1* gene in numerous cell types, including bone cells, where in addition to the well-known promoter proximal element discussed before, a complex downstream cluster of regulatory elements exists in both the mouse and the human genes (Meyer et al., 2010a); the *Vdr* gene in bone cells, where both upstream regulatory regions and several intronic elements are present, a topic to be considered later (Lee et al., 2015a; Zella

TABLE 30.1 Overarching principles of vitamin D action in target cells.

Active transcription unit for induction: the VDR/RXR heterodimer
VDR binding sites (the VDR cistrome): 2000−8000 $1,25(OH)_2D_3$-sensitive binding sites per genome whose number and location are chromatin dependent and a function of cell type
Mode of DNA binding: predominantly, but not exclusively, $1,25(OH)_2D_3$ dependent
VDR/RXR binding site sequence (VDRE): induction mediated by classic hexameric half-sites (AGGTCA) separated by 3 bp; repression mediated by divergent sites
Distal binding site locations: dispersed across the genome in *cis*-regulatory modules (CRMs, or enhancers); located in a cell-type-specific manner near promoters, but preferentially within introns and distal intergenic regions; frequently located in clusters of elements
Epigenetic CRM signatures: defined by dynamically regulated posttranslational histone H3 and H4 modifications
Modular features of CRMs: contain binding sites for multiple transcription factors that facilitate either independent or synergistic interaction and mediate integration
VDR cistromes: dynamic alterations in the cellular epigenome during differentiation, maturation, and disease provoke changes to the VDR cistrome that qualitatively and quantitatively affect the vitamin D-regulated transcriptome

RXR, retinoid X receptor; *VDR*, vitamin D receptor.

et al., 2010); the *TRPV6* gene in intestinal cells, which contains multiple upstream elements (Lee et al., 2015b; Meyer et al., 2006); the *S100g* and PMCA2b (*Atp2b1*) genes in the intestine, which also contain multiple upstream elements (Lee et al., 2015b); and many target genes such as *c-FOS* and *c-MYC* and others in human colorectal cancer cells as well (Meyer et al., 2012). Indeed, enhancers for other transcription factors have been identified more than a megabase from the genes they are known to regulate, although at present the most distal VDR binding site is located 335 kb upstream of the human *c-MYC* promoter. It is important to clarify, however, that the linear/distal nature of regulatory elements for genes is illusionary, as distances do not take into account DNA packaging and looping events imposed on DNA that bring key regulatory segments into the proximity of a gene's promoter region (Deng and Blobel, 2010, 2014; 2017; Deng et al., 2012; Whalen et al., 2016). It is also worth indicating that of the tens of thousands of "putative" VDRE-like sequences that occur across the genome based purely on in silico analyses alone, only a small proportion of these elements mediate vitamin D action due to chromatin restriction (Kellis et al., 2014). An additional observation, as indicated earlier, is the finding through ChIP-seq analysis that most genes are regulated by more than one distal enhancer and, in some cases, by multiple regulatory regions. Recent ENCODE (Encyclopedia of DNA Elements) estimates suggest that genes on a genome-wide scale are regulated by an average of 10 independent enhancers (Kellis et al., 2014).

Modularity comprises an additional important regulatory feature of genes. Thus, individual enhancers often contain organized arrays of linear DNA sequences capable of assembling distinct, nonrandom DNA-binding transcription factor complexes that can function uniquely to regulate the gene with which they are linked. Therefore, it is interesting to note that over 42% of VDR-binding sites in bone cells are located in enhancers that contain prebound CCAAT/enhancer binding protein β (C/EBPβ) and the master regulator RUNX2 (Meyer et al., 2014a, 2014b). Indeed, these factors assemble in a highly organized fashion relative to each other, a nucleoprotein structure we have termed an osteoblast enhancer complex. Not surprisingly, both RUNX2 and C/EBPβ in this configuration can positively and perhaps negatively influence the overall regulatory activity of $1,25(OH)_2D_3$ and its receptor. An alternative and dispersed arrangement has also been identified in bone cells as highlighted in the *Mmp13* gene. Here, binding sites for the VDR, C/EBPβ, and RUNX2 are located across three separate upstream enhancers (Meyer et al., 2015a, 2015b). The activities of these three regions do not function independently, however, but rather influence one another's activity in an overall hierarchical manner to modulate the expression of *Mmp13*. It is known that many other genes contain this or similar arrangements as well. A collective summary of many of the newly acquired features of vitamin D-mediated gene regulation obtained via genome-wide analyses is provided in Table 30.1.

Genome-wide coregulatory recruitment to target genes via the vitamin D receptor

The primary function of the VDR is to recruit chromatin-active coregulatory complexes that facilitate in turn the modulation of gene output. Numerous studies at single-gene levels support the capacity of the VDR to recruit these complexes, and ChIP-seq analyses support the presence of these complexes on a genome-wide scale as well. Thus, for example, the VDR was found to recruit coactivators such as SRC1, CBP, and MED1 as well as the corepressors NCoR and SMRT in colorectal LS180 cells (Meyer and Pike, 2013). This recruitment was correlated with VDR binding sites linked to genes that are modulated directly by $1,25(OH)_2D_3$, although not preferentially to either induced or suppressed genes, as might be expected, suggesting that the roles of coregulators are not limited specifically to activation or repression and that their activities may be gene-context driven. On the other hand, studies in liver stellate cells suggest that $1,25(OH)_2D_3$-mediated repression of a profibrotic gene expression program induced by transforming growth factor β (TGFβ) does not involve the apparent recruitment of corepressors SMRT and NCoR (Ding et al., 2013). In addition to SRC1, CBP, and MED1, Brahma-related gene 1 (BRG1), an ATPase that is a component of the SWI/SNF chromatin remodeling complex, also plays a fundamental role in $1,25(OH)_2D_3$-induced transcription (Seth-Vollenweider et al., 2014). In previous studies cooperative effects between the C/EBP family of transcription factors and the VDR in $1,25(OH)_2D_3$-induced *CYP24A1* transcription were noted (Dhawan et al., 2005). C/EBP and BRG1 were subsequently found to be components of the same complex that are recruited to the C/EBP site of the *CYP24A1* gene by $1,25(OH)_2D_3$, resulting in activation of *CYP24A1* transcription (Seth-Vollenweider et al., 2014). PRMT5, a type II protein arginine methyltransferase that interacts with BRG1, represses $1,25(OH)_2D_3$-induced *CYP24A1* transcription via its methylation of H3R8 and H4R3 Seth-Vollenweider et al. (2014). Thus, the SWI/SNF complex can play a role in the silencing as well as in the activation of VDR mediated transcription.

Identifying underlying early mechanistic outcomes in response to VDR/RXR binding

The ability of the VDR to recruit epigenetically active coregulatory complexes such as HATs, HDACs, and a variety of histone methyltransferases that regulate chromatin structure suggests that $1,25(OH)_2D_3$ may influence the levels of distinct

epigenetic marks imposed by these chromatin modifiers as a means of regulating gene output. Importantly, many such epigenetic marks on histones H3 and H4 are enriched in regions within gene loci that are uniquely active (Ernst and Kellis, 2010; Ernst et al., 2011; Meyer et al., 2015c; Pike et al., 2015). Perhaps of most importance are changes in the levels of acetylation at H4K5 (H4K5ac), H3K9 (H3K9ac), and H3K27 (H3K27ac) that reflect alterations in the transcriptional activity of the genes with which they are linked; these modifications generally occur within enhancers that regulate these genes, although they can also occur at locations within genes as well. Regulatory regions that are marked by both genetic and epigenetic information at gene loci are frequently termed variable chromatin modulators (Deplancke et al., 2016). An increase in several of these acetylation marks occurs at specific sites of VDR binding in genes such as *Opn* and *Cyp24a1*, *Lrp5*, *Tnfsf11*, and *Vdr* following $1,25(OH)_2D_3$ stimulation (Pike et al., 2014, 2015, 2016) and can be used to define sites of action of $1,25(OH)_2D_3$ even in the absence of evidence of VDR occupancy. Overall, histone modification analyses suggest that $1,25(OH)_2D_3$ promotes VDR/RXR binding at sites on cellular genomes that are marked by acetylated H3K9, H3K27, and H4K5, and that these interactions frequently result in an upregulation of acetylation that facilitates enhanced levels of gene expression. These studies provide a global perspective on the actions of vitamin D in several cell types, indicating that the primary role of the VDR is to facilitate the recruitment of chromatin modifiers such as acetyltransferases and deacetyltransferases that function to impose epigenetic histone changes within the enhancers of some but not all vitamin D-sensitive target genes.

The dynamic impact of cellular differentiation and disease on vitamin D receptor cistromes and transcriptional outcomes

Perhaps the most important observation made on a genome-wide scale has been the discovery that cellular differentiation exerts a dramatic quantitative and qualitative impact on sites of genomic VDR binding, an effect that correlates directly with the hormone's ability to regulate the differentiating cell's transcriptome in a highly dynamic manner (Meyer et al., 2014b; St John et al., 2014). This process is probably responsible for the cell-type-specific nature of VDR binding and thus transcriptional outcomes at diverse sets of genes that can be measured in different tissues. A general change in the cellular RNA profile in response to $1,25(OH)_2D_3$ is perhaps not surprising, given the fact that the overall effects of $1,25(OH)_2D_3$ on osteoblast lineage cells are known to differ significantly depending upon the state of bone cell differentiation. This concept of differentiation-induced changes in VDR binding and transcriptional integrity is aptly illustrated through a detailed examination of the differential expression of several genes, including *Mmp13*, in osteoblast precursors and mature mineralizing osteoblasts (Meyer et al., 2015a).

With respect to disease processes, Evans and colleagues have demonstrated that these can affect VDR cistromes as well (Ding et al., 2013). The activation of hepatic stellate cells via the upregulation of TGFβ in the liver induces the expression of a collagen program that causes hepatic fibrosis and can induce cirrhosis of the liver. This disease progression can be ameliorated by simultaneous treatment in vivo with an analog of vitamin D. The authors show that the VDR cistrome, which functions normally to suppress the program of collagen expression, is altered as a result of TGFβ action, redirecting VDR binding to alternative sites of action away from collagen genes, thereby blunting opposing sites of vitamin D action. Interestingly, while these findings identify an important action of the VDR to prevent liver fibrosis, they also highlight the role of the VDR in the disease-potentiating activation of stellate cells, a process that could be considered analogous to that of differentiation. Further studies of this system identify the role of the chromatin regulator BRD4 in this activity, and suggest that direct inhibition of this downstream factor by a small-molecule epigenetic regulator can bypass the positive effects of a vitamin D analog (Ding et al., 2015).

New approaches to the study of vitamin D-mediated gene regulation in vitro and in vivo

Although ChIP-seq analyses are able to identify transcription factor sites of occupancy and the epigenetic landscape that characterizes these regions, the frequently distal nature of these regulatory sites prevents direct identification of the genes with which they are functionally linked (Ong and Corces, 2008; Whalen et al., 2016). It has therefore become a requirement to study genes in the endogenous genomic environment in which they are located, whether in cells in culture or in tissues in vivo. One approach has been to create large minigenes that not only span the transcription unit of interest, but also contain all the putative regulatory regions identified surrounding the gene of interest (Meyer et al., 2010a). A second and perhaps more robust strategy is to create individual enhancer deletions within the context of the genome itself, a homologous recombination approach that is highly amenable to studies in the mouse in vivo (Galli et al., 2008; Onal et al., 2015, 2016a, 2016b). A third approach represents a modification of the second: introducing mutations into genomes using RNA-directed CRISPR/Cas9 nuclease methods, which create precise genomic deletions, insertions, and/or mutations at

specific gene locations both in vitro and in vivo (Meyer et al., 2015a, 2015b). In the last two approaches, the phenotypic consequences of specific enhancer deletion can be assessed directly in cells or tissues at the level of the putative target gene's expression as well as at the levels of the gene product's biological function. This loss-of-function approach enables a determination of the functional relationship between a distal enhancer and its target gene and, as importantly, facilitates assessment of the biological function of the enhancer in question through phenotyping. Studies of this nature have been conducted for a number of genes, including *Tnfsf11* (RANKL), *Mmp13*, *Lrp5*, *Sost*, *Cdon*, *Boc*, *TRPV6*, and *VDR* itself. The location and distribution of enhancers that have been identified as responsible for the regulation of VDR gene expression by $1,25(OH)_2D_3$ and other hormones in bone and other cell types are described in Lee et al. (2015a, 2017). As can be seen, these sites of regulation are located near the promoter, within several introns, and at multiple intergenic locations many kilobases upstream of the VDR gene itself. Most importantly, these sites have been validated functionally not only in cell-based studies, but in target tissues in the mouse as well, thereby illustrating many of the overarching principles documented in Table 30.1.

Defining the regulatory sites of action of $1,25(OH)_2D_3$, PTH, and FGF23 in the *Cyp27b1* and *Cyp24a1* genes in the kidney

As discussed in an earlier section of this review, vitamin D is metabolized sequentially in the liver by *Cyp2R1* to $25(OH)D_3$ and then in the kidney by *Cyp27b1* to $1,25(OH)_2D_3$, the active hormonal form of vitamin D_3. Its circulating levels are similarly regulated through degradation in the kidney by *Cyp24a1*. Ironically, while it has long been known that $1,25(OH)_2D_3$ suppresses the expression of the *Cyp27b1* gene in the kidney and that PTH induces the gene's expression in this tissue as well, neither the sites of action of these hormones at the *Cyp27b1* gene nor their mechanisms have emerged. A similar commentary can be made for the observed suppression of *Cyp27b1* in the kidney by FGF23, the more recently discovered phosphaturic hormone. Interestingly, these same hormones reciprocally regulate *Cyp24a1* as well, although aside from $1,25(OH)_2D_3$, the mechanisms underlying this regulation also remain obscure (Meyer et al., 2010a). However, a series of experiments conducted using ChIP-seq and other genomic analyses of kidney tissue and loss-of-function enhancer deletion studies in the mouse in vivo have revealed these sites of hormonal regulatory action (Meyer et al., 2017). Indeed, ChIP-seq analysis identified sites of VDR binding within the *Cyp27b1* gene locus in response to $1,25(OH)_2D_3$, while cAMP-responsive element−binding protein (CREB) binding sites were identified in response to PTH. That these sites represented bona fide regulatory regions was confirmed through the presence of regulated epigenetic histone signatures as well as the presence of DNase I sites in these regions reflective of true enhancers. Although not surprising, given the earlier narrative with regard to the frequent distal locations of enhancers relative to the genes they regulate, a single colocalized VDR and CREB site was located within an intron of the upstream neighboring gene *Mettl1*, and three sites for both factors were located within a large intron of *Mettl21b* located even farther upstream and adjacent to *Mettl1*, while no evidence was found for regulatory activity immediately proximal to the *Cyp27b1* promoter.

Deletion of the *Mettl1* intronic site in the mouse in vivo (loss-of-function analysis) resulted in a striking decrease in *Cyp27b1* expression in the kidney due to loss of sensitivity to PTH, the consequence of which was hypocalcemia, hypophosphatemia, elevated blood PTH, absent FGF23, highly reduced levels of $1,25(OH)_2D_3$, and severe skeletal and other aberrations. Sensitivity to FGF23 and $1,25(OH)_2D_3$ suppression was unaltered. On the other hand, although deletion of the *Mettl21b* intron in the mouse also led to a significant decrease in basal expression of *Cyp27b1*, PTH response was retained, while FGF23 response was lost. In these animals, $1,25(OH)_2D_3$ levels were generally normal and the systemic and skeletal phenotype was near normal. Coincident with the reduction in *Cyp27b1* levels in both enhancer-deleted mouse strains was a coordinated reduction in renal *Cyp24a1* expression levels due to aberrant PTH and FGF23 levels, which limited the turnover of $1,25(OH)_2D_3$ in the blood, thereby enabling higher sustained levels of blood $1,25(OH)_2D_3$ than would ordinarily have been suspected. Interestingly, the expression of *Cyp27b1* in nonrenal target tissues such as skin, immune cells, and bone, expression that is largely insensitive to PTH, FGF23, or $1,25(OH)_2D_3$ and has been suggested to account for local production of $1,25(OH)_2D_3$ as a function of $25(OH)D_3$, was unaffected by these enhancer deletions and at the same time retained broad sensitivity to the inflammatory modulator lipopolysaccharide. These results suggest that key genomic elements within the *Cyp27b1* locus, but not immediately upstream of the gene, have been identified that mediate basal and PTH, FGF23, and $1,25(OH)_2D_3$ regulation in the kidney in vivo, and that this collective regulatory module is structurally and functionally unique to the kidney (Fig. 30.3). Similar features are resident at the *Cyp24a1* gene, where PTH suppresses and both FGF23 and $1,25(OH)_2D_3$ induce this gene in the kidney. Further studies will be necessary to define the mechanisms through which PTH/CREB, $1,25(OH)_2D_3$/VDR, and FGF23/(transcription factor unknown) actually modulate the reciprocal expression of *Cyp27b1* and *Cyp24a1* in the kidney. Regardless of this, however, these studies of the two key genes involved in the activation and degradation of vitamin D continue to highlight the utility of

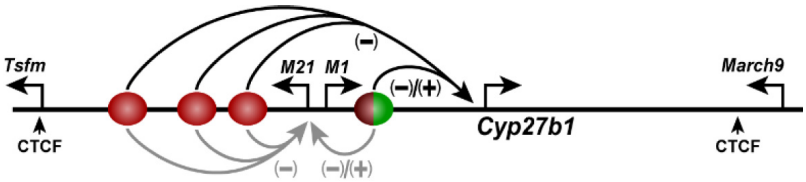

FIGURE 30.3 Schematic diagram of the kidney-specific endocrine regulatory module that controls renal *Cyp27b1* expression. The single enhancer submodule in the *Mettl1* intron and the triple components of the enhancer submodule in the *Mettl21b* intron are shown as *circles*. *Arrows* from each enhancer component are directed to the *Cyp27b1* gene as well as to the *Mettl21b* gene; both are regulated by parathyroid hormone (PTH), fibroblast growth factor 23 (FGF23), and $1,25(OH)_2D_3$. *Green* indicates a positive regulator (PTH) and *red* indicates negative regulators ($1,25(OH)_2D_3$ and FGF23). The active sites of the two hormonal suppressors have not been resolved functionally within the *Mettl21b* intron. *Arrows* above the line indicate transcriptional start sites for the *Tsfm*, *Mettl21b* (*M21*), *Mettl1* (*M1*), *Cyp27b1*, and *March9* genes. March9 is a member of the March family of membrane-bound E3 ubiquitin protein ligases. The *March9* gene is immediately downstream of *Cyp27b1*. Active CCCTC-binding factor (CTCF) sites are indicated below the line.

emerging genomic principles that are consistent with the mechanisms of action of $1,25(OH)_2D_3$ (and other hormones) at many of its target genes.

Future directions

New target genes and new factors involved in vitamin D-mediated transcription will undoubtedly be identified in numerous different systems that are known to be affected by $1,25(OH)_2D_3$. The new methodology that has enabled the study of these transcriptional mechanisms in unprecedented detail in cells and animal models will lead to new insights into mechanisms through which $1,25(OH)_2D_3$ controls calcium homeostasis and also modulates cell-specific biological processes in numerous extraskeletal systems. In addition to studies concerning the mechanisms involved in mediating the genomic actions of $1,25(OH)_2D_3$, further studies related to the physiological significance of target proteins using null-mutant mice and transgenic mice are needed. Although the principal function of vitamin D is intestinal calcium absorption, the mechanisms involved are still incompletely understood. To identify new therapeutic approaches to sustain calcium balance, mechanisms by which $1,25(OH)_2D_3$ acts at both the proximal and the distal segments of the intestine need to be defined. In vivo studies addressing physiological significance combined with studies related to the molecular mechanisms involved in $1,25(OH)_2D_3$ action are needed to provide new insight into the role of $1,25(OH)_2D_3$ in calcium homoeostasis and extraskeletal health, which could lead to the development of vitamin D therapeutics with selective modulation of responses in bone and other target tissues.

Chapter outline

Introduction

It is widely assumed that hypovitaminosis D is highly prevalent worldwide (Palacios and Gonzalez, 2014). This is reasonable as humans historically obtained vitamin D via cutaneous production upon UVB exposure, and sun avoidance is now common and widely advocated (USDDH, 2014). Vitamin D deficiency could potentially have widespread adverse health consequences (Holick, 2017). As many tissues possess both the vitamin D receptor and the 1-hydroxylase, it can be hypothesized that active vitamin D (i.e., $1,25(OH)_2D$) is produced locally, i.e., that vitamin D has autocrine/paracrine effects in addition to the classic endocrine effects on calcium homeostasis (Holick, 2008). The effects of vitamin D deficiency on the musculoskeletal system are well established. However, it is reasonable that vitamin D inadequacy could, potentially, compromise the functions of multiple organs and systems (in addition to the musculoskeletal system) and thereby, ultimately, lead to dysfunction leading to acute and chronic disease (Holick, 2011). Consistent with this, hypovitaminosis D, generally defined as low circulating 25-hydroxyvitamin D (25(OH)D), has been associated with a multitude of human diseases, e.g., muscular dysfunction, cardiovascular disease (CVD), cancer, immune function, hypertension, obesity, diabetes mellitus, and many, many others (Holick, 2017; Wang et al., 2017). If these associational studies are reflective of causality, i.e., if vitamin D inadequacy is contributing in a causal way to a multitude of human diseases with

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00031-2

immense impact upon quality of life, mortality, and health care expense, then widespread screening for this deficiency is needed and societal efforts such as food supplementation are needed. Indeed, vitamin D inadequacy (using the Institute of Medicine guidance) is present in over 30% of Americans (Looker et al., 2011). This prevalence is comparable to those of obesity, hypertension, and hyperlipidemia, other widely recognized contributors to chronic diseases for which widespread public health efforts to manage exist. Alternatively, it could be hypothesized that the association of low vitamin D status with the multitude of human conditions is nothing more than the use of circulating 25(OH)D to identify those with poor nutritional status and/or suboptimal health, thereby reducing the likelihood of sun exposure. If this is true, widespread 25(OH)D measurement and supplementation is an unnecessary waste of limited health care resources and must cease. Clearly, it is essential to determine whether vitamin D inadequacy does, or does not, contribute to nonskeletal disease.

As such, it is not surprising that a plethora of observational and prospective studies evaluating the association of vitamin D status with many diseases has been and is being performed and published. As systematic reviews of randomized trials are considered the highest level of evidence-based medicine (Sackett et al., 1996), it is expected that meta-analyses relating vitamin D to nonskeletal disease are often being performed. Indeed, a PubMed search in March 2018 found that 747 vitamin D-related meta-analyses were performed from 2013 through 2017, an average of approximately three every week. Moreover, a number of authoritative reviews have evaluated the potential role of vitamin D in nonskeletal conditions (Autier et al., 2017; Rejnmark et al., 2017; Rosen et al., 2012). To succinctly summarize these reviews, it remains unclear what role, if any, vitamin D inadequacy plays in causing nonskeletal diseases. We believe this state of uncertainty reflects deficiencies in assessment of vitamin D status and clinical trial design as is discussed later. As such, this chapter will not replicate recent reviews. However, as examples of existing data suggesting a potential importance in human disease, we will briefly overview data relating vitamin D status to cancer, immune function, falls, and CVD. These conditions were selected as they cause immense morbidity, mortality, and health care cost worldwide.

Vitamin D and immunity

There are many extensive reviews that explore the possible role of vitamin D in the immune system (Colotta et al., 2017; Hayes et al., 2015; Peelen et al., 2011). Certainly, the vitamin D receptor (VDR) is found in activated T cells and macrophages (Wang et al., 2012c). In vitamin D deficiency the VDR is either low or absent from T cells but is present in macrophages. The receptor quickly appears in T cells following vitamin D administration. B cells lack the VDR in our hands, while others claim its presence in these cells. By autoradiography, Stumpf et al. demonstrated that titrated $1,25(OH)_2D_3$ is found in the nuclei of thymus, spleen, lymph nodes, and macrophages, but interestingly not in lymphocytes (Stumpf et al., 1990; Stumpf and Downs, 1987). There is little doubt vitamin D plays a role in immunity; however, there is much debate and little agreement on how vitamin D is involved in immunity.

A great deal of information has been generated, primarily by in vitro methods, on cytokine levels in T cells, with concentrations of $1,25(OH)_2D_3$ higher than found in vivo. Although arguments that these levels can be achieved locally have been made, no such in vivo demonstration has appeared. Further, rarely has true vitamin D deficiency through dietary means been achieved, and most studies examine the effect of supplemental vitamin D above normal. In this brief review an attempt will be made to present the effects of vitamin D deficiency versus sufficiency in animal models when available. Unfortunately, consistent information on whether vitamin D deficiency has any impact on innate or acquired immunity in animals or humans is unavailable.

On the other hand, some information is available in situations in which the adaptive immune system fails, or autoimmunity, in animals. One example is in type 1 diabetes. Vitamin D deficiency accelerated both the onset and the severity of the disease in the NOD mouse (Zella et al., 2003). In this circumstance a major consideration is that the insulin-producing islet cells have a high concentration of the VDR (Wang et al., 2012b). While vitamin D through its active form suppresses the disease (Zella et al., 2003), the suppression could be a result of $1,25(OH)_2D_3$ action on the islet cell rather than an action on cells of the immune system. A combination of cellular targets is also possible, as specific T cell populations show small alterations in NOD mice when the VDR is eliminated (Gysemans et al., 2008). However, the consequences of these changes are not clear.

The opposite impact of vitamin D status is found in the case of experimental autoimmune encephalomyelitis (EAE), a model of multiple sclerosis (MS). Quite unexpected is the finding from our group (DeLuca and Plum, 2011), and independently by a group in France (Fernandes de Abreu et al., 2010), that vitamin D deficiency suppresses EAE instead of exacerbating disease. Thus, vitamin D is required and functions in some manner to program T cells and/or macrophages to attack the spinal cord, precipitating EAE, a widely accepted model of MS. Originally Lemire and Archer reported that

$1,25(OH)_2D_3$ could suppress EAE, a finding that was repeated in other laboratories (Lemire and Archer, 1991; VanAmerongen et al., 2004). In our group the suppression of EAE by $1,25(OH)_2D_3$ is accompanied by hypercalcemia (Cantorna et al., 1996). When dietary calcium was reduced to 0.02%, the effectiveness of $1,25(OH)_2D_3$ to suppress EAE was severely limited (Cantorna et al., 1999). Further hypercalcemia itself suppresses EAE (Meehan et al., 2005). Therefore, the suppression of EAE by $1,25(OH)_2D_3$ is linked to dietary and perhaps serum calcium. Consistent with the removal of vitamin D from the diet, the ablation of VDR also blocks the development of EAE (Wang et al., 2012b). Thus, in contrast to type 1 diabetes, vitamin D is required for the development of the disease, reducing the likelihood vitamin D might be used to suppress MS. Results from meta-analyses of the clinical trials done to test the use of vitamin D to suppress MS seem to confirm this idea (Cashman et al., 2016b; Hempel et al., 2017; Zheng et al., 2018).

Distinct from this finding, a narrow band of UV light (295−315 nm) suppresses EAE by a mechanism not involving vitamin D. Although this may provide an explanation of the low incidence of MS in high-sunlight areas, its mechanism is largely unknown.

Another disease that involves the immune system is inflammatory bowel disease, which has been extensively studied by Cantorna et al. (Bora and Cantorna, 2017). Their results are similar to those observed in animal models of type 1 diabetes, i.e., that VDR and ligand deficiency both exacerbate the disease. The intestinal epithelium possesses large amounts of the VDR and it is unclear whether the effect of the vitamin D is directly on immune cells or through its action on the intestinal villi. It is clear that subsets of T cells, i.e., invariant natural killer T cells as well as CD8aa populations, are significantly reduced in the gastrointestinal tract of mice lacking VDR (Bora and Cantorna, 2017). Whether the decrease in these populations can explain the reduction of disease is unclear.

In conclusion, the presence of the VDR and its ligand in cells of the immune system strongly suggests a role for vitamin D in immunity. However, little in vivo evidence is available on the role of vitamin D in the immune system. Vitamin D deficiency and/or a lack of the VDR does suppress the animal model of MS (EAE). Quite differently, 1,25-dihydroxyvitamin D, the active form of vitamin D, suppresses type 1 diabetes in NOD mice, while vitamin D deficiency exacerbates the disease. A similar relationship is found in the case of inflammatory bowel disease. Although these effects of vitamin D are clear, the underlying mechanisms remain unknown.

Vitamin D and muscle performance, balance, and falls

Physiology

VDRs are present in many tissues, including muscle, but their role in muscle is not entirely clear. The number of VDRs in muscle (Bischoff-Ferrari et al., 2004) and the number of type 2 muscle fibers (Vandervoort, 2002) decline with aging, and preliminary evidence indicates that similar changes may occur in vitamin D deficiency (Ceglia et al., 2013). In a small study of 21 older women with a low mean serum 25(OH)D level of 18.4 ng/mL, daily supplementation with 4000 IU of vitamin D_3 for 4 months increased the intramyonuclear VDR number and the cross-sectional area of type 2 muscle fibers compared with placebo (Ceglia et al., 2013). No significant changes in muscle performance were documented.

With aging, the number of motor neurons enervating muscle declines (Brown, 1972), as does balance. There is limited evidence that vitamin D deficiency may adversely affect motor neurons. Skaria documented reduced nerve conduction velocities as well as myopathy in patients with osteomalacia (Skaria et al., 1975). However, treatment with vitamin D reversed the myopathy but did not improve nerve conduction velocity in these patients, leaving open the possibility that the patients had unrelated peripheral neuropathies (Skaria et al., 1975). Irani (1976) observed no nerve conduction abnormalities in patients with osteomalacia.

Clinical studies of muscle performance and balance

Based on the histomorphometric muscle changes seen in severe vitamin D deficiency, many investigators have hypothesized that supplementation with vitamin D may reduce muscle wasting and improve muscle performance in older adults with milder degrees of vitamin D deficiency. A 2014 meta-analysis of 30 randomized controlled clinical trials (RCTs) involving 5615 older adults examined the impact of vitamin D supplementation on muscle strength, mass, and power (Beaudart et al., 2014). In 29 of these trials, supplemental vitamin D significantly increased a global index of strength comprising mainly grip and leg strength. Subset analyses indicated that benefit was greater for participants with 25(OH)D levels <12 ng/mL, and that leg strength but not grip strength improved significantly with supplementation. In the trials that

measured muscle mass (N = 6) and power (N = 5), no significant effect of vitamin D was observed (Beaudart et al., 2014). Several subsequent trials have found no impact of supplemental vitamin D on muscle function in older adults (Hansen et al., 2015; Levis and Gomez-Marin, 2017; Uusi-Rasi et al., 2015), possibly because the study participants were not vitamin D deficient (see "Clinical studies"). In contrast, a study by Cangussu et al. reported improved chair rise performance with vitamin D supplementation over 9 months in postmenopausal women with a mean serum 25(OH)D level of 15 ng/mL (Cangussu et al., 2015).

The role of vitamin D in muscle mass and performance in young adults is less extensively studied. In a large clinical trial in school girls with a mean serum 25(OH)D level of 14 ng/mL, vitamin D supplementation for 1 year increased lean tissue mass (and bone mass) but had no effect on grip strength (El-Hajj Fuleihan et al., 2006). Similarly, in a study of young women, mean age 21 years, with a low mean 25(OH)D level of 9.3 ng/mL, treatment over 6 months increased serum 25(OH)D to near 30 ng/mL but had no significant effect on grip strength (Goswami et al., 2012). Thus current evidence indicates that supplementation modestly increases muscle mass and bone mass, but does not improve muscle strength.

Several trials conducted in older adults have reported vitamin D treatment to improve balance, measured under static conditions by body sway, compared with placebo (Cangussu et al., 2016; Pfeifer et al., 2009). The impact of vitamin D on dynamic balance (a complex process involving sensory information, selection of the appropriate response to maintain balance, and efficient activation of the muscles that respond to a balance disturbance) is unknown, but it may be inferred by the effect of vitamin D on risk of falling (see the next section).

Vitamin D and falls

Prevention of falls is a public health priority because 1%–2% of falls lead to hip fractures, falls are independent determinants of functional decline, and falls lead to 40% of all nursing home admissions (Tinetti and Williams, 1997). Moreover, falls are a substantial and increasing cause of mortality in the very old (Hartholt et al., 2018).

The role of vitamin D in preventing falls has been studied extensively and clinical trials have produced mixed findings. Two meta-analyses published in 2009 and 2011 found that vitamin D supplementation had a modest beneficial effect on fall risk in older adults (Bischoff-Ferrari et al., 2009; Murad et al., 2011). One of these papers suggested that fall risk reduction with supplementation may be more effective in individuals with low 25(OH)D levels (Murad et al., 2011). In 2014, a meta-analysis concluded that the effect estimate for vitamin D with or without calcium on falls did not alter the relative risk by 15% or more (Bolland et al., 2014). A 2015 meta-analysis found vitamin D supplementation to be more effective in elders with low 25(OH)D levels (LeBlanc and Chou, 2015). Since this most recent meta-analysis (LeBlanc and Chou, 2015), several large, placebo-controlled trials have been published that collectively appear to fit the pattern that only vitamin D-insufficient elders are responsive to supplementation with vitamin D. Hansen et al. treated postmenopausal women with a mean serum 25(OH)D level of 21 ng/mL with 50,000 IU of vitamin D_3 twice monthly or 800 IU daily for 1 year and observed no effect on falls (Hansen et al., 2015). Similarly, the Vitamin D Assessment (ViDA) Study found no effect of treatment for 3.4 years with 100,000 IU of vitamin D_3 per month on fall risk in older adults with a mean serum 25(OH)D level of 25 ng/mL (Khaw et al., 2017). In contrast, in postmenopausal women with a very low mean 25(OH)D level of 15 ng/mL, treatment with 1000 IU of vitamin D_3 per day for 9 months reduced fall risk by about 50% (Cangussu et al., 2016).

In summary, available evidence indicates that elders with low 25(OH)D levels are most likely to benefit from supplementation with vitamin D and the degree of fall risk reduction may be proportional to the degree of insufficiency. The results of a large ongoing trial (as of this writing) testing several doses of vitamin D in elders with 25(OH)D levels in the range of 10–29 ng/mL should provide a more precise estimate of the segment of the elderly population that is likely to benefit from supplementation and the optimal replacement dose(s) (NCT02166333).

Several studies have indicated that supplementation under certain circumstances can increase risk of falling. This was first noted by Sanders et al., who found that a large annual oral dose of 500,000 IU of vitamin D increased risk of falls (and fractures) in elders (Sanders et al., 2010). An increase in fall risk was also seen in a trial administering an oral dose of 60,000 IU of vitamin D_3 monthly (Bischoff-Ferrari et al., 2016). In long-term care residents, treatment with 100,000 IU of vitamin D_3 per month, compared with standard dosing, significantly increased fall risk (secondary end point), while significantly lowering the risk of developing an acute respiratory infection (primary outcome) (Ginde et al., 2017). A common feature of these trials is that they employed high intermittent doses of vitamin D. But treatment with 100,000 IU per month does not always increase risk of falls; this dose administered in the ViDA study had no significant effect on the fall rate (Khaw et al., 2017). Nonetheless, there is sufficient evidence for risk that daily or weekly dosing is preferred to higher intermittent dosing.

Vitamin D and cancer

The antiproliferative, prodifferentiating effects of vitamin D signaling on many, if not all, cell types have raised the hope that vitamin D, $1,25(OH)_2D$, or one or more of its analogs would prove useful in the prevention and/or treatment of cancer. Although the cellular and animal studies have been promising, and at least for some cancers epidemiologic evidence is suggestive, to date the RCTs are less compelling. That said, a number of mechanisms by which $1,25(OH)_2D$ and its analogs might alter tumor development and progression have been documented, at least in the cellular and animal studies as reviewed in 2016 (Bikle, 2016).

Cellular mechanisms

Vitamin D metabolism

Most tumors express the VDR and often express cytochrome P450 27B1 (CYP27B1), the enzyme that converts 25(OH)D to $1,25(OH)_2D$, thus producing the ligand for VDR. Their expression is often lost as the tumor undergoes progressive dedifferentiation (Brozek et al., 2012; Matusiak and Benya, 2007; Santagata et al., 2014). On the other hand CYP24A1 expression is also often increased in tumors, and is associated with resistance to $1,25(OH)_2D$ (Brozek et al., 2012; Tannour-Louet et al., 2014). These changes in vitamin D metabolism and responsiveness reduce the ability of $1,25(OH)_2D$ to control the proliferation and differentiation of these tumors.

MicroRNA

A number of microRNAs that alter tumor proliferation have been identified as being regulated by $1,25(OH)_2D$ (Christakos et al., 2016). This includes increased expression of miR-145, which blocks the expression of E2F3, a key regulator of proliferation (Chang et al., 2015), and miR-32, which blocks the proapoptotic protein Bim, protecting the cell (human myeloid leukemia) from AraC-induced apoptosis (Gocek et al., 2011).

Cell cycle regulation and proliferation

$1,25(OH)_2D$ typically causes arrest at the G0/G1 and/or G1/S transition in the cell cycle, associated with a decrease in cyclins and an increase in the inhibitors of the cyclin-dependent kinases such as p21cip1 and p27kip1 (Hager et al., 2001; Palmer et al., 2003). The family of Forkhead box O proteins blocks proliferation. $1,25(OH)_2D$ promotes their interaction with the VDR as well as their regulation by Sirt1 and protein phosphatase 1, maintaining these proteins in the transcriptionally active dephosphorylated state (An et al., 2010). On the other hand $1,25(OH)_2D$ reduces the expression of proproliferative genes such Myc, Fos, and Jun (Meyer et al., 2012), while stimulating the expression of insulin-like growth factor (IGF)-binding protein 3 (IGFBP3) in prostate and breast cancer (BCa) cells. The increased expression of IGFBP3 would bind the IGFs, blocking their ability to stimulate proliferation (Colston et al., 1998; Huynh et al., 1998). In epithelial cells $1,25(OH)_2D$ stimulates the expression of transforming growth factor β2, which is antiproliferative in these cells (Peehl et al., 2004; Swami et al., 2003; Yang et al., 2001) and suppresses components of the Hedgehog pathway, which when overexpressed result in basal cell carcinomas (BCCs) (Aszterbaum et al., 1998; Teichert et al., 2011). $1,25(OH)_2D$ inhibits the proliferative effects of epidermal growth factor by inhibiting the expression of its receptor in breast cell lines (McGaffin and Chrysogelos, 2005). Constitutive activation of the Wnt/β-catenin pathway is the cause of most colorectal cancers (CRCs). When activated, β-catenin enters the nucleus, where it binds to T cell factor/lymphoid enhancer-binding factor (TCF/LEF) sites in genes promoting proliferation (e.g., cyclin D1). VDR, on binding to its ligand, blocks this pathway both by binding to β-catenin, limiting its access to the TCF/LEF sites in the nucleus, and by stimulating the formation of the E-cadherin/catenin complex in the cell membrane to which β-catenin is bound, limiting its translocation to the nucleus (Byers et al., 2012). Moreover, $1,25(OH)_2D$ can increase the expression of the Wnt inhibitor dickkopf (Dkk)-1 (Aguilera et al., 2007) while inhibiting that of the Wnt activator Dkk-4 (Pendas-Franco et al., 2008) in colon cancer cells.

Apoptosis

$1,25(OH)_2D$ stimulates the expression of a number of proapoptotic genes, such as GOS2 (G0/G1 switch gene 2) (Palmer et al., 2003), Bax (Kizildag et al., 2010), DAP (death-associated protein)-3, CFKAR (caspase 8 apoptosis-related cysteine peptidase), FADD (Fas-associated death domain), and caspases (e.g., caspases 3, 4, 6, and 8) (Swami et al., 2003) in a variety of cell lines, while suppressing the expression of proapoptotic genes such as Bcl2 and Bcl-XL in these and other cell lines (Kizildag et al., 2010; Weitsman et al, 2003, 2005).

Animal studies

Animal studies demonstrating the efficacy of $1,25(OH)_2D$ in preventing or slowing the progression of various tumors are numerous, with those of the colorectum (CRC), breast, prostate, and skin being most studied. Below are selected examples.

Colorectal cancer

Diets that are low in calcium and vitamin D (Western diet) fed to mice increase the risk of CRC for these mice. This risk can be reversed by diets supplemented with calcium and vitamin D (Newmark et al., 2009). The administration of vitamin D metabolites to mice in which CRC was induced by azoxymethane and dextran sulfate incorporated into the diet is at least partially protective (Murillo et al., 2010). Activation of the Wnt/β-catenin pathway caused by mutations in adenomatous polyposis coli (APCmin) results in tumor formation much faster when the mice are placed on a low-calcium, low-vitamin-D Western diet (Yang et al., 2008) or on a vitamin D-deficient diet (Xu et al., 2010). Similarly, these tumors develop faster when these mice are bred with VDR-null mice (Zheng et al., 2012).

Breast cancer

BCa induced by dimethylbenzanthracene (DMBA) are increased in number when rats are fed the low-calcium, low-vitamin-D Western diet (Lipkin and Newmark, 1999) or when VDR-null mice are administered DMBA (Zinser and Welsh, 2004). The growth of BCa xenografts can be prevented by vitamin D analogs (VanWeelden et al., 1998).

Prostate cancer

Vitamin D analogs can also inhibit the growth of prostate cancer (PCa) regardless of androgen receptor status (Bhatia et al., 2009). A vitamin D-deficient diet will promote the growth of PC3 PCa cells in bone (Zheng et al., 2011). Breeding the transgenic prostate tumor model LPB-Tag with VDR-null mice stimulates the growth of these tumors (Mordan-McCombs et al., 2010). The development of tumors in the TRAMP (transgenic adenocarcinoma of the mouse prostate) model of PCa can be prevented with high doses of $1,25(OH)_2D$ (Krishnan et al., 2010).

Skin

The most common skin cancers are squamous cell carcinomas (SCCs) and BCCs. VDR-null mice develop skin tumors when exposed to DMBA (with or without topical application of phorbol myristate acetate (TPA)) or after chronic exposure to UVB at a rate far greater than that of their wild-type controls (Ellison et al., 2008; Teichert et al., 2011). Topical $1,25(OH)_2D$ is protective at least from the early effects of UVB on markers of DNA damage such as cyclobutane pyrimidine dimers (Gupta et al., 2007), although extended studies to determine whether topical application of $1,25(OH)_2D$ is protected in UVB-induced tumor formation have not been done.

Clinical studies

The inverse relationship between solar exposure and cancer mortality in North America was first noted by Apperly (1941) in 1941, and then popularized and linked to vitamin D by the Garland brothers (Garland and Garland, 1980) in 1980 in their epidemiologic studies with colon cancer. With the exception of skin cancer, this inverse relationship between solar exposure and cancer has been reported for many types of cancer (van der Rhee et al., 2006). More recent studies have examined the association of vitamin D intake or serum levels of 25(OH)D, generally using case−control and cohort studies. RCTs have generally been smaller, and often do not support the positive associations between sunlight, dietary vitamin D, or 25(OH)D levels and cancer prevention found in the epidemiologic studies. As for animal studies, most data come from studies of colorectal, breast, prostate, and skin cancer.

Colorectal cancer

In meta-analyses of nine studies (eight cohort, one nested case−control; 6466 subjects) evaluating the relationship of vitamin D intake and CRC and nine studies (seven cohort, two case−control; 2764 cases, 3948 controls) evaluating serum levels of 25(OH)D and CRC, Ma et al. (2011) found an overall relative risk (RR) of 0.88 (CI 0.8−0.96) comparing the highest with the lowest categories of vitamin D intake and an RR of 0.67 (CI 0.54−0.80) for the highest to lowest 25(OH)D levels. When dietary calcium was taken into account (higher calcium is better) the risk reduction was enhanced. These

meta-analyses confirm previous results from the American Cancer Society cohort study (120,000 men and women) (Cho et al., 2004) and the National Institutes of Health (NIH; 16,000 participants) (Carroll et al., 2010). Thus, at least for CRC, there is a reasonably consistent set of epidemiologic data supporting the protective effect of vitamin D (and calcium) with respect to CRC incidence. However, RCTs have been disappointing. The Women's Health Initiative (WHI), in which 400 IU of vitamin D daily was assessed, failed to show protection against CRC (Wactawski-Wende et al., 2006). The low dose of vitamin D used in this trial may have limited the likelihood of observing an effect. However, a study of 1000 IU vitamin D daily for 3−5 years also failed to show a benefit in the reduction of colon adenomas and colon cancer even in a high-risk population (Baron et al., 2015). Perhaps vitamin D supplementation over short time spans relative to the time required for cancer to manifest is a limiting factor.

Breast cancer

In a large case−control study from Italy (Rossi et al., 2009) a 34% decrease in BCa was found in those ingesting the highest level of vitamin D (>194 IU/day) versus those ingesting the lowest level (<60 IU/day). The largest cohort studies (Lin et al., 2007; Shin et al., 2002) (Nurses Health Study with 88,891 participants and WHI with 31,487 participants) showed a reduction in risk (RR 0.72, CI 0.55−0.94, and RR 0.65, CI 0.42−1.00, respectively) in those ingesting the highest amount of vitamin D, but only in the premenopausal women. Chlebowski (2011) reviewed 10 case−control and 10 cohort studies with respect to vitamin D intake and BCa and four case−control and six nested case−control studies with respect to 25(OH)D levels and BCa. Only when premenopausal/perimenopausal women were included in the analysis was a significant negative association between increased vitamin D intake and BCa incidence found (RR 0.83, CI 0.73−0.95) (Chen et al., 2010). Of the six nested case−control studies assessing the relationship of serum 25(OH)D and BCa, only one showed a significant negative association between high 25(OH)D levels and incidence of BCa. In a separate meta-analysis by Gandini et al. (2011) an RR of 0.89 (0.82−0.98) for a 10 ng/mL increase in 25(OH)D was found when all studies were included and an RR of 0.83 (0.79−0.87) when only case−control studies were pooled. As for CRC, the WHI did not show a protective role for vitamin D in BCa. Thus the epidemiologic data tend to support a protective role for vitamin D against BCa, but the data are not as consistent as for CRC.

Prostate cancer

In contrast to CRC, the role of vitamin D in PCa is decidedly mixed. In a summary of 14 prospective studies (not RCTs) examining the association between 25(OH)D levels and the development of PCa, van der Rhee et al. (2006) found that 11 studies showed no association, and one study (Ahn et al., 2008) showed a positive association with PCa aggressiveness, although this was not seen in other studies (Gilbert et al., 2011). In particular, a meta-analysis of six cohort/nested case−control studies (8722 cases) examining the association of dietary vitamin D intake with PCa found an RR of 1.14 (CI 0.99−1.31) for an increase in dietary vitamin D of 1000 IU (Gilbert et al., 2011). Similarly, a meta-analysis of 14 cohort/nest case−control studies, including 4353 cases, examining the association of serum 25(OH)D and PCa found an RR of 1.04 (CI 0.99−1.1) for a 10 ng/mL increase in 25(OH)D for all PCas (Gilbert et al., 2011). Although an initial phase I clinical trial (ASCENT I) with high dose of $1,25(OH)_2D$ and docetaxol seemed to show promise in the treatment of castration-resistant PCa, this initial success could not be repeated in a larger phase II trial (ASCENT II) potentially flawed by differences in the dose of docetaxol between the calcitriol plus docetaxol arm and that with docetaxol alone (Scher et al., 2011). These trials did establish the safety of using high doses of calcitriol in the treatment of cancer when administered under controlled conditions. Nevertheless, the clinical evidence weighs against vitamin D being beneficial in the prevention or treatment of PCa.

Skin cancer

Skin cancer, in particular nonmelanoma skin cancer (NMSC), is by far the most common cancer, with over 1 million skin cancers occurring annually in the United States. Of these, 96% are NMSC (80% BCC, 16% SCC), with melanomas making up the remaining 4%. Because UVB is the major etiologic agent for NMSC, but is also the major means by which the body makes vitamin D, it has been difficult to separate out the beneficial effects of vitamin D on NMSC from the deleterious effects of UVB exposure. Moreover, most national registries do not include NMSC, leaving no easily accessible database with which to track the development of these cancers. That said, a few epidemiologic studies have been published. An earlier study on vitamin D intake found no association between vitamin D and BCC risk (Hunter et al., 1992). However, some clinical studies of BCC patients show a potential beneficial role for vitamin D. In a nested case−control study of 178 elderly men with NMSC compared with 930 without skin cancer enrolled in the Osteoporotic Fractures in Men (MrOS)

study, men with the highest baseline serum 25(OH)D levels (30 ng/mL) had 47% lower odds of NMSC (CI 0.3−0.93) compared with those with the lowest baseline 25(OH)D levels (Tang et al., 2010). However, this observation has not been confirmed in other studies, which have shown a positive correlation between 25(OH)D levels and BCC (Asgari et al., 2010; Eide et al., 2011). In an analysis of 36,282 postmenopausal women in the WHI, no difference was found in the incidence of melanoma between women receiving 400 IU vitamin D plus calcium (1000 mg) supplementation compared with placebo over a follow-up period of 7 years, although a subgroup analysis of women at high risk based on a previous history of NMSC showed a reduction in the incidence of melanoma in those receiving calcium and vitamin D supplementation (Tang et al., 2011).

Vitamin D and cardiovascular disease

In observational studies, low circulating 25(OH)D concentrations have been associated with increased risk of CVD. Although these associations are not seen in all studies, there is no evidence that higher 25(OH)D levels are associated with greater CVD risk (Nemerovski et al., 2009). As such, it is plausible that vitamin D is indeed causally related to CVD. Importantly, both blood vessels and cardiac myocytes have been reported to possess VDRs and CYP27B1, the 1α-hydroxylase enzyme (Tishkoff et al., 2008).

Low vitamin D status has been hypothesized to potentially cause CVD by multiple, not exclusive, mechanisms, including regulation of calcium flux altering vascular and myocardial calcification, mediation of inflammation/cell proliferation, and interactions producing antiatherosclerotic effects (among others) (Norman and Powell, 2014; Cashman, 2014; Pilz et al., 2010). For example, it is plausible that the relationship of 25(OH)D with parathyroid hormone (PTH) might be involved in CVD, as elevated PTH is associated with increased blood pressure, which, if sustained, could lead to cardiac hypertrophy and ultimately to heart failure (Rostand and Drueke, 1999). In addition, chronically high inflammation is positively associated with CVD, and $1,25(OH)_2D$ may downregulate proinflammatory and upregulate antiinflammatory cytokines (Cardus et al., 2009; Chen et al., 2013; Helming et al., 2005). Consistent with a potential effect in CVD, a 2018 meta-analysis of six vitamin D supplementation RCTs in adults with heart failure found vitamin D supplementation to lower tumor necrosis factor α (Rodriguez et al., 2018). Other potential linkages of vitamin D status with CVD include potential effects on the functions of endothelial cells (Dong et al., 2012; Merke et al., 1989) and cardiac myocytes (Pilz et al., 2010; Tishkoff et al., 2008).

Epidemiologic evidence supports a potential relationship of low vitamin D status with CVD. For example, over ∼8 years of follow-up, the hazard ratios for heart failure death and sudden cardiac death for those whose 25(OH)D was <10 ng/mL were 2.8 and 5.1, respectively, compared with those with a 25(OH)D of ≥30 ng/mL (Pilz et al., 2008). Similarly, in an NHANES cohort, a composite CVD index (stroke, myocardial infarction, and angina) found that the prevalence of circulating 25(OH)D at <20 ng/mL was higher (29%) in those with CVD than those without (21%) (Kendrick et al., 2009). Moreover, a Framingham Offspring cohort study found circulating 25(OH)D levels below 15 ng/mL to be associated with increased risk of cardiovascular events, with the 5-year rate being double in those with vitamin D deficiency compared with those with higher concentrations (Wang et al., 2008). Importantly, low vitamin D status is associated with increased risk of death due to heart failure, sudden cardiac event, and CVD all-cause mortality. This was demonstrated in the Ludwigshafen Risk and Cardiovascular Health (LURIC) cohort after a median follow-up of 7.7 years. Heart failure and sudden cardiac events were increased in those with 25(OH)D of <10 ng/mL (Pilz et al., 2008) and CVD all-cause mortality was increased in subjects with lower 25(OH)D (Dobnig et al., 2008) even after adjustment for many traditional CVD risk factors. Multiple other observational studies with generally similar results exist and will not be reviewed here; overall, a 2012 meta-analysis of prospective studies relating 25(OH)D with CVD risk found an inverse relationship between 25(OH)D and CVD risk (Wang et al., 2012a).

Issues in existing data and paths forward to resolve the role of vitamin D deficiency in nonskeletal disease

As noted in the introduction, immense interest, clinical trials, publications, and meta-analyses related to vitamin D have been and are currently being published without adequate clarification of the potential role of vitamin D in nonskeletal diseases. As an oversimplification, we believe this reflects two major issues in vitamin D research: inadequate measurement of vitamin D status and limitations in clinical trial design.

Vitamin D status assessment

It is widely accepted that measurement of the circulating total 25-hydroxyvitamin D (25(OH)D) concentration—i.e., the sum of $25(OH)D_3$ and $25(OH)D_2$—is the best way to define vitamin D status (Scientific Advisory Committee on Nutrition (SACN), 2016; Holick et al. 2011; Institute of Medicine, 2010). However, substantial variability in "25(OH)D" results has existed, and continues to exist (Binkley et al., 2004; Carter et al., 2004; de la Hunty et al., 2010; Le Goff et al., 2015; Wallace et al., 2010). This variability confounds in a major way all efforts to clarify a potential role of vitamin D in nonskeletal disease and moreover to develop clinical and public health guidelines. It seems self-evident that use of different "25(OH)D" values could lead to differences in the definition of vitamin D inadequacy. Indeed, the use of differing 25(OH)D assays yields differing estimates of the prevalence of vitamin D inadequacy; retrospective standardization documents that prevalence can increase or decrease based on whether the initial assay was negatively or positively biased (Cashman et al, 2013, 2015a, 2016a; Sarafin et al., 2015; Schleicher et al., 2016). As such, failure to standardize 25(OH)D measurement standardization could be considered the major issue contributing to the "chaos" that continues to surround vitamin D (Binkley et al., 2017b).

Historically, no reference measurement procedure or reference materials existed to allow 25(OH)D measurement standardization. As such, 25(OH)D assay standardization is essential for clinical, research, and public health recommendation clarity. The Vitamin D Standardization Program (VDSP) was developed in an attempt to rectify this situation (Sempos et al., 2012).

Detailed review of the VDSP is beyond the scope of this chapter. Briefly, the VDSP coordinates the international effort to standardize serum 25(OH)D measurement to gold standard reference assays that have been developed (Mineva et al., 2015; Phinney et al., 2017; Stockl et al., 2009; Tai et al., 2017). In addition, guidance for retrospective standardization of previously published research for which stored specimens exist has been published (Durazo-Arvizu et al., 2017). Thus, VDSP approaches exist to allow performance and reporting of standardized 25(OH)D results (Sempos et al., 2017). Such an approach is essential if 25(OH)D data are to be pooled in meta-analyses.

Moreover, we believe that the NIH and other grant-funding agencies around the world should require grant applicants to demonstrate the procedures they will use to standardize 25(OH)D measurement before funding of a vitamin D-related study is approved. In addition, as certain automated immunoassays may not function properly in some patient populations due to altered vitamin D-binding protein levels, e.g., pregnant women and intensive care unit patients, researchers need to demonstrate that the assay can function in the patient populations to be studied (Apperly, 1941). Finally, we suggest that standardization of 25(OH)D data be a requirement for research study publication. Indeed, the Endocrine Society journals have updated their author instructions to require detailed description of hormone assay requirements. Appropriately, these instructions specifically note "…a requirement for traceability of an assay to a certified standard is not yet available for all steroid hormones, but is an important goal" (Wierman et al., 2014). The VDSP has published guidance that allows researchers to meet this goal (Sempos et al., 2017). Such a requirement for 25(OH)D data would allow pooling of results in meta-analyses; failure to implement this requirement will facilitate continuation of chaos regarding the role of vitamin D in health and disease.

Is 25(OH)D measurement enough?

A multitude of vitamin D metabolites exist, some of which may possess physiologic effects. As such, it is appropriate to consider whether the current approach of measuring only 25(OH)D is adequate to define an individual's vitamin D status. Indeed, it is plausible that considering a compilation of all vitamin D metabolites that possess a physiologic effect should be done to define vitamin D deficiency (Jones and Kaufmann, 2016). Such metabolites might include free 25(OH)D, $1,25(OH)_2D_3$, $24,25(OH)_2D_3$, and cholecalciferol, among others (Herrmann et al., 2017; Hollis and Wagner, 2013). Ultimately, low vitamin D status must be defined based on measurement of vitamin D-related metabolites that best predict health outcomes. As of this writing, the importance of these other metabolites, if any, in defining vitamin D status remains to be determined (Scientific Advisory Committee on Nutrition (SACN), 2016; Bouillon, 2017; Holick et al., 2011; Institute on Medicine, 2010). However, the ratio of $24,25(OH)_2D_3$ to 25(OH)D appears to be a promising potential advance as it may be predictive of response to vitamin D supplementation and provide additional insights into vitamin D status (Cashman et al., 2015b; Graeff-Armas et al., 2018; Jones and Schlingmann, 2018; Kaufmann et al., 2014; Molin et al., 2015; Wagner et al., 2011). Further work is clearly needed.

As part of the VDSP effort, the National Institute of Standards and Technology (NIST), with support from the NIH Office of Dietary Supplements, has developed reference methods and materials for standardizing the measurement of 3-epi-25(OH)D_3 and 24,25$(OH)_2D_3$. NIST is also working on a reference method for vitamin D-binding protein, PTH, and 1,25$(OH)_2D_3$. Efforts such as these are essential; it must be emphasized that if and when it becomes established that additional vitamin D metabolite measurements contribute to the definition of hypovitaminosis D, standardization or harmonization of such assays (where tools to do so exist) will be essential to avoid repeating the history of chaos seen with 25(OH)D measurement (Krishnan et al., 2010). Moreover, efforts to develop assays that simultaneously measure multiple vitamin D metabolites should, as a requirement, include steps to standardize measurements of these metabolites (Jones and Kaufmann, 2016).

Clinical and preclinical studies

Animal research and small clinical studies are essential precursors to successful large RCTs. Appropriate animal models are essential in studying vitamin D's role in the pathophysiology of complex human disease. We need to ask: are we using the appropriate animal models? Mouse models are superb for evaluating vitamin D metabolism using targeted knockout mouse models; are they the best and most appropriate surrogates of human physiology? Should additional studies be performed in Old World primates?

Small clinical studies can play a key role in moving toward large RCTs, as they are useful in evaluating potential treatment regimens, including evaluating possible doses and treatment regimens. Finally, has the vitamin D field moved too quickly to large RCTs? In the past, large clinical trials were not begun, generally, unless there was solid evidence from in vivo research, animal studies, and small clinical studies that a large trial was likely to be successful. The rationale was that we should not subject humans to clinical trials unless and until there were good data to support a result consistent with the hypothesis. Not knowing the answer to a question should not be sufficient criteria to expose humans to potential risks associated with large clinical trials without extensive data from in vivo, animal, and small clinical research indicating that the trial is likely to support the hypothesis being tested. It could be argued that the vitamin D field has not adequately followed this logical approach before embarking on large-scale RCTs.

Nonetheless, if vitamin D supplementation has beneficial effects on nonskeletal disease, it is reasonable to expect that RCTs should demonstrate such effects. However, despite multiple RCTs being conducted, with various vitamin D doses, regimens, durations, and end points, clarity regarding nonskeletal effects remains elusive. Why this is the case was noted by Heaney, who emphasized RCT failure to consider the "dose–response relation that vitamin D shares with most nutrients" (Heaney, 2012). To state this slightly differently, nutrients are not drugs. This concept is depicted in Fig. 31.1,

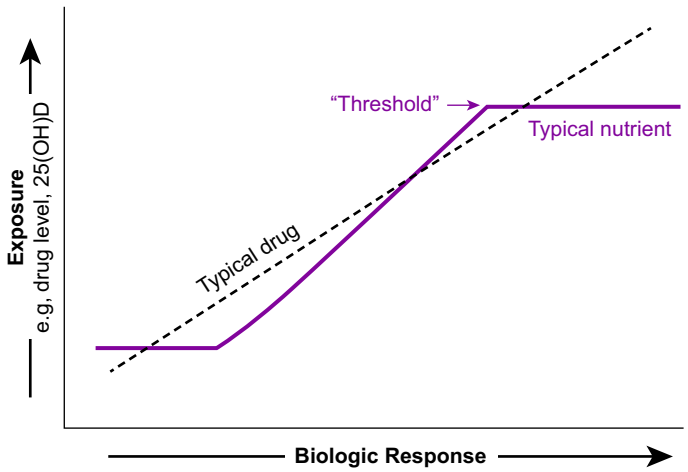

FIGURE 31.1 The sigmoidal relationship of nutrient status ("exposure") to biologic response. Nutrients behave different from drugs; with nutrients a threshold is reached when the individual has an adequate amount of the nutrient. Going above this level does not produce additional beneficial biologic response and could only, potentially, produce toxicity. Failure to consider baseline vitamin D status, specifically, failure to require it to be low as an inclusion criterion for vitamin D supplementation studies, biases such research to a negative conclusion.

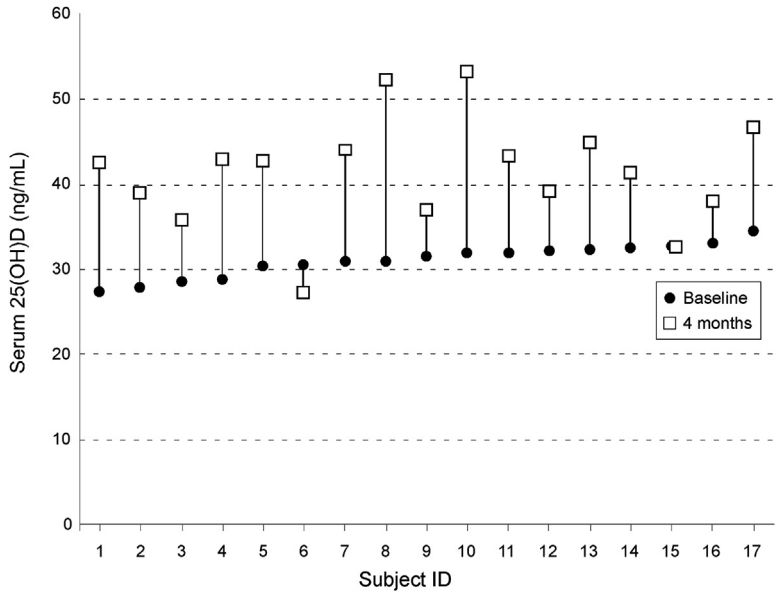

FIGURE 31.2 Variability in 25(OH)D response to a fixed daily supplementation dose. These data demonstrate a substantial variability in the 25(OH)D increase following provision of a fixed supplementation dose. Presented here are 25(OH)D data from postmenopausal women who received 1800 IU of vitamin D_3 daily for 4 months (Binkley et al., 2017a). Among these women, the serum 25(OH)D change ranged from −3.3 ng/mL to +21.4 ng/mL. This variability does not appear to reflect compliance; in this cohort the mean compliance with the daily supplement was 100.3% and ranged from 96% to 105%. Failure to consider such variable response confounds virtually all randomized trials of vitamin D supplementation.

upon review of which it is clear that an adequate dose must be given to individuals who are deficient in the nutrient in question (in this case vitamin D).

Failure to provide a dose that substantially increases 25(OH)D could not be expected to have any beneficial effect. Nonetheless, the vast majority of RCTs simply randomize to a predetermined vitamin D dose without consideration of whether the study subject achieves adequacy. Importantly, between-individual variation in 25(OH)D response to a fixed dose of oral vitamin D supplementation is dramatic (see Fig. 31.2).

Thus, even if a study included only vitamin D-deficient subjects, providing a single dose may not achieve adequacy in all. Perhaps a "treat to target" strategy should be considered in vitamin D supplementation studies (Binkley et al., 2015). Finally, vitamin D supplementation studies have employed various dosing approaches, e.g., daily, weekly, monthly, or less frequently. It has been suggested that daily dosing more closely replicates cutaneous production in circulating cholecalciferol levels (Heaney and Armas, 2015). Indeed, it is plausible that high cholecalciferol concentrations achieved with bolus dosing may induce 24-hydroxylation (Vieth, 2009); a concept supported by work demonstrating that a single vitamin D_3 dose of 150,000 IU led to greater $24,25(OH)_2D$ than daily dosing of 5000 IU for 1 month (Ketha et al., 2018). At a minimum, the possibility that daily and intermittent dosing may have different effects on vitamin D metabolism raises the question of whether these supplementation approaches should be considered equivalent in RCTs.

Of at least equal importance is that nutrients reach a "threshold"; once adequacy is achieved the provision of additional vitamin D could have no beneficial effect and only potentially lead to toxicity (Heaney, 2014). Studies including only those who are deficient in vitamin D could be expected to have a beneficial effect (if one indeed exists), whereas studies of those who are already replete would show no effect. It would seem self-evident that giving "more" vitamin D to a cohort of study subjects who already have "enough" would not inform a potential role of vitamin D in nonskeletal diseases. Nonetheless, the vast majority of vitamin D supplementation RCTs have not required documentation of inadequacy at study baseline. Performing meta-analyses of RCTs conducted without consideration of baseline status or individual response to supplementation should not be expected to clarify whether vitamin D is, or is not, important in nonskeletal disease. Indeed, as Heaney stated, "The question of how much vitamin D is enough is likely to remain muddled as long as meta-analyses focus on trial methodology rather than on biology" (Heaney, 2012). Guidance for the conduct of nutrient supplementation trials have been published and include measurement and use of basal nutrient status as an inclusion criterion, use of a supplementation dose adequate to produce an effect, and documentation of a change in nutrient status (Heaney, 2014). Such guidance must be followed to define what constitutes vitamin D inadequacy.

Conclusion and paths forward

Physiologic rationale combined with in vitro/in vivo preclinical studies and abundant observational data suggest that vitamin D deficiency could contribute to a multitude of human diseases. Unfortunately, despite immense amounts of clinical research and multiple meta-analyses of existing data, we do not know if, or for which nonskeletal diseases, vitamin D deficiency is relevant. This must be resolved. Improvements in clinical trial design and in laboratory measurements to define vitamin D status are needed to clarify what constitutes vitamin D inadequacy and the role, if any, that it plays in nonskeletal disease.
