Macrophage migration inhibitory factor (MIF) was initially identified as an activity in conditioned medium from activated T lymphocytes that inhibited macrophage migration in capillary tube assays (Baugh and Bucala, 2002). Once purified and cloned (Weiser et al., 1989), it became available for functional studies and was shown to have a variety of activities. In addition to T lymphocytes, it is produced by pituitary cells and activated macrophages. MIF is a direct inhibitor of osteoclastogenesis in vitro (Jacquin et al., 2009; Gu et al., 2015) through its ability to activate Lyn tyrosine kinase (Mun et al., 2014) and a variety of RANKL-mediated pathways (Gu et al., 2015). MIF also stimulates the homing of osteoclast precursor cells to sites of osteolysis (Movila et al., 2016).

In vivo, its effects are complex. Mice that overexpress MIF globally have high turnover osteopenia (Onodera et al., 2006), while mice deficient in MIF have low turnover osteopenia with decreased serum indices of bone resorption and bone formation (Jacquin et al., 2009). MIF-deficient mice are also reported to neither lose bone mass nor increase

osteoblast or osteoclast number in bone with ovariectomy (Oshima et al., 2006). Hence, MIF may be another mediator of the effects of estrogen withdrawal on bone. Consistent with this hypothesis, estrogen downregulates MIF expression in activated macrophages (Ashcroft et al., 2003). A similar response may occur in bone or bone marrow and mediate some effects that ovariectomy has on bone mass. It was recently shown that an MIF polymorphism is more frequent in women with osteoporosis (Ozsoy et al., 2018), and there is an inverse correlation between plasma MIF levels and bone mineral density (Kim et al., 2016).

MIF is made by osteoblasts (Onodera et al., 1996), and its production in these cells was upregulated by a variety of growth factors including TGF-β, FGF-2, IGF-II, and fetal calf serum (Onodera et al., 1999). In vitro, MIF increased MMP9 and MMP13 expression in osteoblasts (Onodera et al., 2002) and inhibited RANKL-stimulated osteoclastogenesis by decreasing the fusion of precursors, possibly through its ability to inhibit the migration of these cells (Jacquin et al., 2009).

Deletion of CD74, a putative MIF receptor, in mice produced a phenotype of enhanced osteoclastogenesis and decreased bone mass (Mun et al., 2013).

The interleukin-6 cytokine family

The interleukin-6 (IL-6) family is a large group of cytokines that all use the glycoprotein 130 (gp130) co-receptor, a ubiquitously expressed transmembrane receptor subunit with intracellular signaling capacity. Each family member generates specific intracellular Janus kinase (JAK)/STAT or Erk signaling cascades by forming specific receptor:ligand complexes, each with distinct components (Fig. 50.1). When IL-6 family cytokines form a receptor:ligand complex, gp130 (Haan et al., 1999), oncostatin M receptor (OSMR) (Hermanns, 2015) and/or leukemia inhibitory factor receptor (LIFR) (Stahl et al., 1995) are phosphorylated, providing docking sites for STAT1, STAT3, and STAT5 proteins (Fig. 50.2). Subsequent STAT phosphorylation by JAK allows their homo- or heterodimerization and nuclear translocation to modify transcription. Negative feedback is provided by suppressors of cytokine signaling including suppressor-of-cytokine-signaling (SOCS) proteins SOCS1 and SOCS3, and cytokine-inducible SH2-containing protein (CISH) (Croker et al., 2003; Alexander et al., 1999b; Matsumoto et al., 1997).

IL-6 family cytokines are expressed in all bone cells (Table 50.1); and while early work focused on their levels in the circulation, these cytokines are generally detected at high levels only in pathological states. Studies in knockout mice and human mutations (Table 50.2), outlined below, indicate that IL-6 family cytokines play important paracrine roles to regulate bone formation and resorption during normal bone development, growth, and remodeling.

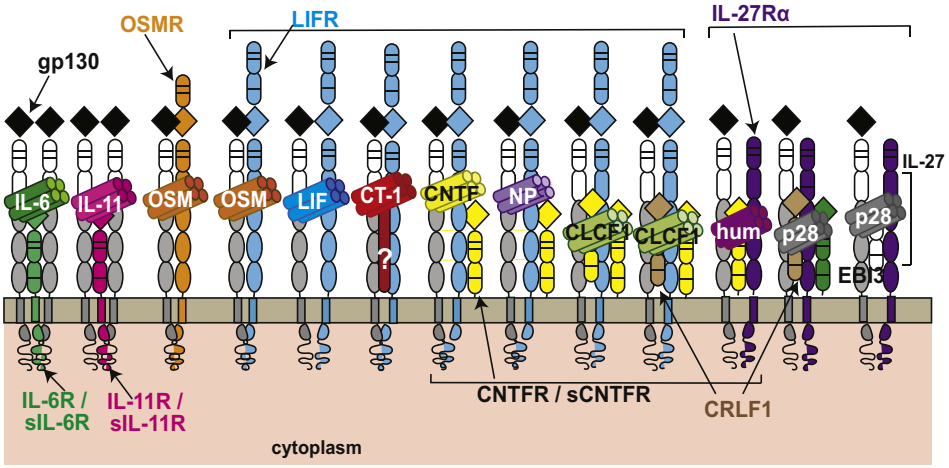

FIGURE 50.1 Cytokine receptor complexes formed by IL-6 family cytokines: Complexes are shown, left to right, in the order in which they are discussed in this chapter. gp130 is shown in gray on the left of each complex. IL-6 and IL-11 bind to ligand-specific β-receptor subunits (IL-6R and IL-11R, or their soluble counterparts, sIL-6R and sIL-11R, respectively) and complex with gp130 homodimers. The Oncostatin M (OSM) receptor (OSMR) is used by OSM, which then recruits gp130 to form a heterodimer. OSM also uses Leukemia inhibitory factor receptor (LIFR). LIFR is also used by LIF in a heterodimer with gp130. Cardiotrophin 1 (CT-1) also signals through LIFR and gp130 as well as, potentially, a CT-1-specific receptor subunit that remains undefined. Ciliary neurotrophic factor (CNTF) and neuropoietin (NP) signal through a complex containing LIFR, gp130 and either the membrane bound or soluble CNTF receptor (CNTFR or sCNTFR). Cardiotrophin-like cytokine factor 1 (CLCF1) acts as a compound cytokine either bound to sCNTFR or cytokine receptor-like factor (CRLF), both of which bind to a gp130:LIFR:CNTFR multimer. Finally, three signaling complexes are shown that contain a heterodimer of gp130 and IL-27Rα: humanin, which requires CNTFR, and p28, which can signal either as a gp130:IL-27Rα complex containing CRLF1 and the IL-6 receptor, or as IL-27, in complex with gp130:IL-27Rα and EBI3. For simplicity, soluble receptors are not pictured.

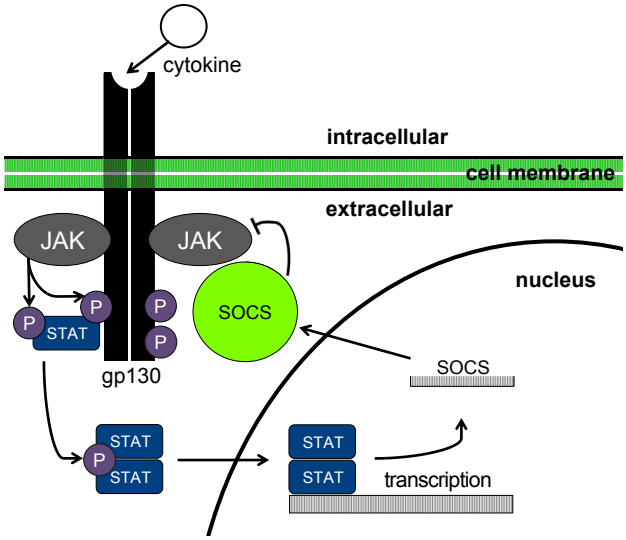

FIGURE 50.2 Basic concept of intracellular signaling by IL-6 family cytokines: Upon formation of a transmembrane signaling complex (as shown in Fig. 50.1), Janus kinases (JAK) phosphorylate the receptor complex, providing docking sites for STAT proteins. Their subsequent phosphorylation, dimerization (either as homo or heterodimers) and translocation to the nucleus initiates transcription of STAT target genes, which includes the transcription of SOCS proteins. SOCS proteins are exported to the cytoplasm where they provide negative feedback to the receptor complex to stop continued phosphorylation and signaling.

We will describe each family member's influences on the mineralized skeleton in turn, beginning with the prototypical ligand, IL-6, and ending with gp130's negative feedback pathways. Although elevated IL-6 family signaling contributes to focal and systemic bone loss in pathologies such as colitis (Mitsuyama et al., 1995), inflammatory arthritis (Kotake et al., 1996; Wong et al., 2006b), multiple myeloma (Kyrtsonis et al., 1996), Gorham−Stout disease (Devlin et al., 1996), breast cancer metastasis to bone (Johnson et al., 2016), and heterotopic ossifications (Torossian et al., 2017), this chapter will focus on their essential physiological functions.

Interleukin-6

A role for interleukin-6 (IL-6) family cytokines in the skeleton was first discovered by the finding that IL-6 robustly stimulates osteoclast formation in culture (Tamura et al., 1993). This did not result from direct action on osteoclasts or their precursors, even though they express transmembrane IL-6 receptor (IL-6R) (Gao et al., 1998). Instead, IL-6 stimulated bone resorption indirectly by promoting the expression of RANKL, the essential osteoclastogenic factor, in osteoblast precursors (Tamura et al., 1993; Palmqvist et al., 2002). This local IL-6 action occurs because it is produced by many cell types in the bone microenvironment, including osteoblasts and osteoclasts (Liang et al., 1999; Ishimi et al., 1990) and other cells such as macrophages, T cells (Briso et al., 2008), and neutrophils (Modur et al., 1997). IL-6 also promotes RANKL expression by pathogenic cells, such as synovial fibroblasts in rheumatoid arthritis (Wong et al., 2006b).

Although IL-6 stimulates osteoclastogenesis, and transgenic mice overexpressing IL-6 exhibit low trabecular bone mass due to elevated osteoclast numbers (De Benedetti et al., 2006), IL-6 knockout mice exhibit no defect in physiological osteoclastogenesis or trabecular bone mass (Table 50.2) (Poli et al., 1994). Instead, IL-6 appears to play a significant role only in pathological conditions in which osteoclast numbers are elevated; IL-6-null mice showed blunted ovariectomy-induced bone loss (Poli et al., 1994) and reduced osteoclast formation in experimental inflammatory arthritis (Wong et al., 2006b).

IL-6 exerts its biological activity via two pathways (Scheller et al., 2014). Classic IL-6 signaling (*cis*) occurs in cells expressing membrane-bound IL-6R. When this pathway is used, IL-6 binds the transmembrane IL-6R and recruits a gp130 homodimer through which it signals (see Fig. 50.1). In contrast, when the alternative *trans*-signaling pathway is used, although IL-6 recruits and signals through a gp130 homodimer, it binds first to soluble IL-6R (sIL-6R); this pathway allows IL-6 to act in cells lacking transmembrane IL-6R and amplifies IL-6 effects in IL-6R-expressing cells. For IL-6 to promote osteoclast formation in culture, sIL-6R must be added (Tamura et al., 1993); therefore, IL-6 promotes osteoclastogenesis only through IL-6 *trans*-signaling.

TABLE 50.1 Expression of IL-6 family cytokines and receptors in the cells of bone and cartilage.

	Osteoclast	Osteoblast	Osteocyte	Chondrocyte

*, neuropoietin is a pseudogene in humans; −, reported as absent at the protein level; +, reported at the protein level; *Implied*, a functional response has been observed, but the receptor has not been detected; *mRNA*, reported at the mRNA level, but not (yet) at the protein level.

TABLE 50.2 Functional characterizations in mice and humans with genetic alterations in IL-6 family receptors and ligands.

	Knockout (murine)	Overexpression/activation (murine)	Human mutation phenotype (only skeletal effects are noted)
Receptors			
gp130	Neonate lethal, low bone mass, many large osteoclasts (Shin et al., 2004; Kawasaki et al., 1997) *Osx1Cre* and *Dmp1Cre* gp130 knockouts: Low trabecular bone mass, increased periosteal diameter, low bone formation, normal osteoclasts (Johnson et al., 2014a). *CtskCre* gp130 knockout: Low bone formation, reduced periosteal diameter (Johnson et al., 2015).	Gp130-STAT3 hyperactivation: Low bone mass, excessive osteoclasts (rescued by IL-6 deletion or STAT3 suppression) (Sims et al., 2004; Walker et al., 2016). gp130-STAT3 deletion: Dwarfism (Sims et al., 2004); *Dmp1CreSocs3* deletion (gp130 hyperactivation): Sex-specific delayed corticalisation (Cho et al., 2017).	Missense mutation with loss of IL-6, IL-11, IL-27, and OSM signaling but intact LIF response: Craniosynostosis, dental abnormalities, progressive scoliosis (Schwerd et al., 2017);
IL-6R	–	–	–
IL-11R	High trabecular bone mass, low bone formation, low resorption (Sims et al., 2005), disturbed cranial growth (Nieminen et al., 2011)	–	Loss of function: Craniosynostosis, dental abnormalities (Nieminen et al., 2011; Keupp et al., 2013)
LIFR	Neonate lethal, low bone mass, many large osteoclasts (Ware et al., 1995)	–	Loss of function: Stüve–Wiedemann syndrome, variable phenotype with bowing of long bones, cortical thickening, flared metaphyses with coarse trabeculae, camptodactyly (Dagoneau et al., 2004; Jung et al., 2010)
OSMR	High trabecular bone mass, low bone formation, low resorption (Walker et al., 2010)	–	Loss of function: No bone defect noted, cutaneous amyloidosis (Arita et al., 2008).
CNTFR	– (Neonate lethal) (DeChiara et al., 1995)	–	–
CRLF1	– (Neonate lethal) (Alexander et al., 1999a)	–	Loss of function: Crisponi/cold-induced sweating syndrome 1, kyphoscoliosis, palatal and frontonasal malformations (Hahn et al., 2006; Piras et al., 2014)
Ligands			
IL-6	Normal trabecular bone mass, reduced periosteal growth (Sims et al., 2005; Johnson et al., 2015; Poli et al., 1994)	Transgenic: Osteopenia, few osteoblasts, many osteoclasts, growth retardation (De Benedetti et al., 2006)	Variants linked with osteoporosis and osteopenia (Ota et al., 1999, 2001).
IL-11	–	Transgenic: Increased bone formation and cortical thickness (Takeuchi et al., 2002)	–
LIF	Dwarfism, region-specific effects on osteoclasts and osteoblasts (Poulton et al., 2012)	Engraftment: High bone mass (Metcalf and Gearing, 1989)	–
OSM	–	Transgenic: High bone mass (Juan et al., 2009)	–
CT-1	High trabecular bone mass, poorly-resorbing osteoclasts, low bone formation (Walker et al., 2008)	–	–
CNTF	High trabecular bone mass, high bone formation in females, low cortical width in males (McGregor et al., 2010)	–	Loss of function in 2.3% of Japanese population; no data on skeletal effect (Takahashi et al., 1994).
CLCF1	– (Neonatal lethal) (Zou et al., 2009)	–	Cold-induced sweating syndrome 2; palatal and frontonasal malformations, kyphoscoliosis (Hahn et al., 2006; Piras et al., 2014).

"–" indicates unknown phenotype or absence of an appropriate model. IL-27R, Sortilin, humanin, IL-27, and neuropoietin are not included due to lack of information on skeletal phenotypes associated with mutations in those genes.

The requirement of IL-6 *trans*-signaling for osteoclastogenesis and elevated circulating sIL-6R levels in pathological bone loss such as rheumatoid arthritis (Kotake et al., 1996) in ovariectomized women (Girasole et al., 1999) and colitis (Mitsuyama et al., 1995) provide a strong case that IL-6 stimulates pathological osteoclastogenesis through *trans*-signaling. Earlier studies assessing IL-6 in estrogen deficiency bone loss used an antibody directed to full-length IL-6 ligand, likely blocking both *cis*- and *trans*-signaling. This led to some conflicting results, with some authors reporting that IL-6 neutralizing antibody treatment blunted the high osteoclast numbers associated with ovariectomy (Jilka et al., 1992) and others showing no effect (Kitazawa et al., 1994). We recently reported, by using *trans*-signaling-specific antibodies, that IL-6 has compartment-specific actions in ovariectomy-induced bone loss. The trabecular bone loss and increased trabecular osteoclast numbers associated with ovariectomy require IL-6 *trans*-signaling (Lazzaro et al., 2018). In contrast, the cortical bone loss associated with ovariectomy was not IL-6-dependent (Lazzaro et al., 2018). This may explain the earlier controversy over antibody-based studies because they did not distinguish between cortical and trabecular bone loss or osteoclastogenesis.

Although IL-6 is best known for stimulating osteoclastogenesis, there is some evidence that IL-6 might also stimulate bone formation, at least in cortical appositional growth. Early in vitro studies showed IL-6 can act directly on osteoblasts. Cultured osteoblast-like UAMS-32 and MG-63 cells expressed IL-6R (Bellido et al., 1996) and responded to IL-6 with STAT dimerization and increased alkaline phosphatase activity (Bellido et al., 1997). This was observed without adding the soluble receptor but was amplified when sIL-6R was provided, indicating that early-stage osteoblasts respond to both *cis*- and *trans*-signaling. Since osteoblasts mount a STAT3 phosphorylation response to IL-6 without requiring sIL-6R addition, it is not clear why they do not support osteoclastogenesis in culture without it; perhaps a higher STAT3 phosphorylation level is required for RANKL production to occur. IL-6 has recently been reported also to stimulate bone formation in vivo through *trans*-signaling (McGregor et al., 2019). The impaired periosteal bone formation (Sims et al., 2005; Johnson et al., 2015) and thin cortices (Poli et al., 1994; Johnson et al., 2015) in IL-6-null mice suggest that IL-6 is required for bone formation on the periosteum.

The impairment in periosteal bone formation and radial growth in IL-6-null mice was also observed in mice lacking gp130 in osteoclasts (*Ctsk.gp130$^{f/f}$* mice) (Johnson et al., 2015). Since the periosteal site at which bone formation was measured in both models lacks osteoclasts, we suggested that osteoclasts on the endocortical surface may respond to IL-6 by releasing signals that are transmitted through the cortical bone to periosteal osteoblasts, either by passing through the lacuno-canalicular network or by acting on osteocytes within the cortical bone. To distinguish this activity from trabecular "coupling factors," the term "osteotransmitter" was coined to emphasize that these factors, released from osteoclasts in response to IL-6, are unlikely to signal directly from the osteoclast to the distant osteoblast on the periosteal surface. Instead, the message is transmitted through other cells (e.g., the cortical osteocyte network) to influence osteoblasts at the appropriate location.

In humans, variants in the IL-6 gene are linked with osteoporosis and osteopenia (Ota et al., 1999, 2001); whether this is due to increased inflammation and elevated osteoclast formation, differences in bone resorption or impaired cortical growth is not known. Treatment with the IL-6 inhibitory antibody tocilizumab in arthritic patients reduces inflammation and leads to reduced biochemical markers of resorption but also elevated bone formation markers (Karsdal et al., 2012; Terpos et al., 2011). Such opposing influences of IL-6 inhibition on bone formation and resorption are consistent with earlier evidence for an IL-6-dependent pathway that couples trabecular bone formation to increased resorption caused by elevated STAT3 signaling (Sims et al., 2004).

Evidence has been accumulating that IL-6 is produced and regulated in osteocytes. The proportion of osteocytes staining for IL-6 by immunohistochemistry was dramatically elevated in models of stress fracture (Wu et al., 2014) and inflammatory bowel disease (Metzger et al., 2017), and IL-6 mRNA levels were elevated when an osteocyte-like cell line was subjected to fluid flow (an in vitro model for mechanical loading) (Bakker et al., 2014). Our recent evidence that the sex-specific differences in cortical bone development requires osteocyte-specific negative feedback and testosterone action through IL-6 in male mice (Cho et al., 2017) implies that local IL-6 regulation in osteocytes may drive the formation of strong, mature cortical bone (see later). Whether IL-6 produced by osteocytes stimulates bone formation or resorption, and whether this is mediated by *cis*- or *trans*-signaling, remains to be established. Our very recent work indicates that osteocytes are responding both to IL-6 *cis*- and *trans*-signaling with STAT3 phosphorylation, and although they produce elevated RANKL in response to *trans*-signaling, this is insufficient to fully support osteoclast formation (McGregor et al, 2019).

Interleukin-11

Like IL-6, interleukin-11 (IL-11) signals by binding to a ligand-specific receptor (in this case, IL-11 receptor [IL-11R]) and then to a gp130 homodimer (Fig. 50.1). Like IL-6, IL-11 also stimulates osteoclastogenesis in coculture (Tamura et al.,

1993) by stimulating RANKL production in osteoblast lineage cells (Horwood et al., 1998a). Although IL-11 can use a soluble receptor (sIL-11R) for *trans*-signaling (Lokau et al., 2016), soluble receptor addition is not required for IL-11 to stimulate osteoclastogenesis (Tamura et al., 1993).

IL-11 stimulates osteoblast differentiation (Sims et al., 2005; Suga et al., 2001) in vitro. It has been suggested that this, rather than its proosteoclastogenic action, is IL-11's dominant effect because mice overexpressing IL-11 exhibit elevated bone formation and cortical thickening but no change in osteoclastogenesis (Takeuchi et al., 2002). There are at least two mechanisms by which this occurs. Osteoblasts are derived from pluripotent progenitors capable also of adipocytic differentiation (Sabatakos et al., 2000), and IL-11 promotes their commitment toward the osteoblast lineage while suppressing adipogenesis (Sims et al., 2005). A second mechanism is that IL-11 suppresses the expression of sclerostin (Walker et al., 2010), an osteocyte-derived inhibitor of bone formation.

Mice null for the IL-11R exhibit features consistent with all three reported effects of IL-11: reduced osteoclastogenesis, impaired bone formation, and increased marrow adiposity (Sims et al., 2005). This indicates IL-11 signaling is essential for these processes, at least in the adult skeleton. IL-11R-null mice, like IL-6-null mice, also exhibit impaired periosteal bone formation, indicating that the effect on osteoblast differentiation is not restricted to the trabecular bone environment (Sims et al., 2005; Sims and Vrahnas, 2014).

IL-11 may also promote bone formation in response to mechanical loading. Early evidence was that IL-11 suppressed expression of the mechanically sensitive osteocyte gene sclerostin (Walker et al., 2010), and IL-11R-null and transgenic mice demonstrated opposing cortical phenotypes (Sims et al., 2005; Takeuchi et al., 2002). IL-11 mRNA levels are elevated in bone after loading (Mantila Roosa et al., 2011), and ΔFosB, an AP-1 family member that promotes osteoblast differentiation (Sabatakos et al., 2000; Sims et al., 2002) and is rapidly upregulated with mechanical load (Kido et al., 2009), promotes IL-11 transcription in osteoblasts (Kido et al., 2009, 2010). Similar mechanisms might promote IL-11 expression in osteocytes during mechanical loading.

After these studies in cell culture and genetically modified mice, IL-11R's importance in human skeletal biology was confirmed when inactivating mutations in the human IL-11R gene were identified (Nieminen et al., 2011; Keupp et al., 2013) (Table 50.2). Individuals lacking IL-11R signaling exhibited multiple symptoms including premature cranial bone fusion (craniosynostosis), dental abnormalities, and digit malformations (Nieminen et al., 2011). The craniosynostosis was mimicked in IL-11R-null mice, and IL-11R expression was shown to be lowest in mature calvarial suture regions (Nieminen et al., 2011). This suggests IL-11 may suppress calvarial suture fusion in addition to its functions listed previously.

Oncostatin M

Oncostatin M (OSM) is a pleiotropic cytokine first identified as a secreted macrophage product (Zarling et al., 1986). Within the skeletal microenvironment, besides macrophages, it is also expressed at all stages in the osteoblast lineage (Table 50.1), including bone-lining cells, matrix-producing osteoblasts, osteocytes in murine bone (Walker et al., 2010), and bone marrow stromal cells (MSCs) and osteoblasts in human bone (Lisignoli et al., 2000); their gp130 and OSMR expression is strongly stimulated by PTH and PTH-related protein (PTHrP) (Walker et al., 2012). Osteoblast lineage cells express all three receptor subunits that can be utilized by OSM (gp130, OSMR, and LIFR) (Walker et al., 2010), but osteoclasts do not (Walker et al., 2010); and in whole bones subjected to mechanical loading, OSM and OSMR are significantly upregulated (Mantila Roosa et al., 2011).

Like IL-11 and IL-6, OSM promotes osteoclast differentiation in vitro (Tamura et al., 1993). Again, this occurs indirectly; OSM promotes RANKL transcription by stromal cells (Palmqvist et al., 2002). OSM also promotes osteoblast differentiation in vitro (Bellido et al., 1997; Walker et al., 2010; Song et al., 2007) and stimulates bone formation when provided in vivo either by injecting recombinant peptide (Walker et al., 2010) or by transgenic overexpression (Juan et al., 2009). OSM's actions to promote bone formation are mediated by promoting stromal cell commitment to osteoblast differentiation rather than adipogenesis (Walker et al., 2010; Gimble et al., 1994; Song et al., 2007), and by suppressing osteocytic expression of the Wnt antagonist sclerostin (Walker et al., 2010; Johnson et al., 2014a). Although OSM stimulates osteoblast commitment in early precursors, OSM promotes bone formation in vivo through osteocytes, as indicated when mice lacking gp130 in osteocytes failed to increase bone formation in response to OSM (Johnson et al., 2014a).

OSM is unusual in the IL-6 family because it can act through two distinct heterodimeric receptor complexes (Fig. 50.1). OSM binds first to gp130, which then heterodimerizes with OSMR or LIFR. OSM has different actions in bone through these receptors; this was uncovered by studying mice lacking OSMR (Walker et al., 2010).

Mice with global OSMR deletion demonstrated low osteoclast numbers, low osteoblast numbers, impaired bone formation on trabecular surfaces, and increased marrow adiposity (Walker et al., 2010), consistent with all effects of

OSM noted previously. In culture, osteoclast differentiation was supported poorly by osteoblasts lacking OSMR, whether OSM or 1,25-dihydroxyvitamin-D_3 was used as the stimulus, and OSM did not stimulate RANKL expression by these cells (Walker et al., 2010). When mice lacking OSMR were treated with OSM, we were surprised to find that bone formation was increased, and that OSM suppressed sclerostin expression in cultured OSMR-null osteocytes to the same level as wild-type osteocytes (Walker et al., 2010). This indicated the presence of an OSMR-independent pathway by which OSM promotes bone formation. Use of an LIFR-antagonist revealed that OSM suppressed sclerostin through the LIFR (Walker et al., 2010). We concluded that OSM stimulated RANKL and osteoclastogenesis through an OSMR:gp130 heterodimer but suppressed sclerostin and stimulated bone formation through an LIFR:gp130 heterodimer. This was surprising because although human OSM recruits OSMR and LIFR with equal affinity (Mosley et al., 1996), murine OSM binds LIFR with only very low affinity and was presumed to act in mice entirely through OSMR (Ichihara et al., 1997).

Initially, sclerostin was the only factor we could find that was regulated through the LIFR:gp130 heterodimer by OSM. A microarray study was used to define the other targets of this interaction that might promote bone formation. This revealed that murine OSM acts through LIFR to stimulate a STAT3-responsive gene signature with little effect on STAT1-responsive genes (Walker et al., 2016). Western blotting analysis revealed that murine OSM induces STAT3, but not STAT1, phosphorylation in OSMR-null cells through LIFR (Walker et al., 2016), suggesting that intracellular action favoring STAT3 over STAT1 signaling may be anabolic for bone. To test this, STAT1-null mice were crossed with an osteopenic mouse model caused by gp130-STAT1/3 hyperactivation ($gp130^{Y757F/Y757F}$, see later). Prevention of that osteopenia by reducing STAT1 availability (Walker et al., 2016) suggests that such an approach could be exploited in skeletal pathologies where gp130 signaling is elevated, such as inflammatory or metastatic bone loss.

In contrast to OSM, LIF action through LIFR (see later section) results in STAT1 and STAT3 phosphorylation in osteoblasts (Walker et al., 2016), stimulates RANKL (Palmqvist et al., 2002), and suppresses sclerostin (Walker et al., 2010). How can murine OSM act through gp130:LIFR to regulate only some gene targets of murine LIF when it binds to the same receptor complex? Such a question is common to all receptors with multiple ligands producing different biological effects within a single cell type. In the case of OSM, our data suggest that impaired gp130 and LIFR phosphorylation may be responsible for the bias toward STAT3 signaling (Walker et al., 2016), but how this is controlled remains unknown. It may relate to altered binding conformation, affinity, or stability that could be better understood by structural studies.

Macrophages support bone formation, and this has been reported to require their OSM production by three groups independently (Fernandes et al., 2013; Nicolaidou et al., 2012; Guihard et al., 2012). The studies differ in their conclusions as to whether OSM production by macrophages requires M1 activation (Guihard et al., 2012), contact with MSCs (Nicolaidou et al., 2012), or M2 polarization (Fernandes et al., 2013). Nevertheless, they provide a mechanism by which resident tissue macrophages may stimulate bone formation both in normal physiology (Chang et al., 2008) and in fracture healing (Alexander et al., 2010).

One recent finding has provided information on a pathological situation that may depend on OSM emanating from resident tissue macrophages. Formation of heterotopic ossifications in muscle resulting from trauma, such as spinal cord injury, has been shown to depend on macrophages (Genet et al., 2015). These ossifications are reduced in OSMR-null mice, suggesting OSMR targeting could provide therapeutic benefit for patients affected by this condition (Torossian et al., 2017). Genetically driven heterotopic ossifications also depend on macrophage activation (Convente et al., 2018) and may also depend on OSMR (Levesque et al., 2018).

Other leukemia inhibitory factor receptor–binding cytokines

Despite its name, the LIF receptor is used by multiple cytokines for intracellular signaling (Fig. 50.1). Leukemia inhibitory factor (LIF) itself, OSM (as described above) and cardiotrophin-1 (CT-1) each signal through a gp130:LIFR heterodimer (Fig. 50.1). In addition, some cytokines utilize a complex containing gp130:LIFR and the ciliary neurotrophic factor (CNTF) receptor (CNTFR). Consistent with LIFR's pleiotropic role, LIF and LIFR knockout mice are not identical. Most strikingly, the LIFR KO exhibits early neonatal lethality (Ware et al., 1995), while LIF knockout mice survive to early adulthood (Poulton et al., 2012).

Osteoblast lineage cells have been shown to express LIF receptor by autoradiography in cultured rat preosteoblasts (Rodan et al., 1990), murine osteoblasts (Allan et al., 1990), and labeled LIF administration in vivo (Hilton et al., 1991). In contrast, osteoclasts did not bind LIF (Allan et al., 1990). LIFR expression in osteoblasts and osteocytes has been confirmed by immunohistochemistry (Walker et al., 2010). Active LIFR signaling in cultured osteoblasts was indicated by LIFR phosphorylation in response to LIF treatment (Lowe et al., 1995; Bellido et al., 1996).

LIFR-null mice are neonatal lethal, indicating that LIFR-binding cytokines are required for early life (Ware et al., 1995). These mice had many enlarged osteoclasts at their growth plates, suggesting LIFR-binding cytokines are essential inhibitors of osteoclast formation (Ware et al., 1995). This finding is opposite to that expected, given that LIFR-binding cytokines stimulate osteoclastogenesis in vitro (Tamura et al., 1993; Richards et al., 2000). This will be discussed in more detail in Leukemia inhibitory factor and Cardiotrophin 1. LIFR-binding cytokines also modify the adult skeleton since systemic treatment with an LIFR antagonist inhibited osteoblast and osteoclast formation and increased bone mass in adult mice (Menkhorst et al., 2011).

In humans, mutations in LIFR are associated with Stüve–Wiedemann syndrome (STWS). This is a rare but severe autosomal recessive condition, often lethal during infancy due to respiratory distress and sporadic hyperthermia (Dagoneau et al., 2004). Patients exhibit dwarfism, bowing of the lower limbs, wide metaphyses, and in contrast to LIFR-null mice, high trabecular bone mass (Cormier-Daire et al., 1998; Jung et al., 2010). Although LIFR is used by many cytokines, the STWS phenotype has many similarities with the LIF-null mice (Poulton et al., 2012), consistent with defective LIF binding reported in fibroblasts from one patient with the disorder (Dagoneau et al., 2004). The mutations leading to this syndrome are diverse, and symptom severity may relate to the LIFR region affected and to which LIFR-binding cytokines have reduced affinity for the receptor. This will be discussed in more detail below.

Leukemia inhibitory factor

LIF is produced in bone by osteoblast precursors, osteoblasts (Shiina-Ishimi et al., 1986; Allan et al., 1990), hypertrophic and prehypertrophic chondrocytes, and mesenchymal cells in the invading vascular sprout during endochondral ossification (Grimaud et al., 2002). Factors that stimulate osteoblast differentiation and osteoclast formation, such as IL-1, TNFα, LPS, TGF-β, PTH, PTHrP, and retinoic acid increase LIF mRNA and protein levels in osteoblast cultures (Allan et al., 1990; Ishimi et al., 1992). In contrast, LIFR mRNA levels are inhibited by PTH treatment in osteoblasts (Walker et al., 2012). Other cells in close proximity to bone secrete LIF, such as exercised myocytes (Broholm and Pedersen, 2010), synovial fibroblasts (Le Goff et al., 2014), and breast cancer cells in the bone microenvironment (Johnson et al., 2016). Neither LIF activity nor expression has been detected in osteoclasts (Allan et al., 1990).

Like IL-6, IL-11, and OSM (Interleukin-6, Interleukin-11, and Oncostatin M sections previously), LIF is a potent stimulus of RANKL in osteoblast lineage cells (Walker et al., 2010). Despite this, and although LIF consistently increased bone resorption in organ culture (Ishimi et al., 1992), LIF concentrations must be 1000-fold greater than other osteoclastogenic factors to stimulate osteoclast formation in coculture with osteoblasts, and even then only a very mild effect is achieved (Tamura et al., 1993).

Like IL-11 and OSM, LIF stimulates bone formation in vivo, either when recombinant LIF is injected (Cornish et al., 1993) or when overexpressing cells are transplanted (Metcalf and Gearing, 1989). LIF effects on osteoblast differentiation in vitro vary between culture models used (Noda et al., 1990; Hakeda et al., 1991; Malaval et al., 1995) (for detailed discussion, see Sims and Johnson, 2012). The mechanisms by which LIF stimulates bone formation reflect many actions noted previously for IL-11 and OSM (Interleukin-11 and Oncostatin M sections). LIF alters stromal cell lineage commitment toward osteoblastogenesis rather than adipogenesis by downregulating peroxisome proliferator-activated receptor gamma (PPARγ) (Poulton et al., 2012), consistent with early effects showing that LIF inhibits adipocyte differentiation when administered early in adipocyte differentiation (Gimble et al., 1994) (for detailed discussion, see Sims and Johnson, 2012). And like IL-11 and OSM, LIF also inhibits sclerostin expression (Walker et al., 2010).

Since LIF promotes osteoclast formation and bone formation in organ culture or in vivo while having mild effects on cultured cells, LIF's osteoclastogenic action may require additional factors and cell types present in vivo but not in vitro. In line with such a hypothesis, the LIF-null mouse showed region-specific phenotypes.

The most obvious change in LIF-null mice was a 20% reduction in bone length that occurred after the immediate postnatal period (Poulton et al., 2012). Since no other gp130 ligand or ligand-specific receptor knockout displayed such a growth defect (McGregor et al., 2010; Walker et al., 2008; Poli et al., 1994; Sims et al., 2005), this suggests LIF is the main gp130-signaling cytokine regulating longitudinal bone growth. The impairment in growth was related to activities at the chondro-osseous junction, not to any change in chondrocyte proliferation.

In normal skeletal development, endochondral ossification begins when chondrocytes in the central region undergo hypertrophy due to hypoxia, followed by vascular invasion and formation of chondroclasts (osteoclasts resorbing cartilage). In LIF-null mice, chondrocyte differentiation, vascular invasion and chondroclast-mediated destruction of the cartilage anlagen followed normal chronology. However, early work noted enlarged, hyperactive osteoclasts at the chondro-osseous junction in LIF, LIFR, and gp130 neonates (Bozec et al., 2008; Ware et al., 1995; Shin et al., 2004). These enlarged osteoclasts were also observed in adult LIF-null mice but only at the chondro-osseous junction (i.e. in

chondro-clasts) and not in remodeling bone (Poulton et al., 2012). This region-specific defect in osteoclast/chondroclast formation was associated with increased VEGFA expression by hypertrophic chondrocytes and enhanced vascularization specific to the chondro-osseous junction (Poulton et al., 2012). The increased vascularization may provide more precursors, thereby allowing larger chondroclasts to form. The enlarged chondroclasts in LIF-null mice might also result from a difference in the cartilage matrix produced by LIF-deficient chondrocytes. The importance of this local influence was indicated by normal osteoclast morphology when LIF-null osteoclasts were formed in vitro. While chondroclast morphology and number depend on LIF, osteoclasts generated on LIF-null trabecular bone surfaces were normal, indicating that osteoclast formation (on bone) is not LIF-dependent.

In LIF-null mice, immediately below the growth plate, newly formed clumps of woven bone formed despite resorption of the calcified cartilage template by the enlarged chondroclasts (Poulton et al., 2012). This was again region-specific because it was not observed in the secondary spongiosa. Increased vessel formation at the transition zone from the growth plate to trabecular bone may also be the stimulus for increased bone formation and bone mass in this region. The sudden end to the growth plate in LIF-null mice and areas of woven bone immediately below it are strikingly similar to STWS histology (Cormier-Daire et al., 1998). The reduced bone length and low trabecular bone mass in remodeling bone are consistent with the growth retardation and osteoporosis in STWS patients that survive beyond 1 year (Jung et al., 2010). This indicates that although there are many cytokines that act through the LIFR, it is most likely that the main defect leading to the STWS skeletal phenotype is defective LIF binding to the LIFR (Dagoneau et al., 2004).

A third region-specific phenotype was observed in LIF-null mice. In the bone remodeling trabeculae in adult mice, blood vessel morphology was normal but trabecular bone mass was low due to suppressed bone formation (Poulton et al., 2012). These mice also exhibited high marrow adiposity (Poulton et al., 2012) consistent with the LIF actions on sclerostin expression and osteoblast and adipocyte differentiation noted in vitro.

Cardiotrophin 1

CT-1 signals through a gp130:LIFR heterodimer in a complex that may include a CT-1-specific receptor (Pennica et al., 1995). Like IL-11, OSM, and LIF, CT-1 acts in vitro to stimulate osteoclast formation in coculture by inducing RANKL in osteoblast lineage cells (Richards et al., 2000). CT-1 also stimulates bone formation in vivo and promotes osteoblast differentiation rather than adipogenesis in vitro (Walker et al., 2008). Like IL-11R and OSMR-null mice, CT-1-null mice exhibit low bone formation and bone resorption in adulthood with elevated marrow adiposity (Walker et al., 2008). The mechanisms by which CT-1 stimulates bone formation appears to relate to three key activities that are again shared by other family members: (1) promoting osteoblast commitment by stimulating C/EBPδ and C/EBPβ transcription (Walker et al., 2008), (2) suppressing adipocyte differentiation by reducing *Zfp467* transcription (Quach et al., 2011), and (3) stimulating Wnt signaling by suppressing sclerostin production in osteocytes (Walker et al., 2010). Even though IL-11, OSM, LIF and CT-1 share all these actions, it is striking that the IL-11R-, OSMR-, LIF-, and CT-1-null phenotypes are all significant, revealing critical roles for each cytokine and their inability to compensate for one another.

CT-1 has two unique functions. The first is its role as a coupling factor. CT-1 expression has not been found in the osteoblast lineage, but it is expressed specifically by osteoclasts in the bone microenvironment (Walker et al., 2008). This suggests it acts as an osteoclast-derived "coupling factor" that stimulates bone formation to follow bone resorption during remodeling (Walker et al., 2008).

CT-1's other unique function was revealed by the enlarged osteoclasts throughout the skeleton of CT-1-null mice (Walker et al., 2008). This was intrinsic to the hematopoietic lineage because CT-1-null osteoclasts were also enlarged when formed in vitro from CT-1-null osteoclast precursors (Walker et al., 2008). CT-1-null osteoclasts also had defective resorption activity and resorbed cartilage with greater than usual efficiency but had poor resorptive action on bone. Consequently, the mice exhibited a mild osteopetrosis with substantial cartilage remnants within the bone matrix in adult mice (Walker et al., 2008). It is not known whether CT-1-deficient osteoclasts are large due to their defective function on bone as observed in other mice with defects in osteoclast attachment or function (Gil-Henn et al., 2007; Neutzsky-Wulff et al., 2010). The mechanisms by which CT-1 controls osteoclast formation, morphology and activity remain unresolved.

Cytokines that complex with ciliary neurotrophic factor receptor

Some LIFR-binding cytokines also complex with the CNTFR (Fig. 50.1). These include CNTF itself, which acts through a gp130:LIFR:CNTFR heteromer, and some less clearly described cytokines: neuropoietin (sometimes known by its gene name *Ctf2/CTF2*) and cardiotrophin-like cytokine factor 1 (CLCF1). The latter has also been known as cardiotrophin-like cytokine and was earlier known as new neurotrophin-1 or B-cell stimulatory factor-3. CLCF1 acts as two possible

"compound cytokines": either bound to the soluble ciliary neurotrophic factor receptor (sCNTFR) or to cytokine receptor-like factor 1 (CRLF1). CRLF1 is also known as cytokine like factor 1 and NR6. These compound cytokines will be referred to as CLCF1/CRLF1 and CLCF1/sCNTFR.

CLCF1, neuropoietin (NP), and CNTF contain a highly conserved tryptophan hot spot that enables them all to bind at the same location on CNTFR (Rousseau et al., 2008). The resulting complex then recruits gp130 and LIFR (Elson et al., 2000; Derouet et al., 2004; Rousseau et al., 2008). Since CNTFR exists as either a membrane-anchored form or a soluble form (sCNTFR) (Davis et al., 1993), these cytokines can also influence cells that do not express the membrane-bound receptor through *trans*-signaling if sCNTFR is made available to them. NP and CLCF1 signaling are reportedly enhanced by sortilin, which binds directly to LIFR and promotes gp130:LIFR heterodimer assembly (Larsen et al., 2010).

CNTFR-binding cytokines differ markedly in their actions to all IL-6 cytokines listed above and have been less intensely studied in the skeleton. Each will now be discussed in turn.

Ciliary neurotrophic factor

CNTF, unlike all the previously described cytokines, does not stimulate osteoclast formation in culture (McGregor et al., 2010), does not suppress sclerostin expression or promote osteoblast mineralization (McGregor et al., 2010), and does not suppress adipogenesis (McGregor et al., 2010; White et al., 2008).

CNTF was detected by immunohistochemistry in osteoclasts, osteoblasts, and osteocytes (McGregor et al., 2010). CNTF is also expressed at very high levels in skeletal muscle, where its mRNA levels were >10-fold higher than all other IL-6 family cytokines (Johnson et al., 2014b). This suggested CNTF is a bone-active myokine, a factor released by muscle either locally or into the circulation. Other IL-6 family members known to modify bone structure have also been postulated to be circulating myokines, including IL-6 and LIF (Whitham et al., 2012; Broholm et al., 2011; Hamrick, 2011). When recombinant CNTF was applied to cultured osteoblasts without adding soluble receptor, it mildly inhibited osteoblast differentiation, reducing their ability to form mineralized nodules, and transiently suppressed osteoblast transcription factor, osterix (McGregor et al., 2010). Adding the soluble receptor amplified this effect but did not modify RANKL expression (Johnson et al., 2014b).

Global CNTF deletion resulted in mice with a mild reduction in bone length (McGregor et al., 2010), indicating a minor role in bone growth. Apart from this, the CNTF-null phenotype was sex-specific—female CNTF-null mice had high trabecular bone volume caused by increased bone formation rate compared with controls, while male CNTF nulls had normal trabecular bone mass but impaired periosteal growth. This suggests that CNTF plays different roles in trabecular and periosteal bone formation. This sex and region specificity may result from a difference in muscle development, which is also sex-specific (Park et al., 1999), and CNTF's myokine action (Johnson et al., 2014b).

Both sex-specific bone CNTF-null phenotypes (high trabecular number in females and slim cortical bone in males) were recapitulated by bone marrow transfer from CNTF-null mice to wild-type recipients (Askmyr et al., 2015). The trabecular phenotype is difficult to interpret due to a 10-fold reduction in trabecular bone mass caused by marrow transfer alone. However, the change in periosteal perimeter induced by marrow transplantation suggests CNTF may influence cortical mass from within the internal bone marrow compartment. This is similar to IL-6's action as an osteotransmitter (Johnson et al., 2015) (see IL-6 section, previous) and suggests that CNTF may also have an osteotransmitter function.

Cardiotrophin-like cytokine factor 1 and cytokine receptor-like factor 1

Although CLCF1 contains a signal sequence (Senaldi et al., 1999), its secretion is inefficient unless coexpressed with its chaperone CRLF1 (Elson et al., 2000; Alexander et al., 1999a). Forced CLCF/sCNTFR coexpression allows sCNTFR to act as a substitute chaperone (Plun-Favreau et al., 2001), but whether this compound cytokine exists physiologically is not known. CLCF1 therefore acts as two possible "compound cytokines": CLCF1/CRLF1 and CLCF1/sCNTFR. Their actions in multiple organs are discussed in a recent review (Sims, 2015).

CRLF1 and CLCF1 human gene mutations both lead to syndromes that include "cold-induced sweating" (CISS—profuse sweating after exposure to cold), suckling problems during infancy and feeding difficulties in adult life, as well as skeletal abnormalities including spinal kyphoscoliosis, and palatal and frontonasal malformations (Knappskog et al., 2003; Rousseau et al., 2006). Since human mutations in CNTF are common, but are not associated with any notable health problems (Takahashi et al., 1994), and neuropoietin is a pseudogene in humans (Derouet et al., 2004), CLCF1 and CRLF1 are the most biologically important ligands for CNTFR in human development. Similarly in mice,

CLCF1 (Zou et al., 2009), CRLF1 (Alexander et al., 1999a) and CNTFR-null (DeChiara et al., 1995) mice all die in the perinatal period due to a suckling defect.

Skeletal symptoms of human *CRLF1* and *CLCF1* mutations are less severe than those observed with *LIFR* mutations, which is not surprising given that many other cytokines use LIFR. The mechanisms by which CLCF1 composite cytokines support skeletal functions have not been examined in either humans or mice deficient in these cytokines or receptors, due to the early lethality. It is unknown whether defects in the skeleton are caused by a lack of direct CLCF1 effect on the skeleton or result from the motor neuron dysfunction and subsequent muscle atrophy.

CLCF1 and CRLF1 are expressed within the developing murine skeleton, both in limb buds (Alexander et al., 1999a; Elson et al., 1998) and in embryonic muscle and cartilage (Forger et al., 2003). CRLF1 was also detected by in situ hybridization in osteoblasts and osteocytes in a mouse model of ectopic bone formation (Clancy et al., 2003). CLCF1 and CRLF1 are detected in cultured murine primary osteoblasts, and are stimulated by PTH (McGregor et al., 2010; Walker et al., 2012). In contrast, CLCF1 and CRLF mRNA levels are lowered in bones subjected to mechanical loading (Zhang et al., 2009). Like CNTF, CLCF1 administration mildly inhibited late osteoblast differentiation and suppressed osterix expression (McGregor et al., 2010), suggesting CLCF1 composite cytokines suppress bone formation by direct action on osteoblasts.

Neuropoietin

NP also forms a receptor complex with CNTFR, LIFR and gp130 (Fig. 50.1). It was identified by an IL-6 structural profile-based computational genetic screen and purified from embryonic mouse brain (Derouet et al., 2004). While the earliest analysis could identify no NP transcripts in adult murine tissues (Derouet et al., 2004), NP mRNA has been detected in bone marrow macrophages isolated from adult mice (McGregor et al., 2010). NP has been reported to inhibit adipogenesis by 3T3-L1 cells in vitro (White et al., 2008), but did not increase osteoblast differentiation or suppress adipogenesis in bipotential mesenchymal cells (McGregor et al., 2010), suggesting this may be an effect on late adipocyte differentiation. While the NP gene has orthologues in rat, chimpanzee and human, the human gene lacks the third exon and NP protein is not expressed (Derouet et al., 2004). This suggests NP exists only as a pseudogene in humans and has no function in human biology or pathology. Since it acts through receptors that are present in the human, further research may reveal roles useful for therapeutic approaches.

IL-27Rα-binding cytokines

Other cytokines that act through gp130-containing complexes utilize a gp130 heterodimer with the interleukin-27 receptor (IL-27Rα/WSX-1) (Fig. 50.1). These include the heterodimeric protein IL-27 (p28:EBI3) and the mitochondrial gene product humanin. Humanin has no known action in bone.

IL-27R is expressed in osteoclast precursors (Kalliolias et al., 2010) and osteoblasts (Kamiya et al., 2011). Although IL-27 does not appear to influence osteoblast differentiation, it suppresses osteoclastogenesis, both by direct action on osteoclast precursors (Kalliolias et al., 2010; Kamiya et al., 2011) and through indirect actions on T cells (Adamopoulos and Pflanz, 2013). IL-27-Fc treatment suppressed both inflammation and osteoclastogenesis in an animal model of rheumatoid arthritis (Park et al., 2012). Although IL-27Rα-null mice have heightened responses to inflammatory stimuli (Batten et al., 2006; Holscher et al., 2005), no bone phenotype has been described for mice or humans null in either IL-27 subunit (p28 or EBI3).

Effects of global, cell-specific, and pathway-specific gp130 modulation

The above work indicates that IL-6 family members have many roles that regulate bone metabolism and that CRLF1/CLCF1 actions through CNTFR and LIFR are necessary for life, as indicated by neonatal lethality in global knockouts for these genes (Ware et al., 1995; Alexander et al., 1999a; Zou et al., 2009; DeChiara et al., 1995). It is not surprising then that global null mice for gp130 itself also exhibited neonatal lethality due to myocardial, skeletal, respiratory and hematological defects (Yoshida et al., 1996). Skeletal analysis showed many large, active osteoclasts (Kawasaki et al., 1997; Shin et al., 2004). Due to the early lethality, gp130-null mice could not provide information on gp130's roles in the adult skeleton, on relative contributions of gp130 signaling in specific cell types, the importance of gp130's specific intracellular downstream signaling pathways, or the requirements for negative feedback mechanisms. The next sections will discuss these aspects.

Insights from mice and a patient with gp130 signaling mutations

A recent publication has identified a human gp130 missense mutation with loss of IL-6, IL-11, IL-27 and OSM signaling, but intact LIF response (Schwerd et al., 2017). This patient exhibited multiple symptoms, including emphysema, immunological defects and skeletal phenotypes including craniosynostosis, dental abnormalities and progressive scoliosis. These are consistent with murine and human deficiencies in IL-6, IL-11, IL-27 and OSM described previously. The authors noted that the phenotype that was similar to the Hyper-IgE syndrome described in patients with dominant negative STAT3 mutations (Minegishi et al., 2007; Holland et al., 2007), consistent with STAT3 as the key signal transducer for IL-6 family cytokines. The parallel syndromes suggest it is the loss of IL-6 family cytokines that cause the phenotypes, even though other cytokines, such as leptin, erythropoietin, and granulocyte colony stimulating factor (G-CSF), signal through STAT3. The human gp130 missense condition has some similarities with a previously described phenotype in mice with a knock-in gp130 mutation lacking STAT3 signaling (Ernst et al., 2001). These mice had immune deficiency and reduced lifespan due to gastrointestinal ulceration (Ernst et al., 2001). They also exhibited reduced femoral length due to early growth plate closure (Sims et al., 2004) and severe inflammatory joint disease (Ernst et al., 2001). Surprisingly, although many IL-6 family cytokines act through STAT3 to induce osteoclast formation and bone formation (O'Brien et al., 1999; Bellido et al., 1997; Walker et al., 2016), the mice showed no alteration in osteoclast or osteoblast numbers, nor any change in trabecular bone mass when corrected for their reduced size (Sims et al., 2004).

In contrast, a second mouse model with a gp130 knock-in mutation targeting the tyrosine that initiates SHP2/Ras/MAPK activation (*gp130*$^{Y575F/Y757F}$ mice) showed normal bone size, but significant osteopenia (Sims et al., 2004). Although both bone resorption and bone formation are elevated, the resorption outstrips formation, resulting in osteopenia. The primary defect in osteoclastogenesis in these mice led to a coupling-induced increase in bone formation that was rescued by deleting IL-6, providing early indication that coupling signals from the osteoclast to the osteoblast may be IL-6-dependent (see Chapter 10) (Sims et al., 2004). While that early work suggested the phenotype resulted from SHP2/Ras/MAPK pathway deletion (Sims et al., 2004), these mice also exhibited elevated hyperactive STAT1 and STAT3 signaling (Jenkins et al., 2005). We recently noted the *gp130*$^{Y575F/Y757F}$ phenotype could be rescued by blocking STAT1 signaling but not by reducing STAT3 activation (Walker et al., 2016). This indicates that increasing the ratio of STAT3:STAT1 signaling downstream of gp130 may provide therapeutic benefit in patients with bone loss related to elevated IL-6 family cytokines, such as colitis or rheumatoid arthritis.

Contributions of gp130 in the osteoblast lineage to bone structure and parathyroid hormone anabolic action

With the advent of mice that express Cre-recombinase in a cell-lineage restricted manner, it became possible to test the contributions of gp130 signaling within the osteoblast lineage to bone formation and resorption. Although most IL-6 family cytokines promote osteoclast formation by promoting RANKL expression in the osteoblast lineage (see previous), when gp130 deletion was directed to the entire osteoblast lineage (*Osx1Cre.gp130*$^{f/f}$) or to late stage osteoblasts and osteocytes (using *Dmp1Cre.gp130*$^{f/f}$), there was no change in osteoclast numbers in vivo (Johnson et al., 2014a). This supported earlier conclusions that RANKL production by osteoblasts in response to IL-6 family cytokines may be restricted to pathological states including inflammatory arthritis, periodontal disease and inflammatory bowel disease (see previous). Although many IL-6 family cytokines shift bipotential osteoblast precursors toward osteoblast differentiation rather than adipogenesis, no change in marrow adiposity was observed in *Osx1Cre.gp130*$^{f/f}$ or *Dmp1Cre.gp130*$^{f/f}$ mice, consistent with these effects occurring earlier in the lineage. Instead, gp130 deletion in committed osteoblasts or osteocytes reduced trabecular bone formation, resulting in low trabecular bone mass (Johnson et al., 2014a). This established that the main role for gp130 in the osteoblast lineage in trabecular bone physiology is not to support osteoclastogenesis, or to suppress adipogenesis, but to promote bone formation. The phenotype was identical in both models, indicating that IL-6 family cytokines promote bone formation through gp130 signaling in osteocytes, consistent with IL-11, OSM, LIF and CT-1 suppressing sclerostin expression (Walker et al., 2010).

In contrast to their low trabecular bone mass, *Osx1Cre.gp130*$^{f/f}$ and *Dmp1Cre.gp130*$^{f/f}$ mice exhibited greater cortical bone diameter than controls (Johnson et al., 2014a). This was in direct opposition to the slimmer cortices observed in global knockouts for IL-6, IL-11R, CT-1 and OSMR (Sims et al., 2005; Walker et al., 2008, 2010), and may occur as compensation for poor cortical bone material properties and low collagen production when osteocytes lack gp130 (Johnson et al., 2014a). IL-6 family cytokines' ability to regulate intrinsic bone matrix strength is consistent with earlier work

showing that IL-6-null cortical bone has a lower mineral-to-matrix ratio than controls (Yang et al., 2007). The mechanisms by which IL-6 family cytokines regulate collagen deposition and mineral accumulation in newly formed bone remain largely unexplored.

Intermittent PTH administration robustly stimulates bone formation, which is why it is used as a bone-building therapy for osteoporosis (Lindsay et al., 1997). Mice with osteocyte-targeted gp130 deletion showed no anabolic response to PTH in trabecular or cortical bone (Standal et al., 2014). This is consistent with PTH actions to rapidly stimulate IL-6 (Greenfield et al., 1996; Lowik et al., 1989), IL-11, OSMR, LIF, CRLF1 (Walker et al., 2012), and gp130 (Romas et al., 1996) expression in osteoblasts. The suppressed PTH effect was explained, at least in part, by impaired osteoblast differentiation and reduced PTH receptor expression in bones lacking gp130 in osteocytes (Standal et al., 2014). PTH anabolic action also requires suppression of the Wnt signaling inhibitors sclerostin and Dickkopf 1 (Dkk1) (Kulkarni et al., 2005; Kramer et al., 2010). In mice lacking osteocytic gp130, although PTH still stimulated RANKL expression, indicating an intact PTH response, it did not suppress sclerostin or Dkk1 transcription (Standal et al., 2014). This suggests PTH anabolic action in bone is mediated by gp130-dependent cytokines acting in osteocytes to suppress sclerostin and Dkk1.

The gp130-binding cytokine mediating PTH anabolic action in osteocytes is not yet known. It may be OSM, LIF, IL-11 or CT-1, or a combination of these because they all suppress sclerostin (Walker et al., 2010). It is unlikely to be mediated by OSMR, because OSMR deletion did not ablate PTH anabolic effect but converted it to a catabolic (bone destroying) action. When OSMR-deficient osteoblasts were stimulated with PTH in vitro, osteoclast formation was much greater than in wild-type osteoblasts (Walker et al., 2012). This was also observed in vivo, where OSMR-null mice treated with PTH converted an anabolic treatment protocol to a catabolic effect (Walker et al., 2012). Anabolic intermittent PTH treatment is normally associated with only a short and transient induction of RANKL (Ma et al., 2001), while persistently high circulating PTH levels are catabolic (Frolik et al., 2003) due to a persistently high RANKL level (Ma et al., 2001). In OSMR-null osteoblasts, RANKL was persistently high after PTH injection; this could explain how a normally PTH anabolic treatment was converted to a catabolic response (Walker et al., 2012). In addition, OSM stimulates Wnt16 production (Moverare-Skrtic et al., 2014) through OSMR (Walker et al., 2016). This is an osteoblast-derived stimulus of OPG production; OSMR may restrain osteoclast formation through this pathway within the osteoblast lineage.

Contribution of gp130 in osteoclasts to bone physiology

Mature osteoclasts have the capacity to respond to IL-6 and IL-11 because IL-6R, IL-11R and gp130 itself have been identified in mature osteoclasts (Table 50.1) (Gao et al., 1998; Romas et al., 1996). OSMR and LIFR have not been detected in osteoclasts or their precursors (Allan et al., 1990; Walker et al., 2010) precluding OSM, CT-1, LIF or CNTFR-associated cytokines from acting on these cells. The direct action of IL-6 on osteoclasts has been controversial. Some studies detected no effect of IL-6 on osteoclastic resorption in vitro (Axmann et al., 2009; Hattersley et al., 1988), others report increased resorption and differentiation (Gao et al., 1998). Others report IL-6 can directly stimulate osteoclast precursors to form osteoclasts (Kudo et al., 2003) and partially facilitate RANKL or TNF-induced osteoclastogenesis (Axmann et al., 2009). However, most published work indicates IL-6 family cytokines require RANKL-producing cells such as osteoblasts (Tamura et al., 1993), or (in the context of arthritis) T lymphocytes (Horwood et al., 1999) to be present to promote osteoclast formation.

When gp130 was deleted from osteoclasts in the *Ctsk.gp130$^{f/f}$* mouse, there was no change in osteoclast numbers, nor any change in bone resorption. In contrast, bone formation was reduced on both trabecular and periosteal surfaces. Although osteoclasts are defined by their ability to resorb bone, they also stimulate bone forming osteoblasts by releasing "coupling factors" (Martin and Sims, 2005), such as CT-1 (described previously and Chapter 10). The phenotype of the *Ctsk.gp130$^{f/f}$* mouse suggests that gp130's main physiological role in osteoclasts is to promote coupling factor release or activity. This was consistent with earlier work showing that coupling factor release in mice with a high osteoclast activity due to enhanced STAT3 signaling requires IL-6 (Sims et al., 2004). While IL-6 stimulated STAT3 phosphorylation in cultured osteoclasts, previously described coupling factors were not regulated by IL-6 at the mRNA level. Since the periosteal site at which bone formation was measured in both models lacks osteoclasts, we suggested that the IL-6 dependent factor/s emanating from the osteoclast to maintain periosteal bone formation is an "osteotransmitter" action. This emphasizes that these factors are unlikely to signal directly from the osteoclast to the distant periosteal surface, but are transmitted through other cells (e.g., the cortical osteocyte network).

The contributions of intracellular negative feedback through suppressor-of-cytokine-signaling proteins

JAK/STAT signaling depends on intracellular negative feedback from SOCS proteins to switch off STAT phosphorylation once target gene transcription is initiated (Croker et al., 2008) (Fig. 50.2). Three SOCS proteins limit IL-6 family cytokines: SOCS1, which provides negative feedback for STAT1; SOCS3, which provides negative feedback for STAT3; and CISH, which provides negative feedback for STAT5. These proteins are not specific for the IL-6 family, because they also provide this feedback to other cytokines and factors that utilize STAT1, STAT3 or STAT5, such as granulocyte-colony stimulating factor (G-CSF), leptin, growth hormone and type I interferons, which all have actions on the skeleton (Winkler et al., 2010; Sims et al., 2000; Takayanagi et al., 2002; Lee et al., 2002b).

Mice with global SOCS1 deletion do not survive beyond weaning (Starr et al., 1998), but exhibit small size and some evidence of low osteoblast activity (Abe et al., 2006). This is consistent with the proposal (Walker et al., 2016) that favoring STAT3 intracellular signaling over STAT1 would suppress osteoblast differentiation. CISH-null mice survive to adulthood (Yang et al., 2013), and our preliminary observations detected increased periosteal growth (Alister Ward, Saeed Mahmoudi Meimand, Natalie A Sims, personal communication) consistent with hyperactive growth hormone signaling. Whether these phenotypes are directly related to hyperactivation of IL-6 family signaling is not known.

SOCS3-null mice are neonatal lethal (Marine et al., 1999), but a requirement for SOCS3 negative feedback in bone has been reported in chondrocytes (Liu et al., 2014), in the hematopoietic lineage (Wong et al., 2006a), and in osteocytes (Cho et al., 2017). Mice lacking SOCS3 in chondrocytes and in the hematopoietic lineage exhibited increased susceptibility to joint disease, including increased osteoclastic bone destruction (Wong et al., 2006a; Liu et al., 2014). In the mice null for SOCS3 in the hematopoietic lineage, increased osteoclast and osteoblast numbers, and low trabecular bone mass were observed (Wong et al., 2006a). This was not reproduced in mice with SOCS3 deletion restricted to the macrophage/osteoclast lineage (Wong et al., 2006a), suggesting it occurs indirectly.

We recently reported that SOCS3 negative feedback in osteocytes is required for the process by which cortical bone forms during growth (corticalization) (Cho et al., 2017). Mice with SOCS3 deletion targeted to osteocytes (*Dmp1Cre.Socs3*$^{f/f}$ mice) showed a unique and dramatic phenotype of delayed corticalization in the metaphysis. In young *Dmp1Cre.Socs3*$^{f/f}$ mice, the same delay in corticalization, associated with high bone formation was seen in both males and females. This phenotype persisted in females, resulting in a profound high trabecular bone mass phenotype in their adult skeleton. In male mice, the phenotype resolved after puberty (Cho et al., 2017). This indicates that SOCS3 in osteocytes restrains bone formation throughout life by providing negative feedback to those cytokines previously shown to promote bone formation, such as OSM, CT-1 and LIF (Poulton et al., 2012; Walker et al., 2008, 2010). The male *Dmp1Cre.Socs3*$^{f/f}$ mice recovered from the phenotype by an increase in resorption to match the high bone formation. This suggests that when osteoblast numbers decrease with maturity, which occurs earlier in male mice than in females, SOCS3 restrains both bone formation and resorption. This is probably achieved by providing negative feedback to cytokines (such as OSM, CT-1, IL-6 and IL-11) that act on the osteoblast lineage to stimulate RANKL production (Tamura et al., 1993; Udagawa et al., 1995; Romas et al., 1996).

Differences in skeletal structure are well-described in male and female mammals. In humans, this difference arises because boys have a longer growth period, during which the periosteum continues to expand, while girls form bone on the endocortical metaphysis via endocortical apposition (Seeman, 1997; Schoenau et al., 2001). The extended delay in corticalization in female *Dmp1Cre.Socs3*$^{f/f}$ mice compared with males suggested that androgen stimulates corticalization through SOCS3 negative feedback in osteocytes. This was confirmed by sex hormone treatment studies (Cho et al., 2017). Since many cytokines that require SOCS3 for negative feedback act in osteocytes, including IL-6 family members (see previously and Table 50.1), G-CSF (Winkler et al., 2010) and leptin (Lee et al., 2002b), the delay in corticalization could be explained by hyperactivity in osteocytes of many cytokines. The specific hyperactive cytokine/s that must be suppressed by SOCS3 for corticalization to occur has not been identified. However, the sex-specificity of the phenotype was partially ablated by genetic deletion of IL-6 (Cho et al., 2017). This is consistent with feminization of cortical bone in male IL-6-null mice, which exhibit narrow cortices equivalent to their female wildtype counterparts (Sims et al., 2005) and indicates that androgen-receptor-mediated regulation of IL-6 in osteocytes promotes male-specific pattern of corticalization.

Chapter 51

Prostaglandins and bone metabolism

Shilpa Choudhary and Carol Pilbeam

Department of Medicine and Musculoskeletal Institute, UConn Health, Farmington, CT, United States

Chapter outline

Introduction

Prostaglandins (PGs) are autocrine–paracrine fatty acids, commonly called local factors. The lipid soluble acid originally identified in seminal fluid as an activity causing muscle contraction was named "prostaglandin" because it was thought to originate from the prostate gland (von Euler, 1936). We now know that PGs are produced in most cells. They are not stored but are synthesized and released as needed and rapidly metabolized. Since prostaglandin E_2 (PGE_2) was first shown to stimulate cyclic AMP production and resorption in bone organ cultures (Klein and Raisz, 1970), bone cells have been shown to produce abundant PGs, especially PGE_2. PGs in bone cells are largely the result of the inducible cyclooxygenase enzyme (COX-2), which can be induced by multiple systemic hormones and local factors involved in bone metabolism. PGE_2 can stimulate bone resorption and formation and mediate the effects of COX-2 agonists. A major function of PGE_2, however, may be to integrate, amplify, or as we have recently shown for PTH, block the responses to these agonists at the cellular level.

Prostaglandin production

Eicosanoids

Eicosanoids are bioactive lipids derived via oxygenation from arachidonic acid (AA) and other 20-carbon polyunsaturated (i.e., containing double bonds) fatty acids (PUFAs). AA is the PUFA precursor for major groups of eicosanoids (Buczynski et al., 2009). AA is metabolized by (1) cyclooxygenases (COXs) to PGs and thromboxanes (TXAs); (2) lipoxygenases 5, 12, and 15 to leukotrienes, lipoxins, and hydroxyeicosatetraenoic acids (HETEs); (3) cytochrome P450 to HETEs; and

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00051-8

(4) nonenzymatic pathways to isoprostanes and HETEs. The term "prostanoid" refers to products of the COX pathway: PGEs, PGDs, PGFs, prostacyclins (PGIs), and TXAs (Smith et al., 2011). PGs are 20-carbon fatty acids with a cyclopentane ring. Although TXAs have an oxane ring, they are generally discussed under the "PG" heading. The subscript for prostanoids denotes the number of double bonds (e.g., PGE_1, PGE_2, and PGE_3).

PUFAs are metabolized from linoleic acid and α-linolenic acid, essential fatty acids that must be obtained from the diet (Wilson, 2004; Edwards and O'Flaherty, 2008). (The shorthand for fatty acids, X:YωZ, refers to X carbon atoms and Y double bonds, while Z is the position of the first double bond counting from the terminal methyl [CH_3] group.) The Western diet is high in an omega 6 fatty acid, linoleic acid (18:2ω6), that is metabolized to dihomo-γ-linolenic acid (20:3ω6). Dihomo-γ-linolenic acid is the substrate for 1-series (1 double bond) PGs (e.g., PGE_1) and gives rise to AA (20:4 ω6), the substrate for the 2 series (e.g., PGE_2). An omega 3 fatty acid, α-linolenic acid (18:3ω3), is metabolized to eicosatetraenoic acid (20:4ω3) and then to eicosapentaenoic acid (EPA, 20:5ω3), which is the substrate of the 3 series (e.g., PGE_3).

The 2-series prostanoids are the most abundant and most characterized. The roles of the 1-series and 3-series PGs in normal physiology are unclear. However, PGE_1 and synthetic analogues have been used to treat many conditions, including patent ductus arteriosus in neonates, arterial occlusive disease, erectile dysfunction, contrast-induced nephropathy, chronic idiopathic constipation, and ARDS (Creutzig et al., 2004; Ivey and Srivastava, 2006; Fuller et al., 2015; Berkseth et al., 2016; Li et al., 2016; Ye et al., 2016). In contrast to 2-series prostanoids, especially PGE_2, which is positively associated with inflammation and tumorigenesis, the 3-series prostanoids, along with the 5-series leukotrienes, derived from EPA and the resolvins derived from the metabolite of EPA, docosahexaenoic acid (22:6ω3), are thought to have some antiinflammatory and antitumorigenic properties (Wiktorowska-Owczarek et al., 2015; Araki et al., 2017).

There are three steps in the production of 2-series prostanoids (Fig. 51.1). The first is the mobilization of AA from membranes by phospholipases. The second step is catalyzed by a bifunctional enzyme that converts free AA to prostaglandin G_2 (PGG_2) in a COX reaction followed by the reduction of PGG_2 to prostaglandin H_2 (PGH_2) in a peroxidase (POX) reaction. The first step or COX reaction is inhibited by nonsteroidal antiinflammatory drugs (NSAIDs). The bifunctional enzyme is formally named prostaglandin endoperoxide H synthase or prostaglandin G/H synthase (PGHS), and the gene name is *Ptgs*. (There are two PGHSs, which will be discussed in more detail later.) PGH_2 is then converted by terminal synthases to PGE_2, PGD_2, $PGF_{2\alpha}$, PGI_2, and TXA_2 (Smith et al., 2011). PGI_2 and TXA_2 are rapidly hydrolyzed to 6-keto $PGF_{1\alpha}$ and TXB_2, respectively. All three enzymatic steps are subject to transient activation, and any of the three steps may be limiting under some circumstances.

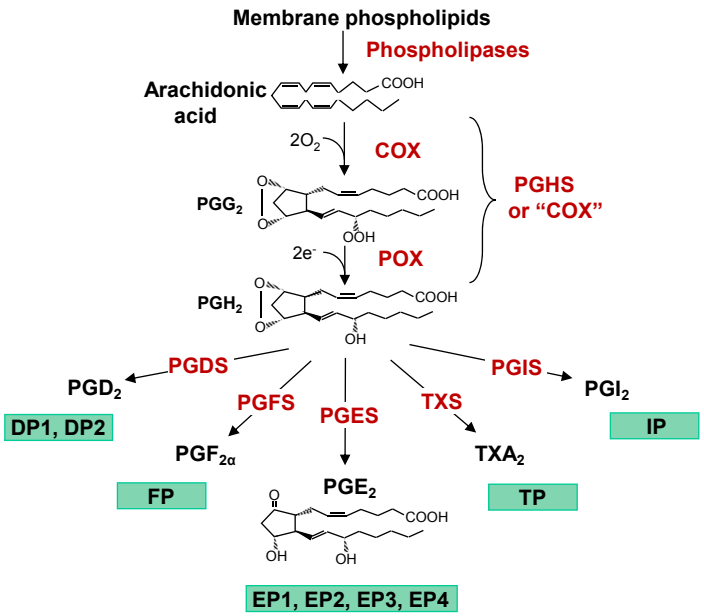

FIGURE 51.1 Major prostanoids generated from arachidonic acid (AA) and their receptors. Free AA, released from membrane phospholipids by phospholipases, is converted by the bifunctional PGHS enzyme (or cyclooxygenase, COX) to prostaglandin G_2 (PGG_2) in a COX reaction followed by the reduction of PGG_2 to prostaglandin H_2 (PGH_2) in a peroxidase (POX) reaction. PGH_2 is then converted to specific prostanoids by the terminal synthases PGDS, PGFS, PGDS, TXS, and PGIS. The respective receptors are shown below the prostanoids.

Mobilization of arachidonic acid

Phospholipase A_2 (PLA_2) enzymes catalyze the hydrolysis of membrane phospholipids from the *sn*-2 position of membrane glycerophospholipids, releasing free fatty acids such as AA. The PLA_2 superfamily is currently divided into 16 groups (GI−GXVI) and many subgroups (Dennis et al., 2011; Murakami et al., 2011, 2015; Vasquez et al., 2017). There is tremendous diversity among these enzymes, with some having actions independent of their phospholipase activity. The most important PLAs for PG production are Ca^{2+}-independent PLA_2s (iPLA_2s), Ca^{2+}-dependent cytosolic PLA_2s (cPLA_2s), and secreted PLA_2s (sPLA_2s). In general, iPLA_2 is thought to be the primary PLA_2 in cells, producing the low levels of free fatty acids, some of which may be AA, needed for daily cellular functions; cPLA_2 is the major inducible enzyme hydrolyzing AA-containing phospholipids during infection or inflammation; and sPLA_2 is also inducible and augments cPLA_2 function (Dennis and Norris, 2015).

Group VI (GVI) enzymes are cytosolic proteins with calcium-independent phospholipase A_2 activity (Dennis et al., 2011). There are six members of the group, but GVIA is the enzyme commonly called calcium-independent PLA_2 or iPLA_2. This group does not show AA specificity in the *sn*-2 position. The activities of this group are diverse, involving many organelles including mitochondria and associated with membrane homeostasis and remodeling and with basic cellular functions of proliferation and apoptosis.

Group IV (GIV) cPLA_2s are large cytosolic proteins dependent on Ca^{2+} activation (Dennis et al., 2011; Vasquez et al., 2017; Murakami et al., 2011). GIVA cPLA_2 (85 kDa) is the most studied of six subgroups and likely the most important cPLA_2 for PG production. GIVA cPLA_2 is highly selective for AA at the *sn*-2 position of membrane lipids. It is constitutively expressed in most cells but can also be regulated. PGs themselves can enhance both COX-2 and cPLA_2 expression (Murakami et al., 1997), and IL-4 can inhibit both COX-2 and cPLA_2 expression (Kawaguchi et al., 1996). Activation of cPLA_2 requires that it be sequestered at a phospholipid interface. The first step is the Ca^{2+} (submicromolar concentration)-dependent translocation of GIV cPLA_2 from the cytosol to nuclear/endoplasmic reticulum (ER) membranes, which is also where the COX enzymes reside. Binding to membranes can be enhanced by several mechanisms including phosphorylation of the enzyme. Since GIV cPLA_2 is the major enzyme for releasing AA substrate for COX activity, its biological functions as determined from knockout (KO) mice are largely those expected from COX or eicosanoid deficiency. For example, KO mice have decreased inflammatory responses and associated diseases, such as collagen-induced arthritis, and less induced tumors than those of wild-type (WT) controls (Dennis et al., 2011). There are multiple inhibitors of GIV cPLA_2, but the therapeutic use of these inhibitors is likely to be hindered by the same side effects as those of NSAIDs.

sPLA_2s are low-molecular-weight secreted proteins that require millimolar Ca^{2+} concentrations for activation. There are 10 isoforms in mammals; 9 are expressed in humans and 10 in mice (Dennis et al., 2011; Vasquez et al., 2017). They have many functions, some independent of their hydrolytic activity. They have antibacterial and antiviral function and are thought to contribute significantly to atherosclerosis, perhaps by increasing fatty acids in plaques. sPLA_2 expression is stimulated by proinflammatory agents, and sPLA_2s play roles in innate immunity and inflammation-associated diseases, such as rheumatoid arthritis (Dennis et al., 2011; Murakami et al., 2015). sPLA_2s do not have a distinct preference for the *sn*-2 position of phospholipid substrates but can release AA. sPLA_2s can hydrolyze phospholipids in the outer plasma membrane of the cell of origin and neighboring cells or can be internalized and release AA from ER/perinuclear membranes.

One of the sPLA_2s, group IIA (GIIA) sPLA_2, deserves special attention. GIIA and the group V sPLA_2s are thought to be the main sPLA_2s for releasing AA for eicosanoid production and are associated with all the functions discussed for sPLA_2s above. However, the mice used for most KO and transgenic studies, C57Bl/6 and 129Sv, are naturally missing the gene for GIIA sPLA_2 (Kennedy et al., 1995) and may have increased resistance to colorectal tumorigenesis (MacPhee et al., 1995). Many KOs of PLA_2s and other enzymes in the eicosanoid pathway are in a C57Bl/6 or 129Sv background, and they are really double KOs. It should also be noted that the MC3T3-E1 osteoblastic cell line, commonly used to study osteoblastic function and differentiation in vitro, was derived from C57Bl/6 mice and should therefore lack GIIA PLA_2.

Two isoforms for prostaglandin G/H synthase (cyclooxygenase)

During the development of drugs specific for inhibiting the COX reaction of PGHS, it became popular to call the bifunctional enzyme "cyclooxygenase" or "COX" in reference to its first function. We will use the colloquial name COX from here on, but it should be noted that much of past literature and some current experts in the field still use the formal name.

The two enzymes for COX, COX-1 and COX-2, are encoded by separate genes. In humans, the gene for COX-1, *PTGS1*, is located on chromosome 9, and *PTGS2* is located on chromosome 1 (Herschman, 1994; Smith et al., 2000). The gene for COX-2 was initially cloned as an inducible gene from murine 3T3 cells (Kujubu et al., 1991), chicken fibroblasts (Xie et al., 1991), and human umbilical vein endothelial cells (Hla and Neilson, 1992). There is 60%−65% amino acid sequence identity between COX-1 and COX-2 isoforms within a species and 85%−90% identity between individual isoforms between mammalian species (Smith et al., 2011). COX-1 is expressed at relatively stable levels in most tissues and is considered "constitutive," while COX-2 is generally expressed at low levels in most tissues but can be induced to high levels by multiple factors. Both COX-1 and COX-2 are N-glycosylated dimeric proteins inserted into the luminal face of the ER and the contiguous inner membrane of the nuclear envelope (Smith et al., 2011).

COXs are said to be sequence homodimers but conformational heterodimers (Dong et al., 2011, 2016; Mitchener et al., 2015; Smith et al., 2011). The primary structure of each monomer is the same, but one monomer functions as a regulatory allosteric subunit and the other as a catalytic subunit. The catalytic subunit binds heme with higher affinity than the allosteric subunit, and maximal activity occurs with one heme bound. Various fatty acids, both substrates and nonsubstrates for COX as well as NSAIDs, can bind to the allosteric site and regulate activity of the catalytic site. Hence, activity and inhibition of the active COX site may be modulated by the fatty acid milieu or "tone" as determined by diet, drugs, and other environmental factors.

COX-1 and COX-2 have similar catalytic mechanisms (Kulmacz et al., 2003; Smith et al., 2011). COX and POX active sites are in physically separated regions of the proteins. The initiation of COX activity is dependent on heme oxidation in the POX site by peroxidase. Heme oxidation leads to oxidation of a critical tyrosine in the COX active site. The tyrosyl radical in the COX site converts AA to an arachidonoyl radical, the arachidonoyl radical reacts with two molecules of oxygen to produce PGG_2, and then PGG_2 diffuses to the POX site where it is reduced to PGH_2.

Despite having similar catalytic mechanisms, COX-1 and COX-2 are independently functioning pathways (Simmons et al., 2004; Smith and Langenbach, 2001). This is due in part to the differential regulation of their expression. The COX-1 promoter has relatively few identified functional regulatory elements, and COX-1 mRNA is constitutively expressed in most tissues. The COX-2 promoter has multiple potential transcriptional regulatory elements typical of early response genes, and COX-2 mRNA is rapidly and transiently inducible in many tissues (Kang et al., 2007). The half-life of COX-2 protein has been reported as 2−7 h in various tissues, whereas the half-life of COX-1 protein is much longer (Kang et al., 2007; Mbonye et al., 2006). The differential responses of COX-1 and COX-2 mRNA are exemplified by their responses to serum in osteoblastic MC3T3-E1 cells (Pilbeam et al., 1993). With the advent of PCR as the routine method for measuring gene expression, it became evident that COX-2 was expressed "constitutively" at low levels in many tissues and cells. A recent study examined the signaling pathways underlying constitutive expression of COX-2 in kidney, gastrointestinal tract, and brain, but it is still unclear how much this expression contributes to PG production (Kirkby et al., 2016).

There are other differences between COX-1 and COX-2 in addition to their patterns of regulation. The active site of COX-2 is larger than that of COX-1, allowing COX-2 to oxygenate bulkier amide and ester analogs of AA that are poor COX-1 substrates, including the endocannabinoids 2-arachidonoylglycerol and arachidonoylethanolamide (Rouzer and Marnett, 2011). This difference has led to the ability to make NSAIDs selective for COX-2. Another difference is that COX-2 is much more efficient at using low AA concentrations (below 5 μM) than is COX-1 (Swinney et al., 1997). This difference is exemplified in studies showing that osteoblasts from COX-2 KO mice make little PG in culture despite the constitutive expression of COX-1 (Chikazu et al., 2005; Choudhary et al., 2003; Okada et al., 2000a; Xu et al., 2007). However, these cells make large amounts of PG when exogenous AA is added. An explanation for this difference may lie in the greater cellular peroxide level required for COX-1 activation compared with COX-2 (Kulmacz et al., 2003). Finally, allosteric regulators can have different effects on COX-1 and COX-2 activities (Smith et al., 2011).

Insertion of *Ptgs1* under the regulatory sequences that drive *Ptgs2* expression in mice or vice versa indicated that in many tissues, each COX isoform could compensate for the other to some degree (Yu et al., 2007; Li et al., 2018a, 2018b). In macrophages, COX-1 was shown to compensate for PG synthesis at high concentrations of substrate, whereas elevated lipopolysaccharide (LPS)-induced PG production was only observed for cells expressing endogenous COX-2. Inflammatory signaling pathways showed reduced activation when endogenous COX-2 was not expressed, indicating that COX-1 could be replaced by COX-2 in the inflammatory milieu but not vice versa. Clearly there is compensation by one COX for the other in some tissues, because double COX-1/COX-2-deficient mice die from failure of ductus arteriosus closure shortly after birth (Loftin et al., 2001). One caveat with regard to these studies is that they were done in C57Bl/6 or mixed C57Bl/6 and 129 background mice, which naturally lack the GIIA $sPLA_2$ as previously discussed, and this could affect the ability of one or both COXs to make PGs.

Because of the differential responses of COX-1 and COX-2, it was initially hypothesized that COX-2 was predominantly responsible for acute pathological PG responses, such as those associated with inflammation and pain, while COX-1

produced those prostanoids needed for ongoing "housekeeping" functions, including maintenance of renal blood flow, platelet aggregation, and gastric cytoprotection. This hypothesis led to the development of highly selective inhibitors of COX-2 activity for the treatment of pain and inflammation associated with diseases such as arthritis and periodontitis. Studies using these inhibitors led to the realization that COX-2 has physiologic functions in many tissues, as well as pathologic functions. COX-2 selective NSAIDs, or coxibs, turned out to have serious adverse side effects, especially on the cardiovascular system, that would limit their use (Grosser et al., 2017a, 2017b).

Prostaglandin E_2 synthases

PGH_2 is converted to each PG species by species-specific PG terminal synthases (Fig. 51.1). The individual synthases influence PG production by determining the predominant type of prostanoid synthesized in a particular tissue. Prostaglandin E synthase (PGES), which converts PGH_2 to PGE_2, occurs in multiple forms (Hara et al., 2010; Hara, 2017). Membrane-bound glutathione-dependent PGES (mPGES-1) is inducible, located in ER and perinuclear membranes, and the predominant PGES metabolizing PGH_2 produced by COX-2. Because mPGES-1 is coordinately regulated by factors that regulate COX-2, mPGES-1 is said to be coupled to COX-2. It has been recently reported that COX-2 and mPGES-1 are also located in the Golgi apparatus (Yuan and Smith, 2015). (COX-1, unlike COX-2, does not have an ER-to-Golgi trafficking signal.) Because $cPLA_2$ preferentially binds to Golgi membranes, the Golgi apparatus may be a site for dedicated COX-2-dependent PGE_2 synthesis (Leslie, 2015).

A second membrane-bound form, mPGES-2, is synthesized in the Golgi membrane and then released into the cytosol after proteolytic removal of an N-terminal hydrophobic domain (Watanabe et al., 1997). mPGES-2 is constitutively expressed and functionally coupled with both COX-1 and COX-2. A third form, cytosolic PGES (cPGES), is preferentially coupled to COX-1 and thought to maintain PGE_2 production for cellular homeostasis (Tanioka et al., 2000).

KO mice for synthases are reviewed in existing research (Hara et al., 2010; Hara, 2017). Mice deficient for mPGES-1 develop normally but have reduced inflammatory and pain responses as well as decreased tumorigenesis. LPS-induced bone resorption and bone loss are reduced in mice deficient for mPGES-1 (Inada et al., 2006), and collagen-induced arthritis is suppressed (Trebino et al., 2003). Mice deficient for mPGES-2 have no specific phenotype, and mice deficient for cPGES are perinatal lethal.

Because inducible mPGES-1 is considered largely responsible for excessive PGE_2 synthesis during inflammation, it is considered a promising drug target, and a number of potential inhibitory drugs have been developed (Psarra et al., 2017). It is possible that an inhibitor of mPGES-1 may have less adverse side effects than traditional NSAIDs but be just as effective. However, because mPGES1-derived PGE_2 is responsible for some homeostatic processes, blockade of mPGES-1 could shunt PGH_2 into the production of other PGs that might not be desirable (Hara, 2017).

Prostaglandin E_2 receptors

There are nine G-protein-coupled receptors (GPCRs) mediating prostanoid actions (Fig. 51.1). A detailed discussion of these receptors, their signaling pathways, and their potential functions is available (Woodward et al., 2011). The GPCRs for $PGF_{2\alpha}$, PGI_2, PGD_2, and TXA are called FP, IP, DP1, and TP, respectively. PGD_2 also acts via DP2, which belongs to the chemoattractant receptor family (Kostenis and Ulven, 2006). $PGF_{2\alpha}$ and TP couple to $G\alpha_q$ and initiate the phospholipase C (PLC) pathway, raising intracellular Ca^{2+} and activating protein kinase C (PKC). DP1 is $G\alpha_s$-coupled and stimulates cAMP formation. The IP receptor is both $G\alpha_s$- and $G\alpha_q$-coupled, resulting in increased cAMP formation, PLC pathway activation, and Ca^{2+} signaling.

PGE_2 effects are associated with four classes of GPCRs, called EP1, EP2, EP3, and EP4. Much of the complexity of PGE_2 effects on skeletal tissues may be attributable to the multiple GPCRs for PGE_2, and these receptors may heterodimerize with other receptors or transactivate the epidermal growth factor receptor (EGFR) signaling pathway (Woodward et al., 2011). The EP1 receptor is known to increase Ca^{2+} and may couple to $G\alpha_q$, because studies have reported the involvement of the PLC/PKC pathway (Tang et al., 2005). The major signaling pathway for EP3 receptors is $G\alpha_i$-induced adenylate cyclase inhibition. However, multiple alternative transcripts of this receptor may act through other signal transduction pathways (An et al., 1994).

EP2 and EP4 are the receptors that have been most extensively studied in bone. Mice deficient in each EP receptor subtype have been generated, and highly selective agonists for the receptors have been developed (Sugimoto and Narumiya, 2007; Woodward et al., 2011). Despite their importance in bone, much of what is known about EP2 and EP4 receptor signaling pathways comes from studies to elucidate the role of PGE_2 in promoting inflammation or tumorigenesis in nonbone tissues (Buchanan and DuBois, 2006; Castellone et al., 2006; Dorsam and Gutkind, 2007; Eisinger et al., 2007;

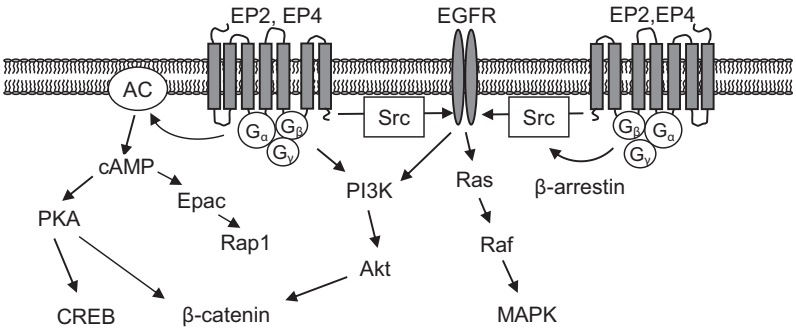

FIGURE 51.2 Signaling pathways activated by PGE_2 acting via the EP2 and EP4 receptors. Both EP2 and EP4 can activate $G\alpha_s$ and activate adenylyl cyclase (AC), leading to an increase in cAMP and activation of protein kinase A (PKA). The increased cAMP can potentially act independently of PKA to activate exchange protein directly activated by cAMP (Epac). The PKA pathway can cross talk with other pathways to activate β-catenin signaling. β-catenin activation may also occur via the phosphatidylinositol 3-kinase (PI3K)-Akt pathway. EP receptors may activate c-Src, which then transactivates epidermal growth factor receptor (EGFR), leading to multiple signaling pathways including PI3K/Akt/β-catenin and Ras/Raf/MAPK. The recruitment of β-arrestin by EP receptors may also activate c-Src, resulting in EGFR transactivation (O'Callaghan and Houston, 2015).

Ganesh, 2014; Jiang and Dingledine, 2013; O'Callaghan and Houston, 2015; Yokoyama et al., 2013). Some potential signaling pathways by which PGE_2 may act via EP2 and EP4 are shown in Fig. 51.2.

Both EP2 and EP4 stimulate $G\alpha_s$ to activate ACs and produce cAMP, which can then activate protein kinase A (PKA) or a PKA-independent pathway mediated by the guanine exchange factor Epac. The PKA pathway is able to cross talk with several other pathways that regulate cell growth, motility, migration, and apoptosis, including the Wnt/β-catenin signaling pathway (Buchanan and DuBois, 2006; Castellone et al., 2005, 2006; Estus et al., 2016; Hino et al., 2005; Shao et al., 2005). Studies in human embryonic kidney-293 cells stably transfected with EP receptors suggested that the activation of β-catenin signaling occurred primarily through a PKA-dependent pathway for EP2 and through a PI3K-dependent pathway for EP4 (Fujino et al., 2002). PGE_2 can also transactivate the EGFR signaling pathway by various mechanisms (Buchanan et al., 2003; Pai et al., 2002; Shao et al., 2003). Recent studies have shown that signaling from both receptors can be modulated by β-arrestin. In brain microglia, IL-10 production was inhibited by PGE_2 via an EP2-β-arrestin signaling pathway (Chu et al., 2015). In gastric mucosal cells, PGE_2 stimulated cell proliferation via activation of a β-arrestin/Src/EGFR/Akt pathway downstream of EP4 (Tan et al., 2017).

Prostaglandin E_2: role in bone formation and resorption

Production in bone and osteoblastic cultures

Early studies showed that complement-sufficient antisera, which contain antibodies to rodent cell surface antigens, could increase resorption of fetal rat long bones by stimulating endogenous PG production (Raisz et al., 1974). Subsequently, many regulators of bone metabolism were found to stimulate PG production in bone, although it was not always clear what cells were responsible. In the early 1990s, inducible COX-2 was identified (O'Banion et al., 1991; Kujubu et al., 1991; Xie et al., 1991). Subsequently, the induction of COX-2 was shown to be responsible for most acutely stimulated PG responses in osteoblastic cells. Multiple agonists were shown to induce COX-2 in osteoblastic cells, including cytokines IL-1 (Harrison et al., 1994; Kawaguchi et al., 1994; Min et al., 1998), TNF-α (Kawaguchi et al., 1996), and IL-6 (Tai et al., 1997); growth factors TGFα (Harrison et al., 1994), TGFβ (Pilbeam et al., 1997a), basic fibroblast growth factor (FGF-2) (Kawaguchi et al., 1995), and bone morphogenetic protein (BMP-2) (Chikazu et al., 2005); systemic hormones PTH (Kawaguchi et al., 1994; Tetradis et al., 1996, 1997) and $1,25(OH)_2$ vitamin D_3 (Okada et al., 2000a); calcium (Choudhary et al., 2003) and strontium (Choudhary et al., 2007); and fluid shear stress (FSS) and mechanical loading (Klein-Nulend et al., 1997; Mehrotra et al., 2006; Pavalko et al., 1998; Wadhwa et al., 2002a).

Serum is also a potent stimulator of COX-2 expression and PG production in cultured osteoblasts (Pilbeam et al., 1993). Endogenous PGs produced by the addition of serum can increase the differentiation of cultured osteoblasts (Choudhary et al., 2013). In the absence of serum, some osteoblastic cell cultures produce little PGE_2 despite the presence of COX-2 expression unless AA is added, suggesting that serum may facilitate substrate in some cultures (Pilbeam et al., 1994). Perhaps the varying ability of serum to induce COX-2/PG production or release AA may contribute to the observation that some batches of serum are "better" for studying osteoblastic differentiation than others.

Some osteoblastic cell lines do not express COX-2. In our studies, the rat osteosarcoma cell line, ROS 17/2.8, expressed only COX-1 mRNA (Pilbeam et al., 1997b). Because of the difficulty of obtaining freshly isolated osteoblasts from humans, osteosarcoma cell lines are often used to study human osteoblastic function. Expression of COX-2 mRNA can be highly variable among and within these osteosarcoma cell lines. Expression of COX-2 mRNA in U2OS, TE85, and Saos-2 osteosarcoma cell lines, measured by reverse transcriptase-PCR, ranged from easily detectable constitutive and inducible expression to no detectable constitutive or inducible expression (Xu et al., 2006). Similar variability was seen in three lines of Saos-2 cells (called strains) derived originally from the same tumor but carried for years by different labs. COX-1 was constitutively expressed in all three Saos-2 strains, but PGE_2 production depended on COX-2 expression. It is unclear which, if any, of these strains reflect the expression of COX-2 in the original tumor.

PGE_2 can amplify its own production by stimulating COX-2 and $cPLA_2$ expression (Kawaguchi et al., 1994; Murakami et al., 1997; Pilbeam et al., 1993, 1994). Agonists acting via IP, TP, FP, and DP receptors have also been shown to stimulate COX-2 expression (Sakuma et al., 2004), and PGE_2 may be the major PG produced in response. For example, $PGF_{2\alpha}$, which is a poor stimulator of resorption, increases PGE_2 production in organ culture that enhances resorptive effects (Raisz et al., 1990). This amplifying mechanism could be important in prolonging the effects of short periods of impact loading on the skeleton or the effects of cytokines in inflammatory diseases. PG autoamplification is likely to involve different signaling pathways than the initial cytokine or other agonist induction of COX-2 and may complicate interpretation if unrecognized.

Glucocorticoids (GCs) are potent inhibitors of stimulated PG production, and their antiinflammatory actions are thought to be due in part to this inhibition. Prior to the identification of COX-2, GCs were thought to work predominantly through interference with the release of AA. Although GCs can inhibit agonist-stimulated release of AA (Sampey et al., 2000), their major inhibitory effect is on inducible COX-2 mRNA and protein expression (Kawaguchi et al., 1994; Pilbeam et al., 1993). GCs can also inhibit mPGES-1(Korotkova et al., 2005). The GC inhibition of COX-2 occurs by both transcriptional and posttranscriptional mechanisms (DeWitt and Meade, 1993; Lasa et al., 2001; Newton et al., 1998). The use of GCs to promote differentiation in osteoblastic cultures may actually decrease osteoblastic differentiation by reducing COX-2 produced PGE_2. This was observed for strontium ranelate−induced osteoblastic differentiation in murine bone marrow stromal cells (Choudhary et al., 2007).

NSAIDs inhibit PG production by binding to the cyclooxygenase catalytic site. Since PGs themselves can induce COX-2 expression, NSAIDs can also decrease COX-2 expression by reducing PG-mediated autoamplification. NSAIDs are widely used to study the effects of endogenous PGs. NS-398 is the selective NSAID most widely available for in vitro and animal studies. In rodent osteoblastic cells, NS-398 at a concentration of 0.01 μM was selective for the inhibition of COX-2 activity; however, at concentrations of 0.1 and 1 μM, NS-398 also inhibited COX-1 activity by 60% and 85%, respectively (Pilbeam et al., 1997b). In addition, NSAIDs can have multiple effects independent of COX activity, especially at high doses (Grosch et al., 2006; Paik et al., 2000). Hence, in using NSAIDs to study PGE_2 effects, the lowest dose that inhibits PGE_2 production should be used.

Prostaglandin E_2 and bone formation

Many studies have shown that PGE_2 stimulates osteoblastic differentiation in murine and rat bone marrow stromal cell and primary osteoblast/calvarial cell cultures (Choudhary et al., 2013; Flanagan and Chambers, 1992; Kaneki et al., 1999; Nagata et al., 1994; Scutt and Bertram, 1995). In addition, PGE_2 given to rats in vivo stimulated osteoblastic differentiation in ex vivo cultured bone marrow (Keila et al., 1994; Weinreb et al., 1997). For some osteogenic factors, such as serum, BMP-2, and strontium ranelate, their ability to stimulate osteoblast differentiation in vitro is due largely to their induction of COX-2 produced PGs (Pilbeam et al., 1993; Chikazu et al., 2005; Choudhary et al., 2007). In cultured marrow stromal cells or primary osteoblasts from mice with deletion of *Ptgs2* or treated with NSAIDs to inhibit COX-2 activity, osteoblastic differentiation is decreased (Choudhary et al., 2007, 2013; Okada et al., 2000b; Xu et al., 2004; Zhang et al., 2002b). An example of osteoblastic differentiation in bone marrow stromal cell cultures from COX-2 WT and KO mice is shown in Fig. 51.3.

Systemic injections of PGE_2 can increase both periosteal and endosteal bone formation in the rat and produce substantial increases in bone mass similar to the effects of PTH (Jee and Ma, 1997; Lin et al., 1994; Suponitzky and Weinreb, 1998). Systemic administration of PGE_2 or PGE_1 in humans (Faye-Petersen et al., 1996; Ueda et al., 1980) and dogs (Norrdin and Shih, 1988) has also been shown to increase cortical and cancellous bone mass. Local infusion of PGE_2 has been shown to increase bone in mice (Yoshida et al., 2002). However, systemic injection of PGE_2 in mice following the

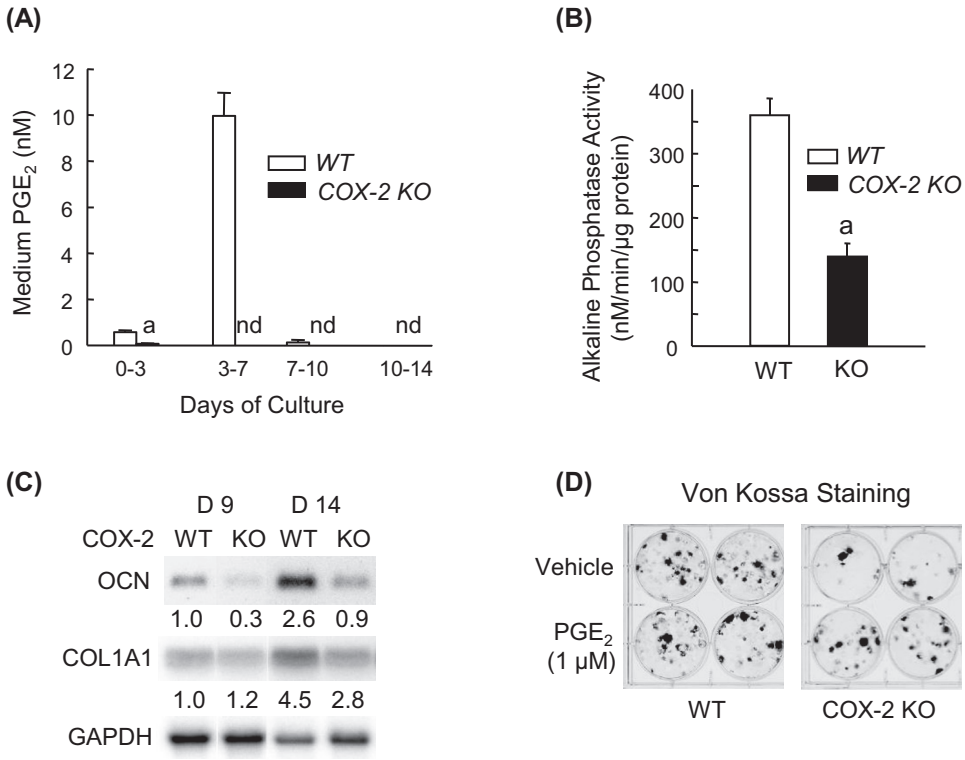

FIGURE 51.3 Osteoblastic differentiation in bone marrow stromal cell cultures from COX-2 knockout (KO) mice compared with cultures from wild-type (WT) mice (Pilbeam, C., unpublished data). Whole bone marrow from long bone was cultured in α-MEM, 10% fetal calf serum, and 50 μg/mL phosphoascorbate. β-glycerophosphate (10 mM) was added for the last 2 weeks of culture. All measures of osteoblast differentiation including alkaline phosphatase (ALP) staining, osteocalcin (OCN) mRNA expression, and Von Kossa staining for mineralization were decreased in COX-2 KO cells compared with WT cells. (A) Medium PGE_2 production peaked between days 3–7 of culture in WT cultures but was undetectable at all times in KO cultures. (B) ALP activity normalized to total protein at day 14. (C) Northern analysis for type 1 collagen and OCN mRNA. Ratio of mRNA level to housekeeping gene GAPDH is shown below the bands. (D) Von Kossa staining of mineralized nodules at day 21. Bars are means ± SEM for $n = 3$ wells. a, Significantly different from WT, $P < .01$.

protocols established for rats was found to increase turnover, with resorption increasing more than formation and resulting in bone loss, or resorption and formation increasing similarly and resulting in no bone loss or a gain (Gao et al., 2009a). Despite using different doses and injection regimens, we were never able to achieve the sort of anabolic effects with systemic PGE_2 in mice that can be seen with intermittent PTH (i.e., increased formation greater than increased resorption) (Raisz and Pilbeam, unpublished data).

Prostaglandin E_2 receptors and bone formation

A review of EP receptor actions in bone is available (Woodward et al., 2011). Both EP2 and EP4 have been implicated in the osteogenic and anabolic effects of PGE_2 (Alander and Raisz, 2006; Choudhary et al., 2008; Li et al., 2007). Bone mechanical properties were reduced in both EP2 and EP4 KO mice (Akhter et al., 2001, 2006). Reduced bone mass and impaired fracture healing were found in aged EP4 receptor KO mice compared with WT mice (Li et al., 2005). However, we did not find any differences in bone formation between aged WT and EP4 KO mice (Gao et al., 2009b). EP4 KO mice are difficult to breed in a pure C57Bl/6 background because neonates die shortly after birth due to patent ductus arteriosus (Segi et al., 1998). To combat this problem, mice for the two latter studies were bred in multiple mixed backgrounds. Hence, the difference in EP4 KO phenotypes might be due to variability in backgrounds.

The EP1 receptor may be a negative regulator of bone formation. EP1 KO mice have been shown to have enhanced fracture healing, stronger cortical bones, higher trabecular bone volume, increased bone formation, and accelerated osteoblastic differentiation compared with WT mice (Zhang et al., 2011, 2015a). The effects of EP1 deletion on osteoblastic differentiation may occur via regulation of energy metabolism (Feigenson et al., 2017).

Prostaglandin E_2 and bone resorption

Early work on the effects of PGs in organ culture showed that exogenous PGs of the E series were potent activators of resorption (Klein and Raisz, 1970). PGE_1 and PGE_2 were shown to stimulate osteoclast formation in marrow cultures (Collins and Chambers, 1991). Subsequently, multiple resorption agonists were shown to stimulate PG-dependent osteoclast formation in marrow cultures including cytokines IL-1 (Akatsu et al., 1991; Lader and Flanagan, 1998; Sato et al., 1996), IL-6 (Tai et al., 1997), IL-11 (Girasole et al., 1994; Morinaga et al., 1998), IL-17 (Kotake et al., 1999), and TNF-α (Lader and Flanagan, 1998); hormones PTH (Inoue et al., 1995; Okada et al., 2000a; Sato et al., 1997) and $1,25(OH)_2D_3$ (Collins and Chambers, 1992; Okada et al., 2000a); and growth factors FGF-2 (Hurley et al., 1998) and BMP-2 at high doses (Chikazu et al., 2005). TGFβ enhanced osteoclastogenesis at low concentrations by a PG-dependent mechanism but inhibited osteoclastogenesis at higher concentrations (Shinar and Rodan, 1990).

The major role for PGE_2 in increasing bone resorption is thought to be indirect via the upregulation of receptor activator of NFκB ligand (RANKL) expression and the inhibition of osteoprotegerin expression in osteoblastic lineage cells (Li et al., 2000; Suda et al., 2004; Suzawa et al., 2000; Tsukii et al., 1998). In models used to study the direct effects of PGE_2 on hematopoietic lineage cells, in which RANKL must be added to stimulate osteoclast formation, the results have been contradictory. For example, exogenous PGE_2 increased RANKL-stimulated osteoclast differentiation in RAW264.7 cells (Kobayashi et al., 2005) and inhibited RANKL-stimulated differentiation in cultured human peripheral blood mononuclear cells (Take et al., 2005). In spleen cells, exogenous PGE_2 had biphasic effects on RANKL-stimulated osteoclast formation, with an initial inhibitory effect and a later stimulatory effect (Ono et al., 2005). COX-2 is also expressed in cells of the hematopoietic lineage (Hackett et al., 2006; North et al., 2007). In bone marrow macrophages cultured with M-CSF, we see the RANKL induction of COX-2/PGE_2 within minutes after addition, but we have been unable to demonstrate any consistent regulation by COX-2 of osteoclast differentiation in these cultures (data not shown). Some inconsistencies between studies may be due to different timing of measurements. The peak in osteoclast number in these culture models generally occurs rapidly and transiently over 24 h. If only a single time point is measured, the results can be misleading if potential shifting of the peak with regard to time is not recognized (Blackwell et al., 2010).

As a further complication, early studies found that PGE_2 added to isolated osteoclasts in vitro transiently inhibited bone resorption (Fuller and Chambers, 1989). A similar transient inhibition of bone resorption in mouse calvarial bone was observed (Lerner et al., 1987). The transient decrease in serum calcium that occurred after systemic injection of IL-1 in mice was PG-mediated and might be related to this early inhibitory effect of PGE_2 (Boyce et al., 1989b).

The effects of PGs in vivo often fail to be predicted by in vitro studies. For example, in vivo injection of IL-1 above the calvaria in mice for 3 days was shown to stimulate PG-independent resorption when mice were sacrificed 24 h after the last injection. However, resorption continued for 3−4 weeks after the IL-1 injections were stopped, and this resorption was PG-dependent (Boyce et al., 1989a).

Prostaglandin E_2 receptors and bone resorption

Studies in bone marrow cultures and cocultures of osteoblasts and spleen cells have shown PGE_2-stimulated osteoclast formation to be impaired when cells from either EP2 or EP4 KO animals are used (Li et al., 2000; Sakuma et al., 2000). A selective antagonist for EP4 partially inhibited osteoclastogenesis in murine marrow cultures not only in response to PGE_2 but also in response to $1,25(OH)_2D_3$ and PTH (Tomita et al., 2002), confirming earlier results using selective EP agonists and antagonists (Ono et al., 1998). However, administration of an EP4 selective agonist to rats subjected to protocols causing bone loss, such as immobilization, did not increase osteoclasts relative to control animals (Yoshida et al., 2002). Neonatal murine calvarial cultures express all PGE_2 receptor subtypes, but PGE_2-stimulated resorption is largely mediated via EP4 with only a minor contribution from EP2 (Suzawa et al., 2000). There was a marked decrease in resorptive response to PGE_2 in cultured calvariae from EP4 KO animals and an impaired response to PGE_2 even in calvariae from mice with only one EP4 allele disrupted (Miyaura et al., 2000; Zhan et al., 2005). In fetal rat long bone cultures treated with agonists selective for EP2 and EP4, only the EP4 agonist was effective in stimulating resorption (Raisz and Woodiel, 2003). Interestingly, aged EP4 KO mice are reported to have significantly increased osteoclast numbers on trabecular surfaces and increased eroded surface on the endocortical surface compared with WT mice (Li et al., 2005).

Thus, the majority of data indicates that EP4 is the more important EP receptor for resorption. It is not clear, however, how the results of PGE_2 experiments in vitro translate to the endogenous effects of PGE_2 in vivo, or why EP4 should be the major receptor involved, when both EP2 and EP4 have so much potential overlap in signaling. It would be helpful to compare resorption in EP2 and EP4 receptor KO mice in response to exogenous PGE_2 and in response to agonists that induce PGE_2, such as PTH and IL-1.

Inducible cyclooxygenase knockout mice

Basal skeletal phenotype

Initial studies by the investigators who generated mice with disruption of COX-1 or COX-2 showed that COX-2 deficiency had more profound effects than deficiency of COX-1 (Dinchuk et al., 1995; Langenbach et al., 1995, 1999; Morham et al., 1995). COX-1 KO mice were healthy, survived normally, and have subsequently been little studied. COX-2 KO mice, on the other hand, had increased mortality. One study reported that 35% of COX-2 KO mice died with a patent ductus arteriosus within 48 h of birth (Loftin et al., 2001). Other studies found shortened life span in COX-2 KO mice secondary to renal dysplasia (Morham et al., 1995). Renal development in COX-2 KO mice appeared normal until postnatal day 10, after which there was progressive renal architectural disruption and functional deterioration, with about 20% of COX-2 KO mice dying from renal failure between 7 and 23 weeks of age (Norwood et al., 2000). COX-2-deficient females were infertile, with multiple failures in female reproductive processes, including ovulation, fertilization, and implantation (Lim et al., 1997). Mice for these initial studies were in a C57Bl/6129 genetic background.

A study of 4.5-month-old female in the C57Bl/6129 background found reduced femoral BMD by DXA, reduced cortical thickness, and reduced mechanical properties, but increased distal femoral trabecular bone volume, in COX-2 KO mice compared with WT (Alam et al., 2005). In this same study, only 60% of KO mice survived to weaning, and 28% died after weaning before they could be studied. In contrast, in another study of 4-month-old mice, COX-2 KO females were normal, but males had decreased femoral trabecular bone volume fraction and cortical bone mineral density compared with WT mice (Robertson et al., 2006).

We found that COX-2 KO mice in the C57Bl/6129 background died four times faster after weaning than was the case for WT mice, with about 40% dying between 2 and 10 months of age, while mice heterozygous for COX-2 gene disruption had normal mortality (Xu et al., 2005). In a cohort of 10-month-old WT and COX-2 KO mice with normal serum creatinine, KO mice had significantly increased levels of PTH (114% in females, 150% in males) and $1,25(OH)_2D_3$ (180% for both genders) compared with WT mice, suggesting that older, apparently healthy COX-2 KO mice might have primary hyperparathyroidism (HPTH). The skeletal phenotype of the COX-2 male and female mice was very difficult to interpret in any consistent manner and was attributed in part to HPTH.

Improved survival was seen in COX-2 KO mice in the DBA1 or DBA1,C57Bl/6 background (Chen et al., 2003; Myers et al., 2006). The bones from COX-2 KO mice in these studies also had inferior mechanical properties compared with those of WT mice. Elevated PTH levels were also found in apparently healthy 3-month-old female COX-2 KO mice in a DBA1 background (Myers et al., 2006).

As discussed above, C57Bl/6 and 129Sv mice are naturally missing the gene for GIIA $sPLA_2$ (Kennedy et al., 1995). It is possible that the absence of type GIIA secretory PLA_2 in mice with C57Bl/6 and 129 genetic backgrounds might result in a more severe phenotype in the absence of COX-2 (Kennedy et al., 1995). We crossed C57Bl/6129 COX-2 KO mice into an outbred CD-1 background. In this background, COX-2 KO mice had no increased mortality after weaning and no renal dysfunction (Xu et al., 2010). In addition, CD-1 COX-2 KO females were fertile, as also observed by others (Wang et al., 2004). The generation of healthy and fertile COX-2 KO mice has made it possible for us to do multiple studies with these mice. Despite being healthy, 5-month-old male COX-2 KO mice in the CD-1 background also had twofold elevated PTH compared with that of WT mice. COX-2 KO mice had increased serum markers of bone turnover, decreased femoral BMD and cortical bone thickness, but no differences in trabecular bone volume by μCT or dynamic histomorphometry. We concluded that this bone phenotype could be due to HPTH, COX-2 deficiency, or both.

Several studies that compared COX-1 mRNA expression in WT and COX-2 KO mice have suggested that COX-1 mRNA was elevated in COX-2-deficient mice (Alam et al., 2005; Wang et al., 2004; Zhang et al., 2002a). However, we have never found increased COX-1 mRNA expression in freshly isolated bone or cultured osteoblastic cells from COX-2 KO mice in the C56Bl/6129 or CD-1 background under basal or stimulated conditions (Pilbeam, unpublished observations). It is possible that other aspects of the PG production pathway may be upregulated in COX-2 KO mice.

Inducible cyclooxygenase modulation of the effects of parathyroid hormone

Inducible cyclooxygenase knockout mice and parathyroid hormone

PTH induces COX-2 in bone rapidly and transiently (Xu et al., 2010). We examined the effects of intermittent PTH for 3 weeks on skeletal responses in WT and COX-2 KO mice (Xu et al., 2010). PTH increased serum markers of bone formation and resorption more in KO than in WT mice, but there was no significant effect of genotype on resorption. We were surprised to find that intermittent PTH increased femoral BMD and cortical bone area more in KO mice than in WT

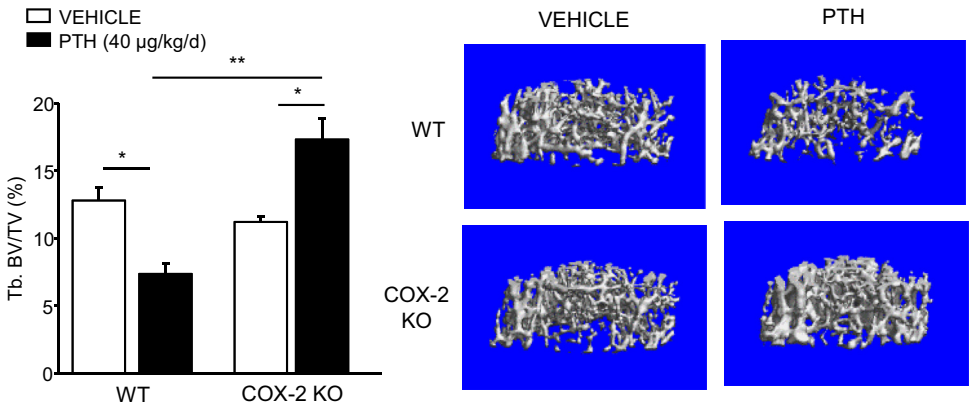

FIGURE 51.4 Continuous PTH infusion caused trabecular bone loss in WT mice but increased trabecular bone in COX-2 KO mice (Choudhary and Pilbeam, unpublished data). Three-month-old WT and COX-2 KO male mice were infused with vehicle or PTH (hPTH 1−34, 40 µg/kg/day) for 12 days using ALZET microosmotic pumps. Left panel: Trabecular bone volume fraction (Tb. BV/TV) in the distal femur as determined by micro-CT. Right panel: representative trabecular bone images. Bars are means ± SEM for $n = 3$ mice per genotype and treatment group. Data were analyzed by two-way ANOVA and post hoc Bonferroni pairwise multiple comparisons. $^{*}P < .05$, $^{**}P < .01$.

mice and that there was a trend for the PTH-stimulated increase in trabecular bone to be greater in KO mice than in WT mice. The ratio of osteoblastic surface to osteoclastic surface was increased only in KO mice. In addition, PTH increased the femoral mineral apposition rates and bone formation rates more in KO mice than it did in WT mice.

We subsequently infused WT and COX-2 KO mice with vehicle and continuous PTH, which generally results in bone loss (Choudhary et al., 2015). Continuous PTH infusion increased COX-2 expression continuously. As seen previously, continuous PTH infusion was catabolic in WT mice. In COX-2 KO mice, however, PTH infusion was anabolic, increasing trabecular bone mass and bone formation. An example of the anabolic effects of continuous PTH infusion in COX-2 KO mice is shown in Fig. 51.4. In contrast to the inhibitory effects of COX-2 expression on PTH-stimulated bone formation, PTH-stimulated bone resorption was the same in both WT and COX-2 KO mice. These data suggested that the bone loss associated with continuously infused PTH was due largely to suppression of bone formation and that this suppression was mediated by COX-2.

An inducible cyclooxygenase–dependent inhibitor of the anabolic effects of continuous parathyroid hormone

Because COX-2 inhibited the anabolic effects of PTH in vivo, we examined its modulation of PTH effects in bone marrow stromal cell cultures (Choudhary et al., 2013). It had been known for a long time that it was difficult to find an in vitro model for the anabolic effects of PTH seen in vivo. Likewise, we found that continuous PTH (added at each media change) inhibited or had no effect on osteoblastic differentiation in WT cultures. However, in COX-2 KO cultures, PTH dramatically and consistently stimulated osteoblastic differentiation. The COX-2-dependent inhibition of the osteogenic effects of PTH were shown to be due to a secreted factor. This factor was secreted by hematopoietic lineage cells in the cultures in response to a combination of RANKL from osteoblastic lineage cells and PGE_2 produced by osteoblastic or hematopoietic lineage cells acting via the EP4 receptor (Choudhary et al., 2013).

We identified the COX-2-dependent secreted inhibitor in vitro as serum amyloid A3 (Choudhary et al., 2016). Serum amyloid A (SAA) is a family of four highly conserved apolipoproteins, some of which can increase 1000-fold in the circulation during episodes of inflammation (De Buck et al., 2016; Sun and Ye, 2016; Uhlar and Whitehead, 1999; Ye and Sun, 2015). Serum amyloid A3 (SAA3) is the major inducible SAA in mice. We also showed that SAA3 was secreted by the preosteoclast population of myeloid cells in response to RANKL (as long as COX-2-produced PGE_2 was present) and inhibited PTH-stimulated cAMP signaling in osteoblastic cells by stimulating Gαi signaling, likely via formyl peptide receptor 2 (Choudhary et al., 2016). Recently, we examined the effects of continuous PTH infusion in SAA3 KO mice, which have a normal COX-2 response to PTH, and confirmed the role of SAA3 in mediating COX-2 suppression of the anabolic effects of continuous PTH infusion on trabecular bone (Choudhary et al., 2018). This study also confirmed that SAA3 had no effect on resorption stimulated by continuous PTH. Thus, COX-2-dependent SAA3 appears to suppress the

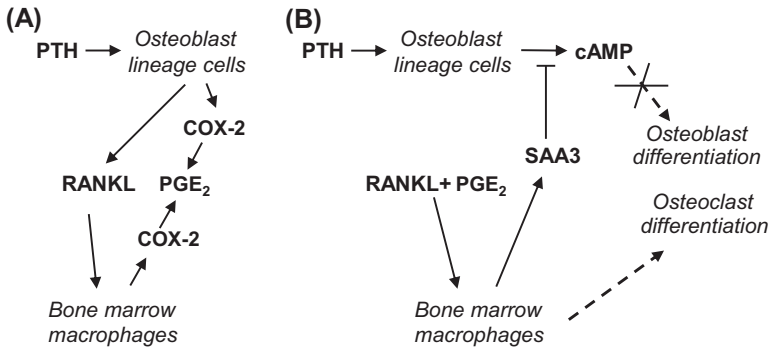

FIGURE 51.5 Role of SAA3 in blocking the osteoblastic response to continuous PTH. Panel (A): PTH induces RANKL and COX-2/PGE_2 in osteoblastic lineage cells. RANKL also induces COX-2/PGE_2 in bone marrow macrophages (BMMs). Panel (B): RANKL initiates the differentiation of BMMs to become osteoclasts at the same time that RANKL in combination with PGE_2 induces the expression of SAA3 in BMMs. SAA3 is secreted and acts on osteoblastic lineage cells to block the PTH stimulation of cAMP production and subsequently PTH stimulation of osteoblast differentiation.

anabolic effects of continuous PTH by inhibiting PTH-stimulated cAMP but has no effect on the resorption stimulated by continuous PTH. A summary of the proposed production and actions of SAA3 in response to PTH is shown in Fig. 51.5.

Prostaglandin E_2 and bone physiology

As discussed above, PGE_2, similar to PTH, can regulate both bone resorption and formation in experimental models. Whether either role is important in bone physiology has been difficult to determine. Here we discuss some proposed roles for PGE_2 in bone physiology.

Mechanical loading of bone

Bone is a dynamic tissue that adapts to mechanical loading with changes in structure to achieve a better balance between stresses and load-bearing capacity.

Early studies showed that mechanical loading of bone cells increased PG production and that inhibition of PG production by NSAIDs could inhibit new bone formation in response to applied loading in vivo (Cheng et al., 1997; Chow and Chambers, 1994; Lanyon, 1992; Li et al., 2006; Pead and Lanyon, 1989; Rawlinson et al., 1991). Orthodontic tooth movement was also shown to stimulate PG production, and it was proposed that PGs enhanced the orthodontic movement of teeth as a result of PG-stimulated bone resorption (Giunta et al., 1995; Kehoe et al., 1996; Sandy et al., 1993).

Osteocytes are thought to be the major strain-sensing cells in bone and coupled to mechanical loading at least in part via interstitial fluid flow in the lacunar–canalicular network in bone, where large stresses on cells can be generated by fluid flow in narrow channels (Burger and Klein-Nulend, 1999; Han et al., 2004; Hillsley and Frangos, 1994; Knothe et al., 1998; Srinivasan and Gross, 2000; Turner et al., 1994; Weinbaum et al., 1994). In vitro studies examining the effects of FSS on osteoblastic cells showed rapid induction of COX-2 mRNA and PG production (Klein-Nulend et al., 1997; Norvell et al., 2004; Pavalko et al., 1998; Wadhwa et al., 2002b). FSS-induced PGE_2 may also mediate intracellular osteocyte communication through gap junctions via the prostaglandin EP2 receptor (Cherian et al., 2003). A role for COX-2-produced PGE_2 in triggering the anabolic Wnt/β-catenin signaling pathway in osteocytes in response to loading has also been proposed (Bonewald and Johnson, 2008; Kitase et al., 2010). PGE_2 is known to inhibit sclerostin, a Wnt antagonist (Genetos et al., 2011), and several studies suggest that this is one way that PGE_2 increases Wnt signaling and bone formation in response to mechanical loading (Galea et al., 2011, 2017; Lara-Castillo et al., 2015; Tu et al., 2012).

However, a study examining ulnar loading in COX-2 WT and KO mice reported that a functional *Ptgs2* gene was not required for anabolic response in the periosteum to loading, suggesting that COX-1 might compensate for absent COX-2 (Alam et al., 2005). It is also possible that HPTH reported in COX-2 KO mice, discussed previously, may have compensated in part for COX-2 deficiency. However, in a more recent study of female mice, NS-398 did not reduce trabecular or cortical bone response to repeated loading (Sugiyama et al., 2013). Until an in vivo loading experiment elucidates a clear role for COX-2/PG in mediating bone formation response to loading, it seems prudent to conclude that COX-2/PG is one of many early responses to strain, all of which interact to regulate the adaptation of bone to loading (Price et al., 2011).

Fracture and wound healing

In the early years following the development of COX-2-selective NSAIDs, many studies in animals suggested that NSAIDs could impair fracture healing, although results were variable (Altman et al., 1995; Bergenstock et al., 2005; Brown et al., 2004; Einhorn, 2003; Endo et al., 2005; Murnaghan et al., 2006; Simon and O'Connor, 2007). Other studies indicated that NSAID impairment of fracture healing was dose- and duration-dependent, and reversible after discontinuation of brief treatment (Gerstenfeld et al., 2007). Mice with absent COX-2 were also shown to have impaired fracture healing and allograft incorporation (O'Keefe et al., 2006; Xie et al., 2009; Zhang et al., 2002b). Several reviews of animal studies concluded that the loss of COX-2 activity primarily affected fracture healing via callus chondrogenesis or endochondral ossification (Geusens et al., 2013; O'Connor et al., 2014), and a recent study in rabbits showed that a selective COX-2 inhibitor (celecoxib) impaired the chondrogenic phase of endochondral ossification (Janssen et al., 2017).

A number of reviews of human data have concluded that there is no compelling evidence that short-term use of NSAIDs impairs fracture healing (Kurmis et al., 2012; Marquez-Lara et al., 2016; Pountos et al., 2012), cruciate ligament repair (Soreide et al., 2016), or spinal fusion surgery (Sivaganesan et al., 2017). In contrast, 6 weeks of indomethacin was reported to increase the risk of nonunion after acetabular fracture surgery (Sagi et al., 2014), and chronic use of NSAIDs was found to increase the risk of a second hip fracture after hip fracture surgery (Huang et al., 2015). Hence, the consensus at this time would be to use NSAIDs cautiously in situations of bone repair, at a low dose and for a short duration.

Agonists of EP2 and EP4 can increase healing in animals. Local application of an EP2 agonist and local and systemic application of EP4 agonists have been shown to accelerate bone repair (Li et al., 2003; Paralkar et al., 2003; Tanaka et al., 2004; Yoshida et al., 2002). Clinical studies have not been done with these agonists, perhaps because increased PG can have adverse effects, and their pharmacological relevance in enhancing human bone repair is still unknown (Markovic et al., 2017).

PGs may also be important for wound healing in unmineralized tissues. The first step in the degradation of PGE_2 is mediated by the enzyme 15-dehydroxyprostaglandin dehydrogenase (15-PGDH), which generates 15-keto-PGE_2, and this intermediate metabolite is further catabolized to 13,14-dihydro-15-keto-PGE_2 by 15-oxoprostaglandin-Δ^{13}-reductase (Tai et al., 2006). These metabolites are orders of magnitude less potent at the EP2 and EP4 receptors than PGE_2 itself (Nishigaki et al., 1996). Inhibition of 15-PGDH increases PGE_2, potentiating recovery in mouse models of marrow transplant and accelerating tissue generation in mouse models of colon and liver injury (Antczak et al., 2017; Desai et al., 2018; Zhang et al., 2015b). Although the known associations of elevated PGE_2 with increased inflammation and tumorigenesis might be thought to limit the usefulness of inhibiting 15-PGDH, initial studies suggest that a small molecule inhibitor can promote transplant recovery without any limiting side effects in animal models (Desai et al., 2018).

Skeletal response to nonsteroidal antiinflammatory drugs

Several studies in older men and women with regular NSAID use suggested some increase in BMD but found no increase in markers of bone formation (Carbone et al., 2003; Cauley et al., 2005; Bauer et al., 1996; Lane et al., 1997). Selective COX-2 inhibitors may affect BMD differently in men and women. In a study of men and women age 65 and older, daily COX-2 inhibitor use in men was associated with 2.4%−5.3% lower hip and spine BMD compared with those of nonusers (Richards et al., 2006). In postmenopausal women not on estrogen replacement therapy, it was associated with 0.9%−5.7% higher BMD. COX-2 inhibitor had no effect in women on estrogen replacement. The authors speculated that the beneficial effects of mechanical loading might be reduced by COX-2 inhibition in men, while the proinflammatory state and increased bone turnover associated with estrogen withdrawal might be suppressed by COX-2 inhibition in postmenopausal women. A recent review of the literature on controlled randomized clinical trials with bone remodeling outcomes concluded that there was some evidence of increased BMD, no evidence for increased bone formation, and some evidence of a decreased resorption rate in NSAID users (Konstantinidis et al., 2013). However, the data were too limited for firm conclusions.

Observational studies of the effect of NSAIDs on bone mass may be misleading because the regular use of NSAIDs is likely to be associated with other characteristics that can affect bone, such as a decreased level of physical activity or the presence of inflammatory conditions. There is also considerable variability at an individual level in the degree of COX-2 inhibition and the selectivity attained by selective COX-2 inhibitors (Fries et al., 2006). Approximately one-third of the variability was attributable to differences between individuals, suggesting the contribution of genetic sources of variance.

A driving factor in producing selective COX-2 NSAIDs was to prevent gastric bleeding, but the adverse cardiovascular side effects of selective NSAIDs have become the current limiting factor. It is a very complex problem, complicated by the variable response to NSAIDs, the interference of selective NSAIDs with the beneficial effect of aspirin (mainly an inhibitor

of COX-1), and an unclear risk−benefit for treating pain (Grosser et al., 2017a, 2017b; Li et al., 2014; Ricciotti et al., 2013). However, given the need to treat inflammation and musculoskeletal pain and the emerging interest in the role of COX-2/PGs in cancer, it is likely that NSAIDs will continue to be widely used.

Summary

PGs are abundant in bone and are potent regulators of bone cell function. Cells of both osteoblastic and osteoclastic lineage produce PGs, and this production is highly regulated by local and systemic factors. Stimulated production of PGs requires the availability of arachidonic acid substrate, the induction of COX-2 expression, and the presence of terminal synthases. PGE_2, which may be the most important local eicosanoid in skeletal regulation, can stimulate both bone resorption and formation. In vitro, PGE_2 can stimulate the differentiation of osteoblast differentiation, and indirectly via the stimulation of RANKL in osteoblastic cells, the differentiation of osteoclasts. The net balance of these two effects under physiologic and pathologic conditions in vivo is not yet clear. Some of the complexity of PG actions on bone can be explained by the multiplicity of receptors for PGs. There are at least four distinct receptors for PGE_2 with differential signaling pathways that have not yet been fully elucidated. Further studies are needed to clarify the specific pathways of PG actions in bone. Once this is accomplished, it may be possible to identify therapeutic applications of manipulating PGs in skeletal disorders.

Acknowledgments

This effort was supported by a National Institute of Health Grants NIAMS award AR060286 (CP). We dedicate the chapter to Larry Raisz, who loved prostaglandins and who was an editor of this book as well as an author of this chapter for the first three editions and whose words still linger on in this one.

Chapter 52

The molecular actions of parathyroid hormone/parathyroid hormone–related protein receptor type 1 and their implications

Michael Mannstadt and Marc N. Wein

Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States

Chapter outline

Introduction

The primary effects of parathyroid hormone (PTH) are to regulate calcium and phosphate homeostasis through signaling in kidney and bone. The parathyroid hormone–related protein (PTHrP) exerts multiple roles during bone, skin, and breast development. PTH and PTHrP trigger downstream signaling in cells through a common shared G-protein-coupled receptor, PTH/PTHrP receptor type 1 (PTH1R) (Gardella and Juppner, 2000). Beyond the crucial roles of PTH and PTHrP in mineral ion homeostasis and development, both hormones play central roles in diseases including osteoporosis, chronic kidney disease, bone metastases, and cancer-related hypercalcemia and cachexia. The PTH/PTHrP analogs teriparatide and abaloparatide are the only FDA-approved osteoporosis medications that stimulate new bone formation (Rubin and Bilizekian, 2003).

Given the immense importance of this signaling system in physiology and disease, it is not surprising that considerable progress has been made in understanding the molecular events immediately downstream of PTH1R signaling (Cheloha et al., 2015). Here we will review recent progress in our understanding of these signaling events. With this information in hand, we will discuss illustrative mechanisms used by PTH/PTHrP to influence the behavior of target cells in kidney and

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00052-X

bone in vivo. Notably, the vast majority of our current knowledge in this area derives from studies in which cells or mice have been treated with high doses of N-terminal PTH or PTHrP peptide fragments. These studies have been extremely important in defining the pharmacologic actions of these hormones. However, phenomena ascribed to pharmacologic PTH/PTHrP treatment may not perfectly reflect the normal physiology of this signaling system. Individuals with hypoparathyroidism reflect an ideal opportunity to define the physiologic actions of parathyroid hormone. Whenever possible, we will highlight potential differences between pharmacologic and physiologic actions of PTH1R in the mechanisms described below.

Parathyroid hormone/parathyroid hormone−related protein receptor type 1 and its ligands

PTH1R is a glucagon-like family B G-protein-coupled receptor (GPCR) (Juppner et al., 1991). Family B GPCR members bind over a dozen different peptide hormones including secretin, glucagon, calcitonin, and growth hormone-releasing hormone (Hollenstein et al., 2014). Among GPCRs, PTH1R is unique, as it transmits extracellular stimuli from two distinct naturally occurring peptide ligands, PTH and PTHrP (Vilardaga et al., 2011). These two ligands have very different physiologic functions. PTH, secreted by the parathyroid glands, is a circulating hormone that acts on target cells in bone and kidney to regulate levels of calcium and phosphate in the blood and enhance bone remodeling, as evidenced by slow bone turnover in individuals with hypoparathyroidism (Potts, 2005). PTHrP, in contrast, is produced in many tissues, acts locally, and has broad roles in cell differentiation and proliferation—for example, in skin cells, breast cells, and the differentiation of chondrocytes in the growth plate (Wysolmerski, 2012).

How does the same receptor carry out the diverse functions of two distinct ligands? The difference in tissue distribution and local concentration of ligand could be major determinants, but another intriguing possibility is that the two ligands activate different intracellular responses from PTH1R. The concept of biased signaling through GPCRs appeals to researchers because ligands that elicit different signaling pathways for a given receptor could be a powerful tool in drug development (Smith et al., 2018).

Indeed, the development of novel PTH1R agonists may be informed by an understanding of the so-called temporal bias, a particular kind of biased signaling of PTH and PTHrP on PTH1R. Intermittent administration of PTH leads to a net increase in bone mass, while persistent exposure to PTH, as in primary hyperparathyroidism, leads to a net bone loss. Work over many years by different laboratories has uncovered mechanisms responsible for the temporal bias of PTH1R activation. Short-acting agonists, such as PTHrP, prefer to bind to the G-protein-bound (R^G) conformation of PTH1R and signal as ligand−receptor complexes from the cell surface; long-acting agonists, such as PTH, show stronger binding to the G-protein-unbound (R^0) state of the receptor (Dean et al., 2006; Ferrandon et al., 2008). These R^0-agonist complexes are internalized but appear to continue to signal from endosomes (Ferrandon et al., 2009). This concept of temporal bias (differences in response duration) has immediate applications for drug development. Short-acting R^G analogs (such as PTHrP) may be ideal candidates for osteoporosis drugs, while long-acting R^0 analogs (such as PTH) are predicted to be better suited for the treatment of hypoparathyroidism (Cheloha et al., 2015). Indeed, the osteoporosis drug abaloparatide is an R^G analog, and long-acting PTH, a drug undergoing evaluation as a treatment for hypoparathyroidism, is an R^0 analog (Hattersley et al., 2016). Nonetheless, here it is important to highlight that differences in R^0- versus R^G-based receptor engagement have yet to be determined in vivo. Therefore, the cellular consequences of these proposed differences in pharmacologic effects of PTH versus abaloparatide remain to be determined.

Native PTH comprises 84 amino acids, and PTHrP has isoforms of 139, 141, and 173 amino acids (Potts, 2005; Wysolmerski, 2012). PTH and PTHrP share high homologies in the amino-terminus; 8 of the first 13 amino acids are identical. The short synthetic amino-terminal peptides PTH(1−34) and PTHrP(1−36) are both fully functional for binding to and activation of PTH1R and have been used for the majority of in vitro experiments to decipher the molecular actions of the receptor (Cheloha et al., 2015). Multiple carboxy-terminal fragments of PTH are present in circulation in humans; in sum, these are more abundant than circulating intact PTH (D'Amour, 2012). It is not known whether these fragments are merely inert degradation products of the intact molecule or if they have specific functions. Although carboxy-terminal fragments of PTH do not activate PTH1R, binding assays using PTH1R knockout cells in culture showed that carboxy-terminal fragments do bind to cells (Divieti et al., 2001; Murray et al., 2005). These observations provide evidence for a specific carboxy-terminal PTH receptor. However, very little is known about its potential function. In rat osteosarcoma ROS17/2.8 cells, PTH(53−84) increased alkaline phosphatase activity, while PTH(1−34) and PTH(1−84) inhibited it (Murray et al., 1989; Rao and Muzaffar, 1991). The proposed carboxy-terminal receptor of PTH has yet to be identified.

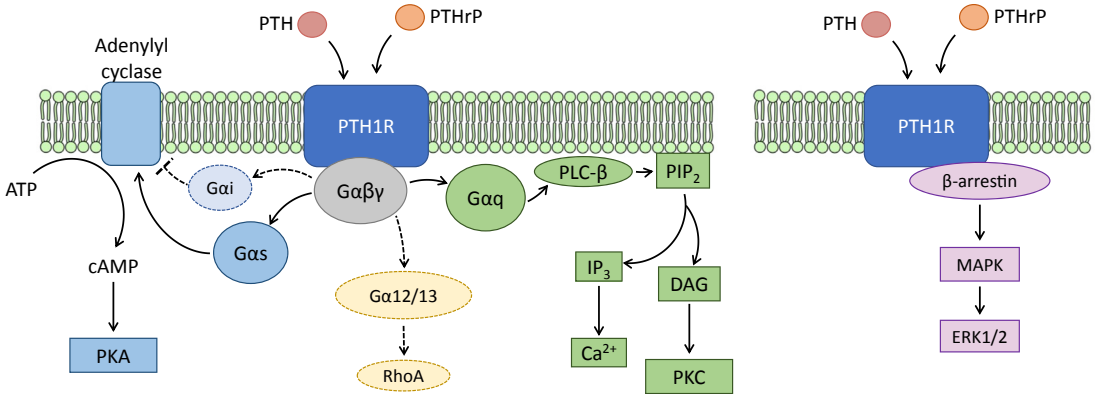

FIGURE 52.1 Overview of known membrane-proximal signaling pathways downstream of the PTH/PTHrP receptor (PTH1R). On activation by PTH or PTHrP, G-protein α subunits exchange GDP for GTP, dissociate from the other G-protein subunits, and regulate activation of downstream enzymes. The Gαs/cAMP/PKA and Gαq/11/PLC/PKC pathways are the principal signaling mechanisms of PTH1R in kidney and bone. β-arrestins play an important role in both G-protein-independent signaling via β-arrestin/MAPK/ERK1/2 and in prolonged signaling from endosomes.

A detailed structure–activity analysis of PTH revealed that the PTH(15–34) fragment contains the major receptor binding domain and that the amino-terminus (PTH(1–14)) comprises the major signaling domain (Cheloha et al., 2015). Activation of PTH1R leads to the activation of two main trimeric G-proteins, Gαs and Gαq/11, which activate the 3′,5′ cyclic AMP (cAMP)/protein kinase A (PKA) and phospholipase C (PLC)/Ca^{2+}/protein kinase C (PKC) pathways, respectively (Cheloha et al., 2015). PTH1R also signals through other G-proteins and G-protein-independent pathways (summarized in Fig. 52.1). These pathways are discussed in more detail in the sections that follow.

Gαs/adenylyl cyclase/protein kinase A signaling

The primary signaling pathway of PTH1R is through the G-protein Gαs (Juppner et al., 1991). Ligand-bound PTH1R couples to and activates Gαs, leading to the activation of adenylyl cyclase (AC), which catalyzes the conversion of adenosine triphosphate (ATP) to cAMP. A classic second messenger, cAMP regulates a wide range of biologic functions. During PTH/PTHrP signaling, it activates PKA by binding to and triggering dissociation of its regulatory subunits (Sassone-Corsi, 2012). Once activated, PKA can phosphorylate other kinases to yield diverse effects. For example, PKA-driven phosphorylation inhibits glycogen synthase kinase 3 β and enhances Wnt signaling in bone (Fang et al., 2000; Kulkarni et al., 2005). Recent studies have revealed that PKA-dependent inactivation of salt-inducible kinases (SIKs) drives expression of genes related to bone turnover in response to PTH (Wein et al., 2016). PKA also activates the transcription factor cAMP-response element-binding protein (CREB), which regulates the expression of other genes necessary for PTH1R-driven cellular processes (Bastepe et al., 2017).

Gαs-cAMP-PKA signaling is activated by the amino terminal residues of PTH or PTHrP. The first nine amino acids are sufficient for cAMP activation; this minimum peptide length was identified using a recombinant tethered ligand-receptor approach in which PTH was tethered to the amino-terminus of PTH1R (Carter and Gardella, 2000). Fragments that lack the amino-terminal residues, such as PTH(3–34), PTH(7–34), and PTHrP(7–36), bind to PTH1R but do not elicit a significant cAMP response.

Ligands designed to be PKA-selective, such as Trp1-M-PTH(1–28) (see later), retain their ability to acutely downregulate expression of the sodium-dependent phosphate cotransporter 2a (Npt2a) in OK cells, indicating that the Gαs pathway is involved in Npt2a regulation (Nagai et al., 2011). PKA-selective analogs have also been shown to mediate the bone anabolic effects of PTH (Yang et al., 2007). Expression of a mutant form of PTH1R, called DSEL, that lacks Gq/11/PLC signaling has been shown to slow the growth and differentiation of hypertrophic chondrocytes in mice (Guo et al., 2002, 2010).

In addition, the critical importance of the Gαs-associated signaling pathway for some functions of PTH1R is demonstrated by the rare disease pseudohypoparathyroidism (PHP), a condition of PTH resistance. Genetic or epigenetic inactivating mutations of the maternal allele of GNAS, the gene encoding Gαs, cause classic PHP types 1a and 1b (Bastepe and Juppner, 2005). In certain tissues, including the thyroid gland, gonads, and pituitary gland as well as in cells such as the proximal renal tubule, GNAS is imprinted to express only from the maternal allele. These mutations result in a loss of Gαs function in these tissues and lead to hypocalcemia, hyperphosphatemia, and relatively low levels of 1,25-$(OH)_2$-vitamin D despite the compensatory elevated PTH levels. Therefore, Gαs signaling is necessary for the calcemic action of PTH, the phosphaturic effect of PTH, and the conversion of 25-(OH)-vitamin D to 1,25-$(OH)_2$-vitamin D.

Gq/11/phospholipase C/protein kinase C signaling

PTH1R also couples to G-proteins of the Gq/11 class. Gq/11-GTP stimulates the membrane-associated PLCβ, which signals through the inositol phospholipid-signaling pathway (Taylor et al., 1991). PLCβ hydrolyzes phosphatidylinositol-4,5-bisphosphate and releases inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) (Neves et al., 2002). Membrane-bound DAG activates PKC, which in turn phosphorylates substrates such as enzymes that drive diverse cellular responses. Cytoplasmic IP_3 binds to and activates an intracellular receptor on the endoplasmic reticulum to release calcium into the cytoplasm, where it plays a similarly vital role in signaling pathways.

At least two regions in PTH determine PKC signaling. One is the first amino acid, which is serine in PTH and alanine in PTHrP. Deletion of this first amino acid or replacement with a bulkier residue selectively impairs PLC-dependent PKC signaling (Takasu et al., 1999). The modified PTH analogs Gly1-PTH(1−34) and Gly1, Arg19-PTH(1−28), as well as truncated peptide PTH(3−34), were all found to be selectively defective in PLCβ activation. A long-acting PTH analog, M-PTH(1−28), when modified at position 1 to produce Trp1-M-PTH(1−28), is PLC-deficient but retains potent cAMP responses (Nagai et al., 2011; Gesty-Palmer et al., 2006). Similarly, substituting Ala1 in PTHrP(1−36) with Bpa (p-benzoyl-L-phenylalanine) or Trp specifically reduces PLC signaling (Behar et al., 2000). These selectively defective analogs have been useful in differentiating the effects of Gαs versus Gαq/11 signaling of PTH1R. The findings are consistent with a predominant role of Gαs/cAMP/PKA in mediating both the bone anabolic response and the phosphaturic response to PTH (Nagai et al., 2011; Yang et al., 2007).

Unlike Gαs-specific signaling, which is also determined by position 1 of PTH and PTHrP, Gq/11 signaling involves additional residues beyond the first nine; PTH(29−32) can activate PKC in a PLC-independent fashion (Jouishomme et al., 1994; Yang et al., 2006). In this case, other phospholipases are likely involved—for example, phospholipase D, which is active in the distal tubular cells in the kidney and involved in the PTH-mediated renal reabsorption of extracellular calcium (Bastepe et al., 2017).

Coupling to other G-proteins

Gα12/13-phospholipase-transforming protein RhoA pathway

Activation of PTH1R by PTH also leads to the stimulation of Gα12/13 proteins and activation of phospholipase D (PLD) through a RhoA-dependent mechanism in UMR-106 osteoblastic cells (Singh et al., 2005). A role for PLD signaling in PTH1R trafficking was proposed and supported by studies in Chinese hamster ovary cells and rat osteosarcoma 17.28 cells (Garrido et al., 2009).

Gαi/o pathway

PTH1R was also shown to couple to the pertussis-toxin-sensitive inhibitory Gαi/o class of G-proteins (Schwindinger et al., 1998; Tanaka et al., 1995). The physiologic role of PTH1R coupling to Gαi is unclear.

Extracellular signal-related 1/2−mitogen-activated protein kinase pathway

PTH activates the extracellular signal-related 1/2 (ERK1/2)−mitogen-activated protein kinase (MAPK) cascade through PKA and PKC in a G-protein-dependent manner (Verheijen and Defize, 1997; Cole, 1999; Lederer et al., 2000). ERK1/2 can also be activated through a G-protein-independent, β-arrestin-associated second mechanism (Gesty-Palmer et al., 2006). When HEK293 cells that transiently express human PTH1R are treated with PTH(1−34), an early (2−5 min) and rapid activation of ERK1/2 phosphorylation is observed that is prevented by inhibitors of PKA or PKC. In contrast, a sustained ERK1/2 activation (lasting 30−60 min) has been shown to be PKA- and PKC-independent. This long-term activation was shown to be dependent on β-arrestins 1 and 2, as knockdown of β-arrestin 1 or 2 specifically decreases the sustained phase of ERK1/2 activation (Gesty-Palmer et al., 2006). PTH-stimulated ERK1/2 activation has been shown to increase DNA synthesis and proliferation in bone cells (Swarthout et al., 2001).

Like most GPCRs, PTH1R is a target for the intracellular G-protein-coupled receptor kinases (GRKs), which phosphorylate the activated receptor and help terminate signaling (Vilardaga et al., 2001). A cluster of seven serine residues in the proximal carboxy-terminal tail of PTH1R are phosphorylated upon agonist activation (Tawfeek et al., 2002). In the canonical model of the activation cycle of PTH1R, receptor phosphorylation leads to the recruitment of β-arrestins followed by clathrin-based endocytosis and rapid desensitization of the receptor (Ferrari and Bisello, 2001; Bisello et al., 2002; Chauvin et al., 2002; Tawfeek and Abou-Samra, 2004; Rey et al., 2006; Sneddon and Friedman, 2007).

β-arrestins function as adapters for other effector molecules and allow ERK1/2-MAPK signaling (DeWire et al., 2007). These mechanisms have been further explored by using signal-selective PTH ligands. The analog D-Trp^{12}bPTH(7–34), which elicits no or minimal cAMP response, is able to induce ERK1/2 phosphorylation and can therefore be regarded as a biased agonist for the β-arrestin pathway (DeWire et al., 2007; Gesty-Palmer et al., 2009). Mice treated with daily injections of bPTH(7–34) show an increase in bone formation and expansion of the osteoblast pool (Gesty-Palmer et al., 2009). Importantly, mice lacking β-arrestin 2 did not show these bone anabolic effects. In addition, transcriptome analysis and in vitro assays demonstrated effects of the β-arrestin-biased analog on cell cycle regulation, cell survival, and migration (Gesty-Palmer et al., 2013). However, not all studies have been successful in replicating these results (Cupp and Thomsen, 2013; van der Lee et al., 2013). These conflicting studies, which were performed in HEK293 or Chinese hamster ovary cells rather than in mice, indicate a probable role for cellular context in driving PTH1R signaling. Although more work remains to be done to establish the efficacy of biased agonists to drive the β-arrestin/ERK1/2 endosomal pathway, evidence suggests specific beneficial effects in vitro and in vivo and reveals opportunities for drug development (Luttrell et al., 2018).

More recently, a different role of β-arrestin recruitment on activated PTH1R has been elucidated. While β-arrestins are involved in the process that leads to signal termination, they are also necessary components for the prolonged signaling of R^0-biased ligands, which are internalized as a ligand-receptor-β-arrestin complex but continue to signal from within endosomes (Vilardaga et al., 2012). The capacity of β-arrestins to recruit signaling proteins and stimulate MAPK has been suggested as the mechanism by which they contribute to prolonged endosomal signaling (Sorkin and von Zastrow, 2009; Feinstein et al., 2011). While it has long been believed that GPCR/β-arrestin interaction requires GRK-mediated GPCR tail phosphorylation, recently a distinct GRK-independent mechanism of β-arrestin recruitment has been described. In this model, GPCR engagement triggers a conformational change in the receptor itself that then recruits β-arrestin (Eichel et al., 2018).

Sodium/hydrogen exchanger regulatory factors

The carboxy-terminus of PTH1R provides likely docking sites for signaling proteins. One group of potential PTH1R-interacting proteins are the sodium/hydrogen exchanger regulatory factors (NHERFs), which interact with the PTH1R carboxy-terminus via a PDZ domain and influence signaling and targeting of the receptor to the plasma membrane. Specifically, NHERFs 1 and 2 can bind the amino acid sequence ETVM located at the extreme carboxy-terminus of PTH1R (Donowitz et al., 2002; Cole et al., 2003; Sneddon et al., 2003). PTH signaling promotes the phosphorylation of NHERF-1, which triggers dissociation from Npt2a and is therefore instrumental for the phosphaturic effect of PTH in the proximal renal tubule.

Parathyroid hormone actions in kidney

Having reviewed the intracellular signaling mechanisms that can be used by PTH1R, next we will discuss current knowledge of how these mechanisms contribute to the physiologic functions of this receptor's action, focusing on kidney and bone. In the kidney, PTH exerts effects on mineral metabolism in vivo via PTH1R, which is expressed at high levels by epithelial cells in the proximal and distal tubules. In the proximal tubule, PTH signaling leads to two actions with respect to mineral metabolism (Gardella and Juppner, 2000): increased synthesis of 1,25-$(OH)_2$-vitamin D and decreased phosphate reabsorption. In the distal nephron, a key net effect of PTH is to stimulate calcium reabsorption (Rubin and Bilizekian, 2003). These physiologic renal actions of PTH are reviewed elsewhere in this textbook. Here we will review current understanding of the intracellular signaling mechanisms used by PTH to cause these effects.

Control of 1,25-$(OH)_2$-vitamin D synthesis by CYP27B1 expression

The ability of pharmacologically administered PTH to control 1,25-$(OH)_2$-vitamin D synthesis was first described in experimental animals over 4 decades ago. In these seminal studies, parathyroidectomized rats were unable to convert 25-(OH)-vitamin D to 1,25-$(OH)_2$-vitamin D, while treatment with purified parathyroid extract restored 1,25-$(OH)_2$-vitamin D production (Garabedian et al., 1972). Subsequent in vitro studies on cultured proximal tubule cells demonstrated that this activity of PTH requires new RNA synthesis (Korkor et al., 1987). As discussed above, signaling downstream of the PTH1R activates multiple second messenger pathways including the Gαs-linked cAMP/PKA pathway and the Gq/11-linked PLC/PKC pathway (Gensure et al., 2005; Bringhurst et al., 1993). Inhibitor-based studies have suggested that PKC activity participates in PTH-induced 1,25-$(OH)_2$-vitamin D synthesis (Janulis et al., 1992); however, multiple laboratories have described the involvement of a cAMP/PKA pathway in cultured proximal tubule cells (Korkor et al., 1987; Henry, 1985). Experiments using mice expressing a PTH receptor that activates AC but cannot activate PLC/PKC

(Guo et al., 2002) showed that PTH-dependent increases in 1,25-$(OH)_2$-vitamin D levels in vivo do not require PKC signaling (Venter et al., 2001).

CYP27B1 encodes the 1α-hydroxylase responsible for conversion of 25(OH)-vitamin D into 1,25-$(OH)_2$-vitamin D. Cloning of the CYP27B1 gene facilitated analysis of its proximal promoter (Shinki et al., 1997; Takeyama et al., 1997; St-Arnaud et al., 1997). In kidney cell lines, PTH increases the activity of the murine and human Cyp27B1 proximal promoters (Brenza et al., 1998; Murayama et al., 1998). This same promoter region linked to a reporter gene in transgenic mice is activated in vivo by secondary hyperparathyroidism due to vitamin D or dietary calcium deficiencies (Hendrix et al., 2005). While a complete understanding of the transcription factors mediating PTH-dependent CYP27B1 promoter activation is lacking, overexpression and mutagenesis studies have suggested stimulatory roles for NR4A2 (Nurr1, whose expression itself is induced by PTH), Sp1, and NF−Y, and an inhibitory role for C/EBPβ (Zierold et al., 2007; Gao et al., 2002).

More recently, studies have identified key hormone-sensitive CYP27B1 regulatory regions beyond the gene's proximal promoter (Meyer et al., 2017). By examining global patterns of phosphorylated CREB binding in mouse kidney after acute administration of 1,25-$(OH)_2$-vitamin D or PTH, a putative "M1" CYP27B1 enhancer region was identified ∼5 kB upstream of the transcription start site of the CYP27B1 gene. This enhancer is located within an intronic sequence of the adjacent gene METTL1. Specific deletion of this evolutionarily conserved noncoding sequence leads to significant mineral metabolism and skeletal consequences. Specifically, "M1" knockout mice show hypocalcemia, secondary hyperparathyroidism, osteopenia, and increased cortical porosity. These phenotypes are remarkably similar to those observed with the deletion of CYP27B1 itself. Indeed, "M1" knockout mice show reduced basal CYP27B1 renal gene expression. Attesting to the importance of this enhancer element in PTH-regulated CYP27B1 expression, "M1"-deficient mice fail to upregulate renal CYP27B1 expression in response to acute PTH administration in vivo (Meyer et al., 2017). Taken together, this work identifies the M1 enhancer as a key element required for PTH to regulate CYP27B1 expression. Future studies are needed to characterize the transcription factors that activate this CYP27B1 M1 element and to understand how their activity is regulated by PTH signaling in renal proximal tubule cells. Moreover, although extrarenal CYP27B1 expression is well documented (Anderson et al., 2008), we currently do not understand the molecular determinants of tissue-specific expression. It is interesting that the expression of this gene in some tissue types is not regulated by PTH or other cAMP-inducing agents (Young et al., 2004).

Parathyroid hormone-mediated control of proximal tubule phosphate handling

The second distinct physiologic action of PTH in the proximal tubule is to increase urinary phosphate excretion. This action of PTH synergizes with that of fibroblast growth factor-23 (FGF-23), the other known circulating phosphatonin (Bergwitz and Juppner, 2010). Phosphate reabsorption in the proximal tubule is controlled by the number of type II sodium/phosphate cotransporters (Npt2a and Npt2c) found on the apical brush border membrane (Biber et al., 1996). Both PTH and FGF-23 acutely inhibit renal phosphate reabsorption in the proximal tubule by reducing the surface levels and activity of these cotransporters (Pfister et al., 1998). In addition, chronic hyperparathyroidism leads to reductions in Npt2a gene expression (Gattineni and Friedman, 2015).

The signaling pathways from the PTH receptor to Npt2a downregulation have been the subject of intense investigation over the past 20 years (Weinman and Lederer, 2012). A major advance came in 2002 when NHERF-1 was identified as a key regulator of apical membrane Npt2a (Hernando et al., 2002; Shenolikar et al., 2002). Mice lacking NHERF-1 have renal phosphate wasting and ineffective membrane targeting of Npt2a (Shenolikar et al., 2002). Furthermore, mutations in NHERF-1 have been described in humans with low tubular phosphate reabsorption, nephrolithiasis, and bone demineralization (Karim et al., 2008).

Proximal tubule cells from mice lacking NHERF-1 show resistance to the inhibitory effects of PTH on phosphate transport (Cunningham et al., 2006). While Npt2a itself is not directly regulated by PTH, NHERF-1 is phosphorylated at serine 77 downstream of PTH receptor signaling in a PKA-dependent manner. Phosphorylation at this site decreases NHERF-1/Npt2a interaction and leads to Npt2a internalization (Weinman et al., 2007). NHERF-1 and NHERF-2 constitutively bind to the PTH receptor and may dictate downstream coupling to a PKA versus PKC pathway (Donowitz et al., 2002). More recently, the cytoskeleton-associated protein ezrin has been implicated in dynamic regulation of NHERF-1/Npt2a interactions by PTH (Wang et al., 2012; Guo et al., 2012).

The relative contribution to PTH-mediated PKA versus PKC activation with respect to Npt2a-mediated phosphate reabsorption has been tested in vivo using two complementary experimental systems. First, PTH analogs defective in PKC activation were competent to cause acute phosphaturia (Nagai et al., 2011). Second, phosphaturic responses to PTH were investigated in mice expressing PTH receptors that cannot activate PKC. Interestingly, while acute hypophosphatemia due to PTH infusion was comparable in control and PTH receptor mutant mice, prolonged hypophosphatemia required PTH

receptors that can activate PKC (Venter et al., 2001). Future studies will be required to completely delineate the mechanism whereby PKC signaling stimulated by PTH1R is required for prolonged (but not acute) PTH-mediated phosphaturia. In addition, an area ripe for future investigation is the interplay between the effects of PTH and FGF-23 on phosphate handling in the proximal tubule (Sneddon et al., 2016).

Parathyroid hormone-mediated control of distal tubule calcium reabsorption

PTH promotes calcium reabsorption in the distal convoluted tubule (DCT) (Lau and Bourdeau, 1995). Conversely, hypoparathyroidism is associated with hypercalciuria and nephrolithiasis (Mitchell et al., 2012). Studies in isolated rabbit kidney tubules demonstrated that PTH (as well as cAMP) increases cytosolic intracellular calcium concentrations, but only when calcium is present in luminal fluid (Bourdeau and Lau, 1989). Pharmacologic inhibitor studies indicate that cAMP-dependent PKA activation is required for this effect (Lau and Bourdeau, 1989). PTH regulates transcellular calcium fluxes in the DCT through apical calcium channel transient receptor potential vanilloid 5 (TRPV5) (Hoenderop et al., 2003). Once calcium enters the cell via the TRPV5 channel, it is chaperoned across the cell via association with carrier proteins (calbindin D28 and calmodulin) and ultimately extruded into the bloodstream via the Na^+/Ca^{2+} exchanger (NCX1) and the plasma membrane Ca^{2+}-ATPase (PMCA1b) (Hoenderop et al., 2002).

Three lines of evidence demonstrate that TRPV5-mediated transcellular calcium transport is regulated by PTH. First, PTH controls expression levels of TRPV5, as evidenced by reduced TRPV5 mRNA after parathyroidectomy (van Abel et al., 2005). Second, PTH increases cell surface TRPV5 levels by reducing TRPV5 endocytosis through an incompletely described mechanism that may be sensitive to PKC inhibitors (Cha et al., 2008). Third, the TRPV5 channel itself is a direct PKA substrate at threonine 709 (de Groot et al., 2009). This phosphorylation event increases the probability of the TRPV5 channel opening. TRPV5 channel activity is negatively modulated by calmodulin binding to its intracellular domain. Calmodulin/TRVP5 binding is diminished by PKA-dependent threonine 709 phosphorylation (de Groot et al., 2009, 2011). At this point, the relative contributions of PKA versus PKC signaling with respect to PTH-mediated transcellular calcium reabsorption in the DCT in vivo have not been reported. In addition, the precise function of TRPV5 threonine 709 phosphorylation in vivo remains to be established.

In addition to PTH-mediated regulation of TRPV5 activity by the mechanisms outlined previously, parathyroidectomy in rodents reduces the expression of calbindin D28, NCX1, and PMCA1b in the DCT (van Abel et al., 2005). However, PTH-dependent expression of these calcium handling factors in the DCT may be regulated in an indirect manner via 1,25-$(OH)_2$-vitamin D. Nonetheless, it is likely that PTH coordinates a program of gene expression in DCT cells that is necessary for optimal transcellular calcium reabsorption. Recently, this model was explored by deleting PTH1R selectively in the DCT (Sato et al., 2017). As predicted, these mice showed hypocalcemia, hypercalciuria, and secondary hyperparathyroidism. Surprisingly, the aforementioned proteins involved in transcellular calcium reabsorption were not affected by DCT PTH1R deletion. However, expression of claudin-14 (CLDN14), a tight junction protein that inhibits paracellular calcium reabsorption, was significantly upregulated (Sato et al., 2017). Therefore, PTH signaling in the DCT might control both transcellular (through TRPV5) and paracellular (through CLDN14) calcium reabsorption. Future studies are needed to clarify the mechanisms through which PTH1R signaling regulates CLDN14 expression and activity and to delineate the relative importance of PTH1R-regulated transcellular and paracellular calcium reabsorption in the distal tubule.

Skeletal parathyroid hormone actions: Focusing on osteocytes

PTH exerts its skeletal effects through multiple cellular mechanisms. The evolved function of this hormone is to maintain normocalcemia; therefore, increasing osteoclastic bone resorption to liberate skeletal calcium stores is a major physiologic action of PTH on bone. However, it has long been appreciated that pharmacologically administered PTH also stimulates bone formation (Lindsay et al., 1997). Consistent with this, individuals with hypoparathyroidism show reduced bone formation (Cusano et al., 2016; Rubin et al., 2008), pointing toward a physiologic role of circulating PTH in controlling osteoblast activity. While the teleology behind this phenomenon remains unknown, perhaps the ability of PTH to stimulate bone formation evolved to protect from excessive bone loss during times of dietary calcium deficiency. Both continuous and intermittent (pharmacologic) hyperparathyroidism increase bone resorption and formation. However, for reasons that remain incompletely understood, continuous hyperparathyroidism causes net bone loss while intermittent hyperparathyroidism boosts bone mass.

Since intermittent PTH is the only FDA-approved osteoporosis treatment strategy that stimulates new bone formation, the mechanisms underlying this therapeutic effect have been a major research focus over the past 30+ years. Multiple complementary cellular mechanisms have been proposed to explain how intermittent PTH treatment increases

bone formation. Intermittent pharmacologic PTH administration reduces osteoblast apoptosis (Jilka et al., 1999) and inhibits adipocyte differentiation of skeletal stem cells (Fan et al., 2017). Direct effects of PTH on early cells in the osteoblast lineage have been suggested from in vitro studies using cultured bone marrow−derived stromal cells (for example, Nishida et al., 1994), and more recently, in vivo lineage tracing studies (Balani et al., 2017; Yang et al., 2017). Rapid increases in osteoblast numbers seen after intermittent PTH treatment can be due to direct conversion of quiescent bone-lining cells into active osteoblasts (Kim et al., 2012). Non-cell-autonomous effects of PTH on osteoblast activity also occur. For example, PTH-induced bone resorption may liberate growth factors from bone matrix that in turn stimulate osteoblast progenitors (Wu et al., 2010; Linkhart et al., 1988). T lymphocytes in the bone marrow microenvironment respond to intermittent PTH by producing cytokines that stimulate osteoblast differentiation on cancellous bone surfaces (Pacifici, 2013).

Osteocytes represent a key additional cell type in bone that responds to PTH and PTHrP through PTH1R. The most abundant cell type in bone (Bonewald, 2011), osteocytes are former osteoblasts ensconced within mineralized bone matrix. Osteocytes relay hormonal and mechanical signals to osteoblasts and osteoclasts on bone surfaces. In the past 10 years, work has demonstrated that osteocytes are central to understanding skeletal responses to PTH and PTHrP (Bellido et al., 2013). Here we will focus on PTH1R signaling in osteocytes, highlighting existing knowledge of the signaling pathways involved and pointing out important and unresolved questions. First, osteocytic mechanisms of PTH-induced bone resorption will be reviewed. Then, mechanisms through which PTH and PTHrP stimulate bone formation through effects in osteocytes will be discussed.

Signaling mechanisms controlling parathyroid hormone-induced nuclear factor kappa-B ligand expression

One major mechanism through which PTH induces osteoclastic bone resorption is via upregulation of receptor activator of nuclear factor kappa-B ligand (RANKL) (Xiong and O'Brien, 2012), the key osteoclastogenic cytokine. Two lines of evidence point to osteocytes as a major source of RANKL during normal bone remodeling. First, osteoblast depletion largely preserves osteoclasts and bone RANKL levels (Corral et al., 1998; Galli et al., 2009). Second, conditional deletion of RANKL using the best-available osteocytic Cre deleter strains leads to reduced osteoclasts and high bone mass (Nakashima et al., 2011; Xiong et al., 2011, 2015). Future studies are needed to determine whether soluble or membrane-bound RANKL (Honma et al., 2013, 2014) participates in osteocyte regulation of remodeling on bone surfaces. An added layer of complexity might emerge from the observation that sclerostin (discussed later) has been suggested to promote RANKL expression by osteocytes (Wijenayaka et al., 2011).

Multiple signals increase skeletal RANKL expression, including PTH, 1,25-$(OH)_2$-vitamin D, and proinflammatory cytokines such as IL-6 and TNFα (Fu et al., 2002; Kondo et al., 2002a). Significant progress has been made toward understanding RANKL transcriptional regulation. Importantly, the majority of these mechanistic studies have been performed in osteoblast-like cell lines. It is possible that some of the lessons learned from immortalized osteoblastic lines may not apply to osteocytes. Cyclic AMP signaling downstream of PTH1R induces RANKL expression via a distinct "D5" enhancer located ~75 kB upstream of the gene's transcription start site (Fu and O'Brien, 2006; Kim et al., 2007; Kim et al., 2006). Deletion of this enhancer reduces basal- and PTH-induced RANKL expression in bone, leading to hypoparathyroidism-like skeletal changes (Galli et al., 2008). Deletion of this enhancer is sufficient to blunt skeletal RANKL upregulation stimulated by dietary calcium deficiency and lactation but does not block bone loss associated with these conditions (Onal et al., 2012). Therefore, additional mechanisms can compensate to promote skeletal calcium liberation when RANKL upregulation cannot occur. Multiple possibilities may explain this apparent paradox. RANKL expression by other cell types might substitute for skeletal sources of RANKL to promote bone loss when this particular enhancer is deleted. PTH-dependent RANKL-independent mechanisms that drive osteocytic perilacunar remodeling (see later) might compensate when RANKL cannot be upregulated due to enhancer deletion. Third, secondary hyperparathyroidism massively increases circulating levels of 1,25-$(OH)_2$-vitamin-D. It is possible that vitamin D also might have direct effects on osteocytes that promote RANKL-independent liberation of calcium stores.

In addition to the −75kB "D5" RANKL enhancer, additional upstream regulatory regions have been identified that contribute to cell-type-specific RANKL expression (Onal et al., 2015). For example, while the D5 enhancer appears to be most important in bone lineage cells, a distinct regulatory region located ~200 kB upstream of the human RANKL gene is involved in T cell RANKL expression (Bishop et al., 2015). GWAS studies have identified several variants near RANKL (TNFSF11) that are linked to bone density variation and fracture risk (Rivadeneira et al., 2009). Several bone mineral density−associated variants map to T cell enhancer regions (Rivadeneira et al., 2009). Corresponding murine enhancer regions are required for T cell RANKL expression during inflammatory conditions in vivo (Onal et al., 2016). Finally, recent studies have identified a second "D2" RANKL enhancer ~23 kB upstream of the gene's start site, the

deletion of which leads to a phenotype similar to mice lacking the −75kB D5 enhancer (Onal et al., 2015). Future studies are needed to define the relationship between the D2 and D5 enhancers in basal and PTH-stimulated osteocytic RANKL regulation.

PTH-induced RANKL upregulation requires cAMP/PKA signaling (Kondo et al., 2002a, 2002b); however, the nature of the downstream signaling steps has remained somewhat mysterious. The transcription factor CREB is a well-known PKA substrate at serine 133 (Shaywitz and Greenberg, 1999), and phospho-CREB RANKL enhancer association is observed in response to PTH and other cAMP-inducing signals (Kim et al., 2007). However, CREB deletion in osteoblast/osteocyte lineage cells does not reduce osteoclast numbers or RANKL expression in vivo (Kajimura et al., 2011). Provocatively, activating transcription factor 4 (ATF4), a related bZIP family transcription factor, is required for RANKL upregulation in osteoblastic cells in response to β2-adrenergic (but not PTH) signaling in osteoblasts. ATF4 binds to the proximal RANKL promoter to mediate RANKL induction downstream of catecholamine signaling (Takeda et al., 2002). Therefore, distinct bZIP family transcription factors likely participate in different ligand-induced RANKL upregulation pathways. Future studies will be needed to understand how two ligands (PTH and isoproterenol) that signal through Gαs-linked GPCRs regulate RANKL through distinct downstream mechanisms.

Cyclic AMP-regulated transcriptional coactivators (CRTCs) (Altarejos and Montminy, 2011) provide an additional layer of regulation in PTH-induced RANKL induction. CRTC proteins are coactivators of CREB (and other bZIP family transcription factors) that shuttle from the cytoplasm to the nucleus in response to upstream signals. In osteocytes, CRTC2 is tonically phosphorylated by SIK2 (see further for additional details) and therefore sequestered in the cytoplasm. Upon PKA-mediated SIK2 phosphorylation and inactivation, CRTC2 phosphorylation levels decrease, and this protein translocates from the cytoplasm to the nucleus. In the nucleus, PTH-regulated CRTC2 associates with the aforementioned D2 and D5 RANKL enhancer regions and is required for PTH-induced RANKL upregulation in vitro in Ocy454 cells (Wein et al., 2016). Whether CRTC2 functions with CREB or with other bZIP factors remains unknown, as does the role of CRTC2 in osteocyte function in vivo.

Sclerostin: a parathyroid hormone-suppressed osteocyte-derived osteoblast inhibitor

A crucial observation for the osteocyte biology field was provided by human genetics. Individuals with sclerosteosis display very high bone mass and fracture resistance. This rare Mendelian skeletal dyscrasia is caused by mutations in SOST, which encodes the protein sclerostin, an osteocyte-specific secreted Wnt inhibitor (Brunkow et al., 2001). Sclerostin inhibits osteoblastic bone formation (Baron and Kneissel, 2013); therefore, reducing SOST expression is a common mechanism through which bone anabolic signals may trigger new osteoblast activity. Indeed, both skeletal loading (Robling et al., 2008) and PTH (Keller and Kneissel, 2005; Bellido et al., 2005) rapidly reduce SOST expression. These simple observations moved osteocytes to the forefront in our thinking about how bone responds to PTH. In addition to SOST, osteocytes also are a major source of RANKL (Nakashima et al., 2011; Xiong et al., 2011). Osteocytic RANKL is upregulated by PTH and plays a key role in how PTH stimulates bone resorption (see previous) (Xiong et al., 2014; Ben-awadh et al., 2014). Therefore, transcriptional regulation of paracrine mediators such as SOST and RANKL is a mechanism through which PTH signaling in osteocytes influences bone remodeling.

Studies in genetically modified mice have highlighted the importance of PTH1R signaling in osteocytes. First, increasing PTH1R signaling in osteocytes (achieved via transgenic expression of a constitutively active PTH1R cDNA under the control of 8 kB osteocyte-enriched DMP1 promoter, DMP1-caPTHR1, in mice) leads to increased trabecular bone mass and high bone turnover (O'Brien et al., 2008; Rhee et al., 2011). In these animals, constitutively active PTH receptor signaling leads to reduced SOST expression and increased Wnt activity in osteocytes and osteoblasts. Accordingly, blocking Wnt signaling (via transgenic SOST overexpression or lipoprotein receptor-related protein 5 deletion) abrogates the bone phenotype in DMP1-caPTHR1 animals.

Since sclerostin, a Wnt inhibitor, is downregulated by PTH, and intact Wnt signaling is required for bone anabolism in response to PTH (Kedlaya et al., 2016), it has been of interest to determine if PTH-induced SOST downregulation is required for PTH-induced bone anabolism. When a human SOST bacterial artificial chromosome (BAC) is used to overexpress sclerostin in bone, PTH responses are blunted (Kramer et al., 2010). In contrast, when similar experiments are performed using an SOST transgene driven by the osteocytic DMP1 promoter, pharmacologic PTH administration normally boosts bone mass (Delgado-Calle et al., 2016). It is likely that differences between these two transgenic models account for these discordant results. For example, the human SOST BAC is probably expressed at higher levels at baseline than the DMP1-SOST transgene. However, the fact that SOST-deficient mice still boost bone mass in response to PTH (Kramer et al., 2010) provides further credence to the notion that sclerostin downregulation is just one of many molecular and cellular mechanisms used by PTH to stimulate Wnt signaling and bone formation. For example, T lymphocytes

produce WNT10B in response to intermittent PTH treatment, and this is needed for gains in trabecular bone mass (Terauchi et al., 2009). T cell−derived WNT10B and SOST downregulation work together for pharmacologic PTH treatment to increase bone mass (Li et al., 2014).

Recent progress has been made toward understanding the molecular mechanisms within osteocytes through which PTH regulates gene expression. Again, insights from human genetics have proved vital. Individuals with van Buchem disease have high bone mass, resistance to fractures, and high sclerostin levels. This monogenic disorder is caused by an intergenic deletion near the SOST gene that includes a key enhancer element (Balemans et al., 2002). Pioneering work toward understanding the function of this downstream enhancer-containing region (Loots et al., 2005) ultimately identified a key binding site for the transcription factor myocyte-specific enhancer factor 2C (MEF2C) (Leupin et al., 2007). Deleting MEF2C in osteocytes (Kramer et al., 2012) or the MEF2 binding enhancer element in osteoblasts and osteocytes (Collette et al., 2012) leads to low SOST expression and high bone mass.

Having identified that MEF2C is a key transcription factor for osteocytes to express SOST, an obvious question that emerges is whether PTH regulates SOST by blocking MEF2C activity. Studies in heterologous reporter systems suggested that cAMP signaling might regulate MEF2C activity in the setting of the +45 kB SOST enhancer (Leupin et al., 2007; St John et al., 2015a). In other cell types, upstream signals regulate MEF2 transcriptional activity via nucleocytoplasmic shuttling of class IIa HDAC proteins that, when present in the nucleus, potently inhibit MEF2 activity (Haberland et al., 2009). PTHrP blocks MEF2C-driven chondrocyte hypertrophy (Arnold et al., 2007) by driving HDAC4 from the cytoplasm to the nucleus (Kozhemyakina et al., 2009). In UMR106 osteocytic cells, PTH-induced SOST suppression is associated with nuclear accumulation of HDAC5 (Baertschi et al., 2014).

Loss-of-function studies in conditionally immortalized Ocy454 cells (a PTH-responsive murine osteocyte-like cell line [Spatz et al., 2015; Wein et al., 2015]) and mice reveal that deletion of both HDAC4 and HDAC5 is required to block PTH-dependent SOST downregulation (Wein et al., 2016). Detailed studies into the signaling mechanisms upstream of PTH-induced HDAC4/5 nuclear translocation have identified SIK2 as a crucial mediator of PTH signaling in osteocytes. SIK2 is a PKA-regulated phosphoprotein; PKA-mediated SIK2 phosphorylation reduces SIK2 cellular activity (Henriksson et al., 2012). In the absence of PKA phosphorylation, SIK2 tonically phosphorylates class IIa HDACs and promotes their cytoplasmic sequestration. As predicted by this model, small-molecule SIK inhibitors (Clark et al., 2012; Sundberg et al., 2014, 2016) such as YKL-05-099 reduce HDAC4/5 phosphorylation, promote their nuclear translocation, and reduce SOST expression in vitro and in vivo without increasing intracellular cAMP levels (Wein et al., 2016).

Small-molecule SIK inhibitors mimic transcriptional effects of PTH beyond SOST regulation. By reducing CRTC2 phosphorylation, these agents induce RANKL expression (see previous). At the transcriptomic level, approximately 32% of PTH-regulated genes are coregulated by SIK inhibitors. While HDAC4/5 deficient mice show normal bone anabolic responses to intermittent PTH, YKL-05-099 treatment boosts bone formation and bone mass in vivo (Wein et al., 2016). These studies highlight the importance of SIK2-regulated phosphoproteins (such as HDAC4/5 and CRTC2) in mediating the intracellular effects of PTH in osteocytes and identify SIK inhibitors as promising agents to mimic skeletal effects of PTH (Fig. 52.2). Many questions remain regarding the role of SIKs downstream of PTH receptor signaling. First, it is not known whether these kinases participate in PTH responses in other PTH target cells. Second, we do not know if PTH-regulated SIK2 substrates in osteocytes exist beyond class IIa HDACs and CRTC proteins. Third, genetic evidence that SIK deletion leads to a skeletal phenotype similar to constitutively active PTH receptor overexpression remains to be determined. Fourth, PKA-mediated inhibition of SIK activity appears to be a conserved feature downstream of multiple Gαs-linked hormonal signaling modules (Henriksson et al., 2012; Screaton et al., 2004; Patel et al., 2014; Wang et al., 2011). Therefore, future studies are needed to understand how unique transcriptional outputs are achieved downstream of PTH/SIK pathway engagement in osteocytes. Finally, additional studies are needed to further explore the utility of small-molecule SIK inhibitors (like YKL-05-099) as potential therapeutic agents for osteoporosis treatment.

Additional parathyroid hormone/parathyroid hormone−related protein receptor type 1 actions in osteocytes

Many PTH-regulated genes in osteocytes are regulated in an SIK-independent manner. Therefore, important additional intracellular signaling mechanisms downstream of the PTH receptor must exist. Nascent polypeptide-associated complex and coregulator alpha (αNAC) is another phosphoprotein that translocates from the cytoplasm to the nucleus upon PKA-dependent phosphorylation (Pellicelli et al., 2014). In the nucleus, αNAC associates with bZIP family transcription factors and enhances their activity (Akhouayri et al., 2005). Low-density lipoprotein receptor-related protein 6 (LRP6) represents one important PTH-induced αNAC target gene (Hariri et al., 2017). As a Wnt coreceptor, LRP6 is needed for intermittent

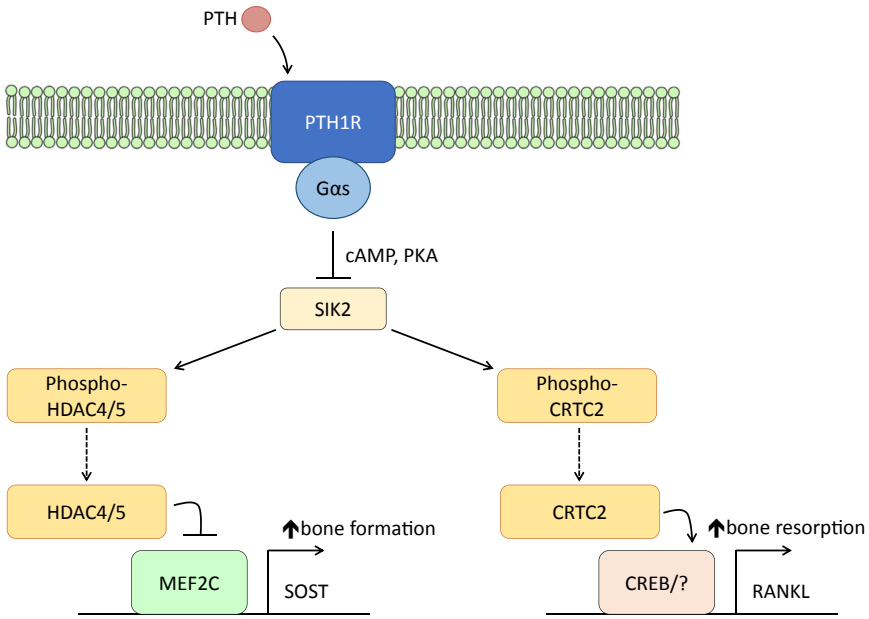

FIGURE 52.2 Model demonstrating the role of salt-inducible kinase 2 (SIK2) in osteocytic PTH1R action. Downstream of Gαs signaling, PKA-mediated SIK2 phosphorylation on S358 (among other sites) blocks SIK2 cellular activity. This leads to reduced phosphorylation of the SIK2 substrates HDAC4/5 and CRTC2. When dephosphorylated (by an unknown phosphatase), these proteins translocate into the nucleus, where they regulate gene expression. Class IIa HDACs block MEF2C-driven SOST expression, while CRTC2 activates RANKL expression through CREB (and perhaps other related transcription factors). Since PTH signaling blocks cellular SIK2 activity, small-molecule SIK inhibitors, such as YKL-05-099, mimic the effects of PTH in osteocytes.

PTH-induced bone anabolism (Li et al., 2013, 2015). Therefore, PTH employs complementary intra- and intercellular mechanisms to stimulate Wnt signaling.

Beyond studies on candidate signaling proteins, several groups have recently performed unbiased approaches to define PTH-regulated genes in osteocytes. Like Ocy454 cells, IDG-SW3 cells are a conditionally immortalized murine osteocyte-like cell line (Woo et al., 2011). RNA-seq profiling of these cells during differentiation and in response to PTH has been reported (St John et al., 2014, 2015b). PTH treatment of IDG-SW3 cells leads to reversion to a less mature, more osteoblastic phenotype. When mature IDG-SW3 cells are treated with PTH, morphologic changes are observed, including fewer dendritic extensions and increased motility (Prideaux et al., 2015). While the mechanistic basis for these phenomena remains incompletely understood, effects on calcium channel gene expression may play a role. PTH increases the expression of L-type (osteoblastic) calcium channels and reduces expression of T-type (osteocytic) channels. L-type calcium channels are partially responsible for PTH-induced changes in osteocyte morphology, as evidenced by pharmacologic experiments with diltiazem (Prideaux et al., 2015).

The physiologic significance of these PTH-dependent changes in osteocyte morphology remains to be determined. Recently, it has been reported that cross talk between PTH and insulin-like growth factor 1 (IGF-1) receptor signaling leads to tyrosine phosphorylation, which localizes the PTH1R to barbed ends of actin filaments. Furthermore, deletion of either the IGF1 receptor or PTH1R in osteoblast lineage cells reduces osteocyte dendritic projections in vivo (Qiu et al., 2018). Therefore, noncanonical PTH1R signaling in preosteocytes may be important for the establishment of the osteocyte lacunar-canalicular network in normal physiologic conditions. The role of PTH1R in establishing an optimal network of osteocyte projections may provide one explanation for the recent observation that mice lacking PTH1R in osteocytes fail to exhibit normal skeletal responses to loading (Delgado-Calle et al., 2016). That being said, it is also known that osteocyte-derived autocrine/paracrine PTHrP promotes bone formation during normal physiologic conditions (Ansari et al., 2018). Therefore, PTH1R signaling in osteocytes can influence bone remodeling through multiple mechanisms. Integrating these findings must be a focus of future studies.

Changes in osteocyte morphology may provide an important mechanistic clue into how PTH and PTHrP rapidly liberate skeletal calcium stores during the normal physiologic stresses of calcium deficiency and lactation (Qing et al., 2012). Osteocytes can remove bone matrix during lactation by reversible remodeling of the perilacunar/canalicular network. Notably, during lactation, osteocytes express "osteoclast specific" genes such as cathepsin K and TRAP.

Pharmacologic infusion of PTHrP, whose levels are normally high during lactation (Kovacs and Kronenberg, 1997), mimics these changes. Mice lacking mammary gland PTHrP fail to lose bone during lactation (VanHouten et al., 2003), highlighting the importance of breast-derived PTHrP as a physiologic signal for lactation-induced bone remodeling. Furthermore, PTH1R-deficient osteocytes fail to undergo perilacunar remodeling during lactation (Qing et al., 2012). Beyond upregulating cathepsin K and TRAP, PTHrP promotes osteocytic expression of ATP6V0D2, the vacuolar ATPase associated with osteoclastic bone resorption. Lactating calcium-deficient mice show reduced perilacunar pH, as assessed using a novel GFP-based reporter system (Jahn et al., 2017). PTH/PTHrP-dependent regulation of perilacunar pH may represent a rapid mechanism for osteocytes to liberate readily accessible pools of calcium. A major unanswered question is the relative contribution of osteocytic osteolysis versus osteoclastic bone resorption in lactation-induced skeletal calcium liberation.

Recent clinical data have suggested potential beneficial effects of the PTHrP analog abaloparatide at predominantly cortical sites (Miller et al., 2016). Therefore, future studies are needed to understand differences between PTH and PTHrP in inducing osteocytic gene expression and perilacunar remodeling. At present, little is known about mechanistic differences between these two PTH1R ligands. In overexpressed receptors in heterologous systems, it appears that PTH preferentially binds to the R^0 PTH1R conformation, while abaloparatide favors the transient R^G configuration (Hattersley et al., 2016). This difference in receptor engagement could lead to biologic differences in signaling outputs, although this appealing hypothesis remains to be tested in bone cells expressing PTH1R at endogenous/physiologic levels.

Summary

Here we have reviewed the cellular and molecular actions of PTH1R in kidney and bone. Starting with a detailed knowledge of the membrane proximal signaling pathways engaged by this class B GPCR, it is now possible to understand some of the major physiologic actions of this hormone in detail. However, major unanswered questions remain. For example, the relative contributions of canonical versus noncanonical PTH1R signaling in distinct physiologic actions of hormone action are still incompletely understood. In addition, whether the signaling pathways described herein also participate in PTH/PTHrP action in cell types and organs outside of bone and kidney remains unknown. Although some differences have been described between PTH and PTHrP with respect to receptor engagement, a complete mechanistic understanding of the differences between these two hormones and their distinct biologic actions remains to be determined. Finally, the paradox of the differential effects on bone mass between continuous and intermittent hyperparathyroidism remains to be solved.

Chapter 53

Multiple endocrine neoplasia type 1

Francesca Giusti, Francesca Marini, Francesco Tonelli and Maria Luisa Brandi
Department of Experimental and Clinical Biomedical Sciences, University of Florence, Florence, Italy

Chapter outline

Introduction

Multiple endocrine neoplasia type 1 (MEN1) is a rare inherited syndrome caused by inactivating heterozygote mutations of the *MEN1* tumor-suppressor gene. It is inherited as an autosomal dominant trait, with complete penetrance by the age of 50 and different clinical phenotypes even in the presence of the same *MEN1* mutation and between identical twins.

MEN1 has a prevalence of approximately 1 in 30,000 births with equal gender distribution. Clinical diagnosis of MEN1 usually includes the presence of at least two neuroendocrine tumors affecting the parathyroid glands, gastroenteropancreatic tract, and anterior pituitary gland or by the occurrence of one of these three main tumors plus one first-degree relative clinically affected by the syndrome.

Principal clinical manifestations of the MEN1 syndrome are primary hyperparathyroidism (PHPT), gastroenteropancreatic neuroendocrine tumors (GEP-NETs), and tumors of the anterior pituitary (Table 53.1).

PHPT is characterized by multiple hyperplasia/adenomas of parathyroid glands (all the glands are usually affected during a lifetime). It can remain asymptomatic and normocalcemic for years and incidentally discovered during blood tests following the development of an increased serum value of parathyroid hormone (PTH).

GEP-NETs usually occur as multiple functioning and/or nonfunctioning (NF) tumors in the stomach, pancreatic islets, and duodenum (Fig. 53.1).

Pituitary tumors are the third most common manifestation of the disease, principally including prolactinoma (PRLoma), and less frequently somatotropinoma, adrenocorticotropina, and NF adenomas.

Other less frequent tumors/lesions affect MEN1 patients: neuroendocrine tumors (NETs) of the thoracic tract (thymus and bronchi), adrenocortical tumors, lipomas, visceral leiomyomas, truncal and facial collagenomas, facial angiofibromas (Fig. 53.2), and breast carcinoma. The presence of these tumors, in particular skin lesions (which often manifest even before main MEN1 tumors), can help the differential and early clinical diagnosis of index cases (Thakker et al., 2012).

Primary hyperparathyroidism

PHPT is generally the first endocrine manifestation in MEN1 patients, affecting more than 95% of cases by the age of 50. Age of onset is between 20 and 25 years, more than 2 decades before sporadic PHPT and with equal distribution between

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00053-1

TABLE 53.1 Main characteristics and frequency of NETs in MEN1.

Syndrome	Prevalence	Gene	Main clinical features	pNETs Type and frequency (%)	Other NET types and frequencies (%)
MEN1	1/30,000	*MEN1*	Multiple adenomas of parathyroid glands (PHPT), adenomas of anterior pituitary, neuroendocrine tumors of the gastroentero-pancreatic (GEP-NETs) and thoracic tracts	Duodenal gastrinoma >50% Pancreatic gastrinoma <10% Insulinoma 15%–30% NFTs and PPoma (60%–80%) Glucagonoma (<3%) VIPoma (<1%) Somatostatinoma (<1%)	Adrenal cortical tumors (40%) PHEOs (<1%) Gastric NETs (10%) Bronchopulmonary NETs (2%) Thymic NETs (2%)

GEP-NETs, gastroenteropancreatic neuroendocrine tumors; *NETs,* Neuroendocrine tumors; *NFTs,* Nonfunctioning tumors, *PHEOs,* Pheochromocytomas; *PHPT,* primary hyperparathyroidism; *pNETs,* pancreatic neuroendocrine tumors; *PPoma,* neuroendocrine tumor secreting pancreatic polypeptide.

males and females. PHPT is generally caused by parathyroid hyperplasia and/or multiple adenomas of the glands; all four parathyroid glands are usually affected during a lifetime. Ectopic or supernumerary parathyroid glands are a frequent occurrence.

PHPT in MEN1 is usually recognized by elevated PTH serum level in association with hypercalcemia, or in some cases with normocalcemia. PHPT can remain asymptomatic for years; symptomatic PHPT causes nephrolithiasis and is responsible for a reduction in bone mass by the age of 35 years. Biochemical screening includes dosage of intact serum PTH, calcemia, and calciuria; they must be measured yearly in all MEN1 patients and all MEN1 mutation carriers. Neck ultrasound and Tc99m-sestamibi parathyroid scintigraphy are of limited benefit as all parathyroid glands may be affected, but can show ectopic parathyroid glands. Ultrasound of the urinary tract (to prevent nephrolithiasis) and bone mineral density evaluation by dual-energy X-ray absorptiometry should be performed regularly (Thakker et al., 2012).

Surgery is the treatment of choice for PHPT. The timing and type of operation for parathyroid surgery in MEN1 patients are still controversial. Three surgical approaches are available: (1) partial parathyroidectomy with ablation of only the enlarged glands (up to three glands); (2) subtotal parathyroidectomy: removal of greater than three glands, leaving a normal parathyroid gland or a viable remnant (approximately 50 mg) from the most normal-appearing gland; and (3) total parathyroidectomy—ablation of all parathyroid glands (including ectopic and supernumerary glands) with the heterotopic autotransplantation of fresh or cryopreserved normal parathyroid tissue into the brachioradialis muscle of the nondominant forearm (Norton et al., 2015). An intraoperative dosage of PTH is suggested to minimize the risk of postintervention persistence of PHPT, allowing the correct ablation of all adenomatous and/or hyperplastic parathyroid glands to be

FIGURE 53.1 Numerous scattered islet cell adenomas (numbered 1 − 6) of various size and architecture in a transverse section of the pancreas of a patient with MEN1 syndrome and ZES (H&E, 4). *Reprinted with permission from Pilato et al. (1988).*

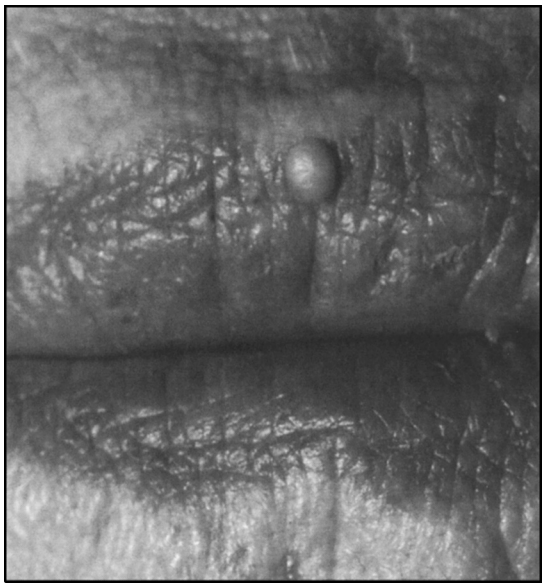

FIGURE 53.2 MEN1-associated angiofibroma.

monitored (Nilubol et al., 2013). Both partial and subtotal parathyroidectomy have a higher probability of persistence and recurrence (i.e., 40%−60% of MEN1 patients within 10−12 years after surgery) than does total parathyroidectomy; total parathyroidectomy, even with reimplantation, presents a higher incidence of permanent hypoparathyroidism but a lower incidence of recurrence than other procedures. Transcervical thymectomy at the time of neck surgery is strongly suggested to remove ectopic parathyroid glands and to avoid thymic NETs. Minimizing the persistence and recurrence of hyperparathyroidism by surgery seems to be an important tool. A recent study shows that persistent hypercalcemia is associated with higher levels of anxiety, depression, and fatigue, as well as decreased social functioning, in MEN1 patients. Interestingly, a similar reduction in the quality of life is not observed in patients affected by hypoparathyroidism after surgery (Goswami et al., 2017).

PHPT can also be pharmacologically controlled by calcimimetics (i.e., cinacalcet) as an alternative to parathyroid surgery in patients who do not meet the criteria for parathyroidectomy, for those who failed a previous intervention, and for those presenting recurrence who refuse to undergo any further surgical interventions. Calcimimetics are a class of calcium-sensing receptor agonists that have been demonstrated to normalize serum calcium level, reduce PTH release by parathyroid cells, and reduce parathyroid cell growth. Cinacalcet has been demonstrated to be well tolerated and safe in MEN1 patients and to restore normal calcium homeostasis (Moyes et al., 2010; Giusti et al., 2016).

Gastroenteropancreatic neuroendocrine tumors

GEP-NETs affect 30%−80% of MEN1 patients and are classified in functioning GEP-NETs and nonfunctioning GEP-NETs (NF GEP-NETs).

NF GEP-NETs are the most frequent pancreatic NETs (pNETs) in MEN1. They are usually multiple, asymptomatic, and characterized by later onset. They are discovered incidentally either by imaging exams or by assessing the increase of the pancreatic polypeptide (PP), which is secreted by approximately half of them.

Functioning GEP-NETs are characterized by excessive hormone production and usually associated with a typical hormone excess clinical syndrome: gastrinoma in over 50% of MEN1 patients (gastrin), insulinoma in 15%−30% of MEN1 patients (insulin), glucagonoma in <3% of MEN1 patients (glucagon), VIPoma in <1% of MEN1 patients (vasoactive intestinal polypeptide; VIP), and somatostatinomas in <1% of MEN1 patients (somatostatin).

Management of functioning GEP-NETs includes:

1. Confirm the diagnosis based on the clinical presentation by dosage of the basal levels of the specific hormones and/or their modifications after provocative test.

2. Assess whether the GEP-NETs belong to the MEN1 syndrome, researching other endocrinopathies either in the patients or in family members and searching for mutations of the *MEN1* gene.
3. Control the life-threatening metabolic consequences (hypoglycemia, hypokalemia, dehydration, etc) and hormonal excess by supportive medical treatment.
4. Localize the site of the primary tumor.
5. Stage the tumor, evaluating the eventual invasion of surrounding structures and/or diffusion into the periduodenal and peripancreatic lymph nodes, liver, and other viscera.
6. Evaluate the possibility of radical surgical resection of the primary functioning NET and/or of the possible metastases.
7. Consider cytoreductive surgery and/or alternative medical therapies for unresectable tumors.
8. Set up an appropriate follow-up for recurrence of NETs or appearance of other MEN1-related endocrine tumors.

Gastrinoma

The most common MEN1 GEP-NET is gastrinoma, occurring principally in the duodenal mucosa or submucosa (more than 90% of cases); less than 10% of MEN1 gastrinomas are located in the pancreas, contrary to its sporadic counterpart.

MEN1 gastrinomas usually manifest as multiple microadenomas (<0.5 cm) with a low grade of growth (Ki67 < 2%) (Fig. 53.3). They are diagnosed by the age of 40, and at the time of diagnosis in 34%−85% of cases present lymph node metastases (Yates et al., 2015); fast growth and liver metastases are rare, but they are principal causes of MEN1-related death. Ectopic gastrinomas, arising in the gallbladder or in the biliary tree, are very rare, but they can be the cause of hypergastrinemia persistence or recurrence after surgical resection of duodenal gastrinoma (Tonelli et al., 2013).

Clinically, gastrinomas induce the Zollinger−Ellison syndrome (ZES), a hypersecretion of gastric acid that causes diarrhea, multiple peptic ulcers, reflux, and esophagitis. The presence of hypercalcemia due to PHPT worsens the symptoms of ZES, as it increases the gastric acid secretion; normalization of calcemia improves gastroenteric symptomatology, and parathyroidectomy is strongly indicated in hypercalcemic patients with gastrinomas.

The diagnosis of gastrinomas is made by elevated basal serum gastrin levels accompanied by the presence of hyperchloryhydria or pH < 2; stimulation tests with secretin, or more rarely calcium, can be performed. Imaging screening is useful in localizing the tumor; these consist of endoscopic ultrasonography (EUS), multislice computed tomography (CT), magnetic resonance imaging (MRI), selective abdominal angiography, and somatostatin-receptor scintigraphy (Thakker et al., 2012). The multiplicity of MEN1 gastrinomas, their very small size, and common localization in the duodenal wall make these tumors very difficult to localize before surgery. Liver MRI is used to detect liver metastases and possible extrahepatic biliary tree ectopic gastrinomas. Neither the diagnostic efficacy of gallium-68 DOTATOC PET/CT nor the prognostic role of Ki67 tumor grading by EUS-guided tissue biopsy has been correctly evaluated in MEN1 patients yet.

The main objective of medical therapy is to reduce and control gastric acid hypersecretion. Medical therapy is the same as sporadic ZES with the administration, alone or in combination, of histamine-2 receptor antagonists (cimetidine, ranitidine, and famotidine), proton pump inhibitors (PPIs: omeprazole, lansoprazole, and pantoprazole), and somatostatin analogues (SSAs: octreotide and lanreotide). All these molecules have demonstrated long-term effectiveness in controlling

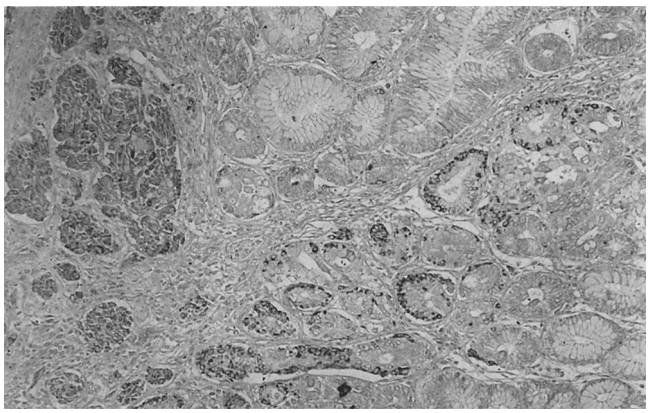

FIGURE 53.3 Immunostaining for basic FGF in the gastric endocrine cells of a patient with MEN1 syndrome and ZES. The peptide is expressed by both intraglandular cells showing hyperplastic pre- tumoral lesions (on the right) and carcinoid tumor (on the left) (immunoperoxidase, 100).

clinical symptoms and an absence of important adverse events. SSAs are synthetic molecules that retain binding affinity for somatostatin receptors (SSTRs), at least with high affinity for SSTR2 and moderate affinity for SSTR5, that are able to inhibit both pancreatic and gastrointestinal hormone secretion (i.e., insulin, glucagon, gastrin, secretin, and VIP) and control the growth of GEP-NETs (Rinke and Krug, 2016; Wolin, 2012).

Surgery is proposed to avoid neoplastic progression and to restore normal gastrinemia, preventing the development of gastric carcinoids. However, timing and type of surgery are still controversial. Some situations pose an absolute indication for surgery: fast-growing gastrinomas, diagnosis of pancreatic gastrinoma, and the presence of severe hypergastrinemia. However, overall growth of concomitant pNETs is what moves to operate in order to avoid the development of a neuroendocrine carcinoma (Falconi et al., 2016). The choice of surgery depends on where the pNETS are prevalently located. When pNETs are predominant in the right pancreas, pancreatoduodenectomy (PD) or pylorus-preserving PD represent a surgical option with a high probability (around 80%) of being curative for hypergastrinemia, because all of the duodenum, where most gastrinomas arise, is removed. When pancreatic NETs are predominant in the left pancreas, Thompson's procedure can be chosen. This procedure consists of a longitudinal duodenotomy with mucosal enucleation or resection by full-thickness duodenal wall excision (if the gastrinoma is > 0.5 cm) of the discovered duodenal gastrinomas and a peripancreatic lymph-node resection associated to distal pancreatic resection (DPR) (Thompson, 1998). Enucleation of tumors in the residual pancreas is necessary, both for PD and DPR, for adenoma greater than 1 cm in diameter. Another surgical option for the cure of ZES is pancreas-preserving total duodenectomy. It consists of the resection of the entire duodenum and gastric antrum, the ligation of the accessory pancreatic duct, the sphincterotomy of the major papilla after removing its mucosal lining, and the anastomosis of the Vater papilla on a Roux-en-Y jejunal loop (Imamura). Surgery carries the risk of mortality and morbidity. The main cause of a compromised quality of life can be the occurrence of insulin-dependent diabetes. However, data on the prevalence of diabetes in MEN1 patients that have undergone pancreatic resection are limited. Currently, the benefit of surgery compared with medical treatment with PPIs and/or SSAs has not been tested with clinical trials. Failure to correct hypergastrinemia can favor the occurrence of gastric carcinoids (type 2 gastric NETs) in MEN1 patients. These tumors arise from ECL cells and grow in the mucosa or submucosa of the stomach. They are multiple and just a few millimeters in size, remaining stable for a long time. Risk of malignant progression is less than 10%. Therefore, endoscopic surveillance with excision of the biggest tumors is currently the most followed therapeutic choice. SSAs and cholecystokinin B receptor antagonists have also been employed for the treatment of type 2 gastric NETs with a significant reduction in gastrin levels and tumor dimension (Norton 2015).

Insulinoma

Insulinoma can represent the first clinical manifestation of the MEN1 syndrome in at least 15% of affected patients (Sakurai et al., 2012; Goncales et al., 2014; Thakker et al., 2012), occurring prevalently in females (Levi-Bohbot 2004; O'Riordain et al., 1994; Sakurai et al., 2012). Mean age at diagnosis for insulinoma varies from 24 to 36 years, but it can manifest as early as 5 years, with an age of onset younger than that of other MEN one associated GEP-NETs (Sakurai et al., 2012). Neuroglycopenic symptoms, due to the oversecretion of insulin, can be the first manifestation of MEN1 syndrome in some patients; the occurrence of insulinomas during childhood or adolescence should suggest the presence of MEN1. MEN1 insulinomas represents 5% of all diagnosed cases in adults, but 15%−20% in childhood (Goncales et al., 2014). MEN1 insulinomas are characterized by (1) localization exclusively pancreatic, (2) scattered through all the pancreas, (3) dimension variable from 2 mm to >3 cm, and (4) multiple insulinomas found in 30%−60% of patients (Giudici et al., 2012; Anlauf et al., 2009). Some authors suggest that a dominant lesion (at least 1 cm in diameter) is responsible for hypoglycemia, also in presence of multiple insulinomas (Bartsch et al., 2013; Jensen et al., 2012), but it is still not clear. It is probable that microinsulinomas (less than 5 mm in diameter) could be clinically silent, since persistence of hypoglycemia after enucleation of a single insulinoma manifests at a lower rate than in the case of multiple insulinomas.

Unlike for sporadic insulinoma, whose localization can be done intraoperatively by inspection, palpation of the pancreas, and ultrasound, in MEN1 multiple insulinomas the challenge is to detect which of several tumors is responsible for the neuroglycopenic syndrome, which is impossible via conventional imaging techniques. Other methods, which are more difficult and invasive, allow the insulinoma to be preoperatively localized:

1. EUS (or CT)-guided fine-needle aspiration collects samples for immunohistochemistry or for insulin dosage (Fig. 53.4). This technique is difficult or impossible to apply if several pancreatic lesions are present or if the nodules are small, and it has rarely been employed in MEN1 patients (Goncales et al., 2014; Tonelli 2014; Lee et al., 2013).
2. Transhepatic portal venous sampling has been widely used in the past, even if rarely used for MEN1 pancreatic lesions, and eventually was abandoned due to the low accuracy of the examination, its invasiveness, and its difficulty.

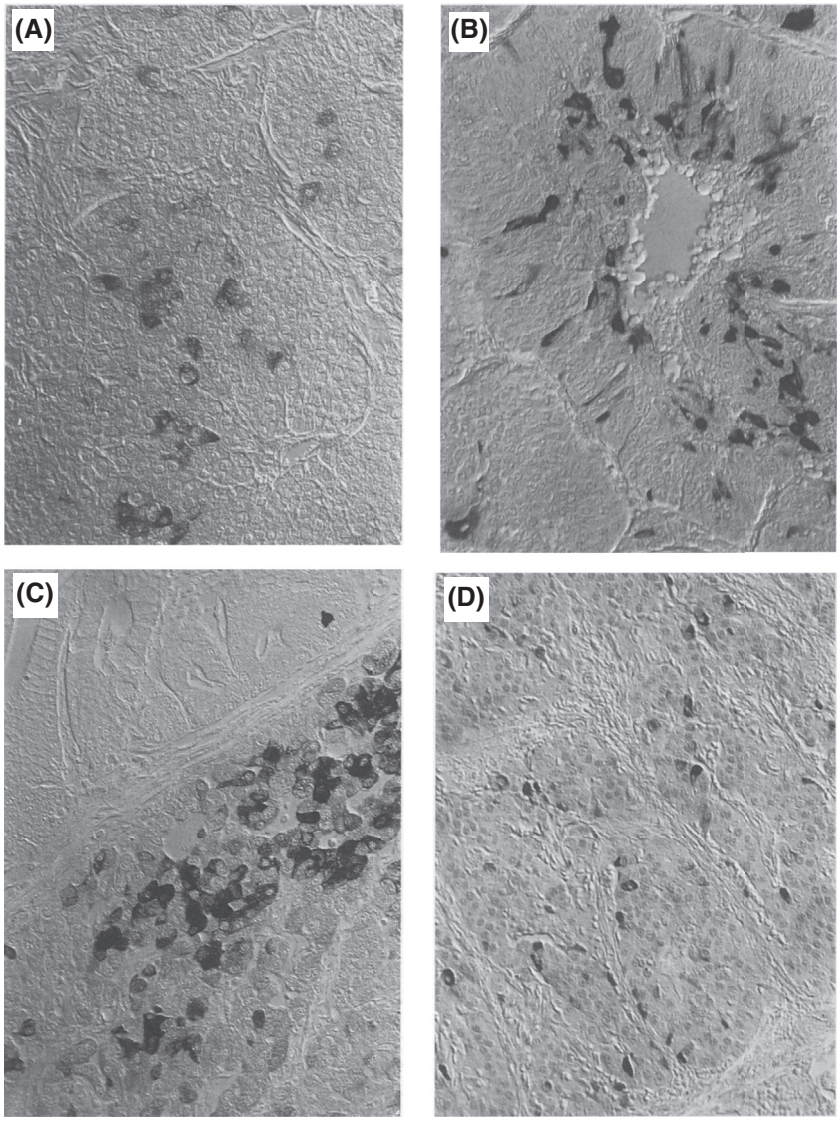

FIGURE 53.4 Immunohistochemical expression of -subunit of glycoprotein hormones in different types of tumors in MEN1 patients: parathyroid (A); lung carcinoid (B); gastric carcinoid (C); duodenal gastrinoma (D); (immunoperoxidase, 170).

3. Selective intraarterial calcium injection (SACI) of the major pancreatic arteries with hepatic venous sampling for insulin assay was developed by Doppman et al., in 1991 (Doppman et al., 1991). The proper hepatic, gastroduodenal, superior mesenteric, and splenic arteries are selectively catheterized and subsequently injected with calcium gluconate (0.025 mEq calcium/kg body weight). Blood samples for insulin determination are obtained from a major hepatic vein prior to and 30, 60, and 120 s after calcium infusion. The detection of insulinomas with this method is based on the production of insulin (or proinsulin and C-peptide) from the insulinomas. Insulinomas with a diameter of less than 1 mm can also be diagnosed by this method (Hayashi et al., 2001). However, the insulinoma cannot be visualized directly but only localized in a part of the pancreas (usually the right or left pancreatic region) on the basis of the insulin dosage in the hepatic venous blood samples. A twofold increase in the insulin concentration from baseline localizes the insulinoma within the anatomic region perfused by the injected artery. SACI requires specific expertise that may be available only in dedicated centers. The experience performed up until now has been done prevalently in sporadic insulinoma, being anecdotal in MEN1 insulinomas (Bartsch et al., 2013; Guettier et al., 2009). Only 14 cases of MEN1 insulinomas can be found in the literature of the last 20 years, and in two of these the examination was not informative. False negatives due to technical flaws and anatomical variants of pancreatic vascularization, or false positives with regionalization of the insulinoma in a wrong pancreatic region, are possible. Therefore, it is not clear whether small

insulinomas are also eventually detected on histological examination of the resected pancreas as evidenced by the SACI test, and how it can be possible to localize more than one insulinoma scattered in different parts of the pancreas.

In conclusion, since these methods are rarely employed, it is currently difficult to establish their accuracy for localizing insulinoma in the MEN1 setting. In a great majority of patients, surgery is carried out without knowing the site, dimension, and number of insulinomas.

Surgery is mandatory to cure severe hypoglycemia in patients with hyperinsulinism and to avoid brain damage from neuroglycopenic attacks. The absence of controlled studies makes the choice of surgery controversial. Data about the modality and result of surgical treatment of MEN1 insulinomas can be retrieved from 10 retrospective case series (O'Riordain et al., 1994; Giudici et al., 2012; Anlauf et al., 2009; Bartsch et al., 2013; Thompson 1998; Demeure et al., 1991; Lo et al., 1998; Jordan 1999). Two surgical modalities are most frequently employed: enucleation of the greatest pancreatic lesions or DPR preserving splenic vessels and spleen. PD rather than DPR should be adopted for MEN1 insulinomas when large and deep tumors are found within the pancreatic head. This is especially important if the insulinomas are situated close to the Wirsung duct, if there is a risk of lymph nodes surrounding the pancreatic head being metastatic, or concomitant ZES syndrome is present (Tonelli et al., 2017).

Glucagonoma

Glucagonomas occur in fewer than 3% of patients with MEN1, usually before 40 years of age. They can manifest with hyperglycemia, anorexia, glossitis, anemia, diarrhea, venous thrombosis, and skin rash. The characteristic sign (necrolytic migratory erythema) can be absent, and the diagnosis is made by hyperglucagonemia (levels >1000 pg/mL). The presence of clinical manifestations and malignancy are related to the size of the tumor. A tumor less than 2 cm in diameter has a low incidence of malignancy, but when the tumor size is more than 5 cm in diameter, two-thirds of glucagonomas are malignant (Economopoulos et al., 2001). The liver is the most common site for distal metastases.

VIPoma

VIPoma is diagnosed in less than 3% of MEN1 patients. Watery diarrhea, hypokalemia, and achlorhydria (WDHA syndrome) are often present. The electrolytic imbalance must be corrected before surgery. The majority of VIPomas are greater than 3 cm in diameter, malignant, and associated with synchronous or metachronous liver metastases.

Somatostatinoma

Somatostatinoma is particularly rare, manifesting in less than 1% of MEN1 patients. Usually, the somatostatin syndrome is absent or incomplete, and diagnosis is based on high levels of somatostatin in the plasma or somatostatin-immunoreactive cells within the tumors (>80%−100%) (Garbrecht et al., 2008). A majority of somatostatinomas are diagnosed in the fifth decade of life. Either pancreas or duodenum and first jejunal loop can be the site of the tumor. Most of the time, somatostatinomas localized in the duodenum or jejunum have a small dimension (around 0.5−1 mm), are multiple, and represent an incidental finding in MEN1 patients suffering from ZES due to duodenal gastrinomas. Metastases in the peripancreatic lymph nodes are found, but they are usually positive for gastrin and not for somatostatin (Garbrecht et al., 2008). Pancreatic somatostatinomas have a large dimension (3−5 cm), are frequently multiple, and can metastasize to peripancreatic lymph nodes and liver (Lévy-Bohbot et al., 2004; Economopoulos et al., 2001).

Nonfunctioning neuroendocrine tumors of the gastroenteropancreatic tract

NF GEP-NETs are the most frequently observed GEP-NETs in MEN1 patients and are characterized by later onset. The number is variable from few to more than 50 tumors. A majority of NF GEP-NETs in MEN1 are microscopic, well differentiated, and have a low (<5%) ki67 index. Their diagnosis is difficult because they are usually asymptomatic and discovered incidentally either by imaging exams or by assessing the increase of PP. NF GEP-NETs are the most common cause of death in MEN1 patients due to their malignant progression and metastases (Thakker et al., 2012). Tumor size is usually correlated with metastases (Triponez et al., 2017). The treatment of choice is surgery. Timing of operation is suggested when the dimension of NF pNETs is approximately 2 cm in diameter or when imaging exams during follow-up show a significant growth of lesions (Table 53.2) (Triponez et al., 2006; Triponez et al., 2017).

The most used surgical procedure is DPR, with or without enucleation of macroadenomas in the pancreatic head. PD is rarely performed. This probably reflects the fear that this more complex operation can be affected by major postoperative

complications more often than DPR. However, overall morbidity, and especially the rate and severity of pancreatic fistulas, are similar when both procedures are compared. Furthermore, morbidity and mortality after PD have been dramatically reduced in current surgical practice, particularly in the experience of dedicated centers.

All surgical procedures on the pancreas are at risk for pancreatitis or pancreatic fistula. Enucleation cannot avoid these postoperative complications. In particular, the rate of pancreatic fistula (grades A, B, and C) observed in recent reviews of large institutional experiences concerning surgery for endocrine pancreatic tumors is often higher than in surgery for pancreatic adenocarcinoma (Fendrich et al., 2011). Furthermore, it is surprising that the rate of fistula is higher for enucleation procedures than for resection of the left or right pancreas (Pitt et al., 2009). In the presence of MEN1 pNETs, postoperative fistulas frequently approach 100% for enucleation and 84% for hemipancreatectomy and have been observed significantly more often than in sporadic pNETs (Inchauste et al., 2012). The MEN1 pancreas harbors all the factors responsible for the occurrence of the fistula: the softness of the pancreatic parenchyma, the small diameter of the Wirsung duct, and the macro- and microscopic pancreatic alterations due to the presence of multiple NETs. The remnant pancreatic volume after the surgical procedure is another risk factor, and the volume is higher after enucleation than after resection.

In case of unresectable tumors or advanced metastatic cancer, some medical therapies, such as SSAs, peptide receptor radionuclide therapy (PRRT), cytotoxic chemotherapy (i.e., streptozocin and 5-fluorouracil, doxorubicin, temozolomide with capecitabine), inhibitors of tyrosine kinase receptors (i.e., sunitinib), and inhibitors of mammalian target of rapamycin (mTOR; i.e., everolimus) have been demonstrated to increase the median progression-free survival in sporadic pNETs. No specific trials have been performed in MEN1 patients (Fine et al., 2013; Bodei et al., 2015; Yao et al., 2011; Raymond et al., 2011).

Anterior pituitary tumors

The incidence of anterior pituitary tumors in MEN1 syndrome varies from 15% to 55% in different series with a mean age of onset in the fourth decade of life, with early cases described by the age of 5. Prolactin-secreting adenoma (PRLoma) is the most common pituitary tumor (60%), followed by growth hormone (GH)-secreting adenoma (somatotropinoma or GHoma; 25%), adrenocorticotropic hormone-secreting adenoma (adrenocorticotropina or ACTHoma; 5%), and NF tumors (10%) (Thakker et al., 2012).

The signs and symptoms of patients with pituitary adenomas are caused by "mass effects" of macroadenomas (mostly NF adenomas) or secondary to excessive pituitary hormone production by functioning adenomas:

1. PRLomas manifest as oligomenorrhea/amenorrhea and galactorrhea in females, and sexual dysfunction and (more rarely) gynecomastia in males.
2. GHomas are tumors that occur with the signs and symptoms of acromegaly.
3. Growth hormone/prolactin-secreting anterior pituitary adenomas manifest as signs/symptoms of acromegaly, as oligomenorrhea/amenorrhea and galactorrhea in females, and as sexual dysfunction and (more rarely) gynecomastia in males.
4. ACTHomas are mostly associated with Cushing's syndrome.
5. Thyroid-stimulating hormone−secreting anterior pituitary tumors occur with the signs/symptoms of hyperthyroidism;
6. Nonsecreting pituitary tumors usually manifest as silent macroadenoma compressing adjacent structures, such as optic chiasm with subsequent severe headaches, visual field defects, and/or hypopituitarism.

Anterior pituitary tumors are relatively benign; however, macroadenomas can be aggressive, invasive, inoperable, therapy-resistant tumors causing significant morbidity even when they are not metastatic (they tend to be larger in size than their sporadic counterparts) (Thakker et al., 2012). Vergès et al., (2002) reported that 32% of pituitary macroadenomas were invasive.

TABLE 53.2 Management in MEN1 nonfunctioning pancreatic NETs.

Tumor size	Follow up	Management
<2 cm	EUS−MRI	Follow-up
>2 cm	EUS−MRI gallium-68 DOTATOC PET/CT	Surgery

EUS, endoscopic ultrasound; *MEN1,* multiple endocrine neoplasia type 1; *MRI,* magnetic resonance imaging; *NETs,* neuroendocrine tumors.

A metastatic gonadotropic pituitary carcinoma in a woman with MEN1 (Benito et al., 2005) and a metastatic prolactinoma that presented as a cervical spinal cord tumor (Gordon et al., 2007) have been described. No increased prevalence of pituitary carcinoma is observed in individuals with MEN1 with respect to sporadic counterpart and general population (Thakker et al., 2012).

Pituitary adenomas can be classified by their size, extent of invasion through the cavernous sinus, and clinical function or ability to produce hormones; in 2017, the revised WHO classification recognized the role of transcription factors in tumor differentiation according to cellular lineage, regulation of specific pituitary hormones production, and possible adenoma tumorigenesis (Lloyd et al., 2017).

MRI is the diagnostic imaging of choice, and timing of screening is controversial (Livshits et al., 2016).

The therapy of MEN1 anterior pituitary tumor adenoma is the same as for sporadic counterparts. Medical therapies of PRLoma with dopamine agonists (bromocriptine and cabergoline) is the gold standard; transsphenoidal surgery and radiotherapy are reserved for drug-resistant tumors and macroadenomas that compress adjacent structures and generate neuro-ophthalmologic complications that cannot be managed through pharmacologic therapy.

Transsphenoidal surgery is the treatment of choice for growing hormone-secreting pituitary adenomas. Pharmacological treatment includes SSAs (octreotide, lanreotide, and pasireotide), dopamine agonist (cabergoline), and GH receptor antagonist (pegvisomant).

In ACTH-secreting pituitary tumors, the treatment is excision of adenoma.

In drug-resistant tumors, macroadenoma radiation therapy can be used as an alternative to surgery or in patients who have failed other modalities. The use of modern stereotaxic radiosurgery can minimize the problem of hypopituitarism often seen after conventional radiation therapy (Lim and Korbonitis, 2018).

Thymic and bronchial neuroendocrine tumors

A percentage of MEN1 patients manifest NETs (previously referred to as carcinoids) in the thoracic tract, affecting thymus and bronchi.

NETs of the thymus occur in 3%−8% of MEN1 patients and are diagnosed at a mean age of 39. They arise almost exclusively in men (male/female ratio = 20:1) with a significantly higher percentage in smokers. However, some authors have recently reported a largely different sex ratio (male/female ratio = 2:1) (Christakis et al., 2016). The great majority of thymic NETs are discovered incidentally or only when they have already invaded adjacent tissues and/or metastasized to the lung, liver, and bones. They represent the second cause of death in MEN1 patients after NF GEP-NETs. This unfavorable outcome indicates the need for accurate screening. MRI or CT has been proposed every 3−5 years, but the cost of the examinations and exposure to radiation limit its use. Preventive total thymectomy is suggested at the time of parathyroid surgery, but its effectiveness in preventing thymic carcinoids is questioned, as cases of thymic carcinoids have been reported in patients who have undergone thymectomy at the time of parathyroidectomy. This phenomenon probably depends on an incomplete thymectomy that leaves a part of the thymus in the mediastinum. Radical surgical removal of thymic carcinoids is possible, especially with early intervention. Frequently, it can require resection of surrounding involved structures, such as pleura, pericardium, lung, and major vessels. Radical surgery may have a solely palliative purpose when the tumor grossly invades mediastinal organs; however, it does serve to limit the effects of local compression. Radiotherapy and chemotherapy (temozolomide/5-fluorouracil/oxaliplatin) can be administered either as adjuvant therapy or as a palliative therapy for advanced cases. SSAs, mTor inhibitors (everolimus), and PRRT have also been employed (Sadowski et al., 2017). The prognosis is poor, with a 10-year survival of around 30%.

Bronchial carcinoids are diagnosed in 4%−6% of MEN1 patients when lesions discovered in the lung are biopsied and studied by immunophenotyping for chromogranin A and/or synaptophysin, but the frequency increases to 31% if only imaging findings are considered (Sadowski et al., 2017). These tumors are discovered at the age of 50 years as a mean, without a predominance of one of the sexes but with a major frequency in smokers and in families with other patients affected by this tumor. The discovery of bronchial carcinoid is usually incidental. A majority of bronchial NETs have an indolent progression, remaining stable for years, and the progression toward more aggressive forms (large-cell neuroendocrine carcinomas or small-cell neuroendocrine carcinomas) is rare. Tumor doubling time in males was 2.5 years versus 5.5 years in females (de Laat et al., 2014). Screening every 2−3 years starting from the age of 20 years is recommended using a low-dosage CT scan (Thakker et al., 2012; de Laat et al., 2014). Future trials will determine if other modalities of screening, such as MRI, can be a valid alternative to CT, thereby eliminating the risk of radiation. Surgery is the therapy of choice and should be as lung-sparing as possible, considering the low malignancy of bronchial NETs.

Genetics and molecular biology of multiple endocrine neoplasia type 1

MEN1 is caused by inactivating mutations of the tumor-suppressor gene *MEN1*, encoding a 610 amino acid nuclear protein named menin. The identification of the causative gene in 1997 gave us the possibility of genetic testing and presymptomatic diagnosis of the disease in mutated pedigrees. Over 1500 different MEN1 loss-of-function mutations (1341 germinal and 203 somatic variants) had been described up to September 2015 (Lemos and Thakker 2008; Concolino et al., 2016), affecting the coding region (exons 2−10) and splicing sites or deleting large intragenic regions (Fig. 53.5). A great majority of mutations account for a truncated protein that is unable to reach the nucleus and exert its biological functions. About 10% of patients have de novo mutations developed at the embryonic level and thus lack a family history; 90% of *MEN1* mutations are inherited from one parent in an autosomal-dominant manner and equal sex distribution. Twelve exon polymorphisms have been reported (Lemos and Thakker 2008), ten synonymous and two nonsynonymous, and need to be distinguished from mutations during genetic screening. Two clinical and functional studies have investigated the two nonsynonymous polymorphic variants, Arg171Gln in exon 3 and Ala541Thr in exon 10, for their potential roles in MEN1 tumorigenesis (De Carlo et al., 2008; Nozières et al., 2014), suggesting that both might be regarded as point mutations with the low-penetrance MEN1 phenotype.

Genetic testing is recommended for index cases with two or more MEN1-associated endocrine tumors (for the confirmation of clinical diagnosis), for first-degree relatives and family members of known *MEN1* mutation carriers, and for patients with a suspicious MEN1 phenotype. First-degree relatives of a mutated individual should undergo the genetic screening as early as possible before the age of 5, since MEN1 tumors have been described in some children at 5−8 years. A positive MEN1 genetic test is an indication for annual biochemical and imaging screenings for MEN1-associated tumor detection, according to international MEN1 guidelines (Table 53.3) (Thakker et al., 2012). Early surveillance in mutation carriers grants the detection of MEN1 tumors about 10 years before clinical manifestation. A negative test in relatives indicates they have the same risk of developing MEN1 as the general population, and it allows them to avoid further nonuseful diagnostic screenings. No direct genotype−phenotype correlation has been reported, and thus the individual

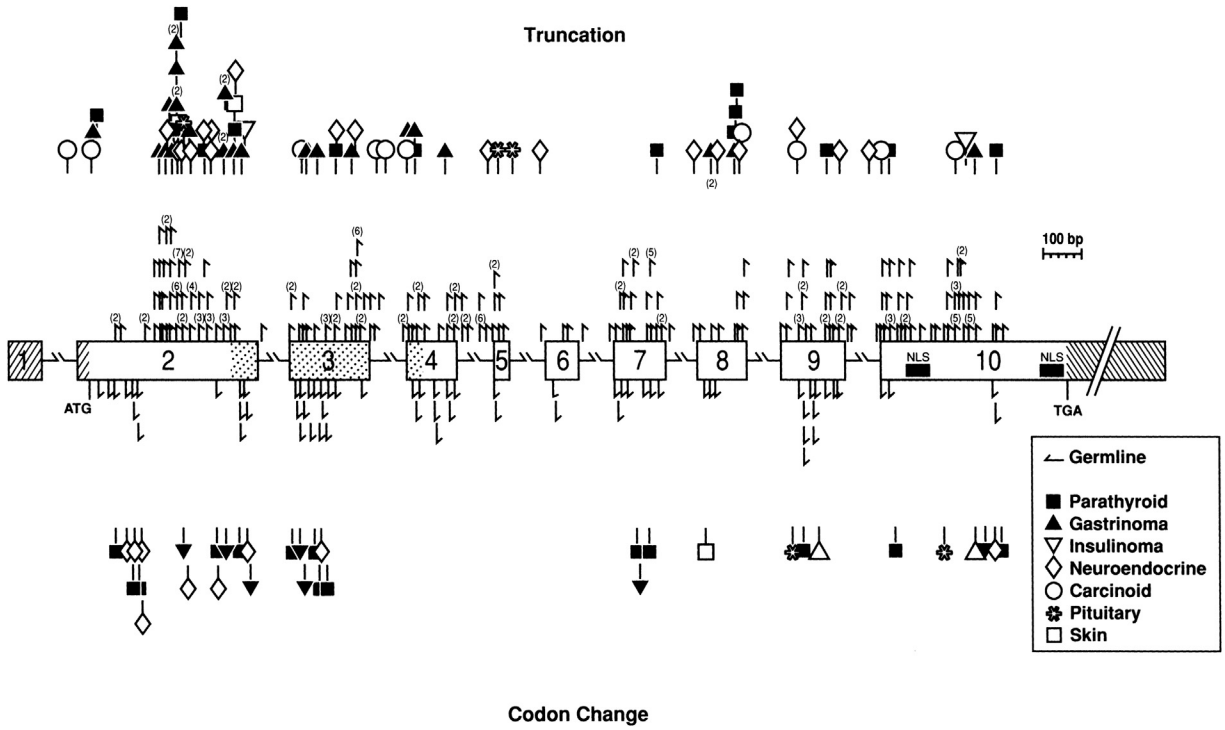

FIGURE 53.5 Genomic organization of the *MEN1* gene and of *MEN1* germline and somatic mutations, published as of June 2000. The gene con- tains 10 exons (with the first exon untranslated) and extends across 9 kb. Mutations shown above the exons cause menin truncation, and those shown below the exons cause a codon change. All unique mutations are represented; numbers in parenthesis designate multiple reports of the same mutation in presumed unrelated persons. The hatched areas indicate the untranslated regions. The location of the two nuclear localization signals (NLS), at codons 479−497 and 588−608, are indicated. Missense mutations in a region of menin (aa 139−242) (identified by stippling) prevented interaction with the AP1 transcription factor JunD.

	Biochemical test		Imaging test	
Syndrome	Type	Surveillance starting age (years) and periodical frequency	Type	Surveillance starting age (years) and periodical frequency
MEN1				
Parathyroid adenoma	Morning fast serum calcium, PTH, and serum ionized calcium1	8 annually	None	–
Anterior pituitary tumors	Morning fast serum PRL, GH, IGF-1, ACTH, cortisol, FSH, LH, TSH	5 annual	Head noncontrast MRI	5 every 3–5 years
Gastrinoma	Fasting serum gastrin (±gastric pH; diagnostic values < 2),	20 annually	None	–
Insulinoma	Fasting plasma insulin and glucose	5 annually	None	–
Other pancreatic NET (glucagonoma, VIPoma, NFTs)	Plasma glucagon, VIP, PP, CgA	10 annually	MRI or EUS or (CT scan)	10 annually
Carcinoids: (Foregut/stomach, lung/bronchi, thymus)	None (they are typically nonsecretory tumors)	–	EUS of the stomach Low dose CT scan and MRI of neck and chest	15 Annually Every 1–2 years
Adrenal lesions	Plasma renin, aldosterone, low-dose dexamethasone suppression test, urinary catecholamines and/or metanephrines	<10	Abdominal imaging by MRI or CT scan	Annually with pancreatic imaging

ACTH, adrenocorticotropic hormone (corticotropin); *CgA*, chromogranin A; *CT*, computed tomography; *EUS*, endoscopic ultrasounds; *FSH*, follicle-stimulating hormone; *GEP-NETs*, gastroenteropancreatic neuroendocrine tumors; *GH*, growth hormone; *IGF-1*, insulin-like growth factor-1; *LH*, luteinizing hormone; *MRI*, magnetic resonance imaging; *PP*, pancreatic polypeptide; *PRL*, prolactin; *PTH*, parathyroid hormone; *TSH*, thyroid-stimulating hormone; *VIP*, vasoactive intestinal peptide.

gene variation cannot lead to a personal diagnostic and therapeutic program; all MEN1 patients and mutation carriers undergo the same diagnostic tumor screenings.

Sequencing analysis fails in identifying mutations in about 10%–30% of clinical MEN1 cases (Agarwal 2017). Multiplex ligation probe amplification can detect large intragenic deletions, which are estimated to represent about 1%–3% of *MEN1* mutations. Current genetic testing does not investigate noncoding and regulatory regions; identification of MEN1 regulatory regions and the application of next-generation sequencing techniques may improve genetic diagnosis and early disease prediction. Clinical phenocopies, presumably caused by mutations in genes encoding menin-interacting proteins (i.e., *CDKN* genes) or in genes regulating *MEN1* expression might account for up to 5% of clinical cases of MEN1 without a *MEN1* mutation.

The protein product of MEN1, menin, is a ubiquitously expressed tumor suppressor showing no homology with any known human protein and having a high sequence homology with other animal species. Menin has been shown to directly interact with more than 50 different proteins involved in the regulation of chromatin modification, DNA repair, cell cycle control, transcription regulation, cell adhesion and mobility, cell signaling, cytoskeletal structure, apoptosis, etc. Also, direct DNA binding property and direct protranscriptional activity of menin have been reported. It is prevalently a nuclear protein that possesses three nuclear localization sites (NLSs) in the C-terminal region; loss of one or more of these NLSs, caused by truncating mutations, makes menin unable to reach the nucleus and become active as a tumor suppressor.

Studies on mouse models knocked out for the *Men1* gene have shown that the germline homozygote loss of *Men1* leads to uterine death, while germline heterozygote loss of *Men1* manifests a clinical phenotype similar to human MEN1

patients, confirming the central role of *MEN1* mutations in MEN1 tumorigenesis. The second wild-type copy of the gene is lost at the somatic level in tumors, as also happens in human MEN1 tumors, according to the "two hits" mechanism of action for tumor-suppressor genes. Somatic *Men1* homozygote knockout in specific endocrine tissues confirmed the development of MEN1 typical tumors, suggesting that menin tumor-suppressor action is tissue-specific (Agarwal 2017). In addition to somatic *MEN1* loss of heterozygosity, epigenetic gene expression regulation by microRNAs (miRNAs) appears to be involved in *MEN1* regulation and MEN1 tumorigenesis. Some miRNAs (i.e., miR-24, miR-17, mir-762, and miR-802) have been shown to directly target MEN1 miRNA (Luzi et al., 2012; Lu et al., 2015; Hou et al., 2017; Wang et al., 2014); particularly, overexpression of miR-24 was described in parathyroid adenomas (Luzi et al., 2012), GEP-NETs (Vijayaraghavan J et al., 2014) and pituitary tumors (Campanini ML et al., 2010), leading to downregulation of menin expression and subsequently enhancing cell proliferation. On the other hand, acting as a transcription factor, menin has been demonstrated to be involved in the biogenesis of let-7 (Gurung et al., 2014a) and miR-155 (Gurung et al., 2014b); let-7 negatively targets proproliferative genes and genes involved in insulin-mediated signals (i.e., *IRS2*) in pancreas beta cells, and thus reduced biogenesis of let-7 due to *MEN1* mutations could be suspected as the molecular mechanism responsible for beta cell uncontrolled growth and insulinoma development (Gurung et al., 2014b).

Chapter 54

Parathyroid hormone-related peptide and other mediators of skeletal manifestations of malignancy

Richard Kremer and David Goltzman

Calcium Research Laboratories and Department of Medicine, McGill University and McGill University Health Centre, Montreal, QC, Canada

Chapter outline

Introduction

Hypercalcemia is one of the most frequent paraneoplastic syndromes and often occurs in advanced stages of the disease. The median survival rate usually varies between 6 and 10 weeks following the onset of hypercalcemia (Body, 2000); however, breast cancer patients experience a somewhat longer median survival of 3–4.5 months (De Wit and Cleton, 1994).

The association between elevated blood calcium and neoplastic disease was first noted in the 1920s (Zondek et al., 1923), when it was postulated that release of calcium from bone by the direct osteolytic action of malignant cells was responsible for hypercalcemia associated with malignancy. However, hypercalcemia was often accompanied by hypophosphatemia, the hallmark of hyperparathyroidism (HPT), and also occurred in the absence of skeletal metastases. In 1941 it was hypothesized that a malignant tumor might release a systemically active factor resulting in hypercalcemia (Albright, 1941). This hypothesis was raised when a patient with a renal carcinoma, metastatic to bone, presented with

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00054-3

hypercalcemia and hypophosphatemia in the absence of any obvious parathyroid dysfunction. The patient's biochemical abnormalities were temporarily normalized following tumor reduction but became apparent again as the tumor resumed its growth. It was reasoned that since hyperphosphatemia did not accompany hypercalcemia despite evidence of osteolysis, perhaps the tumor was secreting a phosphaturic substance like parathyroid hormone (PTH). Although no bioassayable hormone was detected in the tumor, the important observation had been made that malignancy-associated hypercalcemia (MAH) could have a humoral basis and the factor might be related to PTH. The search for a novel protein with PTH-like bioactivity intensified using several bioassays that had been developed for PTH (Goltzman et al., 1981; Nissenson et al., 1981; Rodan et al., 1983). Using both in vivo and in vitro approaches, PTH-like bioactivity was identified in the blood and in tumor extracts from patients with MAH. These same bioassays were used in various combinations during the purification of a novel protein, initially named parathyroid-hormone-like peptide, from tumor tissue (Burtis et al., 1987; Moseley et al., 1987; Strewler et al., 1987). When the gene was cloned and demonstrated to be structurally homologous to PTH, the protein was renamed parathyroid-hormone-related protein, or PTHrP (Mangin et al., 1989; Suva et al., 1987).

The term humoral hypercalcemia of malignancy (HHM) was later coined to distinguish the syndrome caused by a circulating factor, now known to be PTHrP, from hypercalcemia caused by the direct lytic action of tumor cells in bone. The demonstration that neutralizing antibodies to PTHrP could reduce or eliminate the hypercalcemia in animal models of HHM (Kukreja et al., 1988; Henderson et al., 1990a,b) provided strong evidence that this was indeed the causal factor of this syndrome. HHM was associated primarily with renal cell carcinomas and squamous cell cancers originating in a variety of primary sites, whereas hypercalcemia due to local osteolysis was commonly associated with metastatic breast disease and hematologic malignancies. Nevertheless, it is now clear that the "direct" lytic action of tumor cells is also mediated in part by PTHrP, and that PTHrP released by these tumors may also act on a systemic basis.

Characterization of hypercalcemia in malignancy

Despite the striking similarities between the biochemical manifestations of HPT and MAH that precipitated Albright's hypothesis, it subsequently became apparent that there were also a number of important differences between these syndromes.

Early attempts at the differential diagnosis of these hypercalcemic disorders identified not only subnormal concentrations of immunoreactive PTH (Powell et al., 1973) and no detectable PTH mRNA in the tumors (Simpson et al., 1983) but also a mild hypokalemic alkalosis in patients with MAH. In contrast, elevated PTH and mild metabolic acidosis were associated with HPT (Lafferty, 1966). In addition, circulating levels of 1,25D were reported low in PTHrP-associated hypercalcemia in contrast to patients with HPT, where 1,25D is often elevated (Stewart et al., 1980). Potential explanations for this apparent discrepancy were the very high calcium levels often seen in MAH that are known to inhibit 1alpha-hydroxylase in vitro and in vivo (Bikle, 2014) or possibly unknown inhibitors of 1alpha hydroxylase released by tumor cells. Nevertheless, the occurrence of low 1,25-dihydroxyvitamin D(1,25(OH)2D levels in MAH is not widely accepted and low, normal, or even high levels of 1.25(OH)2D were later reported in this syndrome (Schweitzer et al., 1994; Ralston et al., 1984). Indeed, in a large series of hypercalcemic patients with various malignancies and elevated PTHrP levels, the mean circulating levels of 1,25(OH)2D were normal (Donovan et al., 2015). Another important difference between MAH and HPT has been the histomorphometric changes observed in bone biopsy specimens and a report by Stewart et al. (1982) of uncoupling between resorption and formation in hypercalcemic cancer patients. These findings in cancer patients are also in sharp contrast with studies in animal models of MAH, in which circulating 1,25D levels are high and bone turnover appeared to be coupled (Sica et al., 1983; Strewler et al., 1986). Similar results were obtained in tumor-bearing rats producing PTHrP prior to the development of hypercalcemia (Yamamoto et al., 1995). Furthermore, administration of an N-terminal fragment of PTHrP to human volunteers suggests that PTHrP has similar bioactivity to that of PTH (Fraher et al., 1992).

Molecular and cellular biology of PTH-related protein

Purification and cloning of PTH-related protein

Despite many unsuccessful attempts to identify the PTH-like factor(s) in the blood of hypercalcemic patients using immunoassays directed at PTH (Powell et al., 1973), and later the lack of expression of PTH mRNA in tumors of hypercalcemic cancer patients (Simpson et al., 1983), the search for this elusive factor continued. Using several bioassays, PTH-like bioactivity was identified in the blood (Goltzman et al., 1981) and in tumor extracts from patients with MAH (Nissenson et al., 1981; Rodan et al., 1983). Using similar bioassays, a fragment of the PTH-like protein was purified (Moseley et al., 1987; Strewler et al., 1987), and soon after complementary DNA (cDNA) clones encoding PTHrP were isolated (Strewler et al., 1987; Suva et al., 1987; Mangin et al., 1988).

Characteristics of the gene encoding PTH-related protein

The *PTH* and *PTHLH* genes respectively encoding PTH and PTHrP have been localized to the short arms of the respective human chromosomes 11 and 12, placing them among syntenic groups of functionally related genes and suggesting a common ancestral origin (Goltzman et al., 1989). Similarities in their structural organization and the functional properties of their amino termini provide further support for the hypothesis that *PTH* and *PTHLH* are members of a single gene family. The human *PTHLH* gene is a complex unit with at least seven exons driven by several promoters at the 5′ end that span more than 15 kb of DNA (Goltzman et al., 1989; Mangin et al., 1989). Its mRNA is transcribed from at least three promoters and undergoes differential splicing, giving rise to heterogenous mRNA species. The cDNA encodes a prototypical secretory protein with predicted mature isoforms of 139, 141, and 173 amino acids that exhibit a high degree of homology within the first 13 amino acids to the N-terminus of PTH; this facilitates its cross-reactivity with a G-protein coupled PTH receptor, the type 1 PTH/PTHrP receptor (PTH1R) (Jüppner et al., 1991) (Fig. 54.1). The sequence beyond amino acid 141 is unique to the human species and nonhuman primates. Interestingly, the three isoforms were shown to be expressed and secreted by both normal and tumor tissues in humans (Campos et al., 2006), but PTHrP 1−139 and 1−141 were considerably more abundant than PTHrP 1−173 in nonneoplastic tissues, whereas an increase in PTHrP 1−173 was observed in a large proportion of neoplastic tissues. The rat *PTHLH* gene is driven by a single promoter and encodes a protein of 141 amino acids with marked sequence homology to human PTHrP up to residue 111, which suggests conserved functionality (Yasuda et al., 1989). Indeed, species conservation of PTHrP is evident with high homology across a variety of mammalian species (Burtis, 1992). The gene structure of *PTHLH* was also elucidated in several other species (Mangin et al., 1989; Yasuda et al., 1989; Suva et al., 1989; Karaplis et al., 1990) also revealing similarities with the PTH gene structure organization, suggesting that the two genes probably arose from a common ancestor through gene duplication.

Eutopic PTH-related protein overproduction in malignancy

PTHrP is widely distributed in embryonic and adult tissues and has essential functions in development and growth. In view of its broad distribution pattern in many cell types, overproduction of PTHrP by malignant cells most likely results from deregulated expression of an endogenous protein during the process of malignant transformation; that is, "eutopic" rather than "ectopic" production.

Transcriptional and posttranscriptional regulation

A number of potential mechanisms have been invoked to explain overexpression of PTHrP in malignant cells, including gene amplification (Sidler et al., 1996) and alterations in the methylation status of critical regulatory regions of the gene during neoplastic transformation (Broadus and Stewart, 1994; Ganderton and Briggs, 1997). Furthermore, the complex

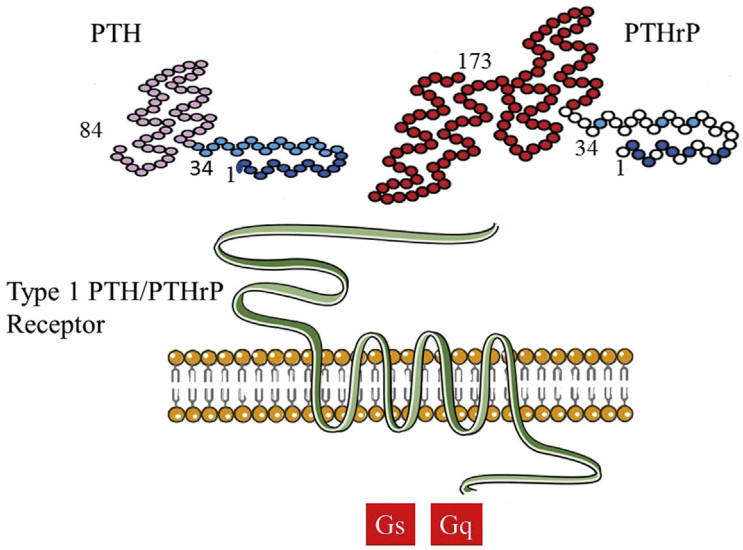

FIGURE 54.1 Interaction of PTH and of PTHrP with the type 1 PTH/PTHrP receptor. PTH(1−84) and PTHrP, which can occur as isoforms of 139, 141, and 173 amino acids, share limited amino acid sequence homology within the 1−34 domain. As a result, they can interact with a G-protein-coupled receptor, the type1 PTH/PTHrP receptor, which is linked to Gs and Gq.

organization of the human PTHrP gene suggests that changes in tissue-specific promoter usage or splice variants might also contribute to overproduction of PTHrP during the process of malignant transformation. One extensive clinical study examined a variety of tumors, including 13 breast malignancies, with exon-specific probes to identify transcripts arising from all three promoters and from the different 3′ splice variants (Southby et al., 1995). Although the authors failed to identify tissue-specific or tumor-specific transcripts, they did show that PTHrP was transcribed from multiple promoters in tumor samples, compared with a single promoter in normal tissue harvested from the same individual. The resulting overall increase in transcription could then lead to cumulative overexpression of the protein in neoplastic tissue. Others, however, have reported the presence of specific transcripts related to the stage of cancer progression. Thus Bouizar et al. (1999) investigated the differential expression of PTHrP isoforms in different stages of breast cancer progression as a result of differential use of a downstream TATA promoter. The amount of mRNA encoding the 1−139 isoform was much higher in the tumors of patients who later developed metastases than in those of patients who developed no metastases. The mRNA encoding this isoform was also more abundant in breast tumors from patients who developed bone metastases than in those of patients who developed metastases in soft tissues. In contrast, the amounts of mRNA encoding the 1−141 isoform were similar in these different groups.

Transcriptional regulators of PTH-related protein

Viral proteins

Viral proteins, notably Tax, have been implicated in transcriptional stimulation of PTHrP production in malignant states. TAX is a 40-kDa nuclear phosphoprotein that transactivates its own promoter as well as those of a number of host genes. It interacts with a variety of transcription complexes that bind to DNA consensus elements in the *PTHrP* promoter including the cAMP response element, Ets-1, serum response element, and the AP-1 binding site (Dittmer et al., 1993; Ejima et al., 1993). PTHrP mRNA has been identified in samples harvested from asymptomatic human T-cell leukemia virus type I (HTLV-I) carriers as well as from leukemic cells of ATL patients (Motokura et al., 1989), and elevated circulating levels of PTHrP were detected in most hypercalcemic individuals in the acute phase of the disease (Ikeda et al., 1993). In view of the documented role of HTLV-I infection in the pathogenesis of adult T-cell leukemia-lymphoma and the high incidence of PTHrP overexpression in these patients, it was proposed that the TAX might stimulate PTHrP gene transcription. The MT-2 cell line, in which TAX is overexpressed, was used to determine that PTHrP gene transcription was indeed enhanced and that maximal stimulation of *PTHrP* involved activation of protein kinase A (PKA) and protein kinase C (PKC) (Motokura et al., 1989).

Growth factors and hormone regulation of PTH-related protein production

Growth factors and cytokines. A variety of growth factors are potent stimulators of *PTHrP* gene transcription: epidermal growth factor (EGF), insulin-like growth factor (IGF)-1 (Kremer et al., 1991; Sebag et al., 1994), and transforming growth factor beta (in both normal and cancer cells).

Whereas mitogenic stimuli induce PTHrP expression in primary rat aortic smooth cells (Hongo et al., 1991), in nonmalignant established cell lines from normal human keratinocytes (Henderson et al., 1991) and normal human cervical epithelial cells (Kremer et al., 1996a,b,c), transforming growth factor (TGF) beta has antagonistic effects to EGF in normal mammary epithelial cells (Feffari et al., 1994). TGF beta enhances the production of PTHrP in cancer cells in vitro (Zakalik et al., 1992; Kiriyama et al., 1993), and cooperating with PTHrP, enhances osteolytic bone metastases in vivo (Yin et al., 1999).

Several studies indicate that PTHrP expression increases in parallel to tumor progression. PTHrP is overexpressed in normal human keratinocytes (Henderson et al., 1991) and normal human prostate cells (Kremer et al., 1997) following activation by the ras oncogene. PTHrP is also overexpressed in the human melanoma A375 cell line compared with normal human melanocytes (El Abdaimi et al., 2000a,b). In the pYMT model of breast tumor progression (Guy et al., 1992; Li et al., 2011), PTHrP expression progressively increases with tumor stage from hyperplasia to carcinoma.

The mechanism(s) of overexpression is still poorly understood. One of the hallmarks of cancer, however, is the growth of cells independently of mitogenic stimuli (Hanahan and Weinberg, 2011). In contrast to normal or established keratinocytes, PTHrP is expressed constitutively in ras-transformed keratinocytes (Henderson et al., 1991).

Signaling by growth factors through receptor tyrosine kinases (RTKs) appears to be an important mechanism for regulating PTHrP gene expression and for oncogenic transformation by the Ras component of the RTK signal transduction pathway in many malignant cells. Transfection of Tpr-Met, a constitutively active derivative of the hepatocyte growth factor receptor, into PTHrP-producing cells resulted in a substantial increase in the expression and release of

PTHrP (Aklilu et al., 1996). Introduction of a point mutation into Tpr-Met, which prevented its association with the Ras signaling pathway, led to a significant reduction in PTHrP expression and release. Similar reductions were observed in cells treated with agents that inhibit Ras function by preventing it from anchoring to the cell membrane and transducing a signal (Ras farnesylation inhibitors) (Aklilu et al., 1997). These studies demonstrated an important role for Ras in enhancing PTHrP production in transformed cells.

Steroid hormones. Several steroid hormones have been reported to influence the production of PTHrP. Thus estradiol has been reported to inhibit PTHrP gene promoter activity in breast cancer cell models in vitro and to diminish PTHrP production in vivo (Rabbani et al., 2005). Similarly androgens (dihydrotestosterone) have also been shown to inhibit PTHrP production in models of prostate cancer both in vitro and in vivo at least in part via a transcriptional mechanism (Pizzi et al., 2003). Glucocorticoids have also been shown to inhibit PTHrP production (Sebag et al., 1994; Tenta et al., 2005; Glatz et al., 1994).

The secosteroid 1,25 dihydroxyvitaminD and its analogs 1,25 dihydroxyvitamin D ($1,25(OH)_2D$) have been shown to inhibit PTHrP gene transcription (Kremer et al., 1991; Sebag et al., 1992). A $1,25(OH)_2D$ responsive repressor sequence was identified between bases −1121 to −1075 upstream of the single promoter in the rat *PTHrP* gene (Kremer et al., 1996a,b,c), and the PTHrP repressor site binds a vitamin D receptor (VDR)-retinoid X receptor (RXR) heterodimer in normal keratinocytes. The VDR−RXR complex was also identified in extracts of nuclei from immortalized keratinocytes but VDR−RXR interaction was disrupted in Ras transformed cells that had previously shown resistance to $1,25(OH)_2D_3$-induced inhibition of PTHrP expression (Solomon et al., 1998). Expression of wild-type RXRα in the transformed cells resulted in reconstitution of the VDR−RXR heterodimer. Subsequent work determined that disruption of the VDR−RXR complex in Ras-transformed keratinocytes resulted from mitogen-activated protein kinase (MAPK)-stimulated phosphorylation of RXRα by the activated Ras/Raf/MAPK pathway (Solomon et al., 1999).

Based on observations that $1,25(OH)_2D$ is a strong inhibitor of PTHrP expression and production in cancer cells, we hypothesized that this mechanism could be used advantageously in MAH. Our strategy was to use $1,25(OH)_2D$ analogs with low calcemic activity that would efficiently inhibit PTHrP expression and production in vivo. One such analog, EB1089, was then used in two animal models of MAH and shown to both prevent and reverse the development of hypercalcemia by inhibiting PTHrP expression in the primary tumor and subsequent release of PTHrP in the circulation (Haq et al., 1993; El Abdaimi et al., 1999).

Regulation by calcium. Early studies in the keratinocyte model of tumor progression showed that an increase in extracellular calcium stimulated the expression and production of PTHrP (Henderson et al., 1991). Following the cloning of the calcium-sensing receptor (CaSR) (Brown et al., 1993) various well-established cancer cell lines have been found to express both CaSR mRNA and protein (Cattopadhyay, 2006). These include cell lines derived from breast cancer [MCF-7, MDA-MB-231] (Sanders et al., 2000) and prostate cancer [PC-3, LnCaP] (Sanders et al., 2001). Both pharmacological and molecular evidence indicates that elevated Ca^{2+} upregulates PTHrP synthesis and release via CasR activation in these cell lines. Stimulation of PTHrP release due to CasR activation involves de novo synthesis of PTHrP mRNA, in view of the fact that the pan-RNA polymerase inhibitor actinomycin D inhibits the effect of Ca^{2+} on the expression of PTHrP mRNA and protein release. Consequently, elevated calcium induced by circulating PTHrP may have a stimulatory effect on further PTHrP release by the tumor. Furthermore, the majority of calcium in the body is stored in bone, and bone-derived calcium is released during bone resorption, resulting in an increase in extracellular calcium (Ca^{2+}) in the bony microenvironment to levels in the vicinity of resorbing osteoclasts that are manyfold higher (ranging from 8 to 40 mM) than the level of systemic Ca^{2+} (Silver et al., 1988). Evidence is accumulating that these large local changes in Ca^{2+} may be "sensed" by cancer cells metastatic to bone and could enhance further PTHrP release from tumor cells metastatic to bone. Additionally, more recent evidence indicates that disruption of upregulation of PTHrP by the CaSR through conditional ablation of the CaR in mammary epithelial cells inhibits tumor growth in the PyMT model of breast cancer progression (Kim et al., 2016).

Overall, therefore, these studies indicate that increased PTHrP production can result from alterations in the interaction between stimulatory and inhibitory signaling pathways in malignant cells.

Processing and degradation of PTH-related protein

Like PTH, PTHrP is synthesized as a prohormone with an amino-terminal extension. The biological potency of pro-PTHrP is considerably less than that of PTHrP-(1−34) (Liu et al., 1995). A furin recognition sequence is found between the propeptide and the mature protein, and studies (Liu et al., 1995) have shown that pro-PTHrP was indeed a substrate for the prohormone convertase furin.

Examination of the amino acid sequences of the three major isoforms of PTHrP revealed the presence of several proteolytic sites, amidation consensus sites, and sites of 0-glycosylation (Philbrick et al., 1996; Orloff et al., 1989;

Wu et al., 1991; Sowers et al., 1996; VanHouten et al., 2003). PTHrP appears to undergo endoproteolytic cleavage in the secretory pathway, resulting in the release of multiple fragments. PTHrP is secreted by normal and cancer cells as short N-terminal fragments of approximately 36 amino acids, as well as longer N-terminal fragments. In vitro studies in human renal carcinoma cell lines and rat insulinoma cell lines (Soifer et al., 1992) transfected with a cDNA encoding PTHrP1-141 demonstrated the presence of several immunoreactive moieties including PTHrP1-36, PTHrP38-94, PTHrP1-74, and a midregion fragment of 7 kDa likely PTHrP38-101 (Wu et al., 1996). Processing of endogenous, internally labeled PTHrP in rat leydig cells revealed the presence of three bioactive moieties, PTHrP1-141, PTHrP1-86, and PTHrP1-36. PTHrP1-141 represented only 7% of newly synthesized material, suggesting rapid degradation of the secreted intact molecule (Rabbani et al., 1993).

Mechanisms of action of PTH-related protein

Interaction of amino-terminal PTH-related protein with cell surface receptors

Sequence homology between PTH and PTHrP is restricted to only 8 of the first 13 residues; however, this domain is known to be required for activation of signal transduction cascades. Additional conformational similarities in the 14−34 region, a domain that appears critical for peptide binding to the receptor, permit amino-terminal fragments of the proteins to act as equivalent agonists for their common receptor, PTH1R (Fig. 54.1). PTH1R is a seven-transmembrane G-protein linked receptor with the "signature" G protein-coupled receptor (GPCR) topology, a seven-membrane-spanning, "serpentine" domain, as well as a large extracellular ligand-binding domain and an intracellular COOH-terminal domain. The receptor couples to Gs and Gq leading to activation of the PKA and PKC pathways (Mannstadt et al., 1999), and like other GPCRs, undergoes cyclical receptor activation, desensitization, and internalization (Weinman et al., 2006) (Fig. 54.1). After ligand binding and endocytosis, the PTH1R is either recycled to the cell membrane or targeted for degradation. Arrestins contribute to the desensitization of both Gs- and Gq-mediated PTH1R signaling. PTH1R activation and internalization can be selectively dissociated (Sneddon et al., 2004). PTH1R signaling can be modified by scaffolding proteins such as the Na^+/H^+ exchanger regulatory factors 1 and 2 through PDZ1 and PDZ2 domains (Mahon et al., 2002; Sneddon et al., 2003).

PTH1R signaling via the cAMP pathway, leading to PKA activation and phosphorylation of the cyclic AMP response element binding protein (CREB), has been extensively documented. CREB binds to the cyclic AMP response element in the promoter region of many genes and transcriptionally modulates their expression.

Although PTHR1 signals primarily by coupling with PKA, it can also signal through PKC (Abou-Samra et al., 1992), RhoA pathway (Singh et al., 2005), and the β-arrestin−extracellular signal-regulated kinase 1/2 (ERK1/2) pathway (Syme et al., 2005; Gesty-Palmer et al., 2006). The PTH and PTHrP 1−34 amino-terminal regions are presumed to contain all the structural elements for downstream signaling through PTH1R.

PTH1R, as with PTHrP, is expressed in a wide variety of embryonic and adult tissues, including cartilage and bone, and therefore mediates the autocrine/paracrine actions of locally produced and secreted PTHrP.

Although PTH is expressed almost exclusively in parathyroid cells, PTHrP is broadly expressed in many fetal and adult tissues (Goltzman et al., 1989), consistent with its physiologic functions as a modulator of cell growth, differentiation, and programmed cell death (see chapter by Martin et al.: "Paracrine PTHrp actions"). Many critical effects of PTHrP are mediated via the interaction of the amino-terminal domain of PTHrP with PTH1R. These include roles in the normal development of the cartilaginous growth plate (Goltzman et al., 1989), in bone anabolism (Miao et al., 2005), in mammary gland development including the development of mammary ducts and nipple formation (Foley et al., 2001) in calcium transport across the placenta (Kovacs et al., 1996), in smooth muscle relaxation, in vasodilatation (Schordan et al., 2004), and in tooth eruption (Philbrick et al., 1998). The most striking developmental effects of PTHrP have been demonstrated in the skeleton of mice with targeted deletion of PTHrP ($PTHrP^{-/-}$ mice), where PTHrP has been shown to be essential for normal development of the cartilaginous growth plate and endochondral bone formation. Thus in the absence of full-length PTHrP, chondrocyte proliferation is reduced and accelerated chondrocyte differentiation and apoptosis occurs in the growth plate; the overall effect is a severely deformed skeleton and early lethality (Karaplis et al., 1994; Amizuka et al., 1994) (see chapter by Martin: "Paracrine actions of PTHrp in bone").

In humans, an inactivating mutation of PTH1R produces a similar lethal chondro-osseous dysplasia, termed Blomstrand syndrome (Zhang et al., 1998). Mice heterozygous for PTHrP ablation appear normal at birth but develop reduced trabecular bone as they age, demonstrating an osseous phenotype due to haploinsufficiency (Amizuka et al., 1996). In humans, variants of the *PTHLH* gene have been associated, in genome wide association studies, with reduced bone mineral density (Estrada et al., 2012).

With respect to ion homeostasis, in the fetus PTHrP appears necessary for normal calcium homeostasis (Kovacs et al., 1996), but in the adult, PTH rather than PTHrP assumes the major role in calcium and phosphorus homeostasis, with serum PTHrP concentrations being either very low or undetectable in normal adults. In contrast, when neoplasms hypersecrete PTHrP, the effects of PTH are mimicked on bone and kidney, and the hypercalcemia that results suppresses endogenous PTH secretion.

Functions of carboxyl and midregion circulating fragments of PTH-related protein

Several investigators have reported a variety of functions for fragments of PTHrP that share no homology with PTH. These include the pentapeptide PTHrP-(107−111), which was named osteostatin for its potential to inhibit osteoclastic bone resorption in culture (Fenton et al., 1991). Other studies using carboxy-terminal fragments of PTHrP have shown that such fragments inhibit production of the early osteoblast marker osteopontin (Seitz et al., 1995) in isolated osteoblasts and are almost as effective as PTHrP-(1−34) in stimulating functional osteoclast formation from progenitor cells (Kaji et al., 1995). These studies support in vivo observations demonstrating decreased osteoblastic and increased osteoclastic activity in association with elevated circulating levels of carboxy-terminal fragments of PTHrP in patients with HHM (Burtis et al., 1994).

In contrast to the well-known mechanism of action of the N-terminal moiety of PTHrP, the mechanism of action of the C-terminal moieties with unique biological functions is poorly understood. It is possible that the distinct biological actions of PTHrP occur through as-yet-unidentified receptors or binding proteins.

In the brain, it has been reported that N-terminal and C-terminal sequences of PTHrP act through distinct signaling mechanism activating cAMP/PKA and changes in intracellular calcium, respectively (Fukayama et al., 1995), suggesting that the C-terminal domain of PTHrP acts through a distinct receptor. Others have reported the presence of cell surface binding proteins for carboxyl terminal fragments of PTHrP on skeletal cells (Orloff and Stewart, 1995); however, to date the molecular nature of these receptors and binding proteins remain unclear.

PTHrP has also been reported to be a key regulator of fetal calcium, in view of the fact that deletion of its gene in murine fetuses of mice with ablation of the PTHrP gene (i.e., in $PTHrP^{-/-}$ mice) results in hypocalcemia and hyperphosphatemia (Kovacs, 2015). Much of the PTHrP in fetal circulation may arise from the placenta. Studies in lambs and rodents have shown that PTHrP stimulates active placental calcium transport. Although there have been no direct measurements of placental mineral transport in human babies, in vitro study of intact placentas as well as isolated trophoblast membranes has provided some supportive evidence for the roles of PTHrP in stimulating placental calcium transport and gene expression. The bioactivity of PTHrP for placental calcium transport is specified by a midmolecular region, PTHrP-(67−86), that does not use PTH1R (Kovacs et al., 1996); however, the receptor for this region has not been identified.

Intracellular mechanism of PTH-related protein action

Although most cellular actions of PTHrP have been attributed to the interaction of its amino-terminus with the cell surface PTH1R, there are also reports that PTHrP may have a direct, intracellular mode of action(Fig. 54.2). There is evidence in the literature for three potential mechanisms for the translocation of PTHrP, a prototypical secretory protein, into the cytoplastic compartment of target cells. One involves the alternative initiation of PTHrP translation to exclude the “pre” or leader sequence, which is necessary for entry of the molecule into the endoplasmic reticulum and secretory pathway (Nguyen et al., 2001). A second involves retrograde transport of nascent PTHrP from the endoplasmic reticulum (Meerovitch et al., 1998) into the cytoplasm. Finally, a third involves internalization of secreted PTHrP via a PTH1R-independent cell-surface-binding protein for PTHrP (Aarts et al., 1999).

The intracrine action of PTHrP appears to be mediated at least in part through residues 87−107 in the midregion of the protein. This region shares sequence homology with a lysine-rich bipartite nuclear localization sequence (NLS) in nucleolin (Schmidt-Zachmann et al., 1993) and with an arginine-rich NLS in the retroviral regulatory protein TAT (Dang et al., 1989). The PTHrP NLS is both necessary and sufficient to direct the passage of PTHrP to the nuclear compartment of transfected cells and to localize endogenously expressed PTHrP to nucleoli in chondrocytes and osteoblasts in vitro and in vivo (Henderson et al., 1995). Endogenous PTHrP has been identified in the coarse fibrillar component of nucleoli by immunoelectron microscopy. This compartment is occupied by complexes of newly transcribed 45s ribosomal RNA and protein that are destined for assembly into ribosomes, and PTHrP has been shown to bind to GC-rich homopolymeric RNA and total cellular RNA with specificity and high affinity (Aarts et al., 1999), compatible with a role in ribosomal biogenesis. The biological impact of nucleolar PTHrP on cell function was demonstrated in vitro when chondrocytes

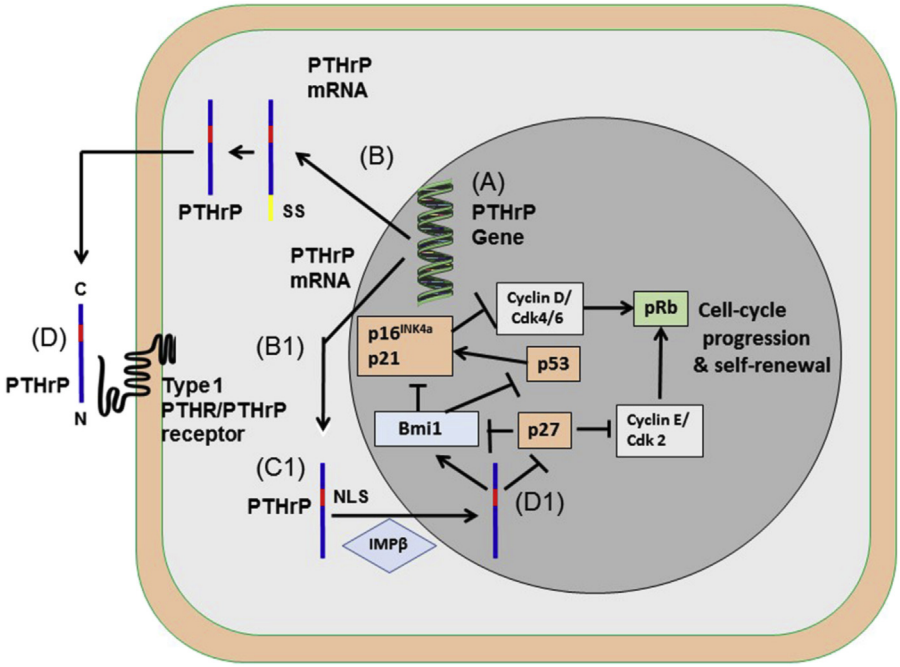

FIGURE 54.2 Model of dual action of PTHrP. PTHrP is transcribed from a single gene, but the translation product may enter the secretory pathway (B) and be secreted from the synthesizing cell to act as an endocrine/paracrine/autocrine factor by interacting with the cell membrane type 1 PTH/PTHrP receptor. Alternatively, PTHrP may be retained within the cytoplasm (B1) and PTHrP may bind with high affinity to importin β1 and the GDP-bound protein, Ran (C). PTHrP, transported into the nucleus(D1), acts as an intracrine factor by increasing the polycomb ring finger oncogene, Bmi1, leading to inhibition of the action of the cyclin-dependent kinase inhibitors p16INK4a and p21 and therefore facilitating increased activity of cyclin-dependent kinase D/Cdk4/6. Bmi1 may also inhibit p53 preventing its stimulation of p16INK4a and p21. Intranuclear PTHrP may also inhibit the cyclin-dependent kinase inhibitor p27, allowing increased cyclin E/Cdk2 activity. The net result is increased phosphorylation and inactivation of the retinoblastoma gene, resulting in increased cell cycle progression and self-renewal.

expressing wild-type PTHrP were protected from apoptosis induced by serum deprivation, whereas cells expressing the protein without NLS were not. Subsequently, the nuclear localization of PTHrP was also found to be protective in studies in vitro for prostate cancer cell apoptosis (Dougherty et al., 1999) and breast cancer (Sepulveda et al., 2002).

Nuclear localization of PTHrP occurs in a cell cycle-dependent manner, with higher expression in the G2 and M phases of the cycle (Okano et al., 1995; Lam et al., 1997). The cell cycle-dependent localization of PTHrP is regulated by the activity of the cyclin-dependent kinases (cdks) cdc2 and cdk2, which phosphorylate PTHrP at threonine 85 within a consensus cdc2/cdk2 site (Lam et al., 2000). Phosphorylation increases as cells progress from G1 to G2 and M of the cell cycle and leads to decreased nuclear entry, perhaps by enhancing binding to a cytoplasmic retention factor. PTHrP appears to bind with high affinity to importin β1 and the GDP-bound protein, Ran (Lam et al., 1999). PTHrP nuclear import seems dependent on microtubular integrity implicating a role for the cytoskeleton in transport to the nucleus (Lam et al., 2002). After translocation across the nuclear envelope, GTP-bound Ran may release PTHrP into the nucleus where it apparently can act, at least in part, in the nucleolus to bind RNA, thereby regulating mRNA processing or mRNA transport. Functionally, intranuclear PTHrP seems to delay apoptosis (Henderson et al., 1995) and increase cell proliferation. Indeed, a series of studies (Zhang et al., 2010; Jiang et al., 2015), using knockin mice that express PTHrP(1−86) but not NLS (nor the carboxy terminal region) have shown that intranuclear PTHrP may increase the polycomb ring finger oncogene, Bmi1, leading to inhibition of the action of the cyclin-dependent kinase inhibitors $p16^{INK4a}$, and p21, and therefore facilitate increased activity of cyclin-dependent kinase D/Cdk4/6. Intranuclear PTHrP may also inhibit the cyclin-dependent kinase inhibitor 1B, $p27^{Kip1}$, allowing increased cyclin E/Cdk2 activity. The net result is increased phosphorylation and inactivation of the retinoblastoma gene, resulting in increased cell cycle progression and self-renewal (Fig. 54.2). This may provide a molecular basis for the phenotypic changes in the knockin mice. Whether this intracrine action of PTHrP promotes tumor progression in tumors in which PTHrP is expressed remains to be determined.

Deletion of the NLS and the C-terminus sequence of PTHrP was engineered in PTHrP "knockin" mice that still expressed PTHrP(1−86). Deletion of these sequences in vivo resulted in growth failure, premature osteoporosis, reduced hematopoiesis, altered energy metabolism, and ultimately premature death (Miao et al., 2008; Toribio et al., 2010).

The abnormality in growth of PTHrP knockin mice expressing PTHrP(1−84) was characterized by a markedly abnormal epiphyseal growth plate, but in contrast to the deletion of the full-length sequence of PTHrP, the abnormality in the knockin mice consisted of a reduced proliferative zone but normal hypertrophic zone architecture, suggesting that secreted PTHrP acting via PTHR1 and intracellular PTHrP may act synergistically to regulate the growth plate. PTHrP knockin mice also develop reductions in osteoblastic activity, again suggesting synergy between the paracrine and intracrine actions of PTHrP (Miao et al., 2005).

PTH-related protein actions to produce the manifestations of humoral hypercalcemia of malignancy

Actions in kidney

An elevation in the circulating level of PTHrP in patients with HHM initially results in phosphate wasting and calcium retention by the kidney in association with an increase in the nephrogenous component of excreted cAMP (Fig. 54.3) (see also chapter by Friedman: "PTH and PTHrp actions on kidney"). This is analogous to the endocrine effects of excess circulating PTH in HPT and results from the interaction of PTHrP with PTH1R. Thus in the proximal tubule, stimulation of adenylate cyclase causes internalization of the type II Na^+/Pi^- (inorganic phosphate) cotransporter, leading to reduced apical Na^+/Pi^- cotransport, decreased phosphate reabsorption, and phosphaturia (Keusch et al., 1998). About 20% of filtered calcium is reabsorbed in the cortical thick ascending limb of the loop of Henle (CTAL) and 15% in the distal convoluted tubule (DCT), and it is here that PTHrP also binds to the PTH1R, and again by a cyclic AMP-mediated mechanism enhances calcium reabsorption. In the CTAL, at least, this appears to occur by increasing the activity of the Na/K/2Cl cotransporter that drives NaCl reabsorption and stimulates paracellular calcium and magnesium reabsorption. PTHrP can also influence transcellular calcium transport in the DCT. This is a multistep process involving transfer of luminal Ca^{2+} into the renal tubule cell via the transient receptor potential channel, translocation of Ca^{2+} across the cell from apical to basolateral surface (a process involving proteins such as calbindin-D28K), and finally active extrusion of Ca^{2+} from the cell into the blood via a Na^+/Ca^{2+} exchanger, designated NCX1. PTHrP most likely stimulates Ca^{2+} reabsorption in the DCT primarily by augmenting NCX1 activity via a cyclic AMP-mediated mechanism. In the proximal tubule, PTH can, after binding to PTH1R, also stimulate the 25-hydroxyvitamin D 1α hydroxylase [1a(OH)ase], leading to increased synthesis of $1,25(OH)_2D$. Consequently, increased circulating levels of $1,25(OH)_2D$ are often observed in HPT. In contrast, circulating $1,25(OH)_2D$ levels may be low in patients with HHM (Stewart et al., 1980). These apparent discrepancies were not resolved by early animal models of HHM, in which circulating $1,25(OH)_2D_3$ levels were high (Sica et al., 1983; Strewler et al., 1986). Neither was the problem solved by in vivo and in vitro studies performed with synthetic amino terminal fragments of PTHrP, which suggested that the peptides had identical bioactivity (Chorev et al., 1994; Fraher et al., 1992; Rabbani et al., 1988). However, continuous infusion of PTH(1−34) and of PTHrP(1−36) into

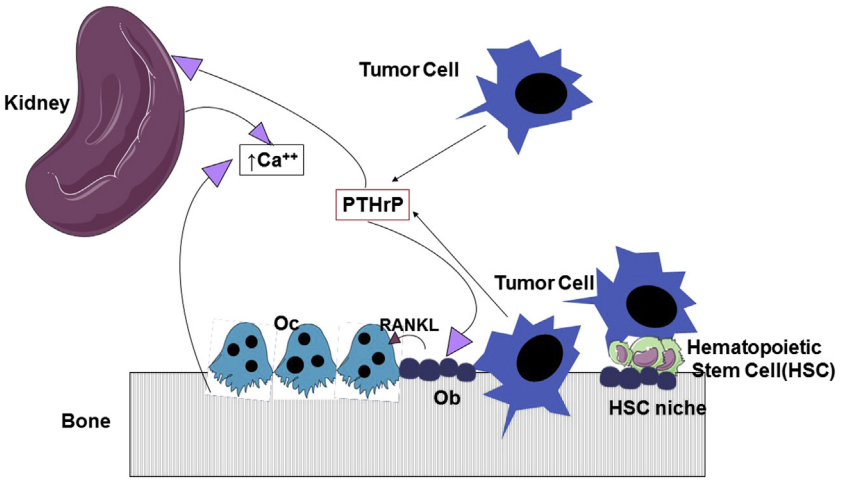

FIGURE 54.3 Interaction of PTHrP with bone and kidney to produce hypercalcemia [$\uparrow Ca^{++}$]. Tumor cells outside of bone can release PTHrP that acts on the renal tubule to enhance calcium reabsorption. PTHrP can also bind to osteoblasts and increase the osteoclastogenic cytokine, RANKL. RANKL can stimulate osteoclasts to resorb bone and mobilize calcium from bone, contributing to hypercalcemia. Tumor cells may also metastasize to bone, and initially bind to cells of the hematopoietic stem cell niche (HSC niche). Tumor cells in bone may also produce PTHrP that can increase bone resorption.

healthy young adults for 2−4 days demonstrated that renal $1,25(OH)_2D$ synthesis was stimulated effectively by PTH but poorly by PTHrP (Horwitz et al., 2005), supporting the apparent discrepancies between the circulating concentrations of $1,25(OH)_2D$ in HPT and HHM.

Actions in bone

In bone, PTH1R is localized on cells of the osteoblast phenotype that are of mesenchymal origin (Rouleau et al., 1990). Nevertheless, both PTH and PTHrP enhance osteoclastic bone resorption (Fig. 54.3). This effect of PTH on increasing osteoclast stimulation is indirect, with PTH binding to the PTH1R on preosteoblastic stromal cells (Rouleau et al., 1990) and enhancing the production of the cytokine RANKL [receptor activator of nuclear factor (NF) kappaB ligand], a member of the tumor necrosis factor (TNF) family. Simultaneously, levels of a soluble decoy receptor for RANKL, termed osteoprotegerin, are diminished, facilitating the capacity for increased stromal cell-bound RANKL to interact with its cognate receptor, RANK, on cells of the osteoclast series. Under the influence of RANKL stimulation, multinucleated osteoclasts, are derived from hematogenous precursors committed to the monocyte/macrophage lineage and then proliferate and differentiate as mononuclear precursors, eventually fusing to form multinucleated osteoclasts. These can then be activated to form bone-resorbing osteoclasts (Fig. 54.3). RANKL can drive all of these proliferation/differentiation/fusion/activation steps although other cytokines, notably monocyte-colony-stimulating factor, may also participate in this process (see Chapter by Martin et al. PTHrp paracrine actions in bone).

As indicated earlier in comparing HPT and HHM, histomorphometric evaluation of bone biopsies revealed that whereas catabolic activity was significantly increased in both disorders, discrepancies in bone formation were noted with decreases in HHM but increases in parathyroid disease (Stewart et al., 1982). Interestingly, in more recent infusion studies in humans, both PTH and PTHrP appeared to produce inhibition of formation and stimulation of resorption when administered continuously (Horwitz et al., 2005), which could explain these earlier findings on uncoupling between resorption and formation on the basis of sustained versus intermittent production of PTH and PTHrP depending on the clinical context. At least part of the osteoblast-stimulating activity of PTH, and therefore likely of PTHrP, occurs via inhibition of sclerostin, an antagonist of the osteoblast growth factor wingless-type (Wnt) (Bellido et al., 2013). Whether this inhibition occurs differently when PTHrP is administered intermittently versus continuously remains to be determined.

Effect of PTH-related protein on tumor progression and survival

PTHrP appears to be a prognostic indicator in patients with MAH (174; 175), with a very significant increase in mortality in patients with elevated circulating PTHrP. This relationship persists in a multivariate model independent of serum calcium elevation (Truong et al., 2003).

PTH1R and PTHrP are frequently coexpressed in tumors (Downey et al., 1997), and PTHrP has been reported to stimulate cell proliferation in MCF-7 breast cancer cells (Hoey et al., 2003), SV-40 immortalized breast epithelial cells (Hoey et al., 2003), renal carcinoma cells (Massfelder et al., 2004), and colon cancer cells (Shen and Falzon, 2005). The amino-terminal domain of PTHrP via PTH1R has also been reported to inhibit apoptosis (Hastings et al., 2003) and to enhance cancer cell adhesion to bone matrix components (Shen and Falzon, 2003). In tumors that secrete it, PTHrP has also been shown to promote growth and survival by the NLS via an intracrine mechanism (Sepulveda et al., 2002). PTHrP could therefore offer a selective advantage to tumor cells by contributing to tumor cell survival and growth.

Several animal cancer models associated with PTHrP production without concomitant hypercalcemia have been reported in the context of skeletal metastases and breast cancer (Guise et al., 1996; Mundy, 2002). PTHrP was described as a predominant mediator of the bone metastatic process. The developmental transcription factor Gli2 was identified as a positive regulator of PTHrP and osteolysis in metastatic human breast cancer cells (Sterling et al., 2006), and necessary for TGF beta activation of PTHrP (Johnson et al., 2011). Similarly, PTHrP overproduction was reported in the A375 metastatic melanoma model (El Abdaimi et al., 2000a,b). Using a PTHrP knockout approach and intracardiac transplantation of cancer cells, Huang et al. (Huang et al., 2014) indicated that PTHrP plays a predominant role in the metastatic process within and outside the skeleton. Furthermore, it would appear that PTHrP regulates cell invasion in vivo through alteration of the actin cytoskeleton. Using the pYMT model of breast tumor progression characterized by rapid progression to metastases in less than 11 weeks, Li et al. (Li et al., 2011) demonstrated that PTHrP is critical for tumor initiation and growth as well as lung metastases. Also, it upregulates tumor cell expression of CXCR4,

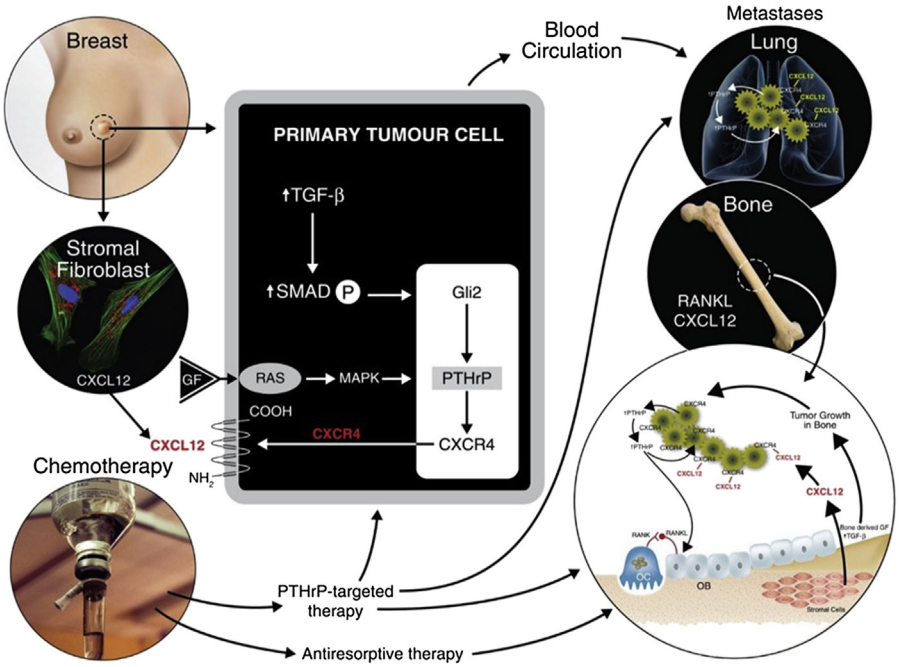

FIGURE 54.4 Figure Y: PTHrP regulation, signaling, and therapeutic targeting. In the breast, PTHrP is overexpressed by tumor cells as compared with the normal mammary epithelium. PTHrP expression is controlled by a variety of growth factors (GFs) that act via the Ras pathway to stimulate MAPK and increase PTHrP gene transcription. After transcription and translation, preproPTHrP is converted to proPTHrP that must then be processed to the active form of PTHrP before it is secreted. PTHrP production is also stimulated by Gli signaling molecules, members of the developmental Hedgehog pathway under the control of TGFβ. In bone, PTHrP-induced osteolysis results from upregulation of RANKL expression by osteoblasts. In addition, the abundance of TGFβ in bone is a major source of activation of PTHrP-induced osteolysis. PTHrP also promotes tumor initiation, growth, and invasion through its regulation of the CXCR4/CXCL12 axis. CXCL12, the natural ligand of CXCR4, is produced by stromal cells surrounding the primary tumor to enhance the metastatic ability of primary tumor cells. In metastatic sites such as bone, lungs, and liver, CXCL12 is also very abundant and acts as a chemoattractant of circulating tumor cells to facilitate seeding of tumor cells. Consequently, PTHrP-targeted therapy may provide a multiprong strategy by preventing tumor expansion and recurrence locally and tumor progression to skeletal and extraskeletal sites. Its combination with antiresorptive agents may prove extremely valuable by targeting both the "seed and the soil" and thus breaking the vicious cycle created by the release of PTHrP and GFs into the bone microenvironment.

a critical mediator of skeletal, liver, and lung metastases, where its ligand CXCL12 is produced in large quantities (Hirbe et al., 2010). This PTHrP CXCR4CXCL12 axis may therefore be critical in the homing of tumor cells in bone (Fig. 54.4). Also, CXCR4 is known to activate the AKT cell survival pathway (Zhang et al., 2009), which is under control of PTHrP (Li et al., 2011), thus supporting the importance of this novel PTHrP-CXCR4-CXCL12 axis. Furthermore, a monoclonal antibody raised against PTHrP1-33 administered to nude mice transplanted with the human breast cancer cell line MDAMB435 into the mammary fat pad, significantly reduced tumor growth and the occurrence of lung metastases (Li et al., 2011). A recent large genome-wide association study, identified PTHrP as one of three critical breast cancer susceptibility genes (Ghoussaini et al., 2012), which supports this novel role of PTHrP in tumor initiation and progression.

Cachexia is yet another syndrome invariably associated with human cancer progression. Its mechanism is complex (Tisdale, 2009). Earlier studies in animal models of lung cancer and skeletal metastases (Iguchi et al., 2001; Hashimoto et al., 2007) indicate that tumor-produced PTHrP is involved in cachexia and accumulation of orixogenic peptides such as neuropeptide Y in the hypothalamus. Administration of monoclonal antibodies against PTHrP ameliorates the condition with a concomitant reduction in expression of the hypothalamic orixogenic peptides. In a rapidly progressing model of human melanoma associated with rapid weight loss, ablation of PTHrP or administration of monoclonal antibodies against PTHrP had a profound effect on weight loss and improved survival (Huang et al., 2014). In a more recent study using a Lewis lung carcinoma model of cancer cachexia, tumour-derived PTHrP drove the expression of genes involved in thermogenesis in adipose tissues, and administration of neutralizating antibodies against PTHrP blocked adipose tissue browning and increased muscle mass and strength, partially reversing cancer cachexia (Kir et al., 2014).

Detection of PTH-related protein produced by tumors

Circulating levels of PTH-related protein

Shortly after the discovery and characterization of PTHrP, assays were developed to detect this factor in the circulation. With the development of immunoassays against specific regions of PTHrP, it was revealed that serum of patients with MAH contained both N and C-terminal reactive fragments (Burtis et al., 1990), including N-terminal moieties of at least 74 amino acids and C-terminal moieties of at least 29 amino acids beyond amino acid 109. Using an immunoassay recognizing both the N-Terminal (1−36) and C-Terminal (109−136) regions (Burtis et al., 1990), little or no immunoreactivity was detected, which suggests that the full length molecule PTHrP1-141 was rapidly metabolized. This latter study also reported the presence of fragments larger than the intact molecule, but their identity has not yet been determined. Discrepancies in results among these assays may depend at least in part on the variable molecular nature of PTHrP forms that circulate, either due to variable tumor production or clearance, especially in the presence of altered hepatic and/or renal function in cancer patients. PTHrP is cleared by the kidney (Imamura et al., 1991) and patients with renal insufficiency have elevated levels of PTHrP C-terminal fragments (Burtis et al., 1990) without elevation of N-terminal fragments. To date the production, circulating nature and clearance of heterogeneous PTHrP forms has not been nearly as well characterized as has the production, circulating nature and clearance of heterogeneous PTH forms. Such heterogeneous PTHrP moieties may be differently detected by individual assays and therefore yield different results. Nevertheless certain consistent themes have emerged from the use of PTHrP assays.

The first generalized finding is that circulating PTHrP levels are increased in virtually all patients with HHM as reported by Burtis et al. (1990). Using a two-site immunoassay, also called sandwich assay, they were able to characterize PTHrP in a variety of cancer conditions. This immunoradiometric assay used two polyclonal antibodies, a capture antibody raised against PTHrP 37−74 and a signal antibody raised against PTHrP1-36. Therefore, the specificity of this two-site assay was for a moiety that contained at least the first 74 amino acids of the molecule. The assay sensitivity was 1.0 pmol/L and did not cross-react with PTH1-84 or C-terminal fragments of PTHrP. Burtis et al. also developed a C-terminal radioimmunoassay using a polyclonal antibody raised against PTHrP 109−138. Although all normal volunteers had undetectable levels, this assay detected high levels of PTHrP in the circulation of renal failure patients, with a mean similar to patients with MAH (29.6 ± 14.1 pmol/L).

The second important observation is that although renal and squamous cell carcinomas have most frequently been associated with HHM, assays capable of directly measuring PTHrP demonstrated a much broader spectrum of tumors associated with excess PTHrP production than was previously considered, including breast, colon, and hematologic cancers (Henderson et al., 1990a,b). Thus, PTHrP overproduction is commonly associated with squamous cell tumors arising in most sites including lung, esophagus, cervix, vulva, skin and head and neck. Bladder and ovarian carcinomas are also commonly associated with the syndrome. On the other hand, patients with colon, gastric, thyroid, and nonsquamous cell lung cancers manifest hypercalcemia less commonly. Several studies have indicated that elevated PTHrP correlates better with hypercalcemia than does the presence or absence of skeletal metastases (Ejima et al., 1993). This appears particularly relevant to certain neoplasms such as breast cancer, which are commonly associated with hypercalcemia but are even more commonly associated with osteolytic skeletal metastases. Furthermore, cases of prostate cancer (Burtis et al., 1990) and melanoma (Kageshita et al., 1999), not typically believed to be part of the HHM spectrum, have been reported in association with high circulating PTHrP levels. Thus, circulating PTHrP levels have been reported as elevated in 50%−90% of hypercalcemic cancer patients with solid tumors (Henderson et al., 1990a,b; Budayr et al., 1989; Ratcliffe et al., 1992; Ralston et al., 1990; Burtis et al., 1990; Kao et al., 1990; Rankin et al., 1997) and in 25%−60% of such patients with hematologic malignancies (Kremer et al., 1996a,b,c; Firkin et al., 1996; Donovan et al., 2015). In support of the clinical usefulness of these two-site immunoassays, reduction in tumor burden following chemotherapy is associated with a reduction in circulating levels of PTHrP and correction of hypercalcemia (Henderson et al., 1990a,b), but to date PTHrP has not been widely utilized to monitor disease status.

The third observation is that circulating PTHrP concentrations have frequently been reported as elevated in hypercalcemic patients having skeletal metastases. Thus, hypercalcemia with breast cancer has been classically associated with osteolytic lesions but assays have generally detected elevated PTHrP in breast cancer, regardless of whether skeletal metastases were present (Grill et al., 1991). These studies therefore suggested that PTHrP as a systemic factor may contribute to the hypercalcemia of tumors that have spread to bone as well as to the hypercalcemia of those that have not.

To date, measurement of serum PTHrP has not, however, been a useful method for early tumor detection, possibly because of assay limitations related to the molecular heterogeneity of PTHrP released into the circulation and the low sensitivity of commercial assays unable to measure normal levels of PTHrP. Almost invariably current assays only detect

PTHrP in advanced cancer stages when hypercalcemia is present (Kremer et al., 1996a,b,c; Rankin et al., 1997). Furthermore, the finding of hypercalcemia in association with suppressed PTH using highly sensitive and specific assays to measure intact PTH has often been taken as presumptive evidence of elevated circulating PTHrP as the cause of the hypercalcemia, in lieu of direct measurement of PTHrP.

PTHrP may have value in prognostic evaluation. Thus, PTHrP assays have generally shown that there is a positive correlation between circulating PTHrP levels and more advanced stages of cancer (Kremer et al., 1996a,b,c; Rankin et al., 1997; Firkin et al., 1996), and several studies have reported that elevation of serum PTHrP levels was associated with a worse prognosis (Truong et al., 2003; Pecherstorfer et al., 1994; Hiraki et al., 2002). One study, which did not find that serum concentrations of PTHrP was associated with a poor prognostic factor, did not correct for confounding factors (Lee et al., 1997).

An ultrasensitive multiplex two-site immunoassay capable of simultaneously measuring several circulating forms of PTHrP with a sensitivity of 150 a.m. (approximately 1000-fold lower than current immunoradiometric assays) (Otieno et al., 2016) has been reported. This assay accurately measures normal levels of PTHrP in healthy volunteers and elevated levels in hypercalcemic cancer patients. Prospective measurements are underway in early-stage cancer patients and normocalcemic cancer patients at more advanced stages to determine its usefulness as a prognostic biomarker and to monitor tumor recurrence.

Overall, the clinical significance of PTHrP assays in diagnosis and disease monitoring requires more extensive evaluation in well-established populations.

PTH-related protein in tumor tissue

PTHrP is frequently expressed in a wide variety of tumor tissues including breast (Southby et al., 1990; Kohno et al., 1994), lung (Brandt et al., 1991), and renal cell cancer (Iwamura et al., 1999). The prognostic value of PTHrP expression in breast cancer tissue is uncertain because PTHrP immunostaining is reported to be either positively or negatively associated with prognosis. The presence of PTHrP in tissue samples from the primary tumor obtained from breast cancer patients has been associated with a more favorable outcome by one group (Henderson et al., 2001), but not by two others (Liapis et al., 1993; Yoshida et al., 2000). The study of Henderson et al. excluded patients with the more aggressive types of breast cancer who were receiving neoadjuvant therapy because tissue was not procured during surgery. The discrepancies in these findings may be due to differences in patient populations or the choice of PTHrP antibodies for immunohistochemical analysis.

PTHrP expression examined in the context of skeletal metastasis was found to be significantly overexpressed in bone metastatic lesions as compared with the primary tumor (Southby et al., 1990; Powell et al., 1991). PTHrP expression examined in prostate cancer tissues in patients without hypercalcemia was found to correlate with tumor stage (Defto, 2000).

Increased PTHrP expression in tumors colocalizes with the PTH/PTHrP receptor (Kunisada et al., 2002), and correlates with tumor grade. Also, a monoclonal antibody against PTHrP was effective in vitro in promoting cell death of chondrosarcoma cells (Bovee et al., 2000; Miyaji et al., 2003) Finally, PTHrP expression in tumor samples appears to be correlated in some reports with poor prognosis in lung cancer (Hidaka et al., 1998), renal carcinoma (Iwamura et al., 1999), and colorectal tumors (Nishihara et al., 1999).

Relationship of PTH-related protein-producing tumors with the bone microenvironment

Up to two-thirds of patients with MAH have bone metastases, and as indicated above, elevated circulating levels of PTHrP have been detected in association with hypercalcemic tumors that have spread to bone (Henderson et al., 1990a,b). Thus, certain malignancies, notably breast, lung, and renal carcinomas, which are frequently associated with hypercalcemia, have as well a strong propensity to spread to bone. PTHrP is thus expressed by not only tissues of tumors associated with hypercalcemia that have not metastasized to bone but also those that have colonized the skeleton (Powell et al., 1991; Southby et al., 1990; Vargas et al., 1992).

Following homing to bone, osteotropic tumor cells adapt to the bone marrow space by producing factors that allow development and progression in their new microenvironment, in part by inducing osteolysis (Waning and Guise, 2014). For example, secreted connective tissue growth factor stimulates osteoblast proliferation, and interleukin (IL)-11 and matrix metalloproteinase 1 (MMP-1) increase osteoblastic RANKL production, thus enhancing bone resorption. Additionally, MMP-1 and a disintegrin and metalloproteinase with thrombospondin motifs suppress osteoprotegerin (OPG) expression in osteoblasts, increasing the ratio of RANKL to OPG and thus further enhance increased osteolysis.

Tumor cells may also produce prostaglandins, and the interleukins Il-1, IL-6, and IL-8, leading to bone resorption. In addition to secreted factors, tumor cells express transcription factors that support growth in bone. These include the transcription factors, GLI2, part of the Hedgehog signaling network, which induces PTHrP expression; runt related transcription factor 2, which regulates matrix metalloproteinase-9 transcription that can degrade the extracellular matrix; hypoxia-induced growth factor 1 α (HIF1α), which promotes osteolysis and inhibits osteoblast differentiation; and Jagged1 (Jag1), which activates the Notch pathway to activate osteoclast differentiation. The result is the facilitation of the growth of the metastases and the mobilization of calcium from resorbed bone that may lead to hypercalcemia.

PTHrP may therefore act as a mediator of focal osteolysis induced by skeletal metastases while acting in a paracrine mode (El Abdaimi et al., 2000a,b; Guise et al., 1996; Rabbani et al., 1999). Tumor cells can thus release PTHrP, which acts at both the systemic (primary tumor) and local (skeletal metastases) levels to stimulate osteoclastic bone resorption, at least in part, through the receptor activator of NF-kappaB ligand (RANKL)/RANK/osteoprotegerin (OPG) system (Fig. 54.3).

Bone provides a fertile environment for the growth of tumors that are metastatic to the skeleton, with a well-developed blood supply (in hematopoietic marrow) as a source of nutrients and numerous growth factors that can provide a growth advantage. Thus, bone matrix is a unique storage site of immobilized growth factors such as TGF-β, IGFs I and II, fibroblast growth factors 1 and 2, and platelet-derived growth factors. Tumor-derived PTHrP that produces osteolysis results in the release of such active growth factors from the matrix, that facilitates the growth of tumor cells. In turn, growth factors such as TGF-β (Kakonen et al., 2002; Yin et al., 1999) as well as calcium per se, following their local release during osteoclastic resorption, may not only enhance the growth of tumor cells but also further stimulate PTHrP production. This enhancement of PTHrP production by tumors in the bone microenvironment may explain the observation that breast cancer tissue from skeletal metastases may be more frequently positive for PTHrP expression than from other sites (Powell et al., 1991), and that patients with PTHrP negative primary breast cancers may have PTHrP positive metastatic lesions (Henderson et al., 2006). PTHrP from skeletal metastases may also have direct effects of PTHrP on tumor growth, survival, and possibly adhesion to bone matrix (Shen et al., 2003).

It seems unlikely that local osteolysis per se will produce sustained hypercalcemia in the absence of a reduction of the renal clearance of calcium caused either by kidney damage or by the calcium-reabsorptive action of a humoral agent such as PTHrP. Therefore, PTHrP as an endocrine factor is an important contributor to the pathophysiology of the hypercalcemia, not only of those tumors that have not metastasized to bone but also for those that have already colonized bone.

Resistance to antiresorptive agents in malignancy-associated hypercalcemia caused by PTH-related protein

From a clinical standpoint, one needs to stress the importance of the biological actions of PTHrP on bone and kidney in the therapeutic approach to patients with MAH. The mainstay of treatment of patients presenting with severe hypercalcemia is a combination of rehydration and antiresorptive agents including bisphosphonates and monoclonal antibodies against RANKL (denosumab). Bisphosphonates work by inhibiting the skeletal component of hypercalcemia and are often less effective in hypercalcemic cancer patients with elevated PTHrP levels. Such patients require a higher dosage of bisphosphonate at shorter intervals, and the proportion of recurrence following calcium normalization is higher than in patients with MAH and normal levels of PTHrP (Grill et al., 1992; Wimalawansa, 1993; Gurney et al., 1993; Walls et al., 1994) despite almost complete suppression of bone turnover markers. Interestingly, a recent report showed that denosumab, a monoclonal antibody to RANKL that inhibits its activity, may be effective in refractory hypercalcemia due to PTHrP (Hu et al., 2014). A possible explanation for this unexpected superior efficacy may be related to a possible direct effect of denosumab on cancer cells. Earlier studies showed that RANK is often overexpressed on the surface of cancer cells and that RANK signaling drives mammary tumorigenesis (Gonzalez-Suarez et al., 2010; Schramek et al., 2010). Importantly, pharmacological treatment with RANK-Fc, which binds to RANKL and subsequently blocks RANK−RANKL signaling, reduces mammary tumorigenesis. In a large cohort of breast cancer patients, RANK overexpression was preferentially associated with triple-negative breast cancer (Pfitzner et al., 2014) a treatment-resistant breast cancer often associated with high PTHrP expression (Camirand et al., 2013). All in all, these studies suggest that denosumab could potentially target cancer cells and bone turnover simultaneously through PTHrP suppression—directly, indirectly, or by both methods. In any event eliminating or diminishing PTHrP production through alternate approaches would be of significant benefit for these patients using novel targeted therapies directed at PTHrP.

Experimental approaches to controlling overproduction or overactivity of PTH-related protein in malignancy-associated hypercalcemia

Although effective antitumor treatment is still the best means to obtain long-term normalization of serum calcium in MAH, a marked reduction of tumor burden often is not attainable because hypercalcemia generally complicates advanced and refractory cancer. Consequently, volume repletion and bisphosphonates, which inhibit osteoclastic bone resorption, have become the standard of therapy for MAH (Body et al., 1998). Newer antiresorptive agents are being developed (Capparelli et al., 2000). Bisphosphonates normalize serum Ca levels in more than 90% of patients with MAH, but they appear to be less efficient when hypercalcemia recurs in association with high circulating levels of PTHrP, possibly due to the renal calcium reabsorbing effects of PTHrP (Rizzoli et al., 1999; Onuma et al., 2005). As indicated earlier, denosumab appears to normalize calcium levels in a significant proportion of patients resistant to bisphosphonate therapy (Hu et al., 2014). The central role of PTHrP in MAH has, however, stimulated the exploration of preventive and therapeutic measures by targeting PTHrP.

Anti-PTHrP neutralizing antibodies have been shown to be effective in reducing skeletal metastasis, bone lesions, and hypercalcemia (Iguchi et al., 1996; Guise et al., 2002), and humanized anti-PTHrP antibody has been engineered for therapeutic purposes (Saito et al., 2005). Administration of $1,25(OH)_2D_3$, which may inhibit PTHrP production, is counterproductive in cases of MAH due to its intrinsic hypercalcemic effects. A concentrated effort has therefore focused on the development of low-calcemic analogs of $1,25(OH)_2D_3$ that will effectively suppress PTHrP production without stimulating calcium absorption by the gut, calcium reabsorption by the kidney, and most importantly, bone resorption. EB1089 and MC903, two $1,25(OH)_2D_3$ analogs with conservative side-chain modifications, have been used to inhibit PTHrP production in vitro, with varying degrees of success, to prevent the hypercalcemic syndrome in models of MAH (El Abdaimi et al., 2000a,b; Haq et al., 1993; Yu et al., 1995; El Abdaimi et al., 1999; Nakagawa et al., 2005). These studies suggest that low-calcemic vitamin D analogs and nonsteroidal activators of VDR that selectively fail to augment intestinal calcium absorption may prove useful in the management of MAH associated with excess PTHrP production.

Growth factors acting via RTKs have been shown to be potent stimuli of PTHrP gene transcription. One of the best characterized signal transduction pathways downstream of RTKs is the Ras/Raf/Mek pathway. Activation of this pathway by growth factors or activated Ras was shown to increase PTHrP expression and release from a variety of cells in culture. Conversely, inhibition of the pathway through pharmacologic intervention—e.g., by small molecules that act as a competitive inhibitor of Ras farnesylation, one of the metabolic conversions required for Ras to be anchored to the inner aspect of the cell membrane and transmit a signal downstream (Aklilu et al., 1997) or by using dominant negative forms of Ras and Raf (Aklilu et al., 2000) successfully reduced PTHrP production. This suggests that specific inhibitors of components of the Ras signaling pathway could be used for therapeutic intervention to prevent the hypercalcemic syndrome associated with PTHrP overproduction in vivo.

An alternative approach for diminishing PTHrP overproduction in malignancy employed antisense technology to inhibit endogenous PTHrP expression and diminish hypercalcemia. The use of antisense PTHrP (Rabbani et al., 1995) and the use of antisense furin (Liu et al., 1995) to reduce bioactive PTHrP in MAH models in vivo led to diminished hypercalcemia, decreased tumor cell proliferation, and the prolonged survival of host animals. To date, neither approach has been shown successful in clinical trials in humans, nor has either been approved by regulatory agencies. Newer techniques using small interfering RNA may prove useful in the future in furthering these initial approaches.

Treatment of local osteolysis

PTHrP may be a valid target in cancer therapy. Targeting PTHrP in skeletal metastases is supported by carefully conducted preclinical studies in animal models of breast, prostate, and lung metastases to bone (Rabbani et al., 1999; Guise et al., 1996; Miki et al., 2004), the three most common human malignancies. The majority of patients suffering from these conditions will develop metastatic spread to the skeleton. Despite the enhanced clinical efficacy of the newest generation of amino-bisphosphonates and the highly potent monoclonal antibody against RANKL denosumab (Coleman et al., 2012), skeletal metastases remain a major public health challenge with few therapeutic options. Emerging evidence in preclinical models of breast and lung cancer support the principle that combination therapies targeting both PTHrP with monoclonal antibodies and the bone microenvironment with the potent bisphosphonate zoledronic acid are superior to either agent administered separately (Luco et al., 2013; Yamada et al., 2009; Powell et al., 1991). Additional support for this approach comes from clinical studies indicating that cancer patients overexpress PTHrP at the bone metastatic site (Powell et al., 1991), a feature that is likely to exacerbate the vicious cycle occurring in bone once cancer cells invade the skeleton.

Another interesting clinical observation is the apparent resistance to bisphosphonate therapy in terminal cancer patients with hypercalcemia and the elevation of circulating levels of PTHrP (Walls et al., 1994). The majority of these patients, particularly breast cancer patients, have both skeletal and extraskeletal tumor spread. A possible explanation of this resistance is the lack of effect of bisphosphonates on the local production of PTHrP by metastatic sites. Although the renal component of MAH through the systemic effect of PTHrP on tubular reabsorption of calcium may play a role in maintaining hypercalcemia (Onuma et al., 2005), it is likely that local production of PTHrP diminishes the efficacy of bisphosphonates on bone. PTHrP has a direct effect on RANKL production by osteoblasts (Roodman, 2004a,b) as well as direct effects on tumor cell proliferation (Maioli et al., 2004; Li et al., 2011). A recent study indicates that the blockade of PTHrP with monoclonal antibodies in PTHrP producing human breast cancer cell lines (Camirand et al., 2013) has a strong antiproliferative effect in vitro. Furthermore, this study shows that zoledronic acid also inhibits breast tumor cell proliferation and that the combination has an additive effect, which suggests that concomitant administration of zoledronic acid and monoclonal antibodies against PTHrP in vivo could target the "seed" and the "soil" in a very powerful way. Indeed, recent studies in animal models of breast cancer suggest that zoledronic acid has a direct effect on tumor cell proliferation in vivo (Ottewell et al., 2008). An alternate approach has been attempted that blocks PTHrP by using small molecule inhibitors of PTHrP transcription in tumor cells (Gallwitz et al., 2002). This approach may also inhibit the intracrine actions of PTHrP and needs further study.

Although skeletal metastases are associated with skeletal related events such as pain, nerve compression and fractures that severely affect the patients' quality of life (Sullivan, 1996), rapid disease progression usually involves extraskeletal sites resulting in metastatic spread to vital organs that is resistant to most therapeutic regimen. This is particularly true for breast cancer expressing the triple-negative phenotype. In a recent study of a model of breast tumor progression, PTHrP was critical for tumor initiation, growth, and metastases to lungs (Li et al., 2011). Targeting PTHrP was proposed as a potential new therapy for breast and other types of cancer. Indeed, administration of monoclonal antibodies against PTHrP reduced breast tumor growth and lung metastases in breast cancer (Li et al., 2011) and reduced disease spread at multiple sites including liver, lungs, and bones in a human melanoma model (Huang et al., 2014). Similarly, in a model of renal cancer, anti-PTHrP antibodies slowed tumor progression and its metastatic spread (Massfelder et al., 2004). Numerous in vitro studies support the role of PTHrP in growth and invasion in breast, colon, prostate, and giant tumor cells of bone cancers, among others (Li et al., 2011; Mula et al., 2010; Downs et al., 2011; Mak et al., 2011). Interestingly, anti-PTHrP monoclonal antibodies have recently been shown to be potent growth inhibitors of triple-negative breast cancer, potentiating the effect of doxorubicin and taxol (Camirand et al., 2013). Taken together, these studies support the rationale of targeting PTHrP as a novel approach to cancer treatment, possibly in the most refractory types such as triple-negative breast cancer.

Overall, these studies suggest that knowledge of the regulation of PTHrP production, processing, and action may identify targets that could prove useful for the development of agents to reduce circulating concentrations of bioactive PTHrP in vivo and diminish hypercalcemia. Furthermore, such agents could prove beneficial in inhibiting the production of PTHrP by tumors, which might diminish the establishment and growth of metastatic lesions and potentially of primary tumors.

Hypercalcemia caused by other systemic and local factors produced by neoplastic cells

Cytokines and humoral hypercalcemia of malignancy

Circulating proinflammatory cytokines most probably contribute to a number of systemic manifestations of malignancy such as anorexia, dehydration, and cachexia (Ogata, 2000). Mounting evidence also suggests that cytokines released into the systemic circulation by a variety of solid tumors, which often coexpress PTHrP, contribute to the bone destruction associated with MAH. In this respect, it is interesting to note that circulating concentrations of IL-6 correlate in a positive manner with tumor burden in patients with squamous and renal cell carcinoma, the two prototypical malignancies associated with hypercalcemia and elevated circulating levels of PTHrP (Costes et al., 1997; Nagai et al., 1998).

Many other factors, including vascular endothelial growth factor, granulocyte colony-stimulating factor, and cytokines such as interleukins 8 and 11, and soluble RANKL (Nagai et al., 2000), have been implicated in promoting HHM (Horwitz et al., 2003). The relative contributions of systemically active PTHrP and cytokines to MAH have been examined in immune-compromised rodents carrying human tumors that overexpress both factors (Nagai et al., 1998). Nude rats transplanted with a human squamous carcinoma of the oral cavity (OCC), which was shown to overproduce both PTHrP and IL-6, rapidly developed severe hypercalcemia in association with high circulating levels of PTHrP and IL-6. Hypercalcemic animals immunized with anti-IL-6 monoclonal antibody demonstrated a complete reversal in the

biochemical abnormalities associated with elevated circulating IL-6 but only a small reduction in serum calcium. As measured by quantitative histomorphometry, there was a significant decrease in indices of bone resorption as well as an increase in the mineral apposition rate in rats that received the neutralizing antibody. These results suggest that although IL-6 contributed to the skeletal abnormalities seen in OCC tumor-bearing rats, its contribution to the hypercalcemic syndrome was minor compared with that of PTHrP.

Using an alternate model, others demonstrated that mice carrying a human esophageal tumor that coexpresses PTHrP and IL-1 develop a modest elevation in blood calcium (Sato et al., 1989). A comparable level of hypercalcemia was observed in normal mice receiving a continuous infusion of IL-1. However, a significant increase in blood calcium was noted in mice that received a minimal daily dose of PTHrP in addition to the IL-1 infusion, suggesting a synergistic effect of PTHrP and IL-1 on bone resorption in this model. This hypothesis was supported by experiments in which the addition of a small amount of synthetic PTHrP to the culture medium greatly enhanced ^{45}Ca release from prelabeled mouse bones in response to recombinant IL-1.

This work using animal models of human disease predicts that PTHrP may be the principal mediator of MAH. The hypothesis is further supported by clinical studies in which elevated circulating levels of PTHrP correlate strongly with hypercalcemia in patients with tumors of widely diverse histological origin (Ogata, 2000). No such correlation has been demonstrated for hypercalcemia and elevated circulating levels of cytokines such as IL-6 or IL-1. However, it has been proposed that a systemic increase in PTHrP not only promotes hypercalcemia but also stimulates normal cells to produce factors such as TNF-α, IL-1, IL-5, IL-6, and IL-8 in patients presenting with end-stage malignancy. The observation that infusion of anti-PTHrP antibody into mice with high circulating levels of PTHrP and IL-6 resulted in a prolonged decrease in the concentration of both factors in the bloodstream lends some support to this hypothesis.

Cytokines and local osteolysis

Multiple myeloma is a B cell malignancy characterized by clonal expansion of terminally differentiated, immunoglobulin-producing, transformed plasma cells in the bone marrow (Roodman, 2004b). Osteolytic bone disease is a central feature of multiple myeloma and is caused by factors produced by tumor cells and the bone microenvironment that stimulate osteoclasts and inhibit osteoblasts (Terpos et al., 2017; Galson et al., 2012). Adhesion of multiple myeloma cells to bone marrow stromal cells in the bone marrow microenvironment stimulates RANKL expression and OPG inhibition by osteoblasts, leading to osteolysis (Pearse et al., 2001). Multiple myeloma, bone marrow stromal, and bone cells also secrete a variety of inflammatory cytokines including IL-6, TNFα, IL-1, IL-3, macrophage inflammatory protein-1α (MIP-1α) MIP-1β, decoy receptor 3, and activin, which activate osteoclasts and inhibit osteoblasts. Wnt signaling inhibitors, including sclerostin and dickkopf-1 (Tian et al., 2003), as well as the growth factor independence-1, are considered among the most important factors for osteoblast inhibition in multiple myeloma (Terpos et al., 2017; Breslau et al., 1984). Such unbalanced bone resorption results in osteolytic bone disease and ultimately in hypercalcemia.

1,25-Dihydroxyvitamin D (1,25(OH)$_2$D) and humoral hypercalcemia of malignancy

The site of conversion of 25 hydroxyvitamin D [25(OH)D] to its active metabolite, 1,25(OH)$_2$D, by the 25(OH)D 1α-hydroxylase enzyme, is known not to be restricted to the kidney. Although the kidney is still recognized as the primary site of circulating 1,25(OH)$_2$D production in vivo, several extrarenal sites of 1 α-hydroxylase activity have been identified. These include cells of the hematopoietic and immune systems as well as cells in many other tissues that give may give rise to solid tumors associated with MAH. In contrast to the systemic role played by kidney-derived 1,25(OH)$_2$D$_3$ in calcium homeostasis, locally produced hormone is thought to regulate cell proliferation and differentiation in normal cells (Holick, 1999) and could modulate the development of neoplastic transformation within these cells.

Elevated serum concentrations of 1,25(OH)$_2$D$_3$ have been reported in some cases of non-Hodgkin's (Breslau et al., 1984) and Hodgkin's lymphoma (Jacobson et al., 1988), in contrast to the low circulating levels seen in the majority of hypercalcemic cancer patients. This increase in circulating 1,25(OH)$_2$D$_3$ was often seen in the presence of renal impairment, suggesting an extrarenal source of the hormone. Occasionally solid tumors such as the human small cell lung cancer cell line NCI H82 have been reported to synthesize a vitamin D metabolite with similar biochemical properties and bioactivity to authentic 1,25(OH)$_2$D$_3$ (Mawer et al., 1994). The systemic increase in 1,25(OH)$_2$D$_3$ may be accompanied by the elease of lymphoid cytokines and PTHrP, which are also known mediators of MAH and may therefore contribute to the hypercalcemia.

Parathyroid hormone and humoral hypercalcemia of malignancy

Although PTH is normally only secreted by the parathyroid glands, authentic ectopic secretion of PTH (ectopic hyperparathyroidism) has been well documented in a variety of histological types of tumors including lung, ovary, thyroid, and thymus and has been associated with hypercalcemia (Nussbaum et al., 1990; Yoshimoto et al., 1989; Strewler et al., 1993; Rizzoli et al., 1994). Although this syndrome is well documented, it appears to represent an exceedingly rare event.

Chapter outline

Introduction

Tumors such as those of the breast, prostate, and lung frequently metastasize to the bone where they induce changes to the bone microenvironment that can lead to bone destruction (osteolytic disease) and/or bone formation (osteoblastic disease) (Mundy, 2002). In many patients there is a mix of both; patients with primarily osteoblastic tumors may still have some phases of osteolytic disease. In both cases, patients experience an increase in skeletal fracture, pain, and morbidity (Coleman et al., 1998). Despite improvements in the early detection and treatment of primary tumors, patients still experience bone metastases and die from metastatic disease. Once a patient is diagnosed with bone metastases, frequently as a result of a skeletal-related event, they are placed on a bisphosphonate (and in some cases denosumab) to block bone resorption. While these therapies improve morbidity, they do not significantly improve mortality, and patients still die from disease (Coleman et al., 2014a, 2014b; Coleman, 2006; Saad et al., 2007).

Decades of research have described the pathways that regulate tumor metastasis to bone and tumor-induced bone disease. Much of this work has been centered on the "vicious cycle" model originally described by Gregory Mundy et al. (Guise and Mundy, 1998; Mundy, 1997; Sterling et al., 2011). This hypothesis centered on interactions between tumors and osteoblasts and osteoclasts and was one of the first examples of studies of tumor interactions with the microenvironment. In this model, the tumor cells release factors—e.g., parathyroid hormone–related protein (PTHrP), interleukin-8 (IL-8), and interleukin-11—that stimulate the osteoblasts to produce receptor activator of nuclear factor kappa-B ligand (RANKL), which in turn activates osteoclast-mediated bone destruction. RANKL, a member of the tumor necrosis factor family, is a trimeric cell surface ligand that is essential for promoting the fusion of myeloid cells into multinucleated osteoclasts (Kong et al., 1999). Osteoclasts bind to the surface of mineralized bone matrix subsequent to osteoblast retraction and demineralize the bone via the release of hydrochloric acid (Blair, 1998). Tight resorptive seals permit localized acidification under the osteoclast. Approximately 90% of the bone matrix is composed of type-I collagen, and

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00055-5

osteoclast secretion of cathepsin-K, an acidophilic type I collagenase, facilitates the breakdown of the collagen fibers (Saftig et al., 1998). During bone apposition phases, osteoblasts not only lay down extracellular matrix (ECM) proteins but also incorporate a number of growth factors and cytokines into bone such as transforming growth factor-beta (TGF-β) that can be released during osteoclast-mediated resorption (Bonewald and Mundy, 1990; Hock et al., 1990; Robey et al., 1987). Transcytosis of bone matrix products through the osteoclasts in vesicles results in pH buffering prior to apical secretion (Coxon et al., 2008; Salo et al., 1997). The resultant release of bioavailable growth factors in turn supports the growth of cancer cells, thereby generating a feed-forward "vicious cycle" of tumor–bone interactions (Kakonen and Mundy, 2003). Therapies that target factors driving the vicious cycle, such as bisphosphonates and denosumab, have focused on reducing osteoclast-mediated bone destruction. While these approaches have improved morbidity as previously described, they do not eliminate tumor burden. Therefore, more research is needed to develop drugs that can both reach and eliminate tumors growing in the bone. While many overlapping features between tumors can establish in the bone, we will focus the description within this chapter on the mechanisms driving osteotropism, colonization of the bone marrow, and tumor-induced bone disease (Fig. 55.1).

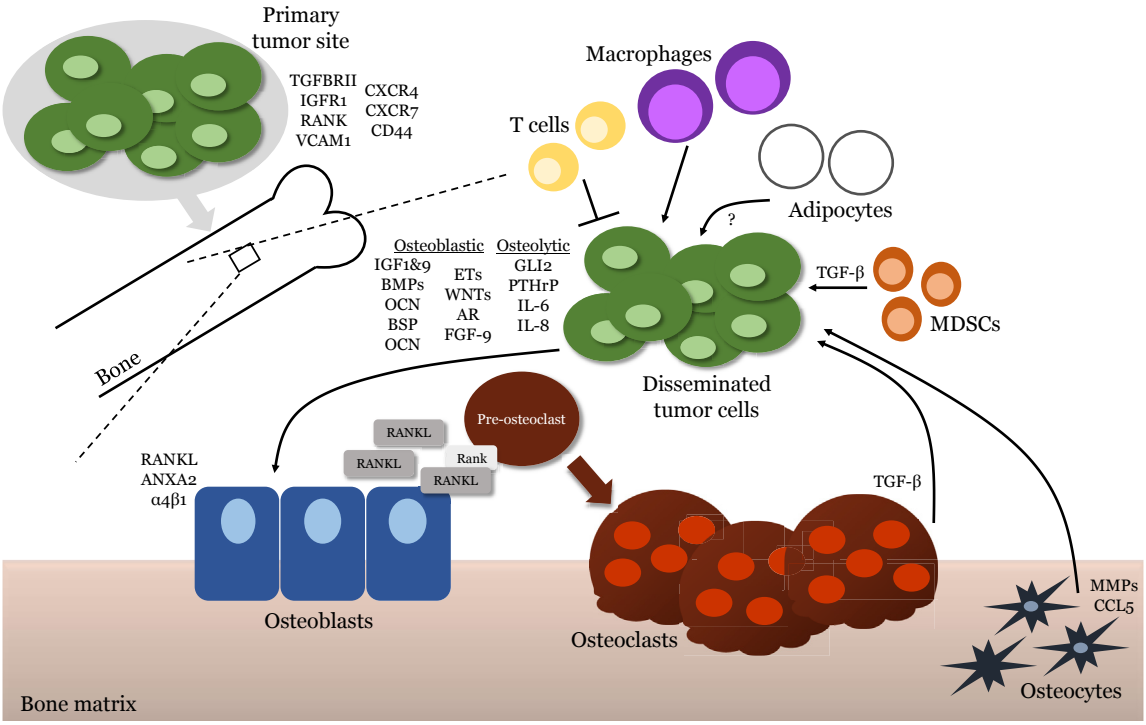

FIGURE 55.1 Key cellular and molecular mechanisms in tumor-induced bone disease. Tumor cells residing in the primary tumor site express factors that promote homing to the bone marrow. These factors interact with receptors expressed by mature osteoblasts and osteoblast precursors in the bone marrow to recruit tumor cells. Once disseminated to the bone marrow, tumor cells express and secrete a number of factors to induce osteolytic/osteoblastic bone disease. These molecules are known to act on the osteoblast lineage cells to promote bone growth or to induce osteoclastogenesis through stimulation of RANK/RANKL signaling between osteoblast lineage cells and osteoclast precursors. Localized induction of osteoclastogenesis leads to the release of factors stored in the bone matrix that promote tumor cell growth and further enhance tumor-induced bone destruction (i.e., the vicious cycle). Other cell types that we are beginning to appreciate in tumor-induced bone disease are T cells, which have been observed to limit tumor growth in bone, as well as osteocytes, macrophages, MDSCs, and adipocytes. Multiple studies suggest that these cell types promote tumor growth in the bone. Future studies will more clearly define the roles of these cell types and the mechanisms by which they limit or promote tumor colonization of the bone marrow. *ANXA2*, annexin A2; *AR*, androgen receptor; *BMP*, bone morphogenetic protein; *BSP*, bone sialoprotein; *CCL5*, C–C motif chemokine ligand 5; *CXCR4*, chemokine receptor 4; *CXCR7*, chemokine receptor 7; *ET*, endothelin; *FGF*, fibroblast growth factor; *GLI2*, GLI family zinc finger 2; *IGF*, insulin like growth factor; *IGFRI*, insulin-like growth factor receptor I; *IL-6*, interleukin-6; *IL-8*, interleukin-8; *MMP*, matrix metalloproteinase; *OCN*, osteocalcin; *OPN*, osteopontin; *PTHrP*, parathyroid 1-related protein; *RANK*, receptor activator of nuclear factor κB; *RANKL*, receptor activator of nuclear factor κB ligand; *TGFβ*, transforming growth factor-β; *TGFβRII*, transforming growth factor-β receptor type II; *VCAM1*, vascular cell adhesion molecule 1; *WNT*, wingless-type MMTV integration site family.

Osteotropism

Intravasation of cancer cells into the vasculature or lymphatics draining the primary cancer is a key event in the dissemination of tumor cells to the bone marrow (Weilbaecher et al., 2011). However, before cancer cells metastasize to the skeleton, it is hypothesized that secreted or shed factors prepare future metastatic niches for cancer cell colonization (Kaplan et al., 2006). While secreted cytokines, growth factors, and RNA molecules can regulate the behavior of these metastatic niches, cancer-derived vesicles such as exosomes, microvesicles, and oncosomes shed by cancer and host microenvironmental cells of the primary tumor are also proposed to play a part (Psaila and Lyden, 2009). These shed vesicles can be loosely categorized based on their size, although there are differences in the mechanisms regulating how they are shed. Exosomes are classified as small vesicles that range from 50 to 150 nm in size and display cell surface receptors that aid in their binding to the ECM of distant sites or their integration/uptake by cells in the evolving pre-metastatic niche. Remarkably, the exosomal cargo contains a vast array of molecules ranging from microRNAs, including microRNA processing machinery, DNA, cytokines, growth factors, and proteases. Causal roles for exosomes in metastasis have been described. For example, exosomes educate the stromal cells of the premetastatic niche and promote ECM remodeling and the recruitment of bone marrow−derived cells that in turn prepare the soil of the niche for the future arrival of metastatic prostate cancer cells (Erler et al., 2009; Shay et al., 2015). This phenomenon has also been demonstrated for the larger microvesicles and oncosomes (Di Vizio et al., 2012). In prostate cancer, the number of oncosomes (vesicles larger than exosomes that range in size from 1 to 10 μm) in patient plasma was found to correlate with Gleason scores of 7 and higher, while exosomes isolated from LNCaP, DU145, and PC3 prostate cancer cell lines have been found to enhance osteoblast differentiation (Itoh et al., 2012) and induce the differentiation of bone marrow−derived mesenchymal stem cells (MSCs) into myofibroblasts that promote tumor growth (Di Vizio et al., 2012; Webber et al., 2010). Collectively, these data suggest a role for oncosomes in cancer malignancy and potentially in the establishment of premetastatic niches in the bone microenvironment. While causal roles for these vesicles in cancer metastasis are being described, it should be noted that they are also proving to be valuable biomarkers of cancer prognosis and therapeutic response (Peinado et al., 2011).

How do prostate cancer cells that have escaped the primary cancer sense or home to prepared premetastatic niches or other niches within the bone microenvironment? Circulating tumor cells (CTCs) isolated from peripheral blood are a poor prognostic indicator for metastasis-free survival, and genetic analyses of the CTCs demonstrate/reflect the heterogeneity of the tumor at the primary site (Millner et al., 2013; Liu et al., 2009; Mader and Pantel, 2017). Not all CTCs will reach bone, but those that do are drawn to the rich milieu of growth factors and nutrients present in the skeletal tissue. Chemokine receptors have been largely implicated in cancer cell osteotropism (Weilbaecher et al., 2011). Chemokine receptors are G-protein-coupled receptors on the cell surface that sense and are chemoattracted to their cognate ligands. Chemokine receptor 4 (CXCR4) is a critical component in driving a bone metastatic program for breast cancer and is also commonly expressed by metastatic prostate cancer cells (Kang et al., 2003; Wang et al., 2006; Sun et al., 2005; Taichman et al., 2002). CXCR4 binds to chemokine ligand 12 (CXCL12) or stromal-derived factor-1 (SDF-1) to promote cell migration. CXCL12 is highly expressed in the skeletal tissue, where it plays important roles in cell−cell communication between bone-lining osteoblasts and hematopoietic progenitor cells. Studies have determined that ablation of CXCR4 on metastatic prostate cancer cells greatly diminishes bone metastasis, implying a major role for this receptor in osteotropism. CXCL12 can also bind to CXCR7 that is expressed at higher levels in aggressive disease (Wang et al., 2008). CXCR7 activation can lead to increased expression of the cell adhesion molecules CD44 and cadherin-11, which can facilitate invasion and metastasis. Other chemokines including CXCL16 have also been demonstrated to play a role in bone homing of prostate cancer cells. Using the Gleason system, the CXCL16 receptor, CXCR6, has been shown to correlate with disease aggressiveness (Lu et al., 2008). Prostate cancer cells are highly migratory toward CXCL16. Studies exploring the inhibition of CXCR6 with small-molecule inhibitors show that inhibiting this receptor can greatly mitigate prostate cancer cell invasion and metastasis *in vivo* (Hershberger et al., 2010). Like CXCL12, CXCL16 has been shown to be highly expressed in bone tissue (Ha et al., 2011).

In addition to chemokine-regulated osteotropism, several growth factors, cytokines, and bone remodeling by-products have been implicated in the process. Bone is one of the richest reservoirs of TGF-β, insulin-like growth factors (IGFs I and II), and RANKL (Cook et al., 2014). The expression of cognate receptors for these ligands on metastatic cancer cells (TGFβ receptor I and II, IGF-receptor 1, and RANK, respectively) have been described as increasing the frequency of bone metastasis given the heightened levels of these ligands in the bone microenvironment. By-products of the normal bone remodeling process, such as collagen fragments generated by osteoclast-mediated bone resorption, can also act as a potent chemoattractant for cancer cells, thus influencing the osteotropic nature of the metastases (Mundy et al., 1981).

Adhesion and invasion into bone metastatic niches

Once in the bone microenvironment, it is possible for cancer cells to bind to or interact with the ECM/cells of vascular or endosteal niches (Yu et al., 2012; Dasgupta et al., 2017). Both niches play important roles in maintaining hematopoietic stem cell (HSC) quiescence and mobilization from the bone marrow (Levesque et al., 2010). The ECM and cellular landscape of the niches and their interaction with metastatic cancer cells are critical steps during the early phases of cancer cell extravasation. Cell and matrix adhesion molecules are implicated in this process. αvβ3 integrin is expressed by metastatic cancer cells and binds to arginine−glycine−asparagine sequences in ECM proteins such as vitronectin and osteopontin, and binding to these proteins promotes reassembly of the cancer cell cytoskeleton and the activation of kinases such as focal adhesion kinases and SRC that promote cell survival (Kwakwa and Sterling, 2017; Teti et al., 2002). Lateral associations between αvβ3 other receptor tyrosine kinases such as TGF-β receptor II (TGFβRII) further promote cancer survival and growth, provided the cancer cells do not become quiescent/dormant (Galliher and Schiemann, 2006). α4β1, also known as very late antigen-4 (VLA-4), binds to CD106/vascular cell adhesion molecule-1 (VCAM-1), which is highly expressed by the bone marrow MSCs present in vascular and endosteal niches (Esposito and Kang, 2014; Ren et al., 2010). Similarly to αvβ3, α4β1 binding to VCAM-1 promotes the activation of c-Src to promote colonization of the bone microenvironment (Esposito and Kang, 2014; Hsia et al., 2005). Further, in the endosteal niche, osteoblast soluble-derived factors such as WISP-1 promote the expression of α4β1, reinforcing the interaction between metastatic VCAM-1-expressing cells and α4β1 (Tai et al., 2014). Cancer cells have also been shown to express α2β1, α5β1, and α9β1 that bind to ECM proteins in the bone microenvironment such as collagen, fibronectin, and tenascin, respectively, thereby further enhancing the ability of the metastases to invade the bone matrix (San Martin et al., 2017).

Additional classes of cell adhesion molecules such as annexin II (ANXA2) and CD44 are also implicated in bone homing and colonization. ANXA2 is commonly expressed by osteoblasts and endothelial cells and is an important regulator of HSC homing and adhesion to the endosteal and vascular niches (Jung et al., 2007). Cancer cells are known to express the ANXA2 receptor, and the interaction between the receptor and ligand facilitates colonization of HSC niches in bone (Shiozawa et al., 2008). CD44, a heavily glycosylated transmembrane protein, has long been associated with cancer cell migration and invasion and is commonly used as one of a number of markers for cancer stem cells. CD44 post-translational modifications also facilitate interaction with selectins on the endothelial cell surface that can help in the attachment of cancer cells to the sinusoidal vasculature prior to extravasation. Further, CD44 interacts with a variety of molecules present in the bone microenvironment including ECM proteins (collagens and osteopontin), hyaluronic acid, and growth factors such as TGFβ (Draffin et al., 2004) that can enhance cell adhesion, invasion, and survival in the bone marrow microenvironment.

Tumor dormancy and awakening

Prior to the initiation of osteolysis, tumor cells may enter a prolonged latency period after disseminating to the bone marrow. The mechanisms that direct these disseminated tumor cells (DTCs) to enter and exit a dormant state remain largely unknown, and it remains unclear whether this is driven by cell-autonomous mechanisms, the bone microenvironment, or a combination of both. Tumor dormancy itself remains ill-defined; during prolonged latency periods, tumor cells in the bone marrow may (1) reside as truly quiescent, nonproliferating cells, (2) slowly proliferate, or (3) proliferate and turn over at the same rate such that the undetectable micrometastasis remains below the level of clinical detection. Evidence for all three mechanisms exists (Zhang et al., 2013a), and it is possible that these mechanisms are not mutually exclusive. It is possible, if not likely, that multiple mechanisms of tumor dormancy exist even within the same patient. DTCs are protected from neoadjuvant or adjuvant therapies or immune surveillance, and the mechanisms that enable tumor cells to evade these systems are beginning to emerge.

To date, relatively few targets have been identified as dormancy-regulating genes in the bone marrow, and interestingly, the dormancy genes that have been identified appear to be highly tissue- and isoform-specific (Dasgupta et al., 2017). For example, TGFβ has three isoforms, and TGFβ2, expressed in bone marrow, has been shown to promote dormancy in breast cancer via the activation of TGFβR1 and TGFβR3 receptors. This interaction activates MAPK p38α/β, resulting in an ERK/p38 low signaling ratio (Bragado et al., 2013). Subsequent reductions in the cell cycle promoter CDK4 render the cells dormant. Interestingly, TGFβ1, which is highly sequestered in the bone matrix, promotes the awakening of dormant cells in neovascular tips (Ghajar et al., 2013), suggesting distinct roles for TGFβ isoforms in regulating the process. Mechanisms specific to prostate cancer dormancy in bone have been described in the context of the endosteal niche. The binding of annexin II receptor−expressing prostate cancer cells to osteoblasts in the endosteal niche promotes the expression and secretion of growth arrest specific 6 (GAS6), which in turn binds to the receptor Axl and results in a

suppression of prostate cancer cell growth (Yumoto et al., 2016). Bone morphogenetic proteins (BMPs) regulate osteoblast behavior, and one family member, BMP-7, is described as playing a role in dormancy. BMP-7 secretion by bone stromal cells can bind to BMP receptor II (BMPR-II) on prostate cancer cells and induce p21-mediated cell cycle arrest via activation of p38 (Kobayashi et al., 2011). Metastatic cancer cell–derived proteins such as SPARC (secreted protein acidic and rich in cysteine—osteonectin) also induce the expression of BMP-7 in bone stromal cells and osteoblasts in addition to the Wnt antagonist Dickkopf-1 (DKK-1), which in other metastatic settings has been implicated in promoting dormancy (Malladi et al., 2016; Sharma et al., 2016). Leukemia inhibitory factor (LIF) receptor (LIFR) is expressed on breast cancer cells that disseminate to the bone marrow but do not induce osteolysis. Loss of LIFR expression on breast cancer cells enables the tumor cells to aggressively colonize the bone marrow, and loss of LIFR is hypothesized to be driven in part through the low oxygen tensions of the bone marrow microenvironment (Johnson et al., 2016). It remains unclear whether the effects of LIFR are ligand-dependent, and if so, which of the IL-6 family cytokines induce dormancy, since several members of this cytokine family can complex with LIFR. Many IL-6 family cytokines are produced by osteoblasts, including LIF and oncostatin M, which suggests that the bone may provide prodormancy signals that are lost when breast cancer cells lose or downregulate LIFR. Thrombospondin 1 has been identified as a microenvironmental prodormancy factor that is produced by endothelial cells in the perivascular niche and may function to promote adhesion of tumor cells to endothelial stalks (Ghajar et al., 2013). Many of the just-illustrated mechanisms primarily relate to single-cell dormancy, but population dormancy in which the rates of cancer cell proliferation and apoptosis are balanced have been described. This steady-state phenomenon can be enforced by the microenvironment due to restricted blood supply or active immune surveillance recognizing and eliminating metastatic cancer cells (Osisami and Keller, 2013).

It is feasible that in the endosteal niche, factors involved in mobilizing HSCs can perturb DTCs occupying those niches, causing cancer cell outgrowth. Osteoclasts are essential for HSC mobilization, and recruited osteoclasts expressing MMP-9 can result in KIT-ligand cleavage. KIT-ligand is essential for maintaining HSCs in the niche, and HSCs are mobilized as a result of MMP-9 processing (Heissig et al., 2002). The recruitment of osteoclasts to the endosteal niche can also be mediated by α4β1 binding to VLA-4 on the cell surface of niche resident cancer cells (Lu et al., 2011). The resultant bone remodeling and release of cytokines such as the TGFβ1 isoform from bone can in turn override the dormancy program and result in the establishment of micrometastatic outgrowth (Bragado et al., 2012, 2013).

Cancer-induced bone disease

Breast cancer

The majority of studies investigating tumor-induced bone disease (TIBD) have focused on studying breast tumors that have metastasized to the bone. This is primarily because between 70% and 90% of breast cancer patients that die from disease will have bone metastatic disease (Johnson et al., 2015). In these cases, the women are often younger, and reducing TIBD has a high potential to improve their quality of life. While triple-negative (ER-, PR-, Her2-) breast cancer has been the focus of most breast cancer TIBD studies, in part due to the availability of preclinical models that aggressively colonize the bone and accurately mimic the late stages of disease, these patients often have widespread metastatic disease. In contrast, ER+ patients frequently experience more bone-only metastatic disease (Coleman et al., 1998; Coleman, 2006; Kennecke et al., 2010; Smid et al., 2008; Kunikullaya et al., 2017; Wu et al., 2016). Thus, these patients would likely experience the most impact from improved therapies. However, since even ER+ patients can have ER- tumor cells or metastases, and patient ER status can change (Schrijver et al., 2018), studies in both patient populations can yield promising new leads to improve therapy.

Much of the focus on studying signaling pathways in breast cancer–induced bone disease has been on the regulation of PTHrP by the TGF-β signaling pathway. Early studies by the Guise and Mundy groups demonstrated that tumor expression of TGF-βRII was required for tumors to produce PTHrP (Guise and Mundy, 1998; Kakonen and Mundy, 2003; Yin et al., 1999; Guise et al., 1996). In these and other studies, loss of TGF-β response reduces bone destruction. Other studies have shown that TGF-β inhibitors also reduce tumor burden and bone destruction. Although some groups only see a moderate (not complete) reduction in tumor burden, all groups see an improvement in bone volume (both new bone generation and smaller osteolytic lesions) (Yin et al., 1999; Biswas et al., 2011; Edwards et al., 2010; Johnson et al., 2011a; Nyman et al., 2016; Hu et al., 2012; Javelaud et al., 2011a; Kakonen et al., 2002; Mohammad et al., 2011; Waning et al., 2015). This suggests that while TGF-β is an important factor in TIBD, inhibiting it alone is not sufficient to eliminate tumor.

Other signaling pathways that have been implicated in breast cancer–induced bone disease include the Hedgehog signaling transcription factor GLI2, which is overexpressed in tumors that induce bone destruction (Sterling et al., 2006).

Work from multiple groups has demonstrated that GLI2 expression can be regulated by TGF-β to stimulate the transcription of PTHrP (Johnson et al., 2011a, 2011b; Javelaud et al., 2011a; Cannonier et al., 2016; Cannonier and Sterling, 2015; Alexaki et al., 2010). It remains unclear whether GLI2 regulates other pathways involved in TIBD beyond the regulation of TGF-β and PTHrP signaling, but other pathways are currently being investigated (Page et al., 2015a, 2015b; Johnson et al., 2014; Shimoyama et al., 2007).

Endothelins (ETs) consist of three related 21-amino-acid peptides (ET-1, ET-2, and ET-3) with ET-1 being the most abundantly expressed (Carducci and Jimeno, 2006). ETs are recognized for their role in vasoconstriction, but depending on the cell context, ET-1 can, for example, promote angiogenesis by stimulating endothelial cell proliferation and expression of vascular endothelial growth factor-A or bone formation by promoting osteoblast differentiation. While on balance, human bone metastatic breast cancers tend to be more osteolytic, some lesions can be osteoblastic or have areas of osteoblastic activity. This is reflected in cell line models of the disease. A differential analysis of factors derived from an osteolytic (MDA-MB-231) versus osteoblastic (ZR-75-1) breast cancer cell line revealed ET-1 as a major driver of breast cancer–induced bone formation (Yin et al., 2003). Normal and cancerous prostate cells express high amounts of ET that can protect cells from undergoing apoptosis (Nelson et al., 2005). ET expression is associated with advanced and bone metastatic prostate cancer, where a number of studies have described a role for ET-1 in driving the sclerotic phenotype of these lesions.

Prostate cancer

Similar to bone metastatic breast cancer cells, prostate cancer cells can secrete PTHrP, IL-6, and IL-8, which can induce RANKL expression (Liao et al., 2008; Deftos et al., 2005; Park et al., 2015; Pencik et al., 2015; Rojas et al., 2011). While bone metastatic prostate lesions contain areas of bone destruction, in contrast to other lytic metastases such those of a breast, lung, or renal origin, the lesions are typically hallmarked by areas of extensive bone formation (Keller and Brown, 2004). Metastatic prostate cancer cells are often resistant to androgen deprivation therapy (ADT) but are still dependent on androgens for survival and growth (Frieling et al., 2017). This is in large part due to mutations in the androgen receptor (AR) itself that make it highly efficient in using low levels of androgen, ligand-independent, or able to synthesize testosterone through the rewiring of metabolic pathways (Mostaghel et al., 2011; Kantoff and Mohler, 2013). AR activity in bone stromal cells such as osteoblasts enhances bone formation and mass, and therefore androgens derived from bone metastatic prostate cancer cells can have potent effects on bone formation. In addition to AR activity, Wnts, BMPs, and as discussed in breast cancer, ETs, have been noted as having roles in promoting prostate cancer induced osteogenesis.

Wnts have noted roles in cancer progression and in the regulation of bone remodeling. In prostate cancer, Wnt pathway activation (canonical and noncanonical) has been associated with poor outcomes and resistance to ADT (Thiele et al., 2016; Miyamoto et al., 2015; Wang et al., 2017). Canonical pathways involve Wnt ligand binding to receptors such as Frz, lipoprotein receptor-related proteins (Lrps), and receptor tyrosine kinase-like orphan receptors, leading to the stabilization of β-catenin and the transcription of β-catenin target genes. Noncanonical activation generally involves protein kinase A or Jun kinase activation. Evidence supports roles for Wnts 1, 2, 3a, 4, 7b, and 10b in promoting osteoblast differentiation. Studies have revealed that osteogenic prostate cancer cell lines express several of these Wnt ligands (Hall et al., 2005; Li et al., 2008a). For example, approximately 42% of prostate cancer specimen patient tissues were positive for Wnt7b compared with normal tissues. Wnt7b is a potent mediator of MSCs to osteoblast differentiation and is highly expressed by prostate cancer (Zheng et al., 2013). Endogenous natural Wnt antagonists such as members of the DKK and secreted frizzled-related proteins can block the potent effects of Wnt ligands. Paradoxically, DKK-1 has been shown to be highly produced during the early development of skeletal metastases but decreases as those metastases progress (Hall and Keller, 2006). These data suggest that in the initial phase of the vicious cycle, DKK-1 may tip the balance in favor of osteolysis prior to giving way to heightened Wnt expression and increased osteoblast activity.

Fibroblast growth factors (FGFs) play important developmental roles, are often highly expressed in the tumor microenvironment, and mediate their effects via binding to FGF receptors (FGFRs 1–4) (McKeehan et al., 1998; Powers et al., 2000; Wan et al., 2014). Analysis of human samples shows that FGFR1 is overexpressed in prostate cancers and that prostate cancer cell–derived factors induce the expression of FGFRs 1 and 2 in osteoblasts (Wan et al., 2014). Activation of the receptors by FGF ligands has effects on both the prostate cancer and bone stromal compartments (Murphy et al., 2010). For example, FGF-8 was discovered in the conditioned medium of an androgen-dependent mouse mammary tumor cell line and can promote osteoblast differentiation via three distinct transmembrane tyrosine kinase receptors (FGFR2-IIIC, FGFR3-IIIc, and FGFR-4) (Valta et al., 2006; Ellman et al., 2013). Studies have shown that over 75% of human bone metastatic prostate cancer specimens are positive for FGF-8 (Valta et al., 2008). *In vivo* studies demonstrated that FGF-8 can promote prostate cancer growth in bone and modulate bone formation (Valta et al., 2008). Several

patient-derived xenograft (PDX) models from bone metastatic prostate cancer have been generated, with some models having the ability to promote ectopic bone formation upon subcutaneous implantation. Differential analysis of PDX models that can generate ectopic bone versus those that do not revealed IGF-1 and FGF-9 as major candidates driving bone formation. Further tests of the effect of these factors on the growth of primary mouse osteoblasts revealed that FGF9, but not IGF1, induced osteoblast proliferation. Furthermore, FGF9-induced osteoblast proliferation and bone formation could be significantly blocked *in vitro* and *in vivo* via an FGF-9 neutralizing antibody, underscoring the potential importance of this ligand in mediating prostate cancer–induced bone formation (Li et al., 2008b).

Over 30 members of the BMP family exist, but to date functions with respect to modulating osteoblast function and bone formation have been best described for BMP-2 and BMP-7. BMPs mediate their action via signaling through BMP receptors (BMPR-IA, BMPR-IB, and BMPR-II). Several BMPs can be inhibited by noggin and gremlin, which bind directly to BMP and prevent receptor interaction (Chen et al., 2004). Prostate tumors have been shown to express BMPs (BMP-2, BMP-4, and BMP-7) (Yang et al., 2005) and their receptors, BMPR-IB and BMPR-II (Yang et al., 2005; Ye et al., 2007). The expression of BMPs and the BMP receptors in primary prostate cancer is intriguing and may play an important role in prostate cancer osteotropism. In this regard, the overexpression of noggin in the prostate tumor cell line PC-3 significantly reduced the size of the osteolytic lesions induced by the tumor (Feeley et al., 2006). Stromal-derived factors such as Wnt5a promote the expression of BMP-6 in prostate cancer cells, and this process is implicated in resistance to ADT (Miyamoto et al., 2015). Conversely, roles for BMPs 2, 6, and 7 have been defined in regulating osteoblast differentiation, underscoring the importance of BMP signaling in prostate cancer cell–osteoblast cross talk.

While these cancer cell–derived factors can induce osteoblast responses, studies have also revealed that prostate cancer cells can acquire an osteoblast-like phenotype that contributes to their ability to colonize and grow in the bone microenvironment (Curatolo et al., 1992). In clinical specimens, prostate cancer cells were found to express osteocalcin, bone sialoprotein (BSP), and osteopontin (OPN), ECM proteins that can facilitate attachment and invasion into the bone matrix. Further, analysis of prostate cancer cells exposed to osteoblast-derived factors revealed an increase in BMP-2, alkaline phosphatase, α-type I collagen, OPN, and osteocalcin (Koeneman et al., 1999). Runx2 has been shown to be induced in prostate cancer cells as a result of heightened TGFβ and BMP signaling in the bone. EMT program drivers such as TWIST also lead to the activation of Runx2 and the subsequent activation of downstream targets such as BSP and OPN (Yuen et al., 2008). Runx2 also regulates RANKL expression, and previous reports have shown that prostate cancer cell–derived RANKL can kick-start osteoclastogenesis, bypassing the need for osteoblast-derived RANKL (Inman and Shore, 2003; Banerjee et al., 2001; Enomoto et al., 2003; Barnes et al., 2003). Interestingly, the induction of the osteomimetic program contributes to an increase in cellular adhesion and a slowdown in proliferation of the prostate cancer cells (Chung et al., 2005). This in turn could increase the resistance of bone metastatic prostate cancers to applied ADTs and chemotherapies. Furthermore, the increased adhesion of osteomimetic prostate cells to the bone matrix may enhance their bone invasive phenotype via mechanotransductive effects. Scaffolds that mimic the rigidity of the bone matrix (3800 MPa) compared with those of soft tissue (70 MPa) enhanced the expression of factors associated with bone destruction including β3 integrin in PC3 prostate cancer cell lines. Interestingly, β3 integrin associated with the TGFβ type II receptor in rigid conditions to trigger the expression of PTHrP and GLI2, which promote osteoclast formation (Sterling et al., 2011; Ruppender et al., 2010).

Other skeletal malignancies

While much research has focused on breast and prostate cancer metastasis to bone, other tumor types that metastasize to the bone marrow include lung, multiple myeloma, osteosarcoma, invasive melanoma, and invasive head and neck tumors (Johnson et al., 2015). While each has a different primary tumor signature, they share many similarities behind the signaling pathways involved. For example, the most common primary bone tumors are osteosarcomas. While the initiating mutations are likely quite different from metastatic tumors, osteosarcoma cells often express factors that promote bone remodeling and formation such as PTHrP and RANKL. This heightened remodeling around the developing osteosarcoma can release IGFs and TGFβ that stimulate cancer survival and growth. In a retrospective study, 75% of osteosarcoma tumors ($n = 40$) that stained positive for RANKL had poorer overall survival of 17.8% (Lee et al., 2011). Transduction of osteosarcoma cells with the soluble decoy receptor osteoprotegerin (OPG) prevented osteolytic lesions and reduced tumor growth *in vivo* (Lamoureux et al., 2010). The bone marrow is a natural reservoir for MSCs, and this cell type has been explored as a therapeutic vehicle for the delivery of OPG to block bone destruction in murine models of osteosarcoma and metastatic prostate cancer with some success (Chanda et al., 2010; Qiao et al., 2015). In addition to being used to treat bone metastatic disease, denosumab, a monoclonal antibody against RANKL, is approved for the treatment of other primary

bone lesions such as giant cell tumor, where it has been shown to reduce tumor size by up to 90% (Branstetter et al., 2012) and is currently being clinically evaluated for the treatment of osteosarcoma.

Tumors that originate in the bone marrow can also alter normal bone remodeling. While leukemias and other blood tumors can induce a bone phenotype, the most studied bone marrow tumor that induces bone loss is multiple myeloma (MM). MM is the second most common adult hematologic malignancy and causes osteolytic bone disease in the axial and longitudinal skeleton (Silbermann and Roodman, 2013). However, even the most potent bisphosphonate, zoledronic acid, does not prevent fractures from eventually occurring in many patients, though it reduces the proportion of myeloma patients who experience skeletal-related events (Terpos et al., 2014, 2015). Alternatively, drugs such as the proteasome inhibitor bortezomib have been demonstrated to reduce MM tumor burden (Richardson et al., 2003). Other key pathways in MM that have been investigated include MIP1α (Oyajobi et al., 2003), DKK-1 (Fowler et al., 2012), and TGF-β (Nyman et al., 2016; Matsumoto and Abe, 2011). Important interactions between MM and the bone microenvironment include adipocytes and osteocytes. Adipocytes have been demonstrated to support MM establishment and growth in the bone (Fowler et al., 2011; McDonald et al., 2016). Osteocyte secretion of sclerostin and Wnt-signaling molecules has also been demonstrated to support MM tumor growth in the bone (Delgado-Calle et al., 2016; McDonald et al., 2017).

Other tumors that can invade the bone include melanoma, which can induce similar disease progression as metastatic tumors in bone. These tumors seem to rely on pathways similar to those of metastatic tumors including TGF-β (Mohammad et al., 2011; Javelaud et al., 2011b; Morris et al., 2014), GLI2 (Javelaud et al., 2011c), and hypoxia (Finger et al., 2015). Another common tumor is oral tumor invasion into the mandible (Zini et al., 2010). Much less is known about these tumors, but GLI2 activation and PTHrP have been demonstrated in multiple models to drive mandibular invasion (Cannonier et al., 2016; Jimi et al., 2013; Martin et al., 2011; Takayama et al., 2010; Yan et al., 2011).

Contribution of the bone microenvironment to bone lesion progression

Since osteoclast inhibitors have not significantly impacted patient survival as expected, the idea of the vicious cycle has been questioned. Despite this, the vicious cycle concept seems to accurately describe the interactions between tumor cells, osteoblasts, and osteoclasts. Where it fails to predict drug responses, it is perhaps because it is overly simplified. The bone/bone marrow microenvironment contains many cell types, each of which contributes to aspects of tumor-induced bone disease. Without understanding these interactions, it will not be possible to predict patient outcomes or drug responses. Some of these interactions include myeloid cells, other immune cells, fibroblasts, the physical microenvironment, and hypoxia.

Myeloid cells

One of the first bone marrow cell types investigated in TIBD was the myeloid-derived suppressor cells (MDSCs), due to their known role in other tumors for establishing the premetastatic niche (Yang et al., 2004, 2008a). They have since been demonstrated to expand and contribute to tumor growth and bone destruction in bone metastatic breast and prostate cancer (Park et al., 2011, 2013; Danilin et al., 2012; Capietto et al., 2013; Luo et al., 2016). In prostate cancer, tumor-derived PTHrP was shown to indirectly increase MDSC angiogenic potential, thus promoting tumor metastasis and growth in bone (Park et al., 2013). In breast cancer, Danilin et al. demonstrated that MDSCs contributed to bone destruction by activating tumor expression of GLI2 and PTHrP, thus stimulating bone destruction (Danilin et al., 2012). Two studies have also demonstrated that MDSCs from a tumor-bearing mouse have the potential to differentiate into osteoclasts; therefore, the expansion of this population leads to a larger pool of osteoclast progenitors, which may explain the ability of MDSCs to contribute to bone destruction (Danilin et al., 2012; Sawant et al., 2013). While the signaling pathways involved in the cross talk between MDSCs and tumor cells is still being investigated, the cross talk between phospholipase C gamma 2 (PLCγ2) and β-catenin has been shown to promote MDSC expansion in bone (Capietto et al., 2013).

Macrophages

Another cell type that has been demonstrated to play an important role in TIBD is the macrophage. For example, bone marrow macrophages have been shown to support prostate cancer growth in bone (Park et al., 2011; Soki et al., 2015) and to modulate osteoblasts (Michalski et al., 2016). Another group demonstrated that tumor-associated macrophages (TAMs) may take up bisphosphonates bound to calcified nodules in the primary site (Junankar et al., 2014). Whether this uptake alters the behavior of the TAMS or metastasis to the bone remains to be determined.

T cells

While T cells are known to be important for immune surveillance in tumors, studies on T cells in TIBD have been limited due to a lack of appropriate models of TIBD in immune-competent mice. However, many groups have begun to investigate T cells using syngeneic models and other approaches. As anticipated, it has been demonstrated that stimulating T cell response in mice reduces tumor burden in bone (Zhang et al., 2011), and depletion of CD8+ T cells results in accelerated growth of dormant melanoma cells disseminated to multiple organ sites including the bone marrow (Eyles et al., 2010). However, a recent study also suggests that tumor-associated T cells can induce osteolytic bone disease prior to bone colonization. In this study, they show that T cell−produced RANKL can induce osteoclastogenesis and bone destruction (Monteiro et al., 2013). These data suggest that T cells may have a dual role in bone disease in that they can reduce tumor growth but stimulate bone destruction. As immunotherapy research expands, it has become imperative to better understand these T cell responses to determine if these approaches that have been successful in specific tumor types may be beneficial to patients with TIBD.

Osteoblasts

The importance of the osteoblast in TIBD has been well described in the vicious cycle model, where tumor-produced factors stimulate osteoblasts to produce RANKL to promote osteoclast-mediated bone destruction (Mundy, 2002; Weilbaecher et al., 2011; Guise et al., 1996). More recent studies have suggested that osteoblasts can function as a prometastatic population of cells. Taichman et al. demonstrated that CXCL12/SDF-1 (expressed by osteoblasts and endothelial cells) and its receptor (CXCR4, expressed by prostate cancer cells) regulate the bone-tropism of prostate cancer cells (Taichman et al., 2002). In addition to the CXCL12/CXCR4/CXCR7 axis (Sun et al., 2010), annexin II, expressed by osteoblasts and endothelium, regulates HSC adhesion, homing, and engraftment (Jung et al., 2007). GAS6 in bone stromal cells (predominantly osteoblasts) induces metastatic tumor cell dormancy and determines site-specificity (i.e., increased localization in vertebrae and hind limb long bone compared with forelimb bones) (Jung et al., 2012). The osteoblastic niche has also been implicated as the direct target of tumor cell localization in bone (Jung et al., 2011). This work demonstrated that administration of PTH to induce osteoblast proliferation promoted skeletal localization of prostate cancer cells, while decreasing ablation of the osteoblasts reduced tumor cell localization.

Osteocytes

In addition to osteoblasts, there is an increasing appreciation for tumor−osteocyte interactions in the field. As breast cancer cells expand within the bone marrow microenvironment, they are proposed to increase intraosseous pressure and therefore promote osteocyte MMP and CCL5 signaling to further promote the outgrowth of prostate cancer cells (Sottnik et al., 2015). Multiple myeloma cells also interact with and can induce osteocyte apoptosis and osteolysis, fueling osteolytic bone disease (Delgado-Calle et al., 2016; McDonald et al., 2017).

Bone marrow fibroblasts

Bone marrow fibroblasts have been established in many tumor types to contribute to tumor growth, invasion, and establishment in secondary sites (Direkze et al., 2004; Dutsch-Wicherek and Kazmierczak, 2013; Eck et al., 2009; Luga and Wrana, 2013; Madar et al., 2013; Orimo et al., 2005; Owens et al., 2013; Togo et al., 2013). Their role is less defined in TIBD, but it has been established that they influence bone metastatic diseases (Johnson et al., 2014). When TGF-βRII was deleted in the CAFs in a prostate cancer model, tumor cell growth in bone was increased (Li et al., 2012). Furthermore, fibroblasts have been shown to promote breast and lung cancer growth in bone through Wnt signaling (Johnson et al., 2014). Joan Massague's group demonstrated that bone marrow fibroblast content in triple-negative tumors was associated with bone metastases, but not lung metastases, in patient samples (Zhang et al., 2013b).

Adipocytes

There has been a surge in interest in adipocyte−tumor cell interactions (McDonald et al., 2016; Morris and Edwards, 2016), and while many groups are currently investigating the significance of the marrow adipocyte in bone colonization and disease progression, as of yet little has been published. Bone marrow adipocytes have been shown to enhance the Warburg effect in prostate cancer cells via HIF-1α activation, and tumor cells in turn promote adipocyte lipolysis (Diedrich et al., 2016). This was tested extensively *in vitro* but has not been functionally tested *in vivo*, and thus its role in promoting

bone colonization remains unknown. In support of a role for adipocytes in disease progression, marrow adipose tissue and serum adiponectin increase during cancer therapy (Cawthorn et al., 2014), suggesting marrow adipocytes may play an endocrine role in cancer progression. There is great interest in this particular area of the field, and there is still much to be learned about these interactions.

Sympathetic and parasympathetic nerve system signaling

Interactions between nerves and the tumor—bone microenvironment have been demonstrated to enhance TIBD through osteoblasts (Elefteriou, 2016; Elefteriou et al., 2014). For example, we now know that the increased flow of the sympathetic nervous system stimulates RANKL expression on osteoblast-lineage cells and that the direct interactions of $RANKL^{osteoblast} - RANK^{tumor\ cell}$ promotes breast cancer bone colonization (Campbell et al., 2012). The bone marrow and bone tissue are richly innervated with nerve fibers that typically parallel blood vessels and have been demonstrated to control bone metabolism (Cook et al., 2014; Campbell et al., 2012; Elefteriou, 2008). Studies have shown that the autonomic nervous system contributes to primary prostate cancer growth and metastasis (Magnon et al., 2013). Nerve-derived signals such as epinephrine and norepinephrine may directly drive prostate cancer cell growth and invasion via activation of sympathetic nervous system receptors such as β2-adrenergic receptor (β2AR). In addition, β2AR agonists stimulate osteoblasts to express RANKL and IL-6 that contribute to osteoclast formation. Of note, β2AR inhibits osteoblast proliferation, and therefore these mechanisms may be important in areas of metastases where osteolysis is predominantly occurring (Campbell et al., 2012; Mulcrone et al., 2017). Conversely, parasympathetic nervous system (PSNS) (Magnon et al., 2013) signaling is thought to favor bone formation, with deletion of the muscarinic M3 receptor showing bone mass loss in mice (Shi et al., 2010). Prostate cancer cells express the muscarinic M3 receptor and ligand stimulation—for example, with acetylcholine—can enhance their invasion and growth (Guo et al., 2016). Thus, increased PSNS signaling may be involved with a more osteoblastic lesion phenotype that is commonly associated with prostate cancer.

Physical microenvironment

In addition to interactions between tumor cells and bone/bone marrow cells, several groups have demonstrated that interactions with the physical bone microenvironment also influence TIBD (Kostic et al., 2009; Provenzano et al., 2009). For example, the rigidity of bone has been shown to mediate cross talk between the integrinβ3 and TGF-β signaling pathways (Page et al., 2015b; Ruppender et al., 2010), leading to an increase in GLI2 and PTHrP expression and subsequent bone destruction. Interestingly, the rigidity of the bone not only influences gene expression within the tumor cells but also affects gene expression of fibroblasts (Johnson et al., 2014) and MSCs (Guo et al., 2015). In addition to the influence of the bone on tumor cell behavior, tumor cells and drug treatments are known to alter bone quality and structure (Biswas et al., 2011; Edwards et al., 2010; Nyman et al., 2016), suggesting that there may be a bidirectional interaction between tumor cells and the physical properties of bone.

In addition to the rigidity of the bone microenvironment, the architecture of the microenvironment is an important factor. Bone has unique architecture that varies from bone to bone. While it is unclear whether this contributes to tumor establishment, it has recently been demonstrated that the variable architecture between bones can contribute to bone resorption and formation (Vanderburgh et al., 2017). As pore size and architecture are tuned to increase mechanical forces, bone formation is increased. Since these forces would be internalized similarly to rigidity, it is likely that they would have a similar effect on tumor cell gene expression.

Hypoxia and alteration of cancer cell metabolism

The bone microenvironment is relatively hypoxic (Mohyeldin et al., 2010; Chow et al., 2001; Harrison et al., 2002; Spencer et al., 2014), but much of the data describing oxygen tensions in the bone marrow has relied on fiber optic probes in the calvarium (Spencer et al., 2014) and math modeling of oxygen gradients across the marrow and trabeculae (Zahm et al., 2010). In fact, we know very little about the actual oxygen tensions within the marrow of the long bones. Staining for pimonidazole, a marker of hypoxia that detects oxygen levels below 10 mmHg, reveals that the bone microenvironment is distinctly hypoxic, and it can therefore be assumed with high likelihood that tumor cells will encounter hypoxia in the bone metastatic site; what is less clear are the actual oxygen tensions that they encounter and the oxygen flux throughout the marrow space and across the trabecular bone.

Hypoxia in the primary breast tumor site is well established to promote tumor progression (Finger et al., 2015; Chaturvedi et al., 2013; Erler et al., 2006; Yang et al., 2008b), and staining for HIF1α is correlated with significantly worse

patient survival in breast cancer (Schindl et al., 2002); however, its role in tumor dissemination to bone and the outgrowth of tumor cells in bone is less clear. Previous studies from independent groups indicate that blockade or loss of HIF signaling in MDA-MB-231 breast cancer cells inhibits breast cancer colonization of the bone marrow (Dunn et al., 2009; Hiraga et al., 2007; Lu et al., 2010), but the mechanism by which hypoxia promotes tumor homing to bone marrow remains unclear. It is possible that the effects are through the establishment of a premetastatic niche in bone (Peinado et al., 2017) but may also be due to hypoxic signaling in the primary tumor, possibly through HIF1α induction of a glycolytic phenotype, discussed in more detail following.

Hypoxia is often associated with lower pH. Altered metabolism and the ability to survive in harsh acidic environments is a hallmark of cancer cells. Decades ago, the ability and preference of cancer cells to use glucose metabolism to support anabolic processes for growth was described and is known as the "Warburg effect" (Hanahan and Weinberg, 2011). Of note, the metabolic pathways active in cancer can vary in regards to cancer stage and their interactions with cells of the surrounding microenvironment. Primary prostate cancers have heightened β-oxidation pathway activity and can exploit fatty acids either generated via *de novo* synthesis or uptaken from the microenvironment to support growth and progression (Zadra et al., 2013; Menendez and Lupu, 2007). The bone marrow contains many adipocytes, and *in vitro* and *in vivo* models of bone marrow−adipocyte interaction and *in vivo* models of bone marrow adiposity generated by a high-fat diet have shown that adipocytes regulate the glycolytic phenotype by enhancing glycolytic enzymes, increased lactate production, and decreased mitochondrial oxidative phosphorylation in cancer cells (Diedrich et al., 2016). Heightened metabolic activity in cancer cells and glycolysis also result in further acidification of the cancer bone microenvironment (Damaghi et al., 2013). Lower pH has been demonstrated to be permissive for osteoclast formation, and the increased expression of acid transporters such as carbonic anhydrase XI allow cancer cells to buffer intracellular pH and survive in these conditions (Arnett, 2008; Ibrahim-Hashim et al., 2012).

Monoamine oxidase A (MAOA) is a mitochondrial membrane-bound enzyme that catalyzes the degradation of monoamines by oxidative deanimation (Shih et al., 1999). MAOA is associated with prostate cancer progression and is a poor prognostic indicator (True et al., 2006). MAOA can also induce the EMT program by producing excessive levels of hydrogen peroxide, a major by-product of MAOA activity, and promoting the expression of Sonic Hedgehog (Shh) (Wu et al., 2014). In the context of the bone microenvironment, prostate cancer−derived Shh can bind to the patched homolog 1 (PTCH1) receptor on osteoblasts. Activation of PTCH1 results in increased GLI1/2 transcription factor activity and the induction of target genes such as IL-6 and RANKL that in turn promote osteoclast formation. Increased osteoclast activity then completes the vicious cycle loop via the increased availability of factors such as TGFβ and BMPs (Wu et al., 2017).

Conclusion

Tumor-induced bone disease involves complex interactions between multiple cell types and physical properties that are specific to the bone and bone marrow microenvironment. While substantial research has been performed over several decades, more work is needed to fully understand these interactions. Understanding these interactions will help with beginning to predict patient outcomes and potentially developing novel therapies for patients with TIBD. The multiple and complex mechanisms governing interactions between tumors and bone have revealed a number of exciting therapeutic opportunities that have the potential to impact patient care.

Chapter 56

Genetic regulation of parathyroid gland development

Fadil M. Hannan[1,2] **and Rajesh V. Thakker**[2]

[1]Department of Musculoskeletal Biology, Institute of Ageing and Chronic Disease, Faculty of Health & Life Sciences, University of Liverpool, Liverpool, United Kingdom; [2]Academic Endocrine Unit, Radcliffe Department of Medicine, University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism (OCDEM), Churchill Hospital, Oxford, United Kingdom

Chapter outline

Congenital anomalies of parathyroid gland development, which lead to hypoparathyroidism, are common and occur in more than 1 in 4000 births. The four human parathyroid glands develop from transient bilateral outpocketings of the pharyngeal endoderm, which are referred to as the pharyngeal pouches. There are four pairs of pharyngeal pouches; the superior parathyroid glands develop from the fourth pharyngeal pouches, which are the most caudal, while the inferior parathyroid glands together with the thymus develop from the third pharyngeal pouches. The pharyngeal pouches together with the branchial arches and grooves form the branchial apparatus that gives rise to a number of structures that include the face, jaws, oral cavity, neck, pharynx, larynx, ear, aortic arch, tonsils, thyroid, parathyroids, thymus, ultimobranchial body that results in calcitonin-producing cells, carotid glomus, and the epibranchial placodes that contribute to the facial, glossopharyngeal, and vagus nerves (Grigorieva and Thakker, 2011). Thus, developmental abnormalities of the branchial apparatus and pharyngeal pouches may lead to hypoparathyroidism that may be part of a complex congenital defect, as for example in the DiGeorge syndrome or a solitary endocrinopathy which is called *isolated* or *idiopathic* hypoparathyroidism. In addition, hypoparathyroidism may occur in association with other developmental anomalies involving dysmorphic features, sensorineural deafness, lymphoedema, nephropathy, and growth retardation (Table 56.1). The molecular genetic basis for such forms of hypoparathyroidism has been investigated and this has helped to elucidate further the mechanisms involved in the genetic regulation of parathyroid gland development. This chapter will focus on those forms of hypoparathyroidism that often present in early life, as these are likely to be associated with parathyroid gland agenesis or

TABLE 56.1 Inherited forms of hypoparathyroidism and their chromosomal locations.

Disease	Inheritance	Gene	Chromosomal location
Isolated hypoparathyroidism			
Autosomal dominant hypoparathyroidism	Autosomal dominant	GCM2, PTH	6p24.2, 11p15
Autosomal recessive hypoparathyroidism	Autosomal recessive	GCM2, PTH, AIRE	6p24.2, 11p15, 21q22.3
X-linked recessive hypoparathyroidism	X-linked recessive	SOX3[a], FHL1[a]	Xq26-27, Xq26.3
Autosomal dominant hypocalcemia			
Autosomal dominant hypocalcemia type 1	Autosomal dominant	CASR	3q21.1
Autosomal dominant hypocalcemia type 2	Autosomal dominant	GNA11	19p13.3
DiGeorge syndromes			
DiGeorge syndrome type 1	Autosomal dominant	TBX1	22q11.2
DiGeorge syndrome type 2	Autosomal dominant	NEBL[a]	10p13–14
CHARGE syndrome	Autosomal dominant	CHD7	8q12.1
Syndromes associated with deafness and/or renal anomalies			
HDR	Autosomal dominant	GATA3	10p15
Barakat syndrome	Autosomal recessive[a]	Unknown	Unknown
Nephropathy, nerve deafness	Autosomal dominant[a]	Unknown	Unknown
Nerve deafness without renal dysplasia	Autosomal dominant	Unknown	Unknown
Lymphedema, hypoparathyroidism, nephropathy, mitral valve prolapse, and brachytelephalangy	Autosomal recessive[a]	Unknown	Unknown
Autoimmune polyglandular syndrome type 1	Autosomal recessive	AIRE	21q22.3
Mitochondrial syndromes			
Kearns-Sayre syndrome	Maternal	Mitochondrial genome	-
MELAS	Maternal	Mitochondrial genome	-
MTP deficiency	Autosomal recessive	HADHB	2p23
Syndromes associated with growth failure/dwarfism			
Kenny–Caffey syndrome type 1	Autosomal recessive	TBCE	1q42.3
Sanjad–Sakati syndrome	Autosomal recessive	TBCE	1q42.3
Kenny–Caffey syndrome type 2	Autosomal dominant	FAM111A	11q12.1
Dubowitz syndrome	Autosomal recessive[a]	Unknown	Unknown

HDR, Hypoparathyroidism, deafness, and renal anomalies; MELAS, Mitochondrial encephalopathy, stroke like episodes and lactic acidosis; MTP, Mitochondrial trifunctional protein.

hypoplasia, congenital deficiency of parathyroid hormone (PTH), or early destruction of the parathyroids (Table 56.1). The hypoparathyroidism in these forms is characterized by hypocalcemia and hyperphosphatemia due to a deficiency in PTH secretion (Mannstadt et al., 2017).

Complex syndromes associated with hypoparathyroidism

Hypoparathyroidism may occur as part of a complex syndrome that may be associated with either a congenital developmental anomaly or an autoimmune syndrome (Mannstadt et al., 2017). The congenital developmental anomalies associated with hypoparathyroidism include the DiGeorge, HDR (hypoparathyroidism, deafness, and renal anomalies), Kenny−Caffey, and Barakat syndromes as well as syndromes associated with either lymphoedema or dysmorphic features and growth failure (Table 56.1).

DiGeorge syndrome

Clinical features and genetic abnormalities

Patients with DiGeorge syndrome (DGS) typically suffer from hypoparathyroidism, immunodeficiency, cardiac outflow tract malformations, facial dysmorphia, and palatal dysfunction (Kobrynski and Sullivan, 2007). DGS has been reported in up to 60% of children with familial or idiopathic forms of hypoparathyroidism (Kim et al., 2015) and has a wide spectrum of severity. Most commonly, hypoparathyroidism associated with DGS presents in the neonatal period with marked hypocalcemia, which may cause laryngospasm or seizures (Hieronimus et al., 2006). However, the hypoparathyroidism may be transient and characterized by serum calcium concentrations that normalize during infancy and early childhood. Some individuals with DGS may only develop hypocalcemic symptoms in adolescence or adulthood (Hieronimus et al., 2006; Nakada et al., 2013). The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches with resulting absence or hypoplasia of the parathyroids and thymus. Most cases of DGS are sporadic, but an autosomal dominant inheritance of DGS has been observed in up to 28% of cases (Kobrynski and Sullivan, 2007), and an association between the syndrome and an unbalanced translocation and deletions involving 22q11.2 have also been reported (Scambler et al., 1991), and this is referred to as DGS type 1 (DGS1). Mapping studies of the DGS1 deleted region on chromosome 22q11.2 defined a 250−3000 kb critical region (Gong et al., 1996; Scambler, 2000) that contained approximately 30 genes. Studies of DGS1 patients reported deletions of several genes (e.g., rnex40, nex2.2−nex 3, *UDF1L,* and *TBX1*) from the critical region (Augusseau et al., 1986; Budarf et al., 1995; Scambler et al., 1991; Yamagishi et al., 1999), and studies of transgenic mice deleted for such genes (e.g., *Udf1l*, *Hira,* and *Tbx1*) revealed developmental abnormalities of the pharyngeal arches (Jerome and Papaioannou, 2001; Lindsay et al., 2001). However, point mutations in DGS1 patients have only been detected in the *TBX1* gene (Yagi et al., 2003), and *TBX1* is now considered to be the gene causing DGS1 (Baldini, 2003). *TBX1* encodes a DNA binding transcriptional factor of the T-box family that regulates histone modification (Fulcoli et al., 2016) and is known to have an important role in vertebrate and invertebrate organogenesis and pattern formation. The *TBX1* gene is deleted in ∼96% of all DGS1 patients. Moreover, DNA sequence analysis of unrelated DGS1 patients who did not have deletions of chromosome 22q11.2, has revealed the occurrence of three heterozygous point mutations (Yagi et al., 2003). One of these mutations resulted in a frameshift with a premature truncation, while the other two were missense mutations (p.Phe148Tyr and p.Gly310Ser). All of these patients had the complete pharyngeal phenotype but did not have mental retardation or learning difficulties. These disease-causing mutations may have paradoxical effects on TBX1 function. Thus, while a DGS-associated truncating (c.1223delC) *TBX1* mutation has been shown to impair transcriptional activation in vitro consistent with a loss of function, disease-causing missense *TBX1* mutations may in contrast increase transcriptional activation, suggestive of a gain of function (Zweier et al., 2007). Interestingly, mice with deletion of *Tbx1* have a phenotype similar to that of DGS1 patients (Jerome and Papaioannou, 2001). Thus, *Tbx1*-null mutant-mice ($Tbx1^{-/-}$) had all the developmental anomalies of DGS1 (i.e., thymic and parathyroid hypoplasia; abnormal facial structures and cleft palate; skeletal defects; and cardiac outflow tract abnormalities), while Tbx1 haploinsufficiency in mutant mice ($Tbx1^{+/-}$) was associated only with defects of the fourth branchial pouch (i.e., cardiac outflow tract abnormalities). The basis of the phenotypic differences between DGS1 patients, who are heterozygous, and the $Tbx1^{+/-}$ mice remains to be elucidated. It is plausible that Tbx1 dosage together with the downstream genes that are regulated by Tbx1 could provide an explanation, but the roles of these putative genes in DGS1 remains to be elucidated. In some patients, deletions of another locus on chromosome 10p has been observed in association with DGS (Monaco et al., 1991), and this is referred to as DGS type 2 (DGS2). Patients with DGS2 may have a more severe phenotype than DGS1, and present with marked cognitive impairment in addition to cardiac abnormalities and

immune deficiency (Lindstrand et al., 2010; Van Esch et al., 1999). The nebulette, or *NEBL*, gene has been reported to be heterozygous deleted in cell lines from two female DGS2 patients and thus may be the responsible gene (Villanueva et al., 2002). Moreover, some patients presenting with the clinical manifestations of DGS, such as thymic aplasia and hypoparathyroidism, may additionally have features of the CHARGE syndrome, which is characterized by the combined occurrence of coloboma, heart abnormalities, choanal atresia, retardation of growth and/or development, and genitourinary and/or ear anomalies (Inoue et al., 2010). Such patients with overlapping features of DGS and the CHARGE syndrome have been revealed to harbor heterozygous mutations in the *CHD7* gene on chromosome 8q12.1, which encodes the chromodomain helicase DNA binding protein 7 (Inoue et al., 2010). The *CHD7* gene is expressed within the pharyngeal ectoderm, and *Chd7*-haploinsufficient mice have been noted to have thymic aplasia (Randall et al., 2009). These findings highlight a role for CHD7 in pharyngeal region development during embryogenesis.

Mouse models developing features of DiGeorge syndrome reveal roles of Hox and Pax genes in parathyroid and thymus development

In the mouse, the parathyroids develop with the thymus from common primordia that arise from the third pharyngeal pouch endoderm (Grigorieva and Thakker, 2011). The molecular mechanisms that regulate parathyroid/thymus organogenesis from the pharyngeal pouch endoderm have been investigated using knockout models, and the roles of transcription regulators e.g., Hoxa3, Pax1, Pax9, Eyal, Six1 and Six4 defined (Manley and Capecchi, 1998; Xu et al., 2002; Zou et al., 2006). The roles of *Hoxa3* and *Pax* genes will be briefly reviewed as they form a genetic pathway with glial cells missing homolog 2 (*Gcm2*) (see below) that regulates parathyroid organogenesis (Fig. 56.1).

Homeobox (Hox) genes. The *Hox* genes are a group of evolutionarily conserved genes that contain a 180 bp motif, which encodes a 60 amino acid DNA-binding domain called the homeodomain (Quinonez and Innis, 2014). These genes are involved in early embryogenesis and determine the body plans of invertebrates such as *Drosophila* by specifying the identity of cells within each parasegment along the main anterior–posterior body axis (Deschamps, 2007). The role of the *Hox* genes in mammals remains to be fully elucidated, and recent studies indicate that these genes may not regulate the overall layout of the vertebrate body plan, but instead mediate region-specific patterning and development such as with limb morphogenesis (Mallo, 2018). In mammals, *Hox* genes are distributed in the genome in four separate clusters (Hox A, B, C, and D), which may have arisen during chordate evolution as the result of two duplications of chromosomal segments (Kappen et al., 1989; Manley and Capecchi, 1998). Each *Hox* cluster contains up to 13 genes, which are numbered 1–13 based on their position in the cluster as well as their homology with genes in other *Hox* clusters (Mallo, 2018). In order to determine the genetic function of some *Hox* genes, mouse knockout models have been generated. Disruption of *Hoxa3* resulted in an abnormal phenotype with similarities to DGS (Chisaka and Capecchi, 1991; Manley and Capecchi, 1995). Null mutant mice ($Hoxa3^{-/-}$) died in the neonatal period and were found to be lacking the thymus and parathyroids because of a failure to initiate the formation of the parathyroid–thymus primordia. These $Hoxa3^{-/-}$ mice also had defects

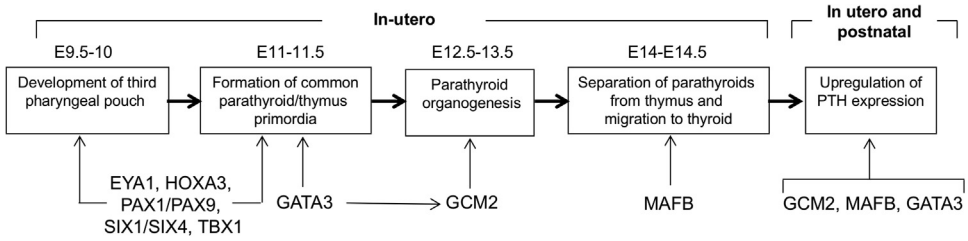

FIGURE 56.1 Transcription factors involved in parathyroid gland development and function. Mouse model studies have shown that a network of transcription factors such as the EYA1, HOXA3, TBX1, PAX1/PAX9, SIX1/SIX4, and GATA3 proteins mediate patterning of the third pharyngeal pouch and formation of the common parathyroid-thymus primordia (Grigorieva and Thakker, 2011; Kamitani-Kawamoto et al., 2011). These transcription factors act in a spatiotemporal manner; for example, TBX1 is expressed in the pharyngeal endoderm and required for the development of the third pharyngeal pouch (Jerome and Papaioannou, 2001); whereas GATA3 is expressed in the common parathyroid-thymus primordia and mediates the differentiation and survival of parathyroid and thymus progenitor cells (Grigorieva et al., 2010; Grigorieva and Thakker, 2011). Moreover, GATA3 regulates the expression of GCM2, which is expressed in the parathyroid domain of the common primordia and mediates the initial stages of parathyroid organogenesis (Grigorieva et al., 2010; Grigorieva and Thakker, 2011). MAFB is also expressed in the parathyroid domain and facilitates the separation of the parathyroid glands from the thymus, and also the migration of the parathyroids toward the thyroid (Kamitani-Kawamoto et al., 2011). GATA3, GCM2 and MAFB also act synergistically to upregulate PTH expression (Han et al., 2015). As the expression of GATA3, GCM2, and MAFB persists into adulthood, it is likely that these transcription factors are required for the postnatal expression of PTH (Han et al., 2015). E = embryonic day. *Adapted from Mannstadt et al.* Nat Rev Dis Primer, *3, 17055.*

of the heart and arteries, craniofacial abnormalities, and a reduction in the mass of the thyroid and submaxillary tissues. The *Hoxa3*$^{+/-}$ mice were phenotypically normal. Thus, although the *Hoxa3*$^{-/-}$ mice clearly indicated an important role for the *Hoxa3* gene in parathyroid and thymus organogenesis, there were nevertheless important differences between this mouse, having an autosomal recessive syndrome, and DGS, which is an autosomal dominant trait. Studies involving mice with an endoderm-specific and/or neural crest cell-specific ablation of *Hoxa3* have shown that *Hoxa3* deletion inhibited parathyroid gland development by impairing the expression of the parathyroid-specific *Gcm2* transcription factor (Chojnowski et al., 2014), which in turn leads to apoptosis of the embryonic parathyroid domain (Liu et al., 2007).

Paired box (Pax) genes. The paired box (*Pax*) genes comprise an evolutionarily conserved family of transcriptional factors that contain a highly conserved 128 amino acid DNA-binding domain, called the paired box (Relaix, 2015). Mammals have nine *Pax* genes, and these are expressed in a spatially and temporally restricted manner during embryonic development and play a key role in the patterning of the nervous system (Relaix, 2015). The Pax1, Pax3, Pax7, and Pax9 transcription factors have been shown to regulate multiple neural crest cell lineages. In particular, Pax1 and Pax9 are expressed in the endoderm-derived epithelium of the third and fourth pharyngeal pouches and play a role in the development of the thymus, parathyroid glands, and ultimobranchial bodies (Monsoro-Burq, 2015). Indeed, mice deficient in either Pax1 or Pax9 (i.e., *Pax1* $^{-/-}$ or *Pax9* $^{-/-}$) have congenital parathyroid and thymic defects (Peters et al., 1998; Su et al., 2001). Studies of double-knockout mice indicated that there is a genetic pathway that involves Hoxa3, Pax1 and Gcm2 (see below) in parathyroid development (Su et al., 2001). Thus, Gcm2 expression is absent in *Hoxa3*$^{-/-}$ mouse embryos that are 10.5 days postcoitum (dpc), reduced in *Pax1* $^{-/-}$ mouse embryos that are 11.5 dpc, and absent in *Hoxa3*$^{+/-}$*/Pax1* $^{-/-}$ mice at 11.5 dpc (Su et al., 2001). These studies have revealed that Hoxa3 is required for initiation of parathyroid organogenesis and for initial Gcm2 expression and that both Hoxa3 and Pax1 are required for Gcm2 expression. Failure of Gcm2 expression results in a lack of parathyroids; this is due to programmed cell death (apoptosis) of the parathyroid primordia at 12 dpc in mouse embryos (Liu et al., 2007; Su et al., 2001). Thus, there is an important transcription cascade involving Hoxa3, Pax1, and Gcm2 in the embryonic development of parathyroids.

Hypoparathyroidism, deafness, and renal anomalies syndrome

Clinical features and role of GATA3 mutations

The combined inheritance of HDR as an autosomal dominant trait was reported in one family in 1992 (Bilous et al., 1992). Patients had asymptomatic hypocalcemia with undetectable or inappropriately normal serum concentrations of PTH and normal brisk increases in serum cAMP in response to the infusion of PTH. The patients also had bilateral and symmetrical sensorineural deafness involving all frequencies. The renal abnormalities consisted mainly of bilateral cysts that compressed the glomeruli and tubules and led to renal impairment in some patients. Cytogenetic abnormalities were not detected, and abnormalities of the PTH gene were excluded (Bilous et al., 1992). However, cytogenetic abnormalities involving chromosome 10p14−10pter were identified in two unrelated patients with features consistent with HDR. These two patients suffered from hypoparathyroidism, deafness, and growth and mental retardation; one patient also had a solitary dysplastic kidney with vesicoureteral reflux and a uterus bicornis unicollis (Fryns et al., 1981), and the other patient, who had a complex reciprocal insertional translocation of chromosomes 10p and 8q, had cartilaginous exostoses (Van Esch et al., 1999). Neither of these patients had immunodeficiency or heart defects, which are key features of DGS2 (see previous), and further studies defined two nonoverlapping regions; thus, the DGS2 region was located on 10p13−p14 and HDR on 10p14−10pter. Deletion mapping studies in two other HDR patients further defined a critical 200-kb region that contained the *GATA3* gene (Van Esch et al., 2000). GATA3 belongs to a family of dual zinc-finger transcription factors involved in vertebrate embryonic development. DNA sequence analysis in other HDR patients identified mutations that resulted in a haploinsufficiency and loss of GATA3 function (Ali et al., 2007; Nesbit et al., 2004; Van Esch et al., 2000). To date, $>$ 50 different heterozygous germline *GATA3* abnormalities, which comprise point-mutations and whole gene deletions, have been reported (Adachi et al., 2006; Ali et al., 2007; Fukami et al., 2011; Gaynor et al., 2009; Mino et al., 2005; Muroya et al., 2001; Nesbit et al., 2004; Van Esch et al., 2000; Zahirieh et al., 2005). The majority ($>$ 75%) of these HDR-associated mutations are predicted to result in truncated forms of the GATA3 protein. Each proband and family will generally have its own unique mutation, and there appears to be no correlation with the underlying genetic defect and the phenotypic variation—e.g., the presence or absence of renal dysplasia. Over 90% of patients with two or three of the major clinical features of HDR syndrome—i.e., hypoparathyroidism, deafness, or renal abnormalities—have a *GATA3* mutation (Ali et al., 2007). The remaining 10% of HDR of patients who do not have a mutation of the *GATA3* coding region may harbor mutations in the regulatory sequences flanking the *GATA3* gene, or they may represent heterogeneity. The phenotypes of HDR patients with *GATA3* mutations appear to be similar to those without *GATA3* mutations (Ali et al., 2007).

The HDR-associated *GATA3* mutations are predicted to disrupt either one or both of the zinc finger domains (Nesbit et al., 2004). The C-terminal finger (ZnF2) of GATA proteins binds DNA, whereas the N-terminal finger (ZnF1) stabilizes this DNA binding and interacts with other zinc-finger proteins, such as friends of GATA (FOGs) (Svensson et al., 1999; Tevosian et al., 1999; Tsang et al., 1997). The functional consequences of these HDR-associated *GATA3* mutations have been assessed by electrophoretic mobility shift assays to detect alterations in DNA binding and by yeast two-hybrid assays to detect alterations in protein−protein interactions (Ali et al., 2007; Nesbit et al., 2004). These studies have revealed that HDR-associated mutations involving the GATA3 ZnF2 or the adjacent basic amino acids result in a loss of DNA binding to the consensus motif, GATA, that would be associated with the promoter of the gene being regulated by GATA3 (Ali et al., 2007; Nesbit et al., 2004; Van Esch et al., 2000). However, those HDR-associated mutations involving ZnF1 led to either a loss of interaction with FOG2 ZnFs or altered DNA-binding affinity (Ali et al., 2007; Nesbit et al., 2004). These findings are consistent with the proposed three-dimensional model of GATA3 ZnF1, which has separate DNA and protein-binding surfaces (Ali et al., 2007; Nesbit et al., 2004). Thus, HDR-associated *GATA3* mutations can be subdivided into two broad classes depending on whether they disrupt ZnF1 or ZnF2 and their subsequent effects on interactions with FOG2 and altered DNA binding, respectively.

Phenotype of the GATA3 knockout mouse model

The HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney, otic vesicle, and parathyroids. However, GATA3 is also expressed in the developing central nervous system (CNS) and the hematopoietic organs, and this suggests that GATA3 may have a more complex role. Indeed, studies of *Gata3*$^{+/-}$ and *Gata3*$^{-/-}$ mice have revealed important roles for *Gata3* in the development of the brain, spinal cord, peripheral auditory system, T cells, fetal liver hematopoiesis, and urogenital system (Pandolfi et al., 1995). *Gata3*$^{-/-}$ mice die between E11.5 and E12.5 (Pandolfi et al., 1995), but *Gata3*$^{+/-}$ mice are viable, appear to be normal with a normal life span, and are fertile (Pandolfi et al., 1995). However, *Gata3*$^{+/-}$ mice have hearing loss that commences in the early postnatal period, is progressive through adulthood, and is associated with cochlear abnormalities, which consist of a significant progressive morphological degeneration that starts with the outer hair cells at the apex and eventually involves all the inner hair cells, pillar cells, and nerve fibers (van der Wees et al., 2004; van Looij et al., 2006). *Gata3* loss also resulted in parathyroid abnormalities. Thus, *Gata3*$^{-/-}$ and *Gata3*$^{+/-}$ embryos lacked or had smaller parathyroid−thymus primordia, respectively, and the parathyroids of adult *Gata3*$^{+/-}$ mice did not enlarge or have an increased proliferation rate in response to hypocalcemia induced by a low-calcium/vitamin D diet (Grigorieva et al., 2010). Moreover, the adult *Gata3*$^{+/-}$ mice had an inadequate increase in plasma PTH in response to the induced hypocalcemia (Grigorieva et al., 2010). These findings in the *Gata3*$^{+/-}$ mice are consistent with the observed hypocalcemia that occurs in association with inappropriately normal or low plasma PTH concentrations in patients who have the HDR syndrome due to *GATA3* haploinsufficiency (Bilous et al., 1992; Van Esch et al., 2000).

Examination of *Gata3*$^{-/-}$ embryos has revealed a variety of abnormalities that include massive internal bleeding resulting in anemia, marked growth retardation, severe deformities of the brain and spinal cord, a hypopigmented retina, gross aberrations in fetal liver hematopoiesis, impaired T cell differentiation, and a retarded or missing lower jaw area (Grote et al., 2006, 2008; Lim et al., 2000; Pandolfi et al., 1995). These *Gata3*$^{-/-}$ mice had an anatomically normal sympathetic nervous system, yet the sympathetic ganglia lacked tyrosine hydroxylase and dopamine beta-hydroxylase, which are key enzymes that convert tyrosine to L-DOPA, and dopamine to noradrenaline, respectively, in the catecholamine synthesis pathway. Thus, the *Gata3*$^{-/-}$ mice lacked noradrenaline in the sympathetic neurons, and this contributed to early embryonic lethality (Lim et al., 2000). Feeding of catecholamine intermediates to pregnant dams helped to partially rescue the *Gata3*$^{-/-}$ embryos from E12.5 to E16.5 (Lim et al., 2000). These older, pharmacologically rescued *Gata3*$^{-/-}$ embryos showed abnormalities that could not be detected in the untreated mice (Lim et al., 2000). These late embryonic defects included thymic hypoplasia, a thin-walled ventricular septum, a poorly developed mandible, other developmental defects in structures derived from the cephalic neural crest cells, renal hypoplasia, a failure to form the metanephros, and an aberrant elongation of the nephric duct along the anteroposterior axis of the embryo (Grote et al., 2006, 2008; Lim et al., 2000). The defect of the nephric duct, which consisted of an abnormal morphogenesis and guidance in the developing kidney, was characterized by the loss of *Ret* expression that is an essential component of the glial-derived-nerve-factor signaling pathway involved in ureteric bud formation and nephric duct guidance (Grote et al., 2006). Thus, *Gata3* has a role in the differentiation of multiple cell lineages during embryogenesis as well as being a key regulator of nephric duct morphogenesis and guidance of the nephric duct in its caudal extension in the pro/mesonephric kidney (Grote et al., 2006; Lim et al., 2000).

Role of GATA3 in developmental pathogenesis

The mechanisms whereby GATA3 haploinsufficiency leads to the phenotypic features of the HDR syndrome remain to be elucidated. Important clues have been obtained from in vitro and in vivo studies of knockout mice. Indeed, the smaller size or absence of the parathyroids in the *Gata3*$^{+/-}$ and *Gata3*$^{-/-}$ embryos, respectively, was found to be associated with a markedly reduced number of *Gcm2*-expressing cells in the third pharyngeal pouch (Grigorieva et al., 2010), thereby indicating that GATA3 is likely to be critical for maintaining differentiation and subsequent survival of parathyroid and thymus progenitor cells. Furthermore, in vitro studies showed that GCM2 is transcriptionally regulated by GATA3 (Grigorieva et al., 2010) and that GATA3 acts synergistically with GCM2 and also the parathyroid MafB transcription factor, most likely by forming a transcriptional complex, to upregulate PTH gene expression (Fig. 56.1) (Grigorieva et al., 2010; Han et al., 2015). GATA3 also plays an essential role in determining T cell lineage during thymopoiesis (Hosoya et al., 2010). However, it is important to note that GATA3 haploinsufficiency in the HDR patients is not associated with immunodeficiency (Lichtner et al., 2000; Van Esch et al., 2000), indicating that either reduced amounts of GATA3 are sufficient for T cell development or that GATA1 and GATA2 may be able to compensate for the loss of GATA3. The urogenital defects of HDR patients and knockout mice have highlighted a role for GATA3 in the development of the kidney and nephric duct. In support of this, mouse embryos with conditional inactivation of Gata3 in the urogenital system have been shown to develop ectopic ureter budding that leads to renal dysplasia, duplex systems, and hydroureter (Grote et al., 2008). These studies have additionally demonstrated that renally expressed Gata3 acts downstream of beta-catenin but upstream of Ret to prevent ectopic uretic budding and premature differentiation of nephric duct cells (Grote et al., 2008). However, it is important to note that the altered renal morphogenesis is observed only in *Gata3*$^{-/-}$ mice and not in *Gata3*$^{+/-}$ mice, which unlike HDR patients who are also heterozygous for the GATA3 mutation, have normal kidneys (Pandolfi et al., 1995). Thus, there are important phenotypic differences between *Gata3*$^{+/-}$ mice and HDR patients, who are heterozygous for GATA3 mutations, and the mechanisms underlying these interspecies differences and the tissue-specific differences that confer susceptibility to GATA3 haploinsufficiency remain to be elucidated. In contrast to these renal differences between HDR patients and *Gata3*$^{+/-}$ mice, there are marked similarities in hearing loss (Bilous et al., 1992; Lichtner et al., 2000; van der Wees et al., 2004; van Looij et al., 2005). It has not been possible to perform detailed functional and histological studies on the auditory system of HDR patients, but such studies in *Gata3*$^{+/-}$ mice have revealed that the hearing loss is due to degeneration and loss of the outer hair cells that progressively involve the other types of hair cells and nerve fibers in the cochlea (van der Wees et al., 2004; van Looij et al., 2005). Moreover, studies involving mice with a conditional knockout of Gata3 specifically in the developing inner ear have shown that this transcription factor specifies the prosensory domain in the cochlea and enhances the survival of spiral ganglion neurons (Luo et al., 2013). However, the genes under transcriptional regulation of GATA3 in the cochlea remain to be identified. The morphological changes and genetic pathways involved in the parathyroids of HDR patients and Gata3 knockout mice also remain to be fully elucidated. Thus, although the HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney (ureteric bud, collecting duct system, and mesangial cells), otic vesicle, and parathyroids, much remains unknown regarding the underlying transcription pathways and the basis of the interspecies differences between *Gata3*$^{+/-}$ mice and HDR patients.

Kenny–Caffey and Sanjad–Sakati syndromes

Hypoparathyroidism has been reported to occur in over 50% of patients with Kenny–Caffey syndrome (KCS), which is associated with short stature, osteosclerosis and cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos, and hyperopia (Bergada et al., 1988; Fanconi et al., 1986; Franceschini et al., 1992). KCS may be inherited as an autosomal recessive (KCS type 1, KCS1) or autosomal dominant (KCS type 2, KCS2) disorder (Mannstadt et al., 2017). Parathyroid tissue could not be found in a detailed postmortem examination of one KCS patient (Boynton et al., 1979), and this suggests that hypoparathyroidism may be due to an embryological defect of parathyroid development. In Sanjad–Sakati syndrome, hypoparathyroidism is associated with severe growth failure and dysmorphic features, and this has been reported in 12 patients from Saudi Arabia (Sanjad et al., 1991). Consanguinity was noted in 11 of the 12 patients' families, the majority of which originated from the Western province of Saudi Arabia. Sanjad–Sakati syndrome, which is inherited as an autosomal recessive disorder, has also been identified in families of Bedouin origin and homozygosity, and linkage disequilibrium studies have mapped this gene to chromosome 1q42-q43 (Parvari et al., 1998). Molecular genetic investigations have identified that mutations of the tubulin-specific chaperone (*TBCE*) are associated with KCS1 and Sanjad–Sakati syndromes (Parvari et al., 2002). *TBCE* encodes one of several chaperone proteins required for the proper folding of α-tubulin subunits and the formation of α-β tubulin

heterodimers (Parvari et al., 2002). Whole-exome sequencing has demonstrated KCS2 to be caused by heterozygous missense mutations of the family with sequence similarity 111 member A (*FAM111A*) gene, which encodes a protein with homology to trypsin-like peptidases (Isojima et al., 2014; Unger et al., 2013). The FAM111A protein has been revealed to modulate DNA replication and chromatin maturation, and may play a role in embryonic development (Alabert et al., 2014; Unger et al., 2013).

Additional familial syndromes

Single familial syndromes in which hypoparathyroidism is a component have been reported (Table 56.1). The inheritance of the disorder in some instances has been established, and molecular genetic analysis of the PTH gene has revealed no abnormalities. Thus, an association of hypoparathyroidism, renal insufficiency, and developmental delay has been reported in one Asian family in whom autosomal recessive inheritance of the disorder was established (Parkinson et al., 1993). An analysis of the PTH gene in this family revealed no abnormalities (Parkinson et al., 1993). The occurrence of hypoparathyroidism, nerve deafness, and a steroid-resistant nephrosis leading to renal failure, which has been referred to as the *Barakat syndrome* (Barakat et al., 1977), has been reported in four brothers from one family, and an association of hypoparathyroidism with congenital lymphoedema, nephropathy, mitral valve prolapse, and brachytelephalangy has been observed in two brothers from another family (Dahlberg et al., 1983). Molecular genetic studies have not been reported from these two families. Hypoparathyroidism has also been reported in association with Dubowitz syndrome, which is characterized by multiple congenital anomalies that include microcephaly and growth retardation (Lerman-Sagie et al., 1990).

Mitochondrial disorders associated with hypoparathyroidism

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: the Kearns−Sayre syndrome (KSS), MELAS syndrome, and a mitochondrial trifunctional protein (MTP) deficiency syndrome. KSS is characterized by progressive external ophthalmoplegia and pigmentary retinopathy before the age of 20 years and is often associated with heart block or cardiomyopathy. MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes. In addition, varying degrees of proximal myopathy can be seen in both conditions. Both the KSS and MELAS syndromes have been reported to occur with insulin-dependent diabetes mellitus and hypoparathyroidism (Moraes et al., 1989; Morten et al., 1993). A point mutation in the mitochondrial gene tRNA leucine has been reported in one patient with MELAS syndrome who also suffered from hypoparathyroidism and diabetes mellitus (Morten et al., 1993). Large deletions, consisting of 6741 and 6903 bp and involving $> 38\%$ of the mitochondrial genome, have been reported in other patients who suffered from KSS, hypoparathyroidism, and sensorineural deafness (Isotani et al., 1996). Rearrangements and duplication of mitochondrial DNA have also been reported in KSS (Abramowicz et al., 1996; Wilichowski et al., 1997). Mitochondrial trifunctional protein deficiency is a disorder of fatty-acid oxidation associated with peripheral neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been reported in three cases of MTP deficiency and presents in the infantile period in association with rhabdomyolysis and polyneuropathy (Naiki et al., 2014). Hypoparathyroidism caused by MTP deficiency has been associated with homozygous mutations of the *HADHB* gene, which encodes the β-subunit of the MTP protein, in two cases (Naiki et al., 2014). The role of mutations affecting the mitochondrial genome or *HADHB* gene in the etiology of hypoparathyroidism remains to be further elucidated, and as yet mouse models have not been generated to facilitate in vivo studies.

Pluriglandular autoimmune hypoparathyroidism

Hypoparathyroidism may occur in association with candidiasis and autoimmune Addison's disease, and the disorder has been referred to as either autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome or autoimmune polyglandular syndrome type 1 (Husebye et al., 2018). This disorder has a high incidence in Finland (Perheentupa, 2002), and a genetic analysis of Finnish families indicated autosomal recessive inheritance of the disorder. In addition, the disorder has been reported to have a high incidence among Iranian Jews, although the occurrence of candidiasis was less common in this population (Zlotogora and Shapiro, 1992). Linkage studies of Finnish families mapped the APECED gene to chromosome 21q22.3 (Aaltonen et al., 1994). Further positional cloning approaches led to the isolation of a novel gene from chromosome 21q22.3. This gene, referred to as *AIRE* (autoimmune regulator), encodes a 545 amino acid protein that contains motifs suggestive of a transcriptional factor and includes two zinc-finger motifs, a

proline-rich region, and three LXXLL motifs (Finnish-German APECED Consortium, 1997; Nagamine et al., 1997). Greater than 100 APECED-causing *AIRE* mutations have been reported to date (Husebye et al., 2018), and four *AIRE* mutations have been shown to commonly occur in APECED families: p.Arg257Stop in Finnish, German, Swiss, British, Norwegian, and Northern Italian families; p.Arg139Stop in Sardinian families; p.Tyr85Cys in Iranian Jewish families; and a 13 bp deletion in exon 8 in British, Dutch, German, Norwegian, and Finnish families (Heino et al., 1999; Nagamine et al., 1997; Pearce et al., 1998; Wolff et al., 2007). Occasionally, biallelic *AIRE* mutations have been reported in patients with isolated hypoparathyroidism (Li et al., 2017; Sahoo et al., 2016). AIRE has been shown to regulate the elimination of organ-specific T cells in the thymus, and thus APECED is likely to be caused by a failure of this specialized mechanism for deleting forbidden T cells and establishing immunologic tolerance (Liston et al., 2003). AIRE also promotes the thymic development of regulatory T cells (Tregs) that express the Foxp3 transcription factor (Husebye et al., 2018; Malchow et al., 2013). These Foxp3+ Treg cells suppress autoreactive T cells and are considered to play a key role in the prevention of autoimmunity (Husebye et al., 2018; Leonard et al., 2017). Furthermore, the T cell−mediated loss of immune tolerance that occurs in APECED is associated with the presence of autoantibodies that target organ-specific antigens such as NACHT leucine-rich-repeat-protein 5, which is mainly expressed in the parathyroid glands (Alimohammadi et al., 2008). Greater than 95% of APECED patients also develop autoantibodies against cytokines such as type 1 interferons, and the detection of autoantibodies against type 1 interferons has been shown to have clinical utility for the diagnosis of APECED (Husebye et al., 2018; Orlova et al., 2017).

Isolated hypoparathyroidism

Isolated hypoparathyroidism may be inherited either as an autosomal dominant, autosomal recessive, or X-linked recessive disorder (Table 56.1) (Mannstadt et al., 2017). Some autosomal forms of hypoparathyroidism have been shown to be due to abnormalities of the *PTH* and *GCM2* genes.

Parathyroid hormone gene abnormalities

Parathyroid hormone gene structure and function

The *PTH* gene is located on chromosome 11p15 and consists of three exons, which are separated by two introns (Naylor et al., 1983). Exon 1 of the *PTH* gene is 85 bp in length and is untranslated (Fig. 56.2), whereas exons 2 and 3 encode the 115-amino-acid pre-pro-PTH peptide. Exon 2 is 90 bp in length and encodes the initiation codon (ATG), the prehormone sequence, and part of the prohormone sequence. Exon 3 is 612 bp in size and encodes the remainder of the prohormone sequence, the mature PTH peptide, and the 3′ untranslated region (Vasicek et al., 1983). The 5′ regulatory sequence of the human *PTH* gene contains a vitamin D response element 125 bp upstream of the transcription start site, which down-regulates PTH mRNA transcription in response to vitamin D receptor binding (Demay et al., 1992; Okazaki et al., 1988). *PTH* gene transcription (as well as PTH peptide secretion) is also dependent upon extracellular calcium and phosphate concentrations (Almaden et al., 1996; Naveh-Many et al., 1995; Slatopolsky et al., 1996), and this effect may potentially be mediated by the parathyroid-expressed calcium-sensing receptor (CaSR), as recent crystallographic studies have shown that the extracellular domain of the CaSR possesses binding sites for calcium and phosphate (Geng et al., 2016). The mature PTH peptide is secreted from the parathyroid chief cell as an 84-amino-acid peptide and this is regulated by the CaSR, which is also expressed in renal tubules. However, when the PTH mRNA is first translated, it is as a pre-pro-PTH peptide. The "pre" sequence consists of a 25-amino-acid signal peptide (leader sequence) responsible for directing the nascent peptide into the endoplasmic reticulum to be packaged for secretion from the cell (Kemper et al., 1974). The "pro" sequence is six amino acids in length, and although its function is less well defined than that of the "pre" sequence, it is also essential for correct PTH processing and secretion (Kemper et al., 1974). After the 84-amino-acid mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation with a short half-life of about 2 min via nonsaturable hepatic uptake and renal excretion. PTH shares a receptor with PTH-related peptide (PTHrP, also known as PTHrH or PTH-related hormone) (Juppner et al., 1991), and this receptor is a member of a subgroup of G-protein-coupled receptors (GPCRs). The PTH/PTHrP receptor gene is located on chromosome 3p21−p24 (Gelbert et al., 1994) and is highly expressed in kidney and bone, where PTH is its predominant agonist (Abou-Samra et al., 1992). However, the most abundant expression of the PTH/PTHrP receptor occurs in chondrocytes of the metaphyseal growth plate, where it mediates predominantly the autocrine/paracrine actions of PTHrP (Segre, 1996). Five polymorphisms of the PTH gene have been reported; two of these are associated with restriction fragment length polymorphisms (RFLPs) (Schmidtke et al., 1984), another two are the result of single base changes not associated with RFLPs (Miric and Levine, 1992), and one is

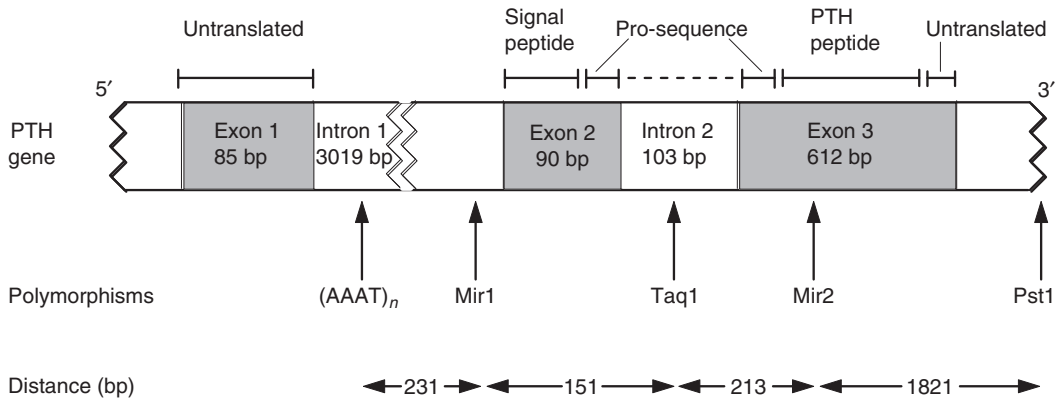

FIGURE 56.2 Schematic representation of the PTH gene. The PTH gene consists of three exons and two introns; the peptide is encoded by exons 2 and 3. The PTH peptide is synthesized as a precursor which contains a pre- and a prosequence. The mature PTH peptide, which contains 84 amino acids, and larger carboxy-terminal PTH fragments are secreted from the parathyroid cell. The polymorphic sites associated with the PTH gene are indicated. Two restriction fragment length polymorphisms (RFLPs) are associated with the PTH gene, and the *Taq*I polymorphic site is within intron 2 and the *PstI* polymorphic site is 1.7 kbp downstream in the 3′ direction of the gene (Schmidtke et al., 1984). Two other polymorphisms (Miric and Levine, 1992) of the PTH gene designated Mir1 and Mir2 are located in intron 1 and exon 3, respectively, and the tetranucleotide $(AAAT)_n$ polymorphism is in intron 1 (Parkinson et al., 1993). The distance between the $(AAAT)_n$ polymorphism and the Mir1 polymorphism is 231 base pairs (bp), that between the Mir1 polymorphism and the *Taq*1 RFLP is 152 bp, that between the *Taq*I RFLP site and the Mir2 polymorphism is 212 bp, and that between the Mir2 polymorphism and the *Pst*I RFLP is 1821 bp. Linkage disequilibrium between the $(AAAT)_n$, *Taq*I, and *Pst*I polymorphic sites has been established (Parkinson et al., 1993). *Adapted from Parkinson, D. B. & Thakker, R. V. 1992. A donor splice site mutation in the parathyroid hormone gene is associated with autosomal recessive hypoparathyroidism. Nat. Genet., 1, 149–152.*

due to a variation in the length of a microsatellite repetitive sequence in intron 1 (Parkinson et al., 1993). These polymorphisms are inherited in a Mendelian manner and are thus useful as genetic markers in family studies. Mutations involving the PTH gene affect the regulation of calcium homeostasis and are associated with hypoparathyroidism (Table 56.1).

Autosomal dominant hypoparathyroidism

DNA sequence analysis of the *PTH* gene (Fig. 56.2) from one patient with autosomal dominant isolated hypoparathyroidism has revealed a heterozygous single base substitution (T→C) in codon 18 of exon 2 (Arnold et al., 1990), which resulted in the substitution of arginine for the normal cysteine (p.Cys18Arg) in the signal peptide. The presence of this charged amino acid in the midst of the hydrophobic core of the signal peptide impeded the processing of the mutant pre-pro-PTH, as demonstrated by in vitro studies. These revealed that the mutation impaired the interaction with the nascent protein and translocation machinery, and that cleavage of the mutant signal sequence by solubilized signal peptidase was ineffective (Arnold et al., 1990; Karaplis et al., 1995). Ineffective cleavage of the pre-pro-PTH sequence results in a molecule that does not proceed successfully through the subsequent intracellular steps required for ultimate delivery of PTH to secretory granules. The parathyroid cell, therefore, cannot respond to hypocalcemia with the secretion of native, biologically active PTH. However, it should be noted that in vitro studies have shown that secretion of the mutant pre-pro-PTH peptide harboring the p.Cys18Arg missense substitution can be enhanced by the addition of 4-phenylbutyric acid, which is a pharmacological chaperone (Datta et al., 2007). Recently, a heterozygous single base substitution (T→A) in codon 14 of exon 2 of the *PTH* gene, which resulted in methionine to lysine substitution (p.Met14Lys) in the signal peptide, has been reported in a family with autosomal dominant hypoparathyroidism (Cinque et al., 2017). This mutation was predicted to impair cleavage of pre-pro-PTH, and studies in HEK293 cells showed intracellular retention of the mutant pre-pro-PTH peptide, which could be partially rescued by the addition of 4-phenylbutyric acid (Cinque et al., 2017).

Autosomal recessive hypoparathyroidism

Autosomal recessive hypoparathyroidism has usually arisen in families with consanguineous marriages (Parkinson et al., 1993; Parkinson and Thakker, 1992). Abnormalities in the *PTH* gene have been sought (Parkinson et al., 1993), and homozygous mutations that lead to impaired processing of the PTH peptide have been identified in three unrelated families (Ertl et al., 2012; Parkinson and Thakker, 1992; Sunthornthepvarakul et al., 1999). In one such family, a donor splice site at

the exon 2−intron 2 boundary has been identified (Parkinson and Thakker, 1992). This mutation involved a single base transition (**g→c**) at position one of intron 2, and the effects of this alteration in the invariant **gt** dinucleotide of the 5′ donor splice site consensus on mRNA processing were assessed by an analysis of the non-tissue-specific transcription of normal and mutant *PTH* genes. This non-tissue-specific expression of genes has been estimated to be at the rate of one molecule of correctly spliced mRNA per 1000 cells (Chelly et al., 1989; von Heijne, 1983). Although the physiological relevance of this low level of non-tissue-specific or illegitimate transcription is not known, it is of clinical importance. Easily accessible peripheral blood lymphocytes can be used to detect abnormalities in mRNA processing, thereby avoiding the requirement for tissue that may only be obtainable by biopsy. Use of these methods revealed that the donor splice site mutation resulted in exon skipping, in which exon 2 of the *PTH* gene was lost, and exon 1 was spliced to exon 3. The lack of exon 2 would lead to a loss of the ATG and signal peptide sequence required, respectively, for the commencement of PTH mRNA translation and translocation of the PTH peptide. Thus, the patients' parathyroid cells would not contain any translated PTH products.

Mutations involving codon 23, which encodes a serine (Ser), have been reported in two unrelated families with autosomal recessive hypoparathyroidism (Ertl et al., 2012; Sunthornthepvarakul et al., 1999). In one family, a homozygous single base substitution (**T→C**) involving codon 23 of exon 2 was detected. This resulted in the substitution of proline for normal serine in the signal peptide (Sunthornthepvarakul et al., 1999). This missense mutation (p.Ser23Pro) alters the −3 position of the pre-pro-PTH protein cleavage site (von Heijne, 1983). Indeed, amino acid residues at the −3 and −1 positions of the signal peptidase recognition site have to conform to certain criteria for correct processing through the rough endoplasmic reticulum (RER), and one of these is an absence of proline in the region −3 and +1 of the site (von Heijne, 1983). Thus, the presence of a proline, which is a strong helix-breaking residue, at the −3 position is likely to disrupt cleavage of the mutant pre-pro-PTH that would be subsequently degraded in the RER, and PTH would not be available (Sunthornthepvarakul et al., 1999). In the other unrelated family, a homozygous single base substitution (**C→A**) involving codon 23 was detected in a proband with isolated hypoparathyroidism (Ertl et al., 2012). This mutation is predicted to result in a stop codon (p.Ser23Stop) being introduced at the pre-pro-PTH protein cleavage site and would lead to a truncated and inactive PTH peptide (Ertl et al., 2012).

Recently, a homozygous arginine-to-cysteine mutation was identified at codon 25, p.Arg25Cys, of the mature PTH (1−84) peptide in a family with hypocalcemia and hyperphosphatemia (Lee et al., 2015). The plasma PTH levels of affected family members varied from low-normal to markedly elevated depending on the type of PTH assay used (Lee et al., 2015). Administration of recombinant PTH (1−34) increased urinary cAMP excretion in affected family members, thus indicating they did not have pseudohypoparathyroidism (Lee et al., 2015). In contrast to previously reported *PTH* gene mutations that affect the secretion of PTH, the p.Arg25Cys missense substitution was shown to diminish the binding of the mutant PTH peptide with the PTH/PTHrP receptor (Lee et al., 2015). Moreover, the *PTH* p.Arg25Cys mutation interfered with PTH immunoassays that utilized antibodies affinity-purified using PTH 1−34 and 13−34 fragments, thereby explaining why some assays were unable to detect the mutant PTH peptide (Lee et al., 2015).

Glial cells missing homolog 2 gene abnormalities

Glial cells missing homolog 2 (GCM2), which is the human homolog of the Drosophila gene, *Gcm*, and of the mouse *Gcm2* gene, is expressed exclusively in the parathyroid glands, suggesting that it may be a specific regulator of parathyroid gland development (Gunther et al., 2000; Kim et al., 1998). In order to investigate this, mice deleted for *Gcm2* were generated by the method of homologous recombination using embryonic stem cells. Mice that were heterozygous ($Gcm2^{+/-}$) for the deletion were normal, whereas mice that were homozygous ($Gcm2^{-/-}$) for the deletion lacked parathyroid glands and developed the hypocalcemia and hyperphosphatemia observed in hypoparathyroidism (Gunther et al., 2000). However, despite their lack of parathyroid glands, $Gcm2^{-/-}$ mice did not have undetectable serum PTH levels but instead had PTH levels identical to those of normal ($Gcm2^{+/+}$, wild-type) mice. This endogenous level of PTH in $Gcm2^{-/-}$ mice was too low to correct the hypocalcemia, but exogenous continuous PTH infusion could correct the hypocalcemia (Gunther et al., 2000). Interestingly, there were no compensatory increases in PTHrP or 1,25$(OH)_2$ vitamin D_3. These findings indicate that $Gcm2^{-/-}$ mice have a normal response (and not resistance) to PTH and that the PTH in the serum of $Gcm2^{-/-}$ mice was biologically active. The auxillary source of PTH was determined by combined expression and ablation studies (Gunther et al., 2000). These revealed a cluster of PTH-expressing cells under the thymic capsule in both $Gcm2^{-/-}$ and wild-type mice. These thymic PTH-producing cells also expressed the CaSR, and long-term treatment of $Gcm2^{-/-}$ mice with 1,25$(OH)_2$ vitamin D_3 restored the serum calcium concentrations to normal and reduced the serum PTH levels, thereby indicating that thymic production of PTH can be downregulated (Gunther et al., 2000). However, it appears that this thymic production of PTH cannot be upregulated, as serum PTH levels are not high despite the hypocalcemia in the

Gcm2$^{-/-}$ mice. This absence of upregulation would be consistent with the very small size of the thymic PTH-producing cell cluster when compared with the size of normal parathyroid glands. The development of the thymic PTH-producing cells likely involves Gcm1, which is the other mouse homolog of Drosophila, Gcm (Kim et al., 1998). Gcm1 expression, which could not be detected in parathyroid glands, colocalized with PTH expression in the thymus (Gunther et al., 2000).

The specific role of Gcm2 in the development of the parathyroids from the third pharyngeal pouch has been further investigated by studying the expression of the Hoxa3-Pax1/9-Eya1 transcription factor and sonic hedgehog−bone morphogenetic protein 4 (Shh-Bmp4) signaling networks (Liu et al., 2007). These studies have revealed that *Gcm2*$^{-/-}$ embryos that are 12 d.p.c. have a parathyroid-specific domain, but that this parathyroid domain undergoes coordinated programmed cell death (apoptosis) by 12.5 d.p.c. in *Gcm2*$^{-/-}$ mouse embryos (Liu et al., 2007). Moreover, the expression of the transcription factors Hoxa3 (see above), Pax 1, Pax 9, Eya1, and Tbx1, as well as Shh and Bmp4, was normal in the third pharyngeal pouch of these *Gcm2*$^{-/-}$ mouse embryos. These findings indicate that the Hoxa3-Pax1/9-Eya transcription factor cascade, the transcription factor Tbx1 (Fig. 56.1), and the Shh−Bmp4 signaling network all act upstream of Gcm2 (Liu et al., 2007). Moreover, these studies have revealed that Gcm2 has a role in promoting differentiation and survival of parathyroid cells in the developing embryo (Liu et al., 2007). The downstream targets of GCM2 within the parathyroid cell have begun to be elucidated, and GCM2 has been shown to upregulate CaSR expression by directly binding to its promoter region (Canaff et al., 2009). Moreover, GCM2 acts together with the GATA3 and MafB transcription factors to upregulate PTH expression (Fig. 56.1) by binding to a conserved region within the *PTH* promoter (Han et al., 2015; Kamitani-Kawamoto et al., 2011). In addition to its in utero role in parathyroid organogenesis, GCM2 is also expressed in the parathyroid glands postnatally, where it may play an ongoing role in upregulating CaSR and PTH expression (Mizobuchi et al., 2009).

Homozygous *GCM2* mutations have been identified in patients with autosomal recessive hypoparathyroidism (Ding et al., 2001), while in another family a homozygous missense mutation (p.Arg47Leu) of the DNA binding domain was identified (Baumber et al., 2005). Functional analysis, using electrophoretic mobility shift assays, of this p.Arg47Leu *GCM2* mutation revealed that it resulted in a loss of DNA binding to the *GCM2* DNA binding site (Baumber et al., 2005). Heterozygous *GCM2* mutations, which consist of single nucleotide deletions (c.1389deT and c.1399delC) that introduce frameshifts and premature truncations, and a missense mutation, p.Asn502His, have also been identified in three unrelated families with autosomal dominant hypoparathyroidism (Mannstadt et al., 2008; Mirczuk et al., 2010). These mutations were shown using a *GCM2*-associated luciferase reporter to inhibit the action of the wild-type transcription factor, thereby indicating that these *GCM2* mutants have dominant-negative properties (Mannstadt et al., 2008; Mirczuk et al., 2010). More recently, activating *GCM2* mutations have been identified in kindreds with familial isolated hyperparathyroidism (Guan et al., 2016), thereby revealing that *GCM2* abnormalities have roles in the etiology of hypo- and hyperparathyroidism.

X-linked recessive hypoparathyroidism

Hypoparathyroidism with an X-linked recessive transmission pattern was initially reported in two multigenerational kindreds (Peden, 1960; Whyte and Weldon, 1981). Only males were affected, and they suffered from infantile epilepsy and hypocalcemia. The hypoparathyroidism is due to a defect in parathyroid gland development (Whyte et al., 1986). Linkage studies utilizing X-linked RFLPs in these two families assigned the mutant gene to chromosome Xq26−q27 (Thakker et al., 1990). An approach utilizing mitochondrial DNA analysis established a common ancestry in these two X-linked hypoparathyroid kindreds (Mumm et al., 1997). A common ancestry for these two kindreds from eastern Missouri had been suspected, but it could not be established despite five generations of extensive genealogical records (Whyte and Weldon, 1981). The mitochondrial genes are transmitted through the maternal line exclusively. If relatedness among the two kindreds involved the maternal lines, analysis of mitochondrial genetic markers would reveal common features. The DNA sequence of the mitochondrial (mt) D-loop was compared among individuals in both kindreds. The mt DNA sequence was identical among affected males and their maternal lineage for individuals in both kindreds, but differed at 3 to 6 positions when compared with the mitochondrial DNA of the fathers. These results demonstrated that the two kindreds with X-linked recessive hypoparathyroidism are indeed related and that an identical gene defect is likely to be responsible for the disease. Additional studies refined the location of this gene to be between the locus for diffuse B cell lymphoma and DXS984, a 906 kb region in Xq27.1 (Andrew Nesbit et al., 2004; Trump et al., 1998). Furthermore, DNA sequence analyses of the coding regions of the three genes—adenosine triphosphatase 11C (*ATP11C*), U7snRNA homolog, and Sry-box3 (*SOX3*)— contained within this 906 kb interval did not reveal any abnormalities (Andrew Nesbit et al., 2004). These findings together with the reported absence of hypocalcemia in a boy with hemophilia B and mental retardation who had a

chromosomal deletion that encompassed the entire 906 kb interval containing *ATP11C*, U7snRNA, and *SOX3* genes (Stevanovic et al., 1993) suggested that other genomic abnormalities such as molecular duplications for translocations, which could cause altered gene function, may underlie the etiology of X-linked recessive hyperparathyroidism (Bowl et al., 2005). Indeed, this proved to be the case, and a complex interstitial deletion-insertion involving chromosomes 2p25.3 and Xq27.1, near *SOX3*, was shown to cosegregate with X-linked recessive hypoparathyroidism (Bowl et al., 2005). This deletion-insertion was located approximately 67 kb downstream of *SOX3*, and hence it was likely to exert a position effect on SOX3 expression. Moreover, *SOX*3 was shown to be expressed in the developing parathyroids of mouse embryos, and this indicates a likely role for *SOX3* in the embryonic development of the parathyroid glands (Bowl et al., 2005). More recently, another unrelated family with X-linked hypoparathyroidism was identified, and whole-genome sequence analysis revealed an interstitial deletion-insertion that cosegregated with the hypoparathyroidism (Taylor et al., 2015). This deletion-insertion involves an approximately 50 kb region of chromosome 2p25.3 that has been duplicated and inserted into the X chromosome, resulting in a 1.4 kb deletion located 81.5 kb downstream of *SOX3* (Taylor et al., 2015). Thus, these findings support a role for *SOX3* in the embryonic development of the parathyroid glands (Taylor et al., 2015).

SOX3 belongs to a family of genes encoding high-mobility group box transcription factors and is related to *SRY*, the sex-determining gene on the Y chromosome. The mouse homolog is expressed in the prestreak embryo and subsequently in the developing CNS, which includes the region of the ventral diencephalon that induces development of the anterior pituitary and gives rise to the hypothalamus and olfactory placodes (Collignon et al., 1996; Rizzoti et al., 2004; Solomon et al., 2002). Patients with X-linked hypopituitarism have been reported to have duplications involving a 686 kb−13 Mb region that contains SOX3 (Solomon et al., 2002, 2004; Woods et al., 2005), and overexpression of SOX3 has been reported to inhibit Wnt signaling, which has an important role in pituitary development (Zorn et al., 1999). Furthermore, increased levels of SOX3 have been shown to cause developmental hypoplasia of tissues, such as the lens and otic placodes in fish embryos (Koster et al., 2000). Reduced levels of SOX3 expression also result in hypopituitarism. Thus, *Sox3* null mice have abnormal pituitary development associated with hypopituitarism, craniofacial abnormalities, and midline CNS defects (Rizzoti et al., 2004). These phenotypic features are similar to those observed in patients with X-linked hypopituitarism as well as with X-linked mental retardation and growth hormone deficiency, who have in-frame duplications of 21bp or 33bp encoding for 7 or 11 alanines, respectively, in a polyalanine tract of the *SOX3* gene (Laumonnier et al., 2002; Woods et al., 2005). The polyalanine tract expansion resulted in a reduction of SOX3 transcriptional activity that was associated with an impaired nuclear localization of the mutant protein (Woods et al., 2005). These findings demonstrate that pituitary development is sensitive to *SOX3* dosage and that both loss- and gain-of-function mutations can result in X-linked hypopituitarism (Rizzoti et al., 2004; Solomon et al., 2002, 2004; Laumonnier et al., 2002; Schlosser and Ahrens, 2004).

Patients with X-linked hypopituitarism have not been reported to suffer from hypoparathyroidism (Solomon et al., 2002, 2004; Laumonnier et al., 2002; Woods et al., 2005) and conversely the patients affected with X-linked recessive hypoparathyroidism do not suffer from hypopituitarism (Peden, 1960; Trump et al., 1998; Whyte and Weldon, 1981). These clinical differences may be due to differences in the temporal expression patterns of SOX3 in the pituitary and parathyroids or to interactions with different tissue-specific enhancers or repressors. Alternatively, they may be due to differences in the locations of the associated *SOX3* genomic abnormalities, and it is important to note that X-linked hypopituitarism is associated with either duplications of the entire *SOX3* coding region or with an intragenic expansion of a polyalanine tract (Solomon et al., 2002, 2004; Laumonnier et al., 2002; Woods et al., 2005), whereas X-linked recessive hypoparathyroidism is associated with deletions that are ∼67 kb and 81.5 kb downstream from the *SOX3* coding region (Bowl et al., 2005; Taylor et al., 2015). This situation may be analogous to that reported to occur in disorders associated with abnormalities of the sonic hedgehog (*SHH*) gene (Kleinjan and van Heyningen, 2005). SHH is a secreted protein that provides key inductive signals for patterning of the ventral neural tube, anterior posterior limb axis, and ventral somites. *SHH* gene abnormalities lead to holoprosencephaly type 3 (HPE3) and preaxial polydactyly (PPD) in man. HPE3 is caused by deletions or point mutations that involve the coding region and result in haploinsufficiency of *SHH*, while PPD is caused by breakpoints or point mutations within a limb regulatory element that is 1 Mb upstream of *SHH* (Kleinjan and van Heyningen, 2005). These findings illustrate that phenotypes caused by mutations in regulatory elements can be very different from those caused by mutations of coding regions, and that point mutations in regulatory elements at a distance as far as 1 Mb from the gene promoter can have a detrimental affect on embryonic development (Kleinjan and van Heyningen, 2005). Thus, it seems likely that the differences between X-linked recessive hypoparathyroidism and hypopituitarism occur because the hypoparathyroidism deletion-insertions, which are ∼67 kb and 81.5 kb downstream of *SOX3*, involve disruption of regulatory elements, whereas the abnormalities resulting in hypopituitarism involve alterations of the *SOX3* coding region. It is also important to note that the disruption in the regulatory region could also lead to upregulation or misregulation of the gene, thereby resulting in phenotypes due to gain-of-function (i.e., hypermorphic or neomorphic).

The location of the deletion-insertions ~67 kb and 81.5 kb downstream of *SOX3* in X-linked recessive hypoparathyroid patients are likely to result in altered SOX3 expression, as SOX3 expression has been reported to be sensitive to position-effects caused by X chromosome abnormalities (Kleinjan and van Heyningen, 2005). Indeed, reporter-construct studies of the mouse *Sox3* gene have demonstrated the presence of both 5′ and 3′ regulatory elements (Brunelli et al., 2003), and thus it is possible that the deletion-insertions in X-linked recessive hypoparathyroid patients may have a position-effect on SOX3 expression and parathyroid development from the pharyngeal pouches. Indeed, such position effects on *SOX* genes, which may be exerted over large distances, have been reported. For example, the very closely related *Sox2* gene has been shown to have regulatory regions spread over a long distance, both 5′ and 3′ to the coding region (Uchikawa et al., 2003), and disruption of sequences at some distance 3′ have been reported to lead to loss of expression in the developing inner ear and absence of sensory cells, whereas expression in other sites is unaffected (Kiernan et al., 2005). Similarly for the *SRY* gene, which probably originated from *SOX3* (Stevanovic et al., 1993), both 5′ and 3′ deletions result in abnormalities of sexual development, and translocation breakpoints over 1 Mb upstream of the *SOX9* gene have been reported to result in campomelic dysplasia due to removal of elements that regulate *SOX9* expression (Kleinjan and van Heyningen, 2005). The molecular deletion-insertions identified in X-linked recessive hypoparathyroidism may similarly cause position-effects on SOX3 expression, and this points to a potential role for the *SOX3* gene in the embryological development of the parathyroid glands from the pharyngeal pouches.

A recent report has also highlighted that the four-and-a-half LIM domains 1 (*FHL1*) gene, which is located on chromosome Xq26.3, may also represent an additional gene for X-linked hypoparathyroidism (Pillar et al., 2017), as an *FHL1* missense variant (p.Arg95Trp) was detected in a 4-year-old male with isolated severe hypoparathyroidism (Pillar et al., 2017). Functional studies have shown that knockdown of the FHL1 paralog in zebrafish increased plasma calcium concentrations, and that introduction of wild-type FHL1 into HEK293 cells transfected with a luciferase reporter gene that is under the control of the human PTH promoter resulted in increased PTH promoter activity (Pillar et al., 2017). However, FHL1 is predicted to have a low level of expression in human parathyroids (Pillar et al., 2017), and thus the role of this protein in calcium homeostasis remains to be established. The possible deleterious effects on mammalian parathyroid gland activity of this p.Arg95Trp missense variant of FHL1 also remain to be established.

Autosomal dominant hypocalcemia

Autosomal dominant hypocalcemia (ADH) is characterized by hypocalcemia in association with inappropriately normal or low PTH concentrations, and comprises two genetically distinct disorders, designated as ADH types 1 and 2, which are caused by germline gain-of-function mutations of the CaSR and G-protein subunit α_{11} ($G\alpha_{11}$) proteins, respectively (Table 56.1) (Hannan et al., 2016).

Calcium-sensing receptor and $G\alpha_{11}$

The human CaSR is a 1078 amino acid dimeric cell-surface protein that belongs to class C of the GPCR superfamily and is encoded by the *CASR* gene on human chromosome 3q21.1 (Hannan et al., 2016). The CaSR is most highly expressed in the parathyroid glands and kidneys, and has a large (612 amino acid) extracellular domain, which is predicted to adopt a venus flytrap (VFT) conformation that binds calcium at multiple sites (Fig. 56.3) (Geng et al., 2016). Activation of the CaSR leads to signaling via intracellular pathways that includes $G\alpha_{11}$-dependent stimulation of phospholipase C, which causes an accumulation of inositol 1,4,5-triphosphate together with the rapid mobilization of intracellular calcium ($Ca^{2+}{}_i$), and also activates the mitogen-activated protein kinase pathway (Fig. 56.3) (Hannan et al., 2016). These intracellular events mediate a reduction in PTH secretion and decrease in renal tubular calcium reabsorption (Fig. 56.3). CaSR cell-surface expression is regulated by agonist-driven insertional signaling, which promotes anterograde trafficking of newly synthesized CaSRs to the plasma membrane (Grant et al., 2011), and also by retrograde trafficking of cell-surface CaSRs, which is mediated by adaptor-related protein complex 2 (Fig. 56.3) (Gorvin et al., 2018).

Autosomal dominant hypocalcemia type 1

Autosomal dominant hypocalcemia type 1 (ADH1), which is due to gain-of-function CaSR mutations, is characterized by mild-to-moderate hypocalcemia in association with mild hypomagnesemia; hyperphosphatemia; and serum PTH concentrations that are often detectable and within the lower half of the reference range (Nesbit et al., 2013). Patients with ADH have significantly increased urinary calcium excretion compared with hypoparathyroid patients (Yamamoto et al., 2000), and ~10% of ADH1 patients have an absolute hypercalciuria (Nesbit et al., 2013). It has been reported that the urinary calcium-to-creatinine (Ca/Cr) ratio may be used to distinguish ADH1 from hypoparathyroidism, with untreated

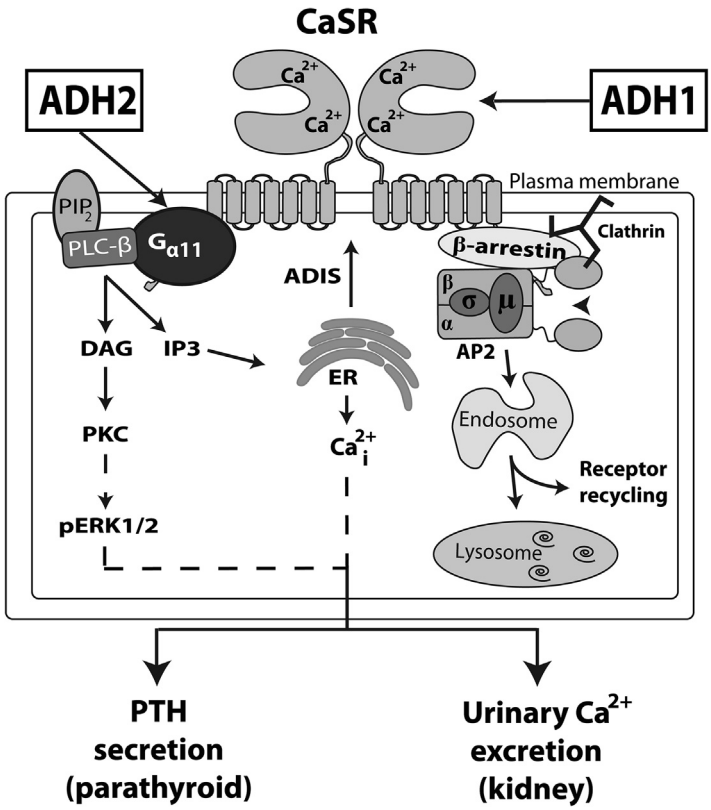

FIGURE 56.3 Overview of calcium-sensing receptor signaling and trafficking. The binding of calcium (Ca^{2+}) to the calcium-sensing receptor (CaSR) extracellular domain leads to $G\alpha_{11}$-dependent activation of phospholipase C-β (PLC-β) and the production of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3) from membrane-bound phosphatidylinositol 4,5-bisphosphate (PIP_2). The increase in intracellular IP_3 levels facilitates the release of Ca^{2+} from intracellular stores such as the endoplasmic reticulum (ER). DAG activates protein kinase C (PKC) and the mitogen-activated protein kinase pathway. These signaling events lead to a decrease in parathyroid hormone (PTH) secretion and reduction in renal tubular Ca^{2+} reabsorption. CaSR cell-surface expression is regulated by agonist-driven insertional signaling (ADIS) (Grant et al., 2011) and also by an endocytic complex comprising clathrin, β-arrestin, and adaptor-related protein complex 2 (AP2) (Gorvin et al., 2018), which may traffic this G-protein-coupled receptor to the endosomal–lysosomal degradation pathway or recycle the CaSR back to the cell surface. Gain-of-function mutations of the CaSR lead to autosomal dominant hypocalcemia type 1 (ADH1), and gain-of function mutations of the $G\alpha_{11}$ subunit cause autosomal dominant hypocalcemia type 2 (ADH2). *Adapted from Hannan et al.* Br J Pharmacol *2017 https://doi.org/10.1111/bph.14086. [Epub ahead of print].*

ADH1 patients having a mean Ca/Cr ratio of >3.0 mmol/mmol creatinine, which was similar to the urinary Ca/Cr ratio of unaffected normocalcemic subjects, whereas untreated hypoparathyroid patients had a significantly lower mean Ca/Cr ratio of <0.1 mmol/mmol creatinine (Yamamoto et al., 2000). Some patients with ADH1 may have ectopic calcifications affecting the basal ganglia and/or elevations in bone mineral density (BMD) (Pearce et al., 1996), and some patients with severe gain-of-function CaSR mutations may also develop a Bartter syndrome (referred to as Bartter syndrome type V), which is characterized by renal salt wasting leading to volume depletion, hyperreninemic hyperaldosteronism and hypokalemic alkalosis (Watanabe et al., 2002). Over 70 different CaSR mutations have been identified in ADH1 patients and families (Hannan et al., 2016; Hannan and Thakker, 2013), and structure–function analysis have shown that ADH1-causing gain-of-function mutations cluster within the second peptide loop of the extracellular VFT domain (residues 116–136), which contributes to the dimeric CaSR interface (Geng et al., 2016). A second hotspot for ADH1 mutations is located in a region that encompasses transmembrane helices 6 and 7, and the intervening third extracellular loop of the CaSR (residues 819–837) (Hannan et al., 2016). This transmembrane region may play a role in locking the ligand-unbound receptor in an inactive conformation by forming a network of interactions with other transmembrane helices (Dore et al., 2014).

Autosomal dominant hypocalcemia type 2

Mutations of the *CASR* gene are not detected in ~30% of ADH patients, and heterozygous germline mutations of $G\alpha_{11}$, which is encoded by the *GNA11* gene, have been reported in seven such ADH patients and families (Li et al., 2014;

Mannstadt et al., 2013; Nesbit et al., 2013; Piret et al., 2016; Tenhola et al., 2016). In vitro functional studies of these $G\alpha_{11}$ mutations, which all comprise missense substitutions, have shown cells expressing the mutant $G\alpha_{11}$ proteins to have enhanced CaSR-mediated signaling responses, consistent with a gain-of-function (Li et al., 2014; Nesbit et al., 2013; Piret et al., 2016). These individuals and families with gain-of-function $G\alpha_{11}$ mutations, who were designated as having ADH type 2 (ADH2), generally had mild-to-moderate hypocalcemia, which is in keeping with the serum biochemical phenotype of ADH1 (Hannan et al., 2016). However, ADH2 is associated with a milder urinary phenotype, with significantly reduced urinary calcium excretion compared with ADH1 (Li et al., 2014). Moreover, short stature caused by postnatal growth insufficiency has been reported in two ADH2 kindreds (Li et al., 2014; Tenhola et al., 2016). Structural and functional studies of ADH2-causing gain-of-function $G\alpha_{11}$ mutations have revealed residues critical for Gα-subunit function. The $G\alpha_{11}$-subunit consists of a Ras-like GTPase domain that binds GDP and GTP, and a smaller helical domain that acts as a clasp to secure these bound guanine-nucleotides (Hannan et al., 2016). The ADH2-causing mutations have been shown to cluster at the interface between these two domains (Piret et al., 2016), and may enhance the exchange of GDP and GTP, thereby leading to G-protein activation. ADH2 mutations also affect the C-terminal portion of the $G\alpha_{11}$ protein, which facilitates G-protein-GPCR coupling (Piret et al., 2016). Thus, these ADH2-causing mutations have provided insights into Gα-subunit structure−function relationships, which may aid the design of targeted therapeutic agents for the treatment of ADH, for which there is currently a lack of adequate drugs (Hannan et al., 2015).

Mouse models for autosomal dominant hypocalcemia types 1 and 2

Mouse models with gain-of-function germline *Casr* or *Gna11* mutations have been generated by chemical mutagenesis and knockin strategies (Dong et al., 2015; Hough et al., 2004; Roszko et al., 2017). One ADH1 mouse model, termed "Nuclear flecks" or "*Nuf*" due to the presence of opaque flecks within the lens nucleus, was generated using the alkylating agent isopropyl methane sulfonate (iPMS) (Hough et al., 2004). The *Nuf* gene locus was mapped to mouse chromosome 16 and a germline leucine-to-glutamine missense substitution identified at codon 723 of the *Casr*. The mutant p.Leu723Gln Casr protein was shown to cause a gain-of-function when expressed in HEK293 cells (Hough et al., 2004). *Nuf* mice have a phenotype consisting of hypocalcemia, hyperphosphatemia, low circulating PTH concentrations and widespread ectopic calcifications (Hough et al., 2004). Homozygote (*Nuf/Nuf*) mice are viable but have a more severe phenotype than heterozygote (*Nuf/+*) mice (Hough et al., 2004). Two *Casr* knockin mouse models, which harbor mutations (p.Cys129Ser and p.Ala843Glu) causing ADH1 in humans, have also been generated. Both knockin mouse models had a more marked phenotype than *Nuf* mice. Thus, the knockin mice with germline homozygous *Casr* mutations had embryonic or perinatal lethality (Dong et al., 2015), and the heterozygous *Casr* knockin mice had a phenotype resembling ADH1, which was characterized by hypocalcemia, hyperphosphatemia, low plasma PTH, and hypercalciuria (Dong et al., 2015). These ADH1 models have been utilized to evaluate calcilytic compounds, which are negative allosteric CaSR modulators that represent a potential targeted therapy for ADH (Hannan et al., 2017). Indeed, single dose administration of a calcilytic compound known as NPS-2143 has been shown in vivo to rectify the hypocalcemia of *Nuf* mice (Hannan et al., 2015), while, longer-term administration of the JTT-305/MK-5442 calcilytic compound in the two knockin *Casr* mouse models, has been shown to lead to sustained increases in serum calcium concentrations and significant reductions in urinary calcium excretion (Dong et al., 2015).

To establish a mouse model for ADH2, studies were undertaken to characterize the calcitropic phenotype of a previously reported mouse mutant known as *dark skin seven* or, "*Dsk7*", which has increased dermal pigmentation in association with a germline hypermorphic *Gna11* mutation, p.Ile62Val (Van Raamsdonk et al., 2004). These findings revealed *Dsk7* mice to have hypocalcemia and reduced PTH concentrations, and in vitro analysis of the mutant p.Ile62Val $G\alpha_{11}$ protein showed this to enhance CaSR-mediated signaling, consistent with a gain-of-function (Gorvin et al., 2017). Another mouse model for ADH2 was generated by the knockin of an ADH2-causing *Gna11* mutation, p.Arg60Cys, and this was found to have a similar phenotype to *Dsk7* mice with hypocalcemia, reduced PTH concentrations and increased skin pigmentation (Roszko et al., 2017). NPS-2143 was shown to rectify the gain-of-function caused by p.Ile62Val and p.Arg60Cys *Gna11* mutations in vitro, and single dose administration of NPS-2143 ameliorated the hypocalcemia of the two ADH2 mouse models in vivo (Gorvin et al., 2017; Roszko et al., 2017). Thus, these in vivo studies have demonstrated that calcilytics have potential as a treatment for ADH2.

Conclusions

Application of the methods of molecular genetics to the study of hypoparathyroid disorders has resulted in considerable advances that have identified some genes and their encoded proteins involved in the embryological development of the

parathyroids and mediating its actions in different target issues. In addition, the identification of mutations has helped to provide molecular explanations and insights into a variety of familial and sporadic forms of hypoparathyroidism. Moreover, investigation of mouse models has helped to increase our understanding of the molecular regulation of pharyngeal pouch development. However, many challenges remain in this complex field, in particular resolving the issues of phenotypic variance and interspecies differences as well as further elucidating the interplay between the genes involved in mediating parathyroid gland development.

Chapter outline

Introduction

The PTH/PTHrP receptor (PTHR1; also referred to as type I PTH/PTHrP receptor; gene name *PTHR1*) is a G-protein-coupled receptor (GPCR) that mediates the actions of two ligands, parathyroid hormone (PTH; gene name *PTH*) and PTH-related peptide (PTHrP; also referred to as PTH-like peptide, PTHLP; gene name *PTHLH*). PTHR1 stimulates at least two distinct second-messenger pathways, cAMP/protein kinase A (PKA) and IP_3/Ca^{++}/PKC (for review see Gardella et al., 2016). It is most abundantly expressed in kidney, bone, and growth plates, as well as at lower levels in a large variety of

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00057-9

other tissues. The critical role of PTH in the endocrine regulation of mineral ion homeostasis had been explored for several decades through numerous studies in intact and parathyroidectomized animals (Potts and Gardella, 2007). Subsequent studies in mice with ablation of the genes encoding PTH (Miao et al., 2002) or GCM2 (Günther et al., 2000), a parathyroid-specific transcription factor, confirmed the importance of PTH for maintaining blood calcium levels within normal limits. PTHrP was first isolated from tumors that cause humeral hypercalcemia of malignancy syndrome (for review see Suva et al., 2015). Because its biological properties were largely indistinguishable from those of PTH, it was predicted that PTHrP acts through the same receptor as that of PTH, which turned out to be the case. However, through analysis of genetically manipulated mice, it became apparent that PTHrP has a particularly important role in the autocrine/paracrine regulation of chondrocyte growth and differentiation. Thus, animals "null" for *Pthlh* die in utero or shortly thereafter, and they show a profound acceleration of growth plate mineralization (Karaplis et al., 1994; Maes and Kronenberg, 2016). In contrast, mice overexpressing PTHrP under the control of a growth plate-specific promoter are viable but show a severe delay in chondrocyte maturation that leads to impaired bone growth and elongation (Weir et al., 1996). Consistent with these latter findings, homozygous ablation of PTHR1 leads to similar, albeit more severe, developmental abnormalities (Maes and Kronenberg, 2016; Lanske et al., 1996). The analysis of different genetically manipulated animals thus provided important clues regarding the phenotypic abnormalities that were to be expected in humans with mutations in PTHR1, its ligands, and some downstream signaling and effector proteins. Likewise, analysis of rare genetic disorders in humans has provided major new insights into the molecules involved in these processes.

The parathyroid hormone/parathyroid hormone–related peptide receptor system

Parathyroid hormone

Besides 1,25 dihydroxy vitamin D {1,25$(OH)_2$D}, PTH is the most important endocrine regulator of extracellular calcium homeostasis in mammals (Gardella et al., 2016; St-Arnaud & Demay, 2011). PTH is almost exclusively expressed in the parathyroid glands; lower protein and mRNA levels were identified only in the hypothalamus and thymus of glial cells missing 2 (*GCM2*)-ablated mice (Günther et al., 2000). Its synthesis and secretion by the parathyroid glands are dependent predominantly on the extracellular concentration of calcium (Silver and Kronenberg, 1996) monitored by the calcium-sensing receptor (Brown et al., 1993), and probably to a lesser extent by 1,25$(OH)_2$D, phosphate and FGF23 (Silver and Kronenberg, 1996; Almaden et al., 1996; Slatopolsky et al., 1996; Ben-Dov et al., 2007; Krajisnik et al., 2007).

PTH acts primarily on kidney and bone, where it binds to cells expressing PTHR1 and thereby initiates a series of processes that serve to maintain blood calcium and phosphate concentrations within narrow limits (Fig. 57.1). In kidney, the mRNA encoding PTHR1 is expressed primarily in the convoluted and straight proximal tubules, the cortical portion of thick ascending limb, and the distal convoluted renal tubules (Riccardi et al., 1996; Lee et al., 1996; Yang et al., 1997)—i.e., in those renal segments that respond to PTH with an increase in cAMP accumulation (Chabardes et al., 1975; Morel et al., 1981). PTHR1s appear to be expressed on the basolateral and brush border membranes, raising the possibility that PTH acts not only via blood circulation from basolateral membrane, but also, after glomerular filtration, from the luminal side (Lupp et al., 2010).

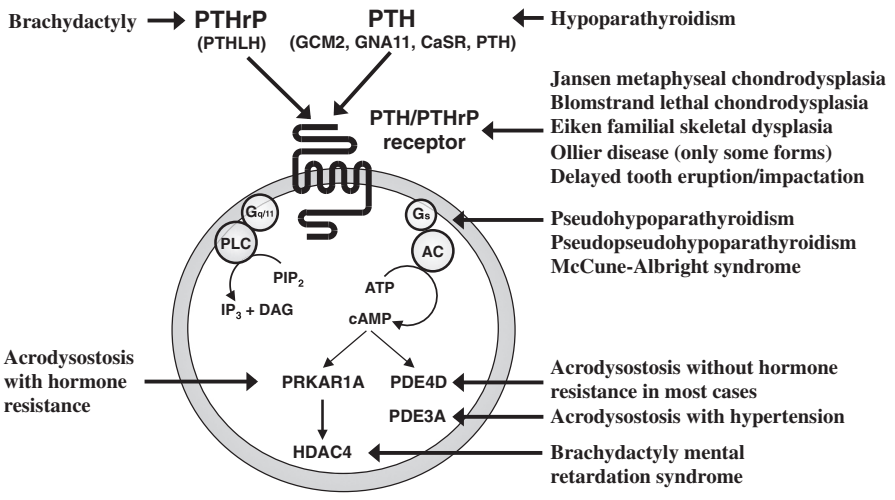

FIGURE 57.1 Human disorders and PTHR1–Gsα–cAMP–PKA signaling pathway. The PTH/PTHrP receptor (PTHR1) is abundantly expressed in kidney and bone, where it mediates the PTH-dependent regulation of calcium and phosphate homeostasis. It is also expressed in numerous other tissues, particularly growth plate chondrocytes, where it mediates, following activation by PTHrP, the regulation of cellular proliferation and differentiation during development. The activated PTHR1 stimulates two second-messenger pathways, cAMP/PKA and IP_3/Ca^{++}/PKC. Genetic diseases associated with defects in the cAMP/PKA pathway are indicated.

The most important PTH-mediated actions in the kidney affect the synthesis of $1,25(OH)_2D$ from its precursor 25(OH)D, excretion of phosphate, and reabsorption of calcium. The stimulation of 1α-hydroxylase activity, an at least partially cAMP-dependent action (Kong et al., 1999; Takeyama et al., 1997), is largely restricted to the proximal convoluted tubule. The resulting increase in $1,25(OH)_2D$ production enhances the absorption of calcium and phosphate from the intestine. PTH-dependent inhibition of renal tubular phosphate reabsorption has been extensively documented in a variety of in vivo and in vitro studies (for reviews see Bacic et al., 2004; Berndt & Kumar, 2007; Bergwitz and Jüppner, 2010; Blaine et al., 2011). To increase urinary phosphate excretion, PTH reduces the abundance of two type II sodium−phosphate cotransporters (NPT2a and NPT2c, also referred to as NaPi-IIa and NaPi-IIc) on the apical surface of proximal tubules (Bacic et al., 2004; Segawa et al., 2002). In rodents, which can be readily studied, Npt2a is expressed in segments S1−S3, while Npt2c is expressed mainly in the S1 segment (Segawa et al., 2007). Acute PTH effects appear to be mediated in vivo prominently by cAMP/PKA-dependent mechanisms (Nagai et al., 2011), which is consistent with the severely diminished PTH-stimulated phosphaturic response in patients with pseudohypoparathyroidism, a group of related disorders caused by maternally inherited mutations in *GNAS*, the gene encoding Gsα, the alpha-subunit of the stimulatory G-protein, and several different splice variants thereof (Patten et al., 1990; Weinstein et al., 1990). However, studies with genetically engineered mice expressing a mutant PTHR1 deficient in signaling through Ca^{2+}/IP_3/PKC-dependent mechanisms have shown that this latter second-messenger pathway contributes also to PTH-mediated phosphaturic response (Guo et al., 2010, 2013). The increase in urinary phosphate excretion stimulated by PTH is associated with increased internalization and subsequent lysosomal degradation of Npt2a, and similar mechanisms appear to apply to the regulation of Npt2c (Segawa et al., 2002, 2007; Biber et al., 2009).

PTHR1 protein expression has been demonstrated by immunohistochemical and immunoelectron microscopic analysis, and functional studies on both basolateral and luminal membranes in proximal tubular cells in vitro as well as in intact proximal tubules (Lupp et al., 2010; Kaufmann et al., 1994; Traebert et al., 2000). Apical receptors may be preferentially coupled to the cAMP-independent signaling pathway, while basolateral receptor activation initiates both cAMP-dependent and cAMP-independent effects (Mahon et al., 2002; Mahon and Segre, 2004). However, PTH(1−34) with a 20-kD polyethylene glycol moiety attached to the C-terminus (PEGylated PTH[1−34]), which shows much reduced glomerular filtration, increases urinary phosphate excretion equivalently to that of unmodified PTH(1−34), indicating that signaling at the basolateral membrane is sufficient for the peptide's phosphaturic response (Guo et al., 2017). On the other hand, megalin, a multifunctional clearance receptor expressed on the apical surface of proximal tubular cells, has been shown to contribute to catabolism of PTH and may antagonize PTHR1 activity (Hilpert et al., 1999). In the distal convoluted tubule, PTH stimulates, possibly through second messengers other than cAMP, the reabsorption of calcium (Friedman et al., 1996; Linglart et al., 2011), which is associated with an increased expression of the calcium channel TRPV5 (Mensenkamp et al., 2007).

Similar to its renal tubular effects, PTH-dependent actions on bone are complex and difficult to study. As outlined later in more detail, PTH can influence, either directly or indirectly, the proliferation and differentiation of several bone cell precursors. Furthermore, the effects resulting from PTH stimulation of mature osteoblasts appear to be different depending on the intensity and duration of the stimulus, type of bone (trabecular vs. cortical), and hormonal exposure of bone. As a result, the hormonal effects observed in vitro often fail to reflect the conditions in vivo. For example, PTH stimulates both bone formation and osteoclastic bone resorption; however, the continuous administration of PTH in vivo is thought to favor bone resorption over formation, whereas intermittent doses of the hormone result in net anabolic effects (Neer et al., 2001; Finkelstein et al., 2003). However, the transgenic expression of a constitutively active human PTHR1 under control of the collagen type Ia1 promoter to target expression to osteoblasts (Calvi et al., 2001), or under the control of the DMP1 promoter to target expression to osteocytes (Rhee et al., 2011), causes a dramatic increase in bone formation, suggesting that continuous low-level receptor activation leads to bone changes similar to those from intermittent treatment with PTH.

Parathyroid hormone−related peptide

PTHrP was first discovered as the major cause of humoral hypercalcemia of malignancy syndrome (for review see Suva et al., 2015). Within its amino-terminal portion, PTHrP shares partial amino acid sequence homology with PTH, and as a result of these limited structural similarities, amino-terminal fragments of both peptides have largely indistinguishable biological properties, at least when tested in different in vitro systems. PTHrP and its mRNA are also found in a large variety of fetal and adult tissues, suggesting that this peptide has an important biological role throughout life. In fact, PTHrP has a prominent role in the regulation of chondrocyte proliferation and differentiation during the process of endochondral bone formation (Maes and Kronenberg, 2016) and epithelial−mesenchymal interactions during

organogenesis of certain epithelial organs including skin, mammary gland, and teeth (Wysolmerski et al., 1996, 1998; Strewler, 2000; Hens et al., 2007).

The parathyroid hormone/parathyroid hormone–related peptide receptor and its role in endochondral bone formation

PTHR1 belongs to the class B family of heptahelical GPCRs, which also comprises the receptors for secretin, calcitonin, glucagon, and several other peptide hormones; it binds PTH and PTHrP (Gardella et al., 2016). Similar to the widely expressed PTHrP, the mRNA encoding PTHR1 is found in a large variety of fetal and adult tissues (Riccardi et al., 1996; Lee et al., 1995) and at particularly abundant concentrations in proximal tubular cells, osteoblasts, and prehypertrophic chondrocytes of metaphyseal growth plate (Maes and Kronenberg, 2016).

Mice with ablation of both *Pthlh* alleles die during the perinatal period and show striking skeletal changes that include domed skulls, short snouts and mandibles, and disproportionately short extremities, yet with no obvious developmental defects in other organs. These skeletal changes are caused by a dramatic acceleration of chondrocyte differentiation that leads to premature growth plate mineralization. Heterozygous animals lacking only one copy of the *Pthlh* gene show normal growth and development and are fertile, but develop, despite apparently normal calcium and phosphorus homeostasis, mild osteopenia later in life (Amizuka et al., 1996). Growth plate abnormalities that are in many aspects the opposite of those found in *Pthlh*-ablated mice are observed in animals that overexpress *PTHLH* under control of the collagen α1(II) promoter (Weir et al., 1996). Throughout life, these animals are smaller in size than their wild-type littermates and show a disproportionate foreshortening of limbs and tail, which is most likely due to a severe delay in chondrocyte differentiation and endochondral ossification. Thus, too little or too much PTHrP expression in the growth plate leads to short-limbed dwarfism, although through entirely different mechanisms.

From these and other studies, it is now well established that PTHrP facilitates the continuous proliferation of chondrocytes in the growth plate and postpones their programmed differentiation into hypertrophic chondrocytes (for review see Maes and Kronenberg, 2016). Consistent with this role of PTHrP in endochondral bone formation, earlier in vitro studies showed that PTH (used in these studies instead of PTHrP) affects chondrocyte maturation and activity. Subsequent studies confirmed these findings by showing that PTH and PTHrP stimulate, presumably through cAMP-dependent mechanisms, the proliferation of fetal growth plate chondrocytes, inhibit the differentiation of these cells into hypertrophic chondrocytes, and stimulate the accumulation of cartilage-specific proteoglycans thought to act as inhibitors of mineralization (Koike et al., 1990; Iwamoto et al., 1994). In the absence of these cartilage-specific PTHrP effects, growth plates of homozygous *Pthlh* gene-ablated mice have a thinner layer of proliferating chondrocytes, while the layer of hypertrophic chondrocytes is relatively normal in thickness but somewhat disorganized. Taken together, these findings suggest that a lack of PTHrP accelerates the normal differentiation process of growth plate chondrocytes—i.e., resting and proliferating chondrocytes undergo fewer cycles of cell division and differentiate prematurely into hypertrophic cells that then undergo apoptosis before being replaced by invading osteoblasts.

The phenotypic changes in mice "null" for either *Pthlh* or PTHR1 are similar, and current evidence indicates that the autocrine/paracrine actions of PTHrP within the growth plate are mediated through the PTHR1 (Maes and Kronenberg, 2016). Furthermore, mice missing either *Pthlh* or its receptor are resistant to the actions of Indian Hedgehog (Ihh), a developmentally important protein that is most abundantly expressed in growth plate chondrocytes, which are about to differentiate into hypertrophic cells. Ihh binds directly to *patched,* a membrane receptor that interacts with smoothened and thereby suppresses the constitutive activity of the latter protein (Stone et al., 1996; Marigo et al., 1996). The ectopic expression of Ihh in the chicken wing cartilage stimulates the production of PTHrP and thereby blocks the normal chondrocyte differentiation program; whether PTHrP represses the expression of Ihh as part of a feedback loop remains to be established. PTHrP and Ihh are thus critically important components of normal bone growth and elongation (Maes and Kronenberg, 2016). However, not all actions of PTHrP appear to be mediated through the PTHR1, since ablation of *Pthlh* or *Pthr1* leads to subtle but distinctly different abnormalities in early bone development (Lanske et al., 1999).

Human disorders caused by mutations in the parathyroid hormone/parathyroid hormone-related peptide signaling pathway

Parathyroid hormone, glial cells missing 2, and *GNA11* mutations

Heterozygous mutations in the calcium-sensing receptor are the most frequent cause of autosomal dominant hypocalcemia (Pollak et al., 1993, 1994; Pearce et al., 1996). Only very few *PTH* gene mutations have been identified as the cause of

isolated hypoparathyroidism (IHP) in families with an autosomal dominant or recessive transmission (Arnold et al., 1990; Parkinson and Thakker, 1992; Sunthornthepvarakul et al., 1999; Ertl et al., 2012; Tomar et al., 2010). Five of these mutations are located in the hormone's prepro-leader segment and thus impair hormone synthesis or secretion. The more recently identified mutation, a homozygous (R25C) in the mature PTH(1−84) polypeptide, reduces the bioactivity of the secreted hormone (Lee et al., 2015). Interestingly, depending on the assay used for evaluating patients carrying this mutation, plasma PTH levels were either low or elevated, thus leading to ambiguities regarding the underlying diagnosis, namely IHP or pseudohypoparathyroidism (PHP) type Ib (PHP1B). In this context, a novel homozygous mutation in PTHR1 (R186H) was hypothesized to result in impaired interaction between PTH and PTHR1, thus postulating that this genetic defect leads to a PHP1B phenotype (Guerreiro et al., 2016). However, the index case presented initially with severe hypocalcemia and hyperphosphatemia yet with normal PTH levels; she revealed no methylation changes at the *GNAS* locus. In contrast, two other family members, both the same homozygous R186H mutation in PTHR1, had laboratory findings consistent with PHP1B; however, no *GNAS* methylation studies were reported for these family members, and no in vitro studies with the mutant PTHR1 were conducted.

More frequently, there are mutations in glial cells missing 2 (*GCM2*), the human homologue of the Drosophila gene, *Gcm*a, and a specific regulator of parathyroid gland development that is expressed exclusively in the parathyroid glands (Günther et al., 2000). Studies of patients with isolated hypoparathyroidism have shown that *GCM2* mutations can be associated with autosomal recessive and dominant forms of the disease (Tomar et al., 2010; Ding et al., 2001; Baumber et al., 2005; Thomee et al., 2005; Mannstadt et al., 2008; Mirczuk et al., 2010; Yi et al., 2012). Mutations in *GNA11* (the gene encoding Gα11, one of the signaling proteins at the calcium-sensing receptor) were shown to cause an autosomal dominant form of hypoparathyroidism (Mannstadt et al., 2013; Nesbit et al., 2013; Piret et al., 2016; Tenhola et al., 2016) that can be associated with short stature (Tenhola et al., 2016; Li et al., 2014). FAM111A mutations have been identified in patients with hypoparathyroidism associated with impaired skeletal development in the context of Kenny−Caffey syndrome type 2 (Unger et al., 2013; Isojima et al., 2014).

Parathyroid hormone−like peptide mutations

Brachydactyly type E (BDE) is characterized by a general shortening of metacarpals, metatarsals, and/or phalanges (Maroteaux, 2002; Mundlos, 2009). BDE can be isolated or occurs as part of familial syndromes such as *GNAS* haploinsufficiency (Bastepe and Jüppner, 2016); furthermore, it is part of a syndrome that includes mental retardation in addition to brachydactyly (Williams et al., 2010). Within families, the phenotype is usually variable, ranging from moderate shortening of individual metacarpals to a shortening of all bones in the hands and/or feet.

Several groups have identified *PTHLH* haploinsufficiency as the cause of autosomal dominant BDE with short stature. *PTHLH* molecular defects causing BDE are heterogeneous and include (1) a balanced translocation with breakpoints upstream of *PTHLH* on chromosome 12p11.2 that introduces a novel C-ets-1/EBS binding site leading to cis-regulated downregulation of *PTHLH* expression (Maass et al., 2010); (2) a microdeletion on chromosome 12p encompassing *PTHLH* (Klopocki et al., 2010) as well as smaller deletions within the *PTHLH* (Thomas-Teinturier et al., 2016); and (3) heterozygous missense, nonstop, and nonsense mutations (Klopocki et al., 2010; Thomas-Teinturier et al., 2016; Wang et al., 2015; Jamsheer et al., 2016; Pereda et al., 2017; Reyes et al., 2019). In all studies, the mutations segregated with the disorder and were not found in control alleles. Thus, BDE with short stature can be caused by mutations that lead to haploinsufficiency of *PTHLH*.

As observed in the other rare human syndromes associated with mutations in the *PTHR1* gene, BDE caused by *PTHLH* haploinsufficiency phenocopies important aspects of PTHR1 functions, albeit with variable expressivity. Interestingly, a de novo duplication in the *PTHLH* gene was associated in one patient with symmetrical enchondromatosis (Collinson et al., 2010). These findings underscore that normal pre- and postnatal bone development and growth require quantitatively normal levels of PTHrP expression (Silve, 2010).

Parathyroid hormone/parathyroid hormone-related peptide receptor mutations

Jansen's metaphyseal chondrodysplasia

Jansen's metaphyseal chondrodysplasia (JMC), first described in 1934 (Jansen, 1934), is a rare autosomal dominant form of short-limbed dwarfism associated with laboratory abnormalities typically observed only in patients with either primary hyperparathyroidism or with humoral hypercalcemia of malignancy syndrome (reviewed in Jüppner et al., 2002; Parfitt et al., 1996). These biochemical changes, i.e., hypercalcemia, increased urinary phosphate excretion and increased urinary

cAMP excretion occur despite low or undetectable concentrations of PTH in the circulation as well as PTHrP concentrations that are not elevated. Severe hypercalcemia and hypophosphatemia had been noted in Dr. Murk Jansen's first patient (De Haas et al., 1969) and a subsequently described child with the same disorder (Cameron et al., 1954). It was not until the description of a third patient, however, that an association between the abnormalities in endochondral bone formation and mineral ion homeostasis was formally considered (Gram et al., 1959). At that time, the biochemical abnormalities could not be readily distinguished from those observed in primary hyperparathyroidism, and the surgical exploration of the patient revealed no obvious abnormalities of the parathyroid glands leading, to the conclusion that the changes in mineral metabolism were caused by an undefined metabolic defect (Gram et al., 1959). Most reported cases of JMC are sporadic, but the description of two unrelated affected females that gave birth to affected daughters (Lenz, 1969; Holthusen et al., 1975; Charrow and Poznanski, 1984) suggested an autosomal dominant mode of inheritance; this conclusion was subsequently confirmed at the molecular level for four families (Schipani et al., 1996; Bastepe et al., 2004; Nampoothiri et al., 2016; Saito et al., 2018).

At birth, some patients with JMC have dysmorphic features, which can include high skull vault, flattening of the nose and forehead, low-set ears, hypertelorism, high-arched palate, and micrognathia or retrognathia (Jüppner et al., 2002; Nampoothiri et al., 2016). Marked hypomineralization may also be observed, suggesting hypophosphatasia (Savoldi et al., 2013). Although body length is within normal limits at birth, growth becomes increasingly abnormal, eventually leading to the development of short stature. Additional signs may include kyphoscoliosis with a bell-shaped thorax and widened costochondral junctions, metaphyseal enlargement of the joints, waddling gait, prominent supraorbital ridges, and frontonasal hyperplasia. The legs are usually bowed and short, while the arms are relatively long.

Radiological studies have shown considerable age-dependent differences in the osseous manifestations of JMC. In younger patients, severe metaphyseal changes, especially of the long bones, are present (Fig. 57.2). The metaphyses are enlarged and expanded, giving a club-like appearance to the ends of the long bones with a wide zone of irregular calcifications. Patches of partially calcified cartilage that protrude into the diaphyses are also present and appear relatively radiolucent. These findings, which are characteristically observed throughout early childhood, are similar to the lesions in rickets. However, distinct from the findings in rickets, metacarpal and metatarsal bones are also involved.

Later in childhood, the changes are no longer reminiscent of rickets. Until the onset of puberty, almost all tubular bones show irregular patches of partially calcified cartilage that protrude into the diaphyses; the spine and vertebral bodies show no obvious abnormalities. After adolescence, cartilaginous tissue in the metaphyses gradually disappears and turns into bone, leading to bulbous deformities (see Fig. 57.2). The ends of most tubular bones remain expanded, deformed, and radiolucent, but a more normal trabecular pattern gradually emerges (Jüppner et al., 2002; Nampoothiri et al., 2016).

In addition, sclerosis and thickening of the base of the skull and of the calvaria are noted in most cases. The former changes are thought to be the cause of cranial auditory and optical nerve compression, which has been observed later in life in some affected individuals. Loss of the normal cortical outline, areas of subperiosteal bone resorption, and generalized osteopenia are reminiscent of the changes seen in hyperparathyroidism. Furthermore, there is an increase in trabecular bone volume and a thinning of cortical bone (Parfitt et al., 1996). The only two reports that investigated histological changes in

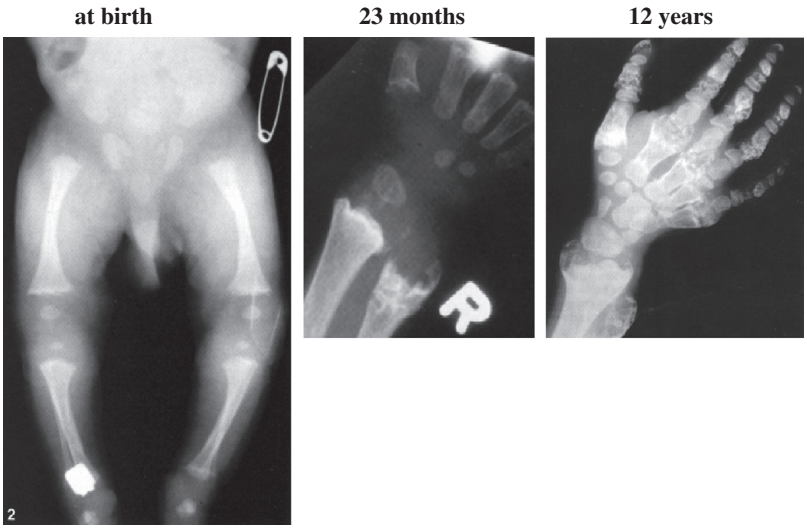

FIGURE 57.2 A patient with Jansen's disease and his radiological findings at birth, 23 months, and 12 years of age. *From Silverthorn, K.G., Houston, C.S., and Duncan, B.P. 1983. Murk Jansen's metaphyseal chondrodysplasia with long-term followup. Pediatr. Radiol. 17, 119–123, with permission.*

the growth plates described a severe delay in endochondral ossification of the metaphyses, including a lack of the regular columnar arrangement of the maturing cartilage cells, a lack of excess osteoid (which is usually indicative of active rickets or osteomalacia), little or no vascularization of cartilage, and no evidence for osteitis fibrosa (Cameron et al., 1954; Jaffe, 1972). Tooth development can be delayed, but enamel formation appears normal in patients with JMC. Intelligence appears normal in all reported cases.

Most laboratory findings of JMC are reminiscent of those observed in patients with primary hyperparathyroidism or with the syndrome of humoral hypercalcemia of malignancy. In the newborn, blood phosphorus levels are typically at the lower end of the normal range, while alkaline phosphatase activity is almost invariably elevated. Hypercalcemia is usually absent at birth but develops during the first months of life and persists throughout life, but is most pronounced during infancy and childhood (Fig. 57.3) (Saito et al., 2018). Hypercalciuria is usually present and can be associated with an increased incidence of nephrocalcinosis (Saito et al., 2018; Kessel et al., 1992; Onuchic et al., 2012). $1,25(OH)_2D$ levels have been reported as normal or at the upper end of the normal range. Serum alkaline phosphatase activity and osteocalcin concentration are elevated throughout life, indicating that osteoblast activity is increased; compatible with increased osteoclastic activity, urinary hydroxyproline excretion is elevated (Kruse and Schütz, 1993; Schipani et al., 1999).

Jansen's disease is caused by activating parathyroid hormone/parathyroid hormone-related peptide receptor mutations

Because of the findings in the various genetically manipulated mice described previously, and because of the abundant expression of PTHR1 in the three organs most obviously affected in JMC—i.e., kidney, bone, and metaphyseal growth plates—activating receptor mutations were considered as a cause of this rare disease. Indeed, in most patients with this disorder, a heterozygous nucleotide exchange, which changes a histidine at position 223 to arginine, has been identified at the border between the first intracellular loop and the second membrane-spanning domain of PTHR1 (Fig. 57.4) (Saito et al., 2018; Nampoothiri et al., 2016; Onuchic et al., 2012; Schipani et al., 1995; Minagawa et al., 1997; Brown et al., 2009). In other patients, four additional heterozygous nucleotide exchanges were identified that change either a threonine at position 410 to proline or arginine (sixth membrane-spanning domain) or isoleucine at position 458 (seventh membrane-spanning domain) to arginine (Schipani et al., 1995) or lysine (Savoldi et al., 2013) (Table 57.1). The mutated residues are predicted to be located at or close to the intracellular surface of the cell membrane and are strictly conserved in all mammalian members of this receptor family (Gardella et al., 2016), suggesting an important functional role for these three residues. With the exception of four families where parental transmission of the *PTHR1* mutation was documented (Schipani et al., 1996; Bastepe et al., 2004; Saito et al., 2018; Nampoothiri et al., 2016). This suggests that JMC is usually caused by de novo mutations.

To test in vitro the functional consequences of the identified missense mutations in JMC, each of the five different nucleotide exchanges was introduced into the cDNA encoding wild-type human PTHR1 (Saito et al., 2018; Savoldi et al., 2013; Schipani et al., 1995; Schipani et al., 1997). Different cell lines transiently expressing PTHR1s with the different H223R mutations showed a significantly higher basal accumulation of cAMP than cells expressing wild-type PTHR1.

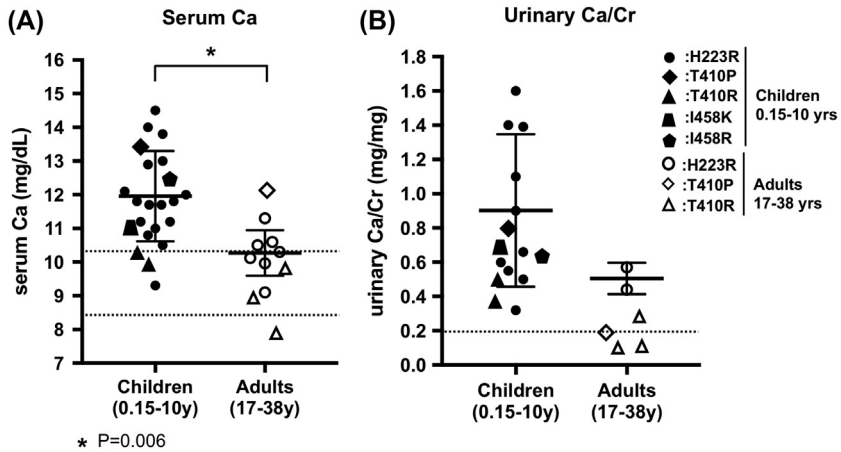

FIGURE 57.3 Serum and urinary calcium measurements for multiple children (0.15−10 years; n = 22 for serum calcium, n = 15 for urinary calcium/creatinine) and multiple adults (17−38 years; n = 11 for serum calcium; n = 8 for urinary calcium/creatinine) with Jansen's disease due to different PTHR1 mutations. Each data point represents the mean if a patient had multiple measurements during the two observation periods. **Panel A:** total calcium levels; dashed lines represent the upper/lower end of the adult normal range (8.6 −10.2 mg/dL). **Panel B:** urinary calcium-to-creatinine (Ca/Cr) ratio; all individual data points are shown. Mean ± SDs for patients with the H223R mutation. Dashed lines represent the upper end of normal for adult patients (<0.2). Children and adults showed no significant difference in the urinary Ca/Cr ratio. *From Saito, H., Noda, H., Gatault, P., Böckenhauer, D., Loke, K., Hiort, O., Silve, C., Sharwood, E., Matsunaga Martin, R., Dillon, M., et al. 2018. Progression of mineral ion abnormalities in patients with Jansen's metaphyseal chondrodysplasia. J. Clin. Endocrinol. Metab. 2018, with permission.*

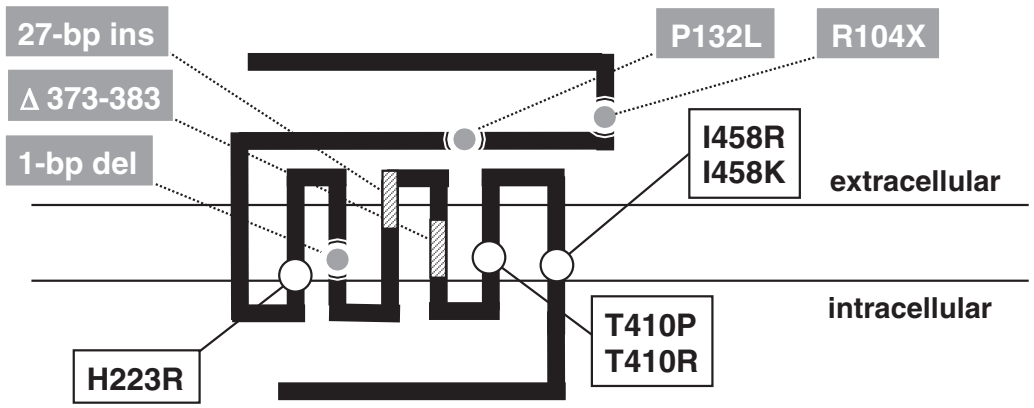

FIGURE 57.4 Schematic representation of the PTH/PTHrP receptor and approximate locations of mutations identified in patients with Jansen's or Blomstrand's disease.

Cells expressing mutant PTHR1s showed no evidence for increased basal accumulation of IP3, indicating that this signaling pathway is either not constitutively activated or that the assays evaluating this signaling pathway are not sufficiently sensitive.

The T410R mutation seems to lead to a less severe form of JMC (Bastepe et al., 2004). Patients carrying this mutation show only mild skeletal dysplasia with relatively normal stature as well as serum calcium levels within the normal range. The adult heights of patients with this mutations are much closer to the reference range (Saito et al., 2018). In fact, while the mean final adult height for patients with the H223R mutation was 127.0 ± 6.0 cm for males ($n = 4$) and 120.4 ± 10.3 cm for females ($n = 5$) (Fig. 57.5), the mean adult height of the three male patients with the T410R mutation was 157.7 ± 6.4 cm; the maximal adult height of the single patient with the T410P mutation was 96 cm. When tested in vitro, the degree of constitutive activity of the T410R mutant was significantly lower when compared with H223R, T410P, and I458R mutants, respectively (Bastepe et al., 2004; Schipani et al., 1997). This finding provided the first evidence for a correlation between severity of phenotypical features and degree of constitutive PTHR1 activity in Jansen's disease. Surprisingly, however, while H223R mutation is typically associated with profound hypercalcemia, a recently reported JMC patient with a de novo H223R mutation revealed no overt hypercalcemia, indicating that the mutation had occurred later in embryonic development (Nampoothiri et al., 2016).

Blomstrand's lethal chondrodysplasia

Blomstrand's lethal chondrodysplasia (BLC) is a recessive human disorder characterized by early lethality, advanced bone maturation, and accelerated chondrocyte differentiation, and most likely severe abnormalities in mineral ion homeostasis. The first patient was described by Blomstrand and colleagues in 1985 (Blomstrand et al., 1985); descriptions of several other patients followed (Young et al., 1993; Leroy et al., 1996; Loshkajian et al., 1997; den Hollander et al., 1997; Oostra et al., 1998; Galera et al., 1999; Karperien et al., 1999). The disorder was shown to occur in families of different ethnic backgrounds and appears to affect males and females equally. Most affected infants are born to consanguineous parents (only in one instance were unrelated parents reported to have two offspring both affected by Blomstrand's disease (Loshkajian et al., 1997), suggesting that BLC is an autosomal recessive disease. Infants with BLC are typically born prematurely and die shortly after birth. Birth weight corrected for gestational age appears to be normal but may be overestimated, because most infants are hydroptic; also, the placenta can be immature and edematous. Nasal, mandibular, and facial bones are hypoplastic; the base of the skull is short and narrow; the ears are low set; and the thoracic cage is hypoplastic and narrow with short, thick ribs and hypoplastic vertebrae. In contrast, the clavicles are relatively long and often abnormally shaped, the limbs are extremely short, and only the hands and feet are of relatively normal size and shape. Internal organs show no apparent structural or histological anomalies, but preductal aortic coarctation was observed in most published cases. The lungs are hypoplastic, and the protruding eyes typically show cataracts. Defects in mammary gland and tooth development, previously overlooked, were demonstrated in two studied fetuses with BLC. In these fetuses, nipples were absent, and no subcutaneous ductal tissue could be identified by histochemical analysis. Tooth buds were present, but developing teeth were severely impacted within the surrounding alveolar bone, leading to distortions in their architecture and orientation (Wysolmerski et al., 2001). Interestingly, heterozygous loss-of-function mutations in PTHR1 have been associated with autosomal dominant isolated primary failure of tooth eruption (PFE) (see paragraph later).

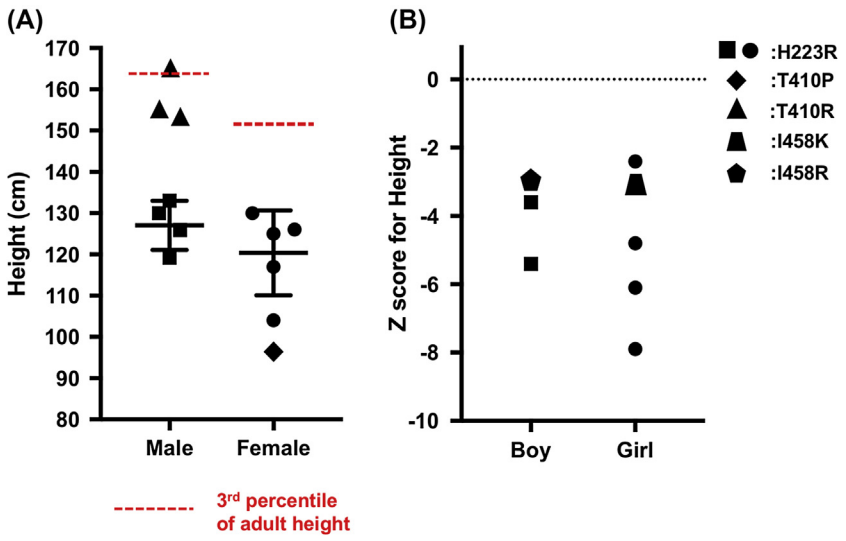

FIGURE 57.5 Height data for different patients affected by Jansen's disease due to different PTHR1 mutations. **Panel A:** individual final heights for 13 adult JMC patients. Mean ± SDs are shown for the final heights of patients with the H223R mutation; the red broken lines indicate the third percentile for normal adult heights. **Panel B:** individual height z scores for eight children. *From Saito, H., Noda, H., Gatault, P., Böckenhauer, D., Loke, K., Hiort, O., Silve, C., Sharwood, E., Matsunaga Martin, R., Dillon, M., et al. 2018. Progression of mineral ion abnormalities in patients with Jansen's metaphyseal chondrodysplasia. J. Clin. Endocrinol. Metab. 2018, with permission.*

Radiological studies of patients with BLC reveal pronounced hyperdensity of the entire skeleton and markedly advanced ossification (Fig. 57.6). As mentioned earlier, the long bones are extremely short and poorly modeled, show markedly increased density, and lack metaphyseal growth plates. Endochondral bone formation is dramatically advanced and is associated with a major reduction in epiphyseal resting cartilage preventing the development of epiphyseal ossification centers (Fig. 57.7). The zones of chondrocyte proliferation and column formation are lacking, and the zone that normally comprises the layer of hypertrophic chondrocytes is poorly defined, narrow, and irregular (Oostra et al., 2000). Cortical bone is thickened and bone trabeculae are coarse with reduced diaphyseal marrow spaces. Capillary ingrowth, bone resorption, and bone formation are reported by some authors as unaltered (Leroy et al., 1996), while others describe these bone remodeling events as deficient (Loshkajian et al., 1997).

Blomstrand's disease is caused by inactivating parathyroid hormone/parathyroid hormone-related peptide receptor mutations

Different defects in the PTHR1 gene have been described in genomic DNA from patients affected by BLC (see Table 57.1). The first reported case, a product of nonconsanguineous parents, was shown to have two distinct abnormalities in the PTHR1 gene (Jobert et al., 1998). Through a nucleotide exchange in exon M5 of the maternal PTHR1 allele, a novel splice acceptor site was introduced that led to a mutant mRNA encoding an abnormal receptor that lacks a portion of the fifth membrane-spanning domain (amino acids 373 to 383; Δ373-383). This receptor mutant fails, despite seemingly normal cell surface expression, to respond to PTH or PTHrP with an accumulation of cAMP and inositol phosphate (Jobert et al., 1998). For yet-unknown reasons, the paternal PTHR1 allele from this patient was very poorly expressed, suggesting an unidentified mutation in one of the different promoter regions or in a putative enhancer element.

A second patient with BLC, the product of a consanguineous marriage, was shown to have a nucleotide exchange that leads to a proline-to-leucine mutation at position 132 (P132L) (Zhang et al., 1998; Karaplis et al., 1998). This residue in the amino-terminal extracellular domain of PTHR1 is invariant in all mammalian members of this family of GPCRs, indicating that the identified mutation is likely to have significant functional consequences. Indeed, COS-7 cells expressing this mutant PTHR1 showed, despite apparently normal cell surface expression, dramatically impaired binding of radiolabeled PTH and PTHrP analogs, greatly reduced agonist-stimulated cAMP accumulation, and no measurable inositol phosphate response. It is important to note, however, that cells expressing the P132L mutant receptor showed some agonist-induced second-messenger response and showed little, yet detectable, specific binding of radiolabeled PTHrP. To date, the P132L mutation has been identified in two additional patients affected with BLC (Hoogendam et al., 2007). Although not definitive, haplotype analysis performed on the genomic DNA of these patients with the P132L mutation is consistent with an ancient founder effect (Hoogendam et al., 2007).

A homozygous deletion of G at position 1093 (from A of the ATG-translation initiation codon) (exon EL2) was identified in a third case of BLC (Karperien et al., 1999). This mutation led to a shift in the open reading frame, which

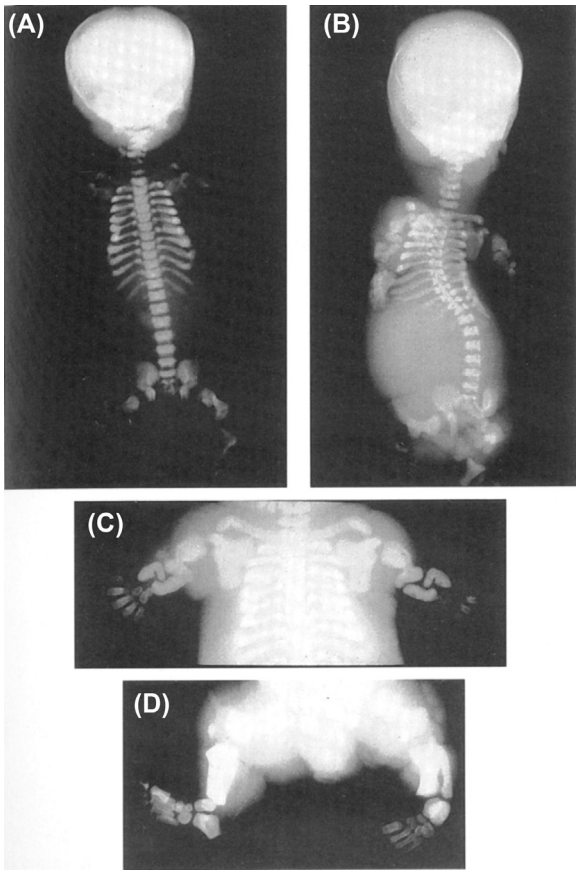

FIGURE 57.6 Radiological findings in two fetuses with Blomstrand's lethal chondrodysplasia (BLC). Anterio−posterior (A) and lateral (B) views of a male fetus at 26 weeks of gestation; upper (C) and lower (D) limbs of a female fetus with BLC at 33 weeks of gestation. Particularly striking is the dramatic acceleration of endochondral bone formation in all skeletal elements. No secondary ossification centers are seen in the long bones. The limbs are coarsely shaped and extremely short, while carpal and tarsal bones have a comparatively normal shape and size. Note also that the clavicles are relatively long but show abnormal bending. *From Loshkajian, A., Roume, J., Stanescu, V., Delezoide, A.L., Stampf, F., and Maroteaux, P. 1997. Familial Blomstrand Chondrodysplasia with advanced skeletal maturation: further delineation. Am. J. Med. Genet. 71, 283−288, with permission.*

resulted in a truncated protein that completely diverged from the wild-type receptor sequence after amino acid 364 and thus lacked transmembrane domains 5, 6, and 7, the connecting intra- and extracellular loops, and the cytoplasmic tail (Δ365-593).

As for the other cases of BLC, these findings provided a plausible explanation for the severe abnormalities in endochondral bone formation. The abnormalities in mammary gland and tooth development further supports the conclusion that

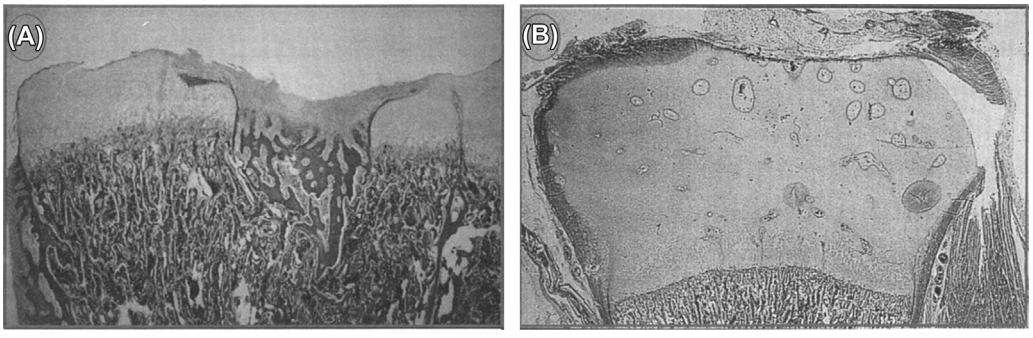

FIGURE 57.7 Section of the upper tibia end from a patient with BLC (A) and an age-matched control. Note the severely reduced size of the growth plate, the irregular boundary between the growth plate and the primary spongiosa, and the increased cortical bone thickness. *From Loshkajian, A., Roume, J., Stanescu, V., Delezoide, A.L., Stampf, F., and Maroteaux, P. 1997. Familial Blomstrand Chondrodysplasia with advanced skeletal maturation: further delineation. Am. J. Med. Genet. 71, 283−288, with permission, and Anne-Lise Delezoide, personal collection.*

PTHR1 has identical roles in humans and mice in the development of these organs. Compatible with the role of PTHR1 and PTHrP in organogenesis, both were demonstrated to be expressed in the developing breast and tooth of human control fetuses (Wysolmerski et al., 2001). It is also worth noting that the abnormalities in skeletal development in fetuses carrying the P132L mutation, which inactivates PTHR1 incompletely, are less severe than those observed in most cases, particularly with regard to the bones of the lower limbs (Young et al., 1993; Karperien et al., 1999). This led to the proposal that two forms of BLC can be distinguished clinically and on the basis of the in vitro characteristics of the mutant PTHR1s (Oostra et al., 2000).

Two additional homozygous mutations in PTHR1 have been identified in fetuses affected by BLC that further document the molecular basis for the two forms of BLC (Hoogendam et al., 2007) (see Table 57.1). A homozygous point mutation causing a premature stop codon at position 104 (R104X) and therefore resulting in a truncated completely inactive protein has been identified in a case affected with the severe (type I) form. A homozygous nucleotide change (c.1049 + 27C > T, hg19) generating a novel splice site has been identified in a case affected with the less severe form (type II). This novel splice site, which results in an aberrant transcript with a premature stop codon after codon 350, was shown to be preferentially used in dermal fibroblasts, but the wild-type transcript remained expressed, albeit at low levels. Taken together, the findings in patients with BLC suggested that this rare human disease is the equivalent of mice "null" for PTHR1 (Lanske et al., 1996).

Eiken familial skeletal dysplasia

In addition to BLC and JMC, PTHR1 gene mutations have been associated with two other diseases, Eiken familial skeletal dysplasia (Duchatelet et al., 2005) and enchondromatosis (Ollier's disease) (Hopyan et al., 2002). Eiken familial skeletal dysplasia has been described in a single consanguineous family (Eiken et al., 1984). The disease is characterized by multiple epiphyseal dysplasia with extremely retarded ossification, abnormal modeling of the bones in hands and feet, abnormal persistence of cartilage in the pelvis, and mild growth retardation. Serum calcium and phosphate levels have been normal in all examined patients; serum PTH level was measured in only one patient and was found to be slightly elevated with a normal $1,25(OH)_2D$ level. A homozygous mutation in PTHR1, R485X, that leads to the truncation of the last 108 amino acids of PTHR1, was identified in all affected patients but was not found in DNA from healthy controls (Duchatelet et al., 2005). The functional properties of mutant PTHR1 have not been characterized in vitro. However, based on the properties of a receptor mutant with deletion after amino acid 480 (Iida-Klein et al., 1995), it appears plausible that the truncated receptor has an imbalance between the different signaling pathways activated by PTH. Why the deletion of the carboxy-terminal tail of PTHR1 results in a bone phenotype but no obvious abnormality in the regulation of mineral ion homeostasis remains unclear.

Enchondromatosis (Ollier's disease)

Enchondromatosis is usually a nonfamilial disorder characterized by the presence of multiple enchondromas. It is characterized by an asymmetric distribution of the cartilaginous lesions, which can be extremely variable (in terms of size, number, location, evolution of enchondromas, age of onset and diagnosis, and requirement for surgery). Clinical problems caused by enchondromas include skeletal deformities, limb-length discrepancy, and the potential risk for malignant change to chondrosarcoma. The condition in which multiple enchondromatosis is associated with soft tissue hemangiomas is also referred to as Maffucci syndrome. The irregular distribution of the lesions in Ollier's disease strongly suggests that it is a disorder of endochondral bone formation that occurs due to a postzygotic somatic mutation that results in mosaicism. A mutant PTHR1 (R150C) was found to be expressed in the enchondromas from two of six unrelated patients with enchondromatosis (Hopyan et al., 2002). The mutation was found on one parental allele in one patient and his father, who presented with atypical mild skeletal dysplasia but not enchondromatosis; interestingly, this PTHR1 variant was furthermore found to be associated with adult height (Marouli et al., 2017). Consistent with a role of PTHR1, in some forms of Ollier's disease novel heterozygous *PTHR1* mutations (either germline or somatic mutations in tumor tissue) have been found in several additional cases; no mutations were identified in *GNAS* or *PTHLH* (Couvineau et al., 2008). As indicated earlier, a de novo duplication comprised in the *PTHLH* gene has been associated with symmetrical enchondromatosis (Collinson et al., 2010). However, neither the R150C mutation (26 tumors) nor any other mutation in the *PTHR1* gene (11 patients) could be identified in another study (Rozeman et al., 2005). In fact, most cases of Ollier's or the related Maffucci disease are now known to be caused by mutations in the isocitrate dehydrogenases IDH1 and IDH2. Somatic heterozygous mutations in IDH1, and less frequently in IDH2, were reported in 35 of 43 (81%) subjects with Ollier's disease, while 10 of 13 (77%) with Maffucci syndrome carried IDH1 (98%) or IDH2 (2%) mutations in their tumors. IDH1 and IDH2 mutations with evidence of intraneoplastic and somatic mosaicism were also identified in 87% of

enchondromas (benign cartilage tumors), 70% of spindle cell hemangiomas (benign vascular lesions), and 40% of solitary central cartilaginous tumors (Pansuriya et al., 2011). IDH1 and IDH2 catalyze the oxidative decarboxylation of isocitrate to 2-oxoglutarate, which increases d-2-hydroxyglutarate production and depletes the formation of α-ketoglutarate, a cofactor for the actions of Jumonji-domain-containing proteins involved in the demethylation of histone arginine and lysine residues. Lack of α-ketoglutarate further increases HIF-1α expression, which cause abnormal sensing of hypoxia within the growth plate cartilage, which may lead to an uncontrolled proliferation of chondrocytes. Taken together, these studies indicate heterogeneity in the molecular defects leading to enchondromatosis.

Delayed tooth eruption due to parathyroid hormone/parathyroid hormone-related peptide receptor mutations

PFE can be associated with several syndromes but is also observed as a nonsyndromic isolated autosomal dominant condition with high penetrance and variable expressivity. Heterozygous *PTHR1* mutations were first identified in individuals affected by PFE after the genetic locus had been determined through linkage analysis in four multiplex pedigrees (Decker et al., 2008). Three distinct mutations were initially identified as truncating the mature protein and are therefore expected to lead to a functionless receptor. These studies were subsequently confirmed and extended (Frazier-Bowers et al., 2007, 2010, 2014; Yamaguchi et al., 2011; Risom et al., 2013; Roth et al., 2014; Pilz et al., 2014; Jelani et al., 2016; Quinque et al., 2016) and indicate that haplo-insufficiency of PTHR1 is an underlying cause of nonsyndromic PFE. The PTHR1 mutations responsible for PFE include nonsense, missense, splice-site mutations, and insertion—deletion mutations. Several missense mutations, including P132L, were first identified in Blomstrand cases (Jobert et al., 1998). Tooth bud impaction has been described in Blomstrand's lethal osteochondrodysplasia (Wysolmerski et al., 2001), thus supporting the important role of PTHR1 in normal tooth development.

Mutations in genes downstream of the parathyroid hormone/parathyroid hormone-related peptide receptor

GNAS mutations

Shortly after Aurbach and colleagues had discovered that kidney- and bone-derived tissues increase cAMP formation in response to PTH (Chase & Aurbach, 1967, 1970; Chase et al., 1969a,b; Marcus and Aurbach, 1971), the same group revealed that patients with PHP and clinically obvious features of Albright's hereditary osteodystrophy (AHO) (now referred to as PHP1A) failed to respond to a PTH challenge with an increase in urinary cAMP excretion (Chase et al., 1969a,b). This observation linked the lack of PTH-induced phosphaturia, initially described by F. Albright and colleagues (Albright et al., 1942), to this second-messenger system. However, homogenates from the renal cortex of a PHP-Ia patient showed PTH-induced cAMP formation, leading Aurbach's group to conclude that this disorder is not caused by a mutation in PTHR1 or the effector enzyme that generates cAMP—i.e., adenylate cyclase (Marcus et al., 1971). In fact, it was the discovery that tissues from PHP1A patients show reduced G-protein activity that provided the first evidence for abnormal coupling between the PTH receptor and adenylate cyclase (Levine et al., 1980; Farfel et al., 1980), which subsequently led to the identification of heterozygous mutations in *GNAS,* the gene encoding the alpha-subunit of the heterotrimeric stimulatory G-protein (Gsα) (Patten et al., 1990; Weinstein et al., 1990). However, it remained a conundrum why heterozygous Gsα mutations should lead to PTH resistance, until Davies and Hughes revealed that PTH resistance becomes apparent only when the genetic defect is inherited maternally (Davies and Hughes, 1993).

It is now well established that Gsα, which is ubiquitously expressed, couples a large number of other GPCRs, including PTHR1, to the effector enzyme, adenylyl cyclase, required for receptor-stimulated intracellular cAMP generation and PKA activation. Gsα is derived from the *GNAS* locus, a complex imprinted genomic region located on chromosome 20q13 that encodes, in addition to Gsα, several other alternatively spliced transcripts (Bastepe and Jüppner, 2016). In some tissues such as renal proximal tubules (PTH target), thyroid, or pituitary gland, the expression of Gsα is predominantly or exclusively monoallelic. In these tissues, Gsα is derived mainly from the maternal allele, while expression from the paternal allele is silenced through as-of-yet unknown mechanisms.

Genetic and epigenetic defects in the *GNAS* complex locus cause, according to their allelic origin, heterogeneous diseases—i.e., different forms of PHP, pseudopseudohypoparathyroidism (PPHP), and progressive osseous heteroplasia—each with distinctive characteristics. The clinical and biochemical distinction between these pathologies relies mainly but not exclusively the presence or absence of AHO and the presence of hormonal resistance, in particular PTH resistance. AHO is a distinctive constellation of variable developmental and skeletal defects (rounded face, short

stocky appearance, brachydactyly type E, early-onset obesity, heterotopic ossification, and variable neurocognitive abnormalities) associated with Gsα haploinsufficiency. Obesity, initially thought to be part of the spectrum of AHO features, has now been shown to occur only upon maternal inheritance of *GNAS* mutations (Long et al., 2007). PHP is divided into type I (PHP1) and type II (PHP2). PHP1 is characterized by resistance to PTH in the proximal renal tubules, resulting in little or no urinary cAMP excretion after injection of PTH. In PHP2, PTH injection causes a normal increase in urinary cAMP excretion but no phosphaturic response. Most forms of PHP1 and PPHP appear to be linked to genetic (PHP1A, PHP1C, and PPHP) and/or epigenetic (PHP1B) abnormalities at the *GNAS* complex locus. Patients who inherit Gsα mutations from their mother express both the AHO phenotype and resistance to various hormones (PTH, TSH, calcitonin, GHRH, epinephrine, LH, and FSH) (for a review see (Bastepe and Jüppner, 2016; Levine, 2002; Linglart et al., 2013; Elli et al., 2016a,b) that stimulate the Gsα-cAMP-PKA pathway in their respective target tissues; this condition is referred to as PHP1A. PTH resistance is the most obvious endocrine deficiency that is almost always accompanied by hypocalcemia, hyperphosphatemia, and low or inappropriately normal levels of $1,25(OH)_2D$ despite elevated PTH levels (and the absence of vitamin D deficiency or chronic kidney disease). Following the injection of PTH, these patients exhibited a defect in the formation of cAMP in the renal proximal tubules and thus reduced phosphaturic response and reduced $1,25(OH)_2D$ production. These findings were consistent with the loss-of-function mutations in Gsα that are required for the formation of cAMP.

Protein kinase type 1A regulatory subunit protein mutations

Acrodysostosis refers to a group of rare skeletal dysplasias that share common characteristic clinical and radiological features, including severe brachydactyly (Fig. 57.8), facial dysostosis, and nasal hypoplasia, and in some cases resistance to multiple hormones that mediate actions through the cAMP/PKA pathway (Ablow et al., 1977; Davies and Hughes, 1992). Several forms of acrodysostosis are now recognized (ACRDYS1: OMIM 101800, ACRDYS2: OMIM 614613, hypertension and brachydactyly syndrome: OMIM 112410), which are caused, respectively, by heterozygous mutations in the genes coding for the cAMP-dependent protein kinase type 1A regulatory subunit protein (PRKAR1A) (Linglart et al., 2011), phosphodiesterase (PDE) 4D (PDE4D) (Lee et al., 2012; Michot et al., 2012; Linglart et al., 2012; Lindstrand et al., 2014), and PDE3A (Bilginturan et al., 1973; Schuster et al., 1996; Maass et al., 2015; Boda et al., 2016). Of note, heterotopic ossifications, a hallmark of AHO and Gsα haploinsufficiency, are rarely observed in acrodysostosis.

Using a candidate gene approach, a recurrent heterozygous missense mutation (c.1101C→T, p.Arg368X) was identified in three unrelated patients affected by ACRDYS1 in the gene *PRKAR1A*, which encodes the regulatory subunit of PKA (Linglart et al., 2011). Since then, 18 additional heterozygous missense *PRKAR1A* mutations have been documented in ACRDYS1 patients (Silve et al., 2012a,b; Silve et al., 2012a,b; Elli et al., 2016a,b) (Fig. 57.9). The first-described mutation, Arg368X, has been subsequently found in 10 additional patients, confirming that it is the most frequent

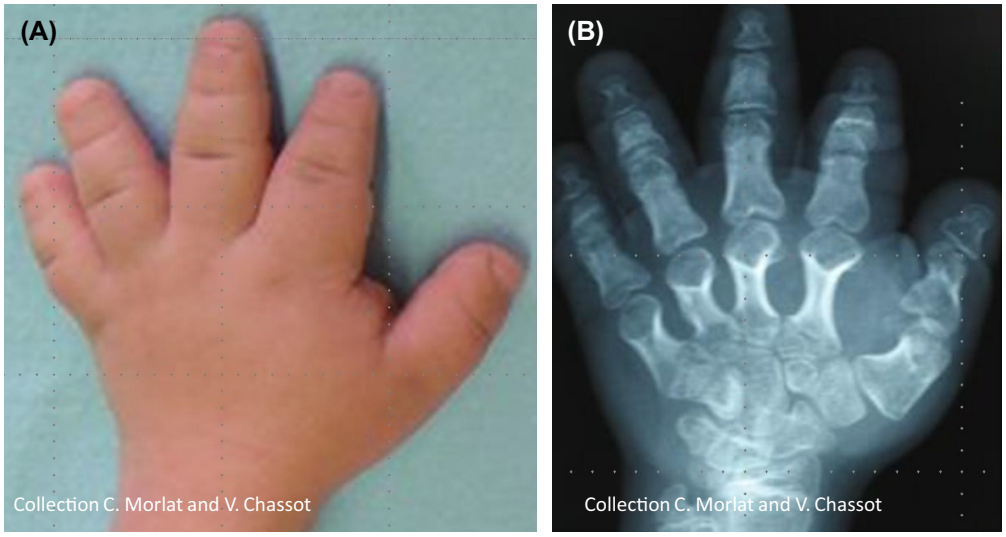

FIGURE 57.8 Picture (A) and X-ray (B) of one hand of a 13-year-old patient affected with ACRDYS1. The patient presents the shortening of metacarpals, metatarsals, and phalanges characterizing brachydactyly type E (BDE). Note the shortening of all bones and the bulky and stocky aspect of affected bones.

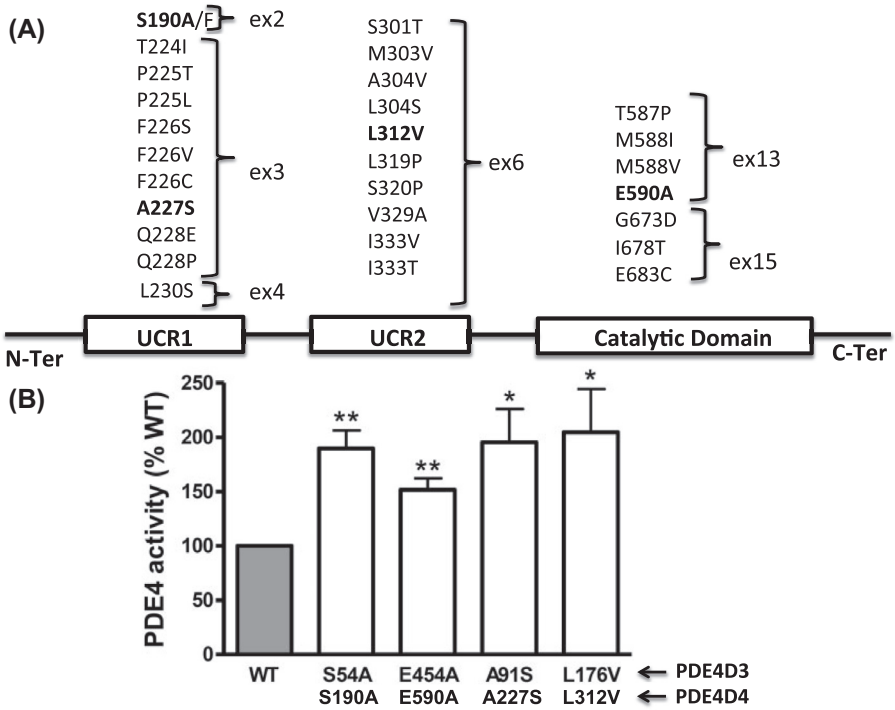

FIGURE 57.9 **Panel A.** Schematic representation of PRKAR1A indicating the functionally important domains and positions of amino acid residues mutated in patients affected with acrodysostosis (ACRDYS1). DD: dimerization domain; IS: inhibitory site; domains A and B: cAMP-binding domains A and B. PBC: phosphate binding cassette. **Panel B.** PKA transcriptional activity in cells cotransfected with plasmids encoding WT PRKAR1A, or the indicated mutants and stimulated with various concentrations of forskolin in the presence of 1 mM isobutylmethylxanthine (IBMX) as measured by the cAMP-responsive element (CRE)—luciferase reporter assay. The results are expressed as fold stimulation over basal. After stimulation with forskolin, the dose—response curves for cells expressing mutant PRKAR1A subunits are all shifted to the right compared with those observed in cells expressing the WT PRKAR1A subunit, indicating that all of the mutant regulatory subunits are less sensitive to cAMP. This results in impaired activation of PKA. *From Rhayem, Y., Le Stunff, C., Abdel Khalek, W., Auzan, C., Bertherat, J., Linglart, A., Couvineau, A., Silve, C., and Clauser, E. 2015. Functional characterization of PRKAR1A mutations reveals a unique molecular mechanism causing acrodysostosis but multiple mechanisms causing carney complex. J. Biol. Chem. 290, 27816—27828, with permission.*

recurrent *PRKAR1A* mutation in ACDRYS1. Each of the other 17 mutations was identified in a single patient, all being sporadic cases.

As indicated above, the most commonly used effector system downstream of cAMP is PKA. In the absence of cAMP, PKA exists as a tetramer in which two regulatory (R) subunits lock the two catalytic (C) subunits in an inactive state. Activation of the enzyme requires the release of the catalytic subunits, which is triggered by the sequential binding of cAMP molecules first to domain B, then to domain A of the R subunit (Tasken et al., 1997; Taylor et al., 1990, 2008). Briefly, there are four different regulatory subunit isoforms: PRKAR1A and PRKAR2A are ubiquitously expressed, whereas PRKAR1B is found only in brain and testis (R1B), and PRKAR2B is found only in adrenal and adipose tissue (R2B). These regulatory subunits associate to two different catalytic subunits, ubiquitous Ca and brain-specific Cb. The quantitatively and qualitatively predominant subunits are Ca and PRKAR1A; the Arg368X mutation results in deletion of cAMP binding site B of this regulatory subunit. This subunit constitutively represses the catalytic subunit, thereby impairing PKA response to cAMP stimulation (Linglart et al., 2011). Subsequent functional characterization of PRKAR1A mutations causing acrodysostosis revealed that all mutations lead to a cAMP binding defect as the unique molecular mechanism for resistance of PKA activation (Rhayem et al., 2015). This mechanism explains the hormonal resistance observed in ACRDYS1 patients and explains why their skeletal abnormalities resemble those observed in PHP1A/PPHP patients.

A knock-in of the recurrent R368X PRKAR1A mutation was recently developed in the mouse (Le Stunff et al., 2017). Heterozygous R368X KI mice presented the two main features of the ACRDYS1 phenotype in humans—i.e., renal proximal tubule resistance to PTH and chondrodysplasia. In addition, heterozygous R368X KI mice presented a striking and unexpected delay in endochondral ossification, raising the possibility that PRKAR1A/PKA is a molecular switch at the crossroads of pathways orchestrating chondrocyte proliferation and differentiation. A dissociation between chondrocyte

proliferation and differentiation is also observed in acromesomelic dysplasia, type Maroteaux (AMDM), a bone dysplasia characterized by severe short stature and short limbs, with no advance in bone age (in fact, a delay is observed) caused by homozygous mutations in the C-type natriuretic peptide-natriuretic peptide receptor B (Bartels et al., 2004). AMDM should be included in the differential diagnosis of acrodysostosis.

Phosphodiesterase 4D mutations

Defects in *PDE4D*, first identified by exome sequencing, cause acrodysostosis without obvious evidence for hormonal resistance (Lee et al., 2012; Michot et al., 2012; Linglart et al., 2012; Lindstrand et al., 2014). PDE4D belongs to the class IV of cAMP-specific phosphodiesterases that hydrolyze cAMP. In humans, a single *PDE4D* gene gives rise, through differential splicing that modifies the N-terminal portion of the protein, to at least nine different isoforms (Houslay and Adams, 2003). All isoforms comprise the same C-terminal catalytic domain. Six isoforms, classified as 'long' PDE4D variants, contain two conserved upstream regions (UCR1 and UCR2), while two short isoforms contain only the UCR2 region, and one 'super-short' isoform of the enzyme contains only the catalytic domain. Little is known about the tissue-specific expression, function, and regulation of each of these isoforms in human tissues. All long isoforms are activated by PKA-mediated phosphorylation of a single serine residue within a PKA consensus phosphorylation site in UCR1. To date, 32 heterozygous missense mutations in PDE4D have been identified in patients with acrodysostosis (ACRDYS2) (Lindstrand et al., 2014; Silve et al., 2012a,b; Silve et al., 2012a,b; Elli et al., 2016a,b; Kaname et al., 2014; Lynch et al., 2013) (Fig. 57.10). Interestingly, PDE4D mutations are located in all three main functional domains (UCR1, UCR2, and catalytic), indicating that defects in all isoforms (long, short, and supershort) can putatively cause ACRDYS2. The location of PDE4D mutations occurring in ACRDYS2 indicate that they could influence the regulation of PDE activity by PKA without impairing the functional activity of the activated enzyme (Cedervall et al., 2015). In agreement, recent findings indicate that PDE4D3 (one of the long PDE4D isoforms) variants carrying ACRDYS2 mutations are more readily activated over a wide range of intracellular cAMP concentrations by PKA-induced phosphorylation than wild-type PDE4D3 (Briet et al., 2017); furthermore, basal activity is enhanced in cells expressing PDE4D3 variants compared with that of cells expressing wild-type PDE4D3 (Briet et al., 2017). These studies indicate that ACRDYS2 mutations result in the increased hydrolytic activity of PDE4D. Mutations in PDE3A causing hypertension and brachydactyly syndrome have also been demonstrated to increase PKA-mediated activation of PDE3A (see later) (Maass et al., 2015). These findings may offer new perspectives into the selection of specific PDE inhibitors and possible therapeutic intervention for these patients.

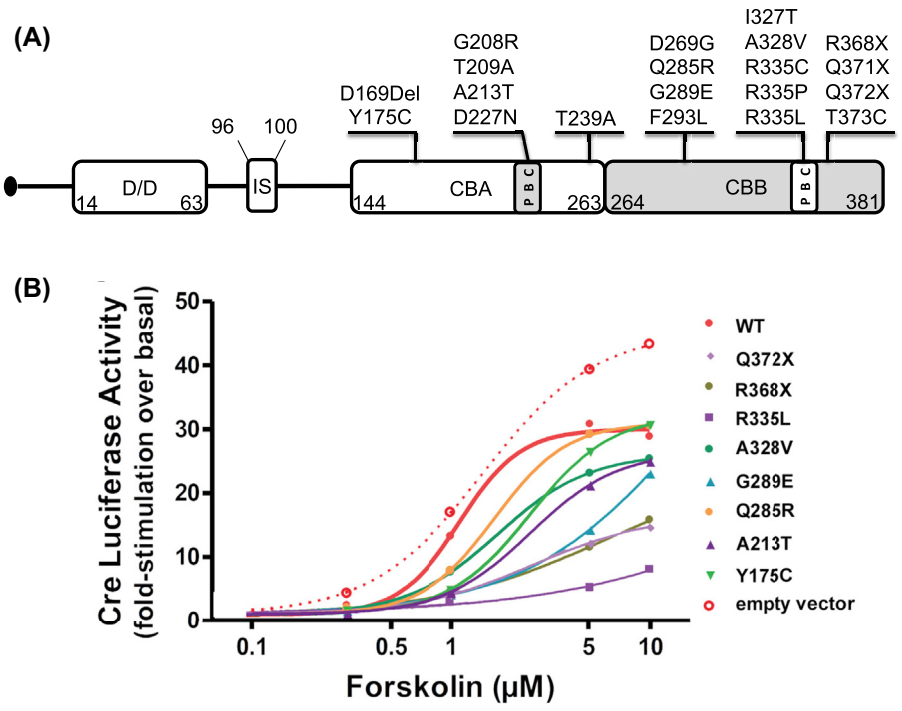

FIGURE 57.10 **Panel A.** Schematic representation of PDE4D indicating the functionally important domains and positions of amino acid residues mutated in patients affected with acrodysostosis (ACRDYS2). The positions are indicated for the PDE4D4 isoform. UCR: upstream conserved region. **Panel B.** Comparison of the phosphodiesterase activity of PDE4D3 carrying ACRDYS2 mutations and WT PDE4D3. The results are expressed as % WT activity. Increases in activity are observed, with the four different ACRDYS2 mutations occurring in the different functional domains of the protein. Mutations causing acrodysostosis-2 facilitate the activation of phosphodiesterase 4D3. *Adapted from Briet, C., Pereda, A., Le Stunff, C., Motte, E., de Dios Garcia-Diaz, J., de Nanclares, G.P., Dumaz, N., and Silve, C. 2017. Mutations causing acrodysostosis-2 facilitate activation of phosphodiesterase 4D3. Hum. Mol. Genet. 26, 3883–3894, with permission.*

Another group, however, reported that PDE4D mutations causing acrodysostosis without hormone resistance resulted in impaired enzyme activity and that the observed phenotype resulted from overcompensatory increased expression of other PDE4 isoforms (Kaname et al., 2014).

Since the first reports, some clinical and radiological findings in acrodysostosis were noted as similar to those observed in PHP1A/PPHP syndromes (Ablow et al., 1977; Davies and Hughes, 1992); however, distinct differences exist. In particular, although the different conditions present with stocky appearance and BDE, brachydactyly type E, the brachydactyly in the *GNAS*-related disorders, is variable and usually less severe than it is in both forms of acrodysostosis. The skeletal phenotype in acrodysostosis is usually quite uniform and more severe than in PHP1A/PPHP (Fig. 57.8). In contrast to severe skeletal dysplasia, resistance toward PTH and other hormones is less pronounced in ACRDYS2 (Linglart et al., 2011, 2012; Lindstrand et al., 2014; Silve et al., 2012a,b). Recent work indicates that the ability of PDE4 to modulate signaling through the GPCR−cAMP−PKA pathway depends on cell type and stimulus intensity. Thus, PDE4D mutations would be expected to impair some but not all responses, potentially explaining the presence of acrodysostosis without hormonal resistance in ACRDYS2 (Motte et al., 2017).

Phosphodiesterase 3A mutations

PDE3A is a member of a PDE family that hydrolyzes both cAMP and cGMP with high affinity. It is characterized by competitive inhibition of its cAMP hydrolytic activity by cGMP and certain positive inotropic agents. Heterozygous mutations that activate PDE3A have been identified in patients affected by BDE with hypertension syndrome (Maass et al., 2015). The mutations, which occur within a cluster located N-terminal to the PDE3A catalytic unit increase PKA-mediated activation of PDE3A, resulting in increased PDE activity (Maass et al., 2015). The increased phosphorylation of PDE3A was found to decrease the Km for cAMP without changing Vmax, whereas phosphorylation of PDE4D has been found to increase Vmax without changing the Km for cAMP (Mika and Conti, 2016).

Histone deacetylase 4-mutations

Brachydactyly mental retardation syndrome (BDMR) presents with a range of features including intellectual disabilities, developmental delays, behavioral abnormalities, sleep disturbance, and craniofacial and skeletal abnormalities comprising brachydactyly type E and autism spectrum disorder. BDMR had been associated with large deletions of 2q37. Clinical and molecular analysis of individuals with overlapping deletions involving 2q37.3 that refined this critical region led to sequencing of histone deacetylase 4 (*HDAC4*) as a candidate gene and the identification of de novo mutations including one intragenic deletion that probably disrupts normal splicing and one intragenic insertion causing a frame shift and premature stop codon in BDMR-affected patients (Williams et al., 2010). HDAC4 is a histone deacetylase that regulates genes important in bone, muscle, neurological, and cardiac development. Identification of *HDAC4* deletions and mutations in multiple subjects with BDMR and the phenotype of *Hdac4*(−/−) mice indicate that haploinsufficiency of *HDAC4* results in BDMR.

Conclusions

Mutations in the genes encoding PTH, PTHrP, or PTHR1 as well as downstream signaling and effector proteins have been identified as causes of rare inherited disorders. Identification of these mutations has provided important new insights into the regulation of bone and cartilage development as well as mineral ion homeostasis.

Chapter outline

Introduction

Over the past several years, the application of powerful molecular biology techniques has provided a wealth of new information and insights into the development of tumors. The purpose of this chapter is to review this information as it relates to our understanding of parathyroid tumorigenesis. Parathyroid hyperfunction is found in several disease states including sporadic primary and secondary hyperparathyroidism (the latter is not addressed in this chapter) as well as familial disorders such as multiple endocrine neoplasia (MEN) and familial hypocalciuric hypercalcemia (FHH) syndromes.

Primary hyperparathyroidism is a common disorder classically characterized by hypercalcemia caused by excessive secretion of parathyroid hormone (PTH). This is due to both an increased parathyroid gland mass and a resetting of the control of PTH secretion from the parathyroid cell by the ambient calcium concentration. Patients with primary hyperparathyroidism have one or more enlarged parathyroid glands with a single benign adenoma occurring in almost 85% of cases; multiple hypercellular glands are present in about 15% of patients (Black and Utley, 1968; Castleman and Roth, 1978). In modern series, parathyroid carcinoma occurs in less than 1% of cases, and the ectopic secretion of PTH from nonparathyroid tumors is extremely rare.

Hyperparathyroidism may also occur as part of familial syndromes, such as MEN types 1 and 2 (MEN1, MEN2), hereditary hyperparathyroidism-jaw tumor syndrome (HPT-JT), FHH, and neonatal severe hyperparathyroidism (NSHPT).

Molecular oncology

Neoplastic cells contain genetic damage to key growth-regulating genes, thus directly contributing to the abnormal neoplastic phenotype. A cardinal feature of cancers is their clonal, or monoclonal, nature. They arise from a single

† Deceased.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00058-0

precursor cell that has a selective growth advantage over normal cells and whose progeny outgrow them and ultimately make up the tumor. Typically, certain identical patterns of DNA damage are seen in each cell of such a tumor, indicating that important underlying genetic events occurred early before the major proliferation or clinically significant clonal expansion took place. The clonality of tumors also implies that the combination of such events necessary for causing neoplasia occurs only rarely in the large population of cells making up a tissue.

It is important to note the molecular heterogeneity underlying the development of neoplasia (Vogelstein and Kinzler, 2004). Generally, accumulating damage to several distinct genes within the same cell is required for the expression of the complete neoplastic phenotype. Whereas certain genes are implicated in tumors of only one or a few cell types, other genes may be involved in many different types of tumor. However, in most cases, no single gene will be both a necessary and a sufficient neoplastic agent. More commonly, the emergence of a particular tumor type may relate to disruption of specific biochemical pathways that can be achieved by different combinations of mutated genes, resulting in similar cellular and clinical consequences.

Clonal DNA damage in two groups of normal cellular genes contributes to the development of neoplasia. These are protooncogenes and tumor-suppressor genes. Protooncogenes are often involved in the physiological control of cellular growth, proliferation, and differentiation. Conversion of a protooncogene to an "oncogene" is caused by deregulation of the expression of its normal protein product or by the formation of an intrinsically abnormal product. The products of tumor-suppressor genes normally restrain cellular proliferation, and their gene inactivation contributes to neoplasia. Protooncogenes can be activated by mechanisms such as chromosome translocations or inversions, gene amplification, and intragenic point mutation. Inactivation of tumor-suppressor genes can occur via mechanisms like missense or frameshift mutation and larger-scale deletion.

Clonality of parathyroid tumors

Assessments of clonality have been crucial to our understanding of human tumors. In this context, evidence that most cells in a hypercellular mass were derived from a single progenitor cell implies a clinically important selective advantage transmittable to progeny of the cell. Even the potential presence of two to three clones in the same mass, for example, would carry similar implications and have similar relevance for tumorigenic mechanisms and vulnerability to therapeutic agents. Such monoclonality, or even oligoclonality, would stand in marked contrast to the generalized growth of an entire tissue or gland (e.g., the thyroid in Graves' disease) in which all cells are responding equally to a proliferative stimulus with no apparent selective advantage to any subpopulation. The latter types of growth/hyperplasia may be best and most intuitively labeled as "nonclonal," but have typically been termed "polyclonal" in classic literature—this unfortunately may have opened the door to potential confusion of the term with oligoclonality. Evidence for clonal (usually monoclonal but including oligoclonal) growth can be direct—i.e., the observation of acquired tumor-specific DNA/chromosomal defects—or indirect as in X chromosome inactivation assays. Interpretation of the latter carries numerous pitfalls, most of which can result in misleading nonclonal/polyclonal patterns even in a monoclonal tumor. Most notably, aberrant DNA methylation—known to be common in human tumors—is a potential source of such error. Thus, in X-inactivation assays a result of monoclonality is much more definitive than a polyclonal result (Arnold et al., 1988), and building a compelling case for polyclonality requires the additional use of more sensitive and direct methods (Corrado et al., 2015).

In the modern era of molecular genetics, the clonal status of parathyroid tumors was initially examined by use of an X chromosome inactivation method and by the direct demonstration of monoclonal DNA alterations in parathyroid adenomas (Arnold et al., 1988). It was determined that most parathyroid adenomas are monoclonal, a novel result that stood in marked contrast with a prior finding of polyclonality from older X-linked G6PD protein isoform expression methodology (Fialkow et al., 1977; Jackson et al., 1982). That many typical sporadic parathyroid adenomas are monoclonal was rapidly confirmed by direct detection of a variety of monoclonal defects including clonal loss of heterozygosity (Arnold and Kim, 1989; Friedman et al., 1989; Bystrom et al., 1990), clonal cytogenetic abnormality (Orndal et al., 1990), and fluorescence in situ hybridization (Yi et al., 2008), emphasizing that they are true neoplastic outgrowths of a single abnormal cell. It is important to understand that the percentages of adenomas shown to be monoclonal by these methods represent only a solid floor/minimum for the true percentage, given the nondefinitiveness of polyclonal patterns in X-inactivation assays and, in the more direct assays, the fact that a tumor without an identified monoclonal defect might still be revealed as monoclonal if subjected to a more sensitive/comprehensive assay. The advent of massively parallel next-generation DNA sequencing tools in recent years has provided just that sort of increased sensitivity for detecting monoclonal tumor-specific alterations. Of 24 parathyroid adenomas subjected to whole-exome sequencing in two studies (Cromer et al., 2012; Newey et al., 2012), fully 23 adenomas (96%) showed clear evidence of monoclonality—i.e., at least one tumor-specific, somatic mutation/variant, independently verified, marking a major dominant clone. Such powerful and direct evidence for clonal growth of the overwhelming majority of sporadic solitary parathyroid adenomas needs to be expanded with larger numbers (and the identical panel subjected to X-inactivation assays as well), but it does suggest that polyclonal X-inactivation

patterns found in a substantial minority (25%–35%) of solitary adenomas (Arnold et al., 1988; Shi et al., 2014) may nonetheless occur in monoclonal tumors, and this potentially misleading pattern should be interpreted with due caution. That said, an interesting and important hypothesis to consider would be whether a polyclonal X-inactivation pattern in adenomas proven to be monoclonal by direct genetic analysis might represent a marker of widespread aberrant DNA methylation in such tumors, reflecting an alternative pathway of molecular pathogenesis. The finding of predominantly clonal growth in solitary adenomas is consistent with the general experience that surgical removal of such tumors is curative of the disease. Not surprisingly, if cases are selected differently to allow the inclusion of multigland disease, the observed yield of polyclonal/nonclonal X-inactivation patterns is higher (Shi et al., 2018; Arnold et al., 1995); it will be informative to analyze such cases directly for clonal changes to help distinguish truly nonclonal hyperplastic growth from dominant clonal outgrowths on a background of nonclonal hyperplasia. As would be expected, parathyroid carcinomas are also monoclonal (Cryns et al., 1994b; Shattuck et al., 2003a,b; Howell et al., 2003; Cetani et al., 2004; Pandya et al., 2017). In addition, monoclonal and oligoclonal parathyroid tumors are seen in familial MEN1 (Friedman et al., 1989; Thakker et al., 1989; Lubensky et al., 1996), in nonfamilial, sporadic, primary parathyroid hyperplasia (Arnold et al., 1995), and in the refractory secondary or tertiary parathyroid hyperplasia of uremia (Arnold et al., 1995; Falchetti et al., 1993). Therefore, even in parathyroid hyperplasia, which begins with a stimulus for generalized, polyclonal, parathyroid cell proliferation affecting all of a patient's glands, clonal tumors can arise, at least in some glands. Such tumors may be more autonomous and exhibit a more marked dysregulation of PTH secretory control than the hyperplastic, polyclonal glands within the same patient.

An important goal is to identify the specific protooncogenes and tumor-suppressor genes that are clonally activated or inactivated, respectively, in parathyroid tumors. Notable successes in approaching this aim have already been achieved.

Genetic derangements in benign parathyroid tumors

DNA rearrangements are some of the best characterized clonal oncogenic abnormalities, and they frequently involve juxtaposition of cellular protooncogenes with regulatory sequences of other genes. This then results in overexpression or deregulated expression of the protooncogene, converting it to an oncogene. To date the only oncogene solidly established to be a driver in benign parathyroid neoplasia is *cyclin D1/PRAD1*, and the sole tumor-suppressor gene established as a major driver in sporadic parathyroid adenomas is *MEN1*.

Cyclin D1/PRAD1

A subset of parathyroid adenomas contains a tumor-specific DNA rearrangement that separates the 5′ regulatory region of the PTH gene from its protein-coding exons (Fig. 58.1). These tumor cells still possess one intact copy of the PTH gene, which accounts for the expression of PTH by the tumor. The non-PTH gene sequences adjacent to the breakpoint were originally cloned from a genomic DNA library (Arnold et al., 1989) and revealed a then-novel putative oncogene, first called PRAD1, located on chromosome band 11q13. PRAD1 is now most often called cyclin D1 or CCND1 and has been fully established as a key human oncogene. The normal chromosomal cyclin D1 gene contains five exons and four introns

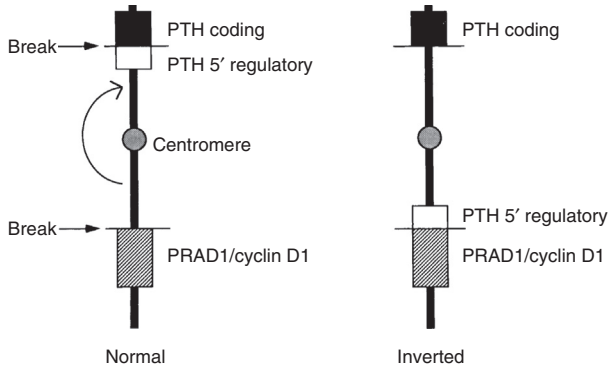

FIGURE 58.1 Schematic diagram of rearrangement of chromosome 11 in parathyroid tumors. In a subset of parathyroid adenomas, a pericentromeric inversion of chromosome 11 is the most likely cause of the observed rearrangement involving the PTH gene and the *PRAD1* gene. Each tumor has another copy of chromosome 11 that bears a normal PTH gene. *Reproduced with permission from Arnold, A. 1993. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. J. Clin. Endocrinol. Metab. 77, 1108–1112.*

spanning approximately 15 kb and is transcribed in a centromeric to telomeric direction (Motokura and Arnold, 1993). In the cases of PTH/cyclin D1 rearrangements characterized to date, the 11q13 breakpoints have occurred from 1 to 450 kb upstream of cyclin D1 exon 1 with the PTH gene 5′ regulatory region and noncoding exon 1 placed upstream of the breakpoint (Friedman et al., 1990; Rosenberg et al., 1991; Mallya et al., 2010) (Fig. 58.2). The overexpression of the cyclin D1 gene is likely caused by its aberrant placement in close proximity to the strong tissue-specific enhancer elements of the PTH gene (Rosenberg et al., 1993; Mallya et al., 2010).

On the order of 8% of parathyroid adenomas have been shown to contain an activated form of the cyclin D1 oncogene (Westin, 2016). However, rearrangement breakpoints on 11q13 associated with overexpression of cyclin D1 in other tumors that occur more than 15−20 kb upstream of the gene could easily have been missed in past studies, and the application of modern molecular cytogenetic approaches could increase the accuracy of this estimate. In addition, it seems plausible that cyclin D1 expression could be deregulated in some parathyroid tumors by rearrangement with genes other than the PTH gene. Thus, previous studies may not have revealed the full frequency with which cyclin D1 deregulation occurs in parathyroid neoplasia. Indeed, studies assessing the cyclin D1 protein product have revealed its overexpression in 20%−40% of parathyroid adenomas (Hsi et al., 1996; Vasef et al., 1999; Tominaga et al., 1999). This overexpression may occur more commonly by a trans-acting regulatory disturbance like that observed for cyclin D1 overexpression in a variety of human cancer cells (Hosokawa and Arnold, 1998) rather than a clonal mutation in one gene allele. However achieved by the cell, such overexpressed cyclin D1 is a potent driver of abnormal parathyroid cell proliferation (Imanishi et al., 2001; Mallya et al., 2005).

Cyclin D1 is a 295-amino acid protein homologous to various members of the cyclin family (Motokura et al., 1991). Cyclins play important roles in the regulation of cell cycle progression, and human cyclins have been grouped into several types based on sequence similarities. Each cyclin appears to regulate the cell cycle at a specific time point by binding to and activating cyclin-dependent kinases (CDKs) (Sherr, 1996; Sherr et al., 2016). Expression of these cyclins is cell cycle phase-dependent and controlled by both transcriptional and posttranscriptional mechanisms. Cyclin D1 is a key regulator of the critical G1−S phase transition in the cell cycle. In so doing, its major CDK partners are CDK4 or CDK6 depending upon the tissue type examined. Evidence indicates that cyclin D1 has other cellular functions as well, mediated through CDK-independent pathways (Bernards, 1999; Arnold and Papanikolaou, 2005; Ewen and Lamb, 2004; Fu et al., 2004; Casimiro et al., 2015).

Adding to the strong genetic evidence for cyclin D1's role as a parathyroid oncogene, animal modeling has provided direct experimental confirmation that cyclin D1 overexpression is capable of driving parathyroid tumorigenesis. A transgenic mouse model for parathyroid neoplasia was generated (Imanishi et al., 2001) in which the cyclin D1 gene is under the control of the regulatory region of the PTH gene, mimicking the rearrangement and resultant overexpression observed in human tumors. These mice develop parathyroid enlargement and increased serum calcium and PTH levels, and their study has illuminated the relationship in hyperparathyroidism between abnormal parathyroid proliferation and the biochemical phenotype (Imanishi et al., 2001; Mallya et al., 2005). Finally, cyclin D1 is being vigorously pursued as a target for antineoplastic therapy, noting its major role in human breast cancer, lymphoma, and squamous cell cancers. If

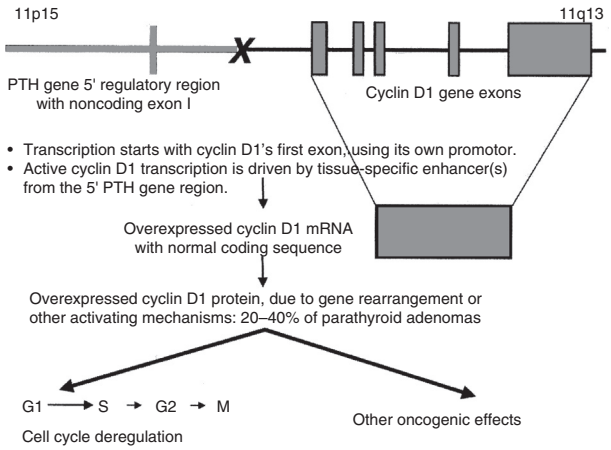

FIGURE 58.2 Diagram of directly observed molecular structure of the PTH/cyclin D1 (PRAD1) DNA rearrangement and its functional consequences. *Modified with permission from Arnold, A. 1993. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. J. Clin. Endocrinol. Metab. 77, 1108−1112.*

such efforts are successful, an anti−cyclin D1 agent would also be expected to have efficacy against the cyclin D1−driven subset of parathyroid tumors. In addition, therapeutic agents that inhibit CDK4 and CDK6 have improved the progression-free survival in breast cancer and been approved for clinical use (Sherr et al., 2016).

Tumor-suppressor genes: multiple endocrine neoplasia type 1 and cyclin-dependent kinase inhibitors

The MEN1 syndrome, which is inherited in an autosomal dominant fashion, is characterized classically by tumors of the parathyroids, pancreatic islets, and anterior pituitary. It was established by genetic mapping studies in families affected by MEN1 that the gene responsible is on chromosome 11q13 (Larsson et al., 1988). Early evidence that the *MEN1* gene is a tumor-suppressor gene was provided by the demonstration of somatic genetic alterations in MEN1 tumors that inactivate one allele of a gene region at 11q13 and so reveal the inherited *MEN1* mutation on the other allele (Fig. 58.3). In fact, allelic loss of polymorphic marker DNAs from this region of chromosome 11 has been found in the majority of MEN1-associated tumors including those of the parathyroid (Thakker, 2010).

The *MEN1* gene was identified by positional cloning (Chandrasekharappa et al., 1997; European Consortium on MEN1, 1997). Almost 600 independent germline mutations scattered throughout the protein-coding region have been identified (Lemos and Thakker, 2007; Concolino et al., 2015). There is no genotype and phenotype correlation. Somatic mutations are common in sporadic parathyroid adenoma (12%−35%) (Heppner et al., 1997; Carling et al., 1998; Farnebo et al., 1998a; Tanaka et al., 2002; Cromer et al., 2012; Newey et al., 2012) and also occur in gastrinoma, insulinoma, lung carcinoid, and anterior pituitary tumors. *MEN1* mutations have been found in familial isolated hyperparathyroidism (FIHP) (Concolino et al., 2015) and very rarely have been associated with parathyroid carcinoma (Cinque et al., 2017a,b). Over 70% of mutations are clearly inactivating, being nonsense or frameshift, leading to a truncated product. This would be consistent with *MEN1* acting as a tumor-suppressor gene and a lack of menin protein caused by the loss of both alleles leading to tumor development. The human gene encodes a 610-amino acid protein, although it should be noted that in addition to this originally identified protein, there is a 615-amino acid form derived from an alternatively spliced transcript. In most publications, mutations are numbered according to the 610-amino acid protein. Confusingly, however, in most

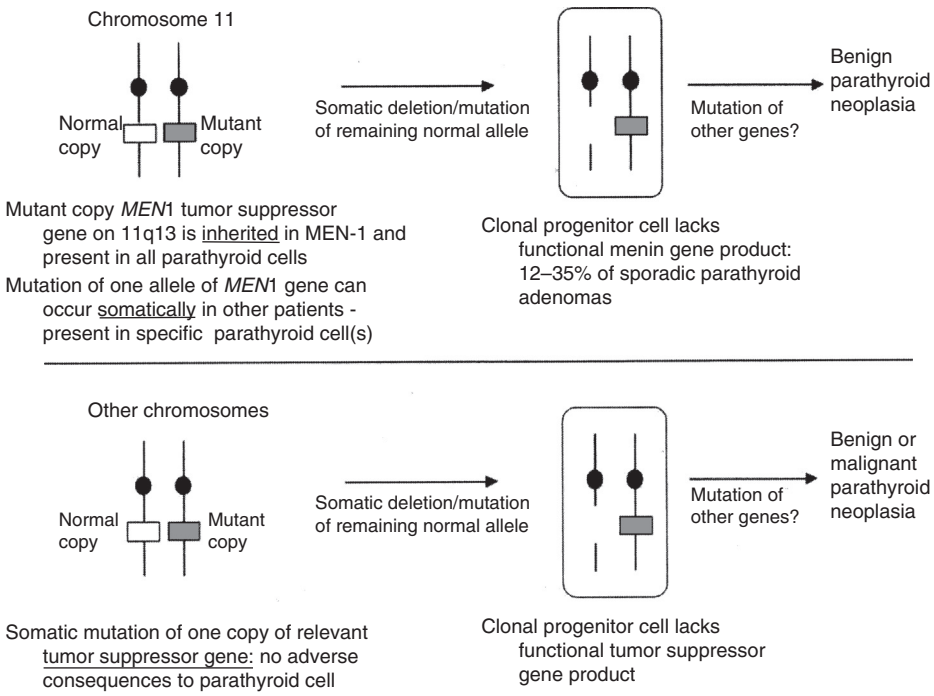

FIGURE 58.3 Schematic diagram illustrating the established (for multiple endocrine neoplasia type 1, *MEN1*) and hypothesized roles of inactivation of classic tumor-suppressor genes as contributory mechanisms in parathyroid neoplasia. A similar scheme applies to the role of the *HRPT2/CDC73* tumor-suppressor gene in the pathogenesis of parathyroid carcinoma. *Modified with permission from Arnold, A. 1993. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. J. Clin. Endocrinol. Metab. 77, 1108−1112.*

databases (such as ExAC and gnomAD) the numbering is according to the 615-amino acid form. The same version of menin must be used for comparative purposes after amino acid 148.

Two main nuclear localization signal sequences are present at the COOH-terminal portion of the menin protein, which is predominantly located in the nucleus (Guru et al., 1998; Kaji et al., 1999). The first protein shown to be a menin-interacting protein was the activator protein 1 factor, JunD, with resultant downregulation of JunD-activated transcription (Agarwal et al., 1999). Because JunD is antimitogenic in contrast to other Jun and Fos family members, and menin is a tumor suppressor, this appeared to be paradoxical. Further studies in vitro have suggested that the functions of JunD as a growth suppressor require interaction with menin, and that JunD is a growth promoter if menin is absent or inactive (Agarwal et al., 2003). The level of menin changes throughout the cell cycle. Pituitary cells synchronized at the G1−S-phase boundary express menin at a lower level than G0−G1-synchronized cells (Kaji et al., 1999). The expression of menin increases as the cell enters S phase, at which time JunD expression also increases. Cells synchronized at the G2−M phase express lower levels of menin.

Menin upregulates the CDK inhibitors (CDKIs), p18 and p27, important for cell cycle regulation (Karnik et al., 2005; Milne et al., 2005). Menin reexpression in *Men1*-deficient cells blocks the transition from G0/G1 to S phase of the cell cycle and increases apoptosis (Hussein et al., 2007). Mice dually deficient in p18 and p27 develop a range of endocrine tumors representing those found in MEN1 and MEN2 syndromes (Franklin et al., 2000). Mice with knockout of genes that regulate the cell cycle (Rb, p53, p18, p27, CDK2, CDK4) have been placed on the Men1+/− background (Bai et al., 2007; Loffler et al, 2007a, 2012). Overall, these studies indicate that decreased p18 and increased CDK4 may contribute further to MEN1-associated tumors upon menin loss, whereas the other cell cycle regulators are functioning in the same pathway as menin.

Mixed lineage leukemia (MLL) proteins are members of the lysine methyltransferase (KMT) family and comprise MLL1/KMT2A and MLL2/KMT2B. Menin functions as a scaffold protein and binds MLL proteins in histone methyltransferase complexes that stimulate H3K4me3, which increases p18 and p27 for cell cycle control, the *Hox* gene expression important for early development, and cell proliferation and differentiation (Hughes et al., 2004; Milne et al., 2005; Yokoyama et al., 2004; Yokoyama and Cleary, 2008). Menin may be involved in telomere biology and DNA replication and repair. Menin interacts with several transcription factors including Smads, JunD, and NF-κB and modulates their activities (see Hendy et al., 2009a; Matkar et al., 2013; Agarwal, 2017 for further details of menin functions and interacting proteins). Menin is a Smad3-interacting protein, and inactivation of menin blocks transforming factor-β (TGF-β) and activin signaling, antagonizing their growth-inhibitory properties (as well as the inhibition of prolactin expression) in anterior pituitary cells (Kaji et al., 2001; Lacerte et al., 2004). In cultured parathyroid cells, menin inactivation achieved by menin antisense oligonucleotides leads to loss of TGF-β inhibition of cell proliferation and PTH secretion (Sowa et al., 2004). Moreover, TGF-β does not affect (decrease) the proliferation and PTH production of parathyroid cells from MEN1 patients (Sowa et al., 2004; Naito et al., 2006). Loss of various TGF-β signaling pathway components by genetic or epigenetic means is common in cancer and is likely to be important in MEN1 tumorigenesis (Canaff et al., 2012a) despite the fact that thus far, no acquired clonal mutations, insertions, or microdeletions in the Smad3 gene have been detected in a series of sporadic parathyroid adenomas and enteropancreatic tumors (Shattuck et al., 2002).

The three-dimensional structure of menin is known, and this has aided its functional analysis. The crystallographic structure of the starlet sea anemone *Nematostella* menin was deciphered initially (Murai et al., 2011), and then a structure of human menin was determined by homology modeling (Canaff et al., 2012a, b) followed by the elucidation of the crystallographic structure of human menin itself (Huang et al., 2012). To facilitate the crystallization of the molecule, modified forms of menin were generated in which some unstructured parts of menin were deleted. Menin is predominantly an α-helical protein with the core comprising three tetratricopeptide motifs flanked by two α-helical bundles and covered by a β-sheet motif. A large central cavity binds the MLL proteins important for histone methyl transferase activity as well as binding the JunD transcription factor (Murai et al., 2011; Huang et al., 2012). The binding site for Smad transcription factors important for TGF-β ligand family member action is distinct from the central cavity and located on the exposed surface neighboring the β-sheet motif (Canaff et al., 2012a).

Mice heterozygous for genetic ablation of the *Men1* gene develop endocrine tumors similar to those of human MEN1 patients (Crabtree et al., 2001; Bertolino et al., 2003a; Loffler et al., 2007b; Harding et al., 2009). Parathyroid gland-specific deletion of the mouse *Men1* gene results in parathyroid neoplasia and hypercalcemic hyperparathyroidism (Libutti et al., 2003). In mice (and humans), tissue expression of menin is widespread throughout development and into adult life and occurs early in fetal life. In mice, homozygous deletion of *Men1* is embryonic lethal. The affected fetuses die at midgestation with defects in multiple organs (Bertolino et al., 2003b). This may reflect defective TGF-β/bone morphogenetic protein ligand signaling or *Hox* gene expression brought about by the epigenetic histone methyl transferase mechanisms alluded to previously.

Conditional knockouts of Men1 in tissues other than those known to be involved in the MEN1 disorder have provided insight into the physiological actions of menin as opposed to its tumor-suppressor actions revealed in MEN1. For example, evidence has been provided for the importance of menin for bone development and maintenance (Kanazawa et al., 2015; Liu et al., 2017). Furthermore, studies of the bone disease of patients with MEN1 versus those with sporadic hyperparathyroidism suggested that the bone disease of the former is more severe than that of the latter despite the fact that the levels of circulating PTH of the former are lower than in the latter group (Eller-Vainicher et al., 2009; Lourenco et al., 2010). Therefore, while menin has been considered haplosufficient with respect to tissue development and function, for tissues such as bone this might not be the case, with haploinsufficiency being suggested by decreased bone volume and trabecular number in Men1+/− mice heterozygous for menin loss (Hendy et al., 2017; Abi-Rafeh et al., 2017).

About 30% of menin mutations are missense (or have small insertions or deletions) and are found throughout the entire sequence with no clear-cut hotspots. It might have been anticipated that analysis of missense mutations would provide insight into which of many proteins that menin interacts with are actually critical for MEN1 tumorigenesis when the interaction is lost; with some exceptions, however, this promise has yet to be fulfilled. To some extent this is because most (but not all) missense menin mutants are markedly unstable, targeted to the ubiquitin−proteasome pathway, and expressed at very low levels if at all (Yaguchi et al., 2004; Shimazu et al., 2011: Canaff et al., 2012b) (see Fig. 58.4).

The frequency of *MEN1* coding region mutations in several kindreds with a variant of MEN1 in which only parathyroid and pituitary tumors develop, is very low (10%) versus typical MEN1 kindreds (75%). In one case of this MEN1 variant in which *MEN1* mutation was not detected, a germline mutation of the *CDKN1B* gene encoding p27 was identified (Pellegata et al., 2006). Heterozygous mutations have been identified in 2% of these MEN1-variant cases and classified as the MEN4 disorder (Pellegata, 2012). Also, less than 1% of MEN1-like cases carry p15, p18, or p21 heterozygous mutations (Agarwal et al., 2009; Thakker, 2014). In addition, germline mutations in *CDKN1B* and the genes encoding p15, p18, and

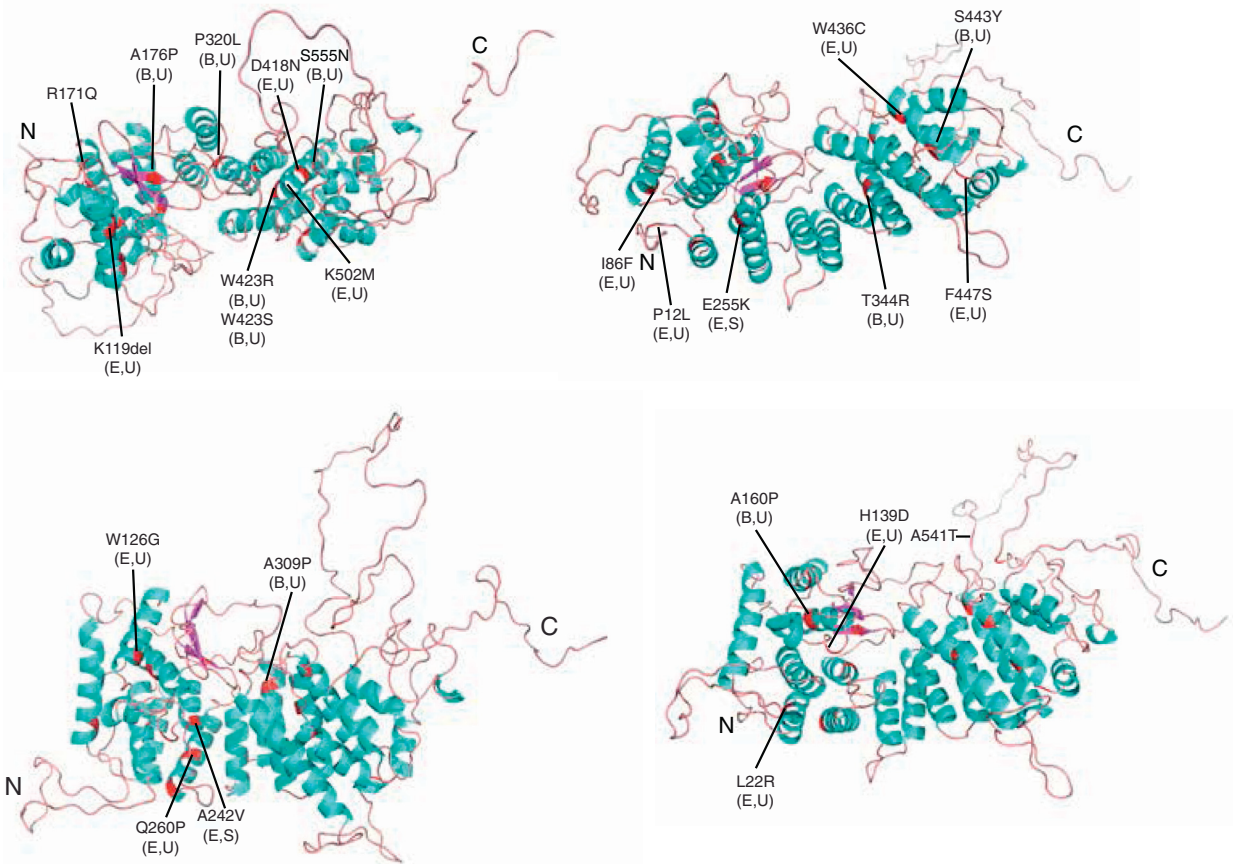

FIGURE 58.4 Positions of missense mutations on a homology model of human menin encoded by the multiple endocrine neoplasia type 1 gene. The majority of the mutants are unstable and poorly expressed but their expression and activity may be restored by siRNA against components of the chaperone machinery that directs the mutants to the proteasome (see Canaff et al., 2012b). E, exposed; B, buried; U, unstable; S, stable.

p21 may be found in sporadic primary hyperparathyroidism (Costa-Guda et al, 2011, 2013a; Borsari et al., 2017), and more frequent loss of p27 expression and cellular mislocalization is associated with MEN1 mutations in sporadic parathyroid adenomas (Borsari et al., 2017).

Candidate oncogenes and tumor-suppressor genes

Comparative genomic hybridization—a molecular cytogenetic technique in which the entire tumor genome is screened for chromosomal gains and/or losses—has identified amplified regions on several chromosomes (most consistently 7, 16, and 19). These observations suggest the presence of novel parathyroid oncogenes (Palanisamy et al., 1998; Agarwal et al., 1998; Farnebo et al., 1999; Dwight et al., 2002) in these locations that remain to be identified.

Besides loci on chromosome 11, several other regions of nonrandom clonal allelic loss have been documented in parathyroid adenomas, pointing to the location of novel tumor-suppressor genes. This finding of the involvement of multiple chromosomal regions, which include 1p (Cryns et al., 1995; Williamson et al., 1997), 1q, 6q, 9p, and 15q (Tahara et al., 1996a, b), emphasize the molecular heterogeneity of parathyroid adenomatosis.

Comparative genomic hybridization has confirmed the chromosomal losses identified by loss of heterozygosity analysis (allelotyping) (Palanisamy et al., 1998; Agarwal et al., 1998; Farnebo et al., 1999). One common defect uncovered to date involves allelic loss on chromosome 1p (Cryns et al., 1995). Interestingly, chromosome 1p loss occurs in several other neoplasms including medullary thyroid carcinomas and pheochromocytomas that occur in association with MEN2A inherited cancer syndrome, of which parathyroid tumors are also a part. Benign parathyroid tumors are found in 10%−20% of MEN2A patients. This pattern of allelic loss is consistent with the existence of a tumor-suppressor gene(s) on 1p, whose loss or inactivation is pathogenetically important. Numerous candidate genes are present in this region, but the involvement of any of them in the development of parathyroid or other types of tumors remains to be established. Some candidates on 1p, such as genes for the p18 CDKI and RAD54, have been excluded as commonly involved parathyroid tumor suppressors (Tahara et al., 1997; Carling et al., 1999a). Mutations within the 9p region of candidate genes encoding the p16 and p15 CDKIs do not appear to be frequently involved in parathyroid tumorigenesis (Tahara et al., 1996b). A major goal for future work is the identification of the entire constellation of oncogenes and tumor-suppressor genes that contribute to the development of parathyroid adenomatosis.

Further genetic aspects

Some genes that play an important role in the pathogenesis of other tumor types might have been expected to be involved in the pathogenesis of benign parathyroid adenomas. However, candidate genes such as *RAS* (Friedman et al., 1990), p53 (Yoshimoto et al., 1992; Cryns et al., 1994a; Hakim and Levine, 1994) and RB (Cryns et al., 1994b) seem rarely, or not at all, to contribute to the development of benign adenomas. The development of primary hyperparathyroidism occurs with increased frequency in individuals exposed to ionizing radiation of the neck. Thus, mutations in genes involved in DNA repair and recombination may contribute to parathyroid tumorigenesis irrespective of the actual involvement of irradiation. Such candidates include the *RAD51* and *RAD54* genes on chromosomes 15q and 1p, respectively, within regions that demonstrate allelic loss in parathyroid adenomas. However, no evidence for a role of somatic inactivation of these particular genes in parathyroid neoplasia has been found (Carling et al., 1999a, b).

In some cases, those genes responsible for the rare inherited predisposition to a particular tumor also play a role in the development of the more common sporadic type. The *MEN1* gene, as detailed earlier, has proved to be such an example. Germline gain-of-function mutations in the *RET* protooncogene cause MEN2 (Eng et al., 1996). This made the *RET* gene, which encodes a tyrosine kinase receptor, a candidate for involvement in nonfamilial hyperparathyroidism. However, although MEN2-type *RET* mutations have been implicated in the pathogenesis of some sporadic medullary thyroid carcinomas and pheochromocytomas, there is no evidence of these *RET* mutations in sporadic parathyroid adenomas (Pausova et al., 1996; Kimura et al., 1996). Thus, while RET is expressed in both MEN2A parathyroid tumors and in sporadic adenomas (Pausova et al., 1996; Kimura et al., 1996), and parathyroid disease is an integral part of the MEN2A syndrome, MEN2-type mutations in *RET* rarely if ever play a role in the pathogenesis of sporadic parathyroid tumors. Mutations within the coding region of glial cell−derived neurotrophic factor, one of the RET ligands, do not appear to play a role in the genesis of MEN2 neoplasms or in sporadic neuroendocrine tumors such as parathyroid adenomas (Marsh et al., 1997). An interesting candidate parathyroid tumor suppressor, the vitamin D receptor, encoded by the *VDR* gene, is also lacking in evidence for a direct pathogenetic driver role by specific clonal mutation (Brown et al., 2000; Samander and Arnold, 2006).

Components of the Wnt signaling pathway, implicated in other forms of tumorigenesis, are candidates for involvement in parathyroid neoplasia. In the absence of Wnt signaling, β-catenin encoded by the *CTNNB1* gene is phosphorylated and

subsequently degraded by a protein complex consisting of axin, adenomatous polyposis coli (APC), and glycogen synthase kinase-3β (GSK3β). Upon Wnt binding to its cell-surface frizzled receptor and a coreceptor such as LRP5, the resultant signaling causes the inhibitory complex to be dissociated, and unphosphorylated (active) β-catenin accumulates in the cytoplasm and the nucleus where it activates cell growth-promoting genes. Virtually all *CTNNB1* mutations identified in human tumors are located in exon 3 (the GSK3β recognition motif) and affect serine-threonine phosphorylation sites or adjacent residues. Studies of Swedish primary hyperparathyroid patients found a somatic homozygous *CTNNB1* S37A mutation in 9 of 194 adenomas studied (Bjorklund et al., 2007a, 2008). Aberrant β-catenin immunohistochemical staining was found in all tumors irrespective of mutation status. In other studies, nearly 600 additional parathyroid adenomas have been examined without the identification of any *CTNNB1* S37A mutations (Semba et al., 2000; Ikeda et al., 2002; Costa-Guda and Arnold, 2007; Juhlin et al., 2009; Cetani et al., 2010; Haglund et al., 2010). A heterozygous somatic *CTNNB1* S33C mutation was identified in distinct patients from two different cohorts (Guarnieri et al., 2012a; Starker et al., 2012). A heterozygous mutation would be more consistent (than a homozygous one) with *CTNNB1*'s direct role as an oncogene as observed in other tumor types. Overall, *CTNNB1*'s mutation frequency in parathyroid adenomas is very low ($< 2\%$), and in studies not including the initial Swedish cohorts, only 2 parathyroid adenomas of 115 examined had abnormal β-catenin immunohistochemical staining (Ikeda et al., 2002; Starker et al., 2012), more consistent with the observed mutation frequency observed in most studies. Aberrant splicing of the Wnt coreceptor LRP5 resulting in increased expression of β-catenin has been described in parathyroid adenomas (Bjorklund et al., 2007b). Lastly, loss of expression for the Wnt pathway components APC and GSK3β has been noted in parathyroid carcinoma, although altered expression of β-catenin and cyclin D1 was not found (Juhlin et al., 2009). Hence, the role of Wnt signaling pathway components in parathyroid tumorigenesis merits further study.

Calcium-sensing receptor and associated proteins

The calcium-sensing receptor (CaSR) expressed in the parathyroid and kidney tubule serves as the body's calciostat for modulating the functions of those cell types that participate in extracellular Ca^{2+} homeostasis (Brown et al., 1993; Brown, 2013; Hendy, 2019). CaSR is a member of G-protein-coupled receptor (GPCR) family C, a GPCR family that includes metabolic glutamate, γ-aminobutyric acid B, and taste and odorant receptors. The single-copy human *CASR* gene has two promoters, P1 and P2, that drive transcription from exon 1A and 1B, respectively, and the alternative transcripts splice to the common exon 2 that has the translation initiation ATG codon (Hendy et al., 2013a). Exons 2 to 7 encode the CaSR protein of 1078 amino acids. Both promoters have vitamin D response elements (Canaff & Hendy, 2002) and cis-acting elements responsive to the parathyroid-specific transcription factor, glial cells missing-2 (GCM2) (Canaff et al., 2009; Hendy and Canaff, 2016). It has been reported that more than half the parathyroid glands of patients with primary and severe uremic secondary hyperparathyroidism show reduced *CASR* expression (Kifor et al., 1996; Farnebo et al., 1997, 1998b; Gogusev et al., 1997; Chikatsu et al., 2000). The reduced levels of vitamin D receptor (VDR) observed in parathyroid tumors may contribute in part to decreased *CASR* expression (Hendy, 2018). A mutation in a gene involved in calcium set point control (Balenga et al., 2017; Mingione et al., 2017) might secondarily stimulate proliferation until the serum calcium concentration surpasses the abnormal set point (Parfitt, 1994). Data indicating that the growth rate of parathyroid tumors is generally low but must have been higher earlier in their development (Parfitt et al., 1994) are consistent with this hypothesis. Interestingly, however, calcium regulatory abnormalities found in transgenic mice with cyclin D1−driven hyperparathyroidism show that mutations in "set point" genes need not be the primary instigators in this disease (Imanishi et al., 2001; Mallya et al., 2005).

The human CaSR has a 19-amino acid signal peptide targeting it to the endoplasmic reticulum (Pidasheva et al., 2005; Hu and Spiegel, 2007), and the mature protein has a 593-amino acid extracellular domain (ECD), a 250-amino acid transmembrane domain (TMD), and a 216-amino acid cytoplasmic tail. In the endoplasmic reticulum (Pidasheva et al., 2006) the receptor dimerizes via both covalent and noncovalent interactions and undergoes immature and mature glycosylation before trafficking to the cell surface in its mature dimeric state (Breitwieser, 2013). CaSR interacts with several diverse proteins that may aid its trafficking to the cell surface, maintain its expression there, and facilitate its signaling, endocytosis, and recycling to the cell surface (Ray, 2015). The ECD of each CaSR monomer has a bilobed Venus flytrap−like structure (VFT). Immediately following the VFT is a cysteine-rich domain and then a linker sequence before the TMD. There is marked cooperativity of binding of Ca^{2+} with the receptor, and several Ca^{2+} binding sites have been proposed, most within the VFT domain.

The crystal structure of the entire ECD (the VFT and the cysteine-rich domain) of CaSR has been determined in resting and active conformations (Geng et al., 2016). Initial binding of an amino acid, in this case L-tryptophan, was essential for the fully active structure to be achieved upon subsequent cation (Ca^{2+}) binding. Multiple novel binding sites were revealed

for Ca^{2+} and PO_4^{3-} ions, with both being crucial for structural integrity of the receptor. Ca^{2+} ions stabilize the active state, and PO_4^{3-} ions reinforce the inactive conformation. In a second study, the crystal structure of the ECD VFT (without the cysteine-rich domain) of human CaSR was determined in the closed state bound with Mg^{2+} (Zhang et al., 2016). A novel high-affinity coagonist, a tryptophan derivative, bound in the hinge region between the two lobes of the VFT, was identified in the crystal. The Ca^{2+} ion is directly involved in receptor activation by stabilizing the unique homodimer interface between membrane proximal lobes 2 of the VFT and the cysteine-rich domains in the active state. Exactly how ligand-activated conformational changes alter the structure of the heptahelical TMD, initiating coupling to G proteins, remains to be elucidated.

Besides Ca^{2+} and Mg^{2+}, CaSR has many other orthosteric ligands that bind within the ECD including other polycations, charged polyamines, and certain L-amino acids that positively modulate sensitivity of CaSR to Ca^{2+} (Conigrave and Ward, 2013). The polycationic agonists have been termed type I agonists and can activate the receptor in the absence of Ca^{2+}. In contrast, type II agonists require some Ca^{2+} (or an equivalent type 1 agonist) to be present to activate CaSR. With respect to binding by anions, such as phosphate, that stabilize the inactive conformation, it can be noted that metabolic balances of Ca^{2+} and PO_4^{3-} are linked through hormones such as PTH, $1,25(OH)_2D$, and the phosphatonin, fibroblast growth factor-23, that control the homeostasis of both ions. CaSR may also regulate phosphate homeostasis independently of other factors, but further studies will be required to evaluate CaSR as a "phosphate sensor."

At the plasma membrane, CaSR can couple to the G proteins Gq/11, Gi/o, G12/13, and in rare cases, Gs (Conigrave and Ward, 2013). The respective signaling pathways activated are phospholipase C, increasing diacyl glycerol and inositol trisphosphate production, inhibition of adenylate cyclase or activating phosphodiesterase, activation of Rho kinases, and in rare cases, activation of adenylate cyclase.

Extracellular Ca^{2+} fluctuations just above or below the normal range do not alter CaSR expression in the parathyroid gland and kidney, consistent with the requirement to maintain the expression of CaSR—the calciostat—at a constant level at these extracellular Ca^{2+} concentrations. In normal rats, no evidence was found for extracellular Ca^{2+} modulation of parathyroid gland CaSR expression (Rogers et al., 1995; Brown et al., 1996). An additional element of the regulation of CaSR by extracellular Ca^{2+} relates to the reported ability of the ligand to stimulate trafficking of CaSR from intracellular stores to the plasma membrane by so-called agonist driven insertional secretion (Breitwieser, 2013). Expression at the cell surface increases, whereas overall CaSR may not necessarily be changed.

Calcimimetics are low-molecular-weight positive allosteric modulators (PAMs) of CaSR. One calcimimetic, cinacalcet (Sensipar, Mimpara), is used clinically to suppress severe secondary hyperparathyroidism in patients with end-stage renal disease on hemodialysis and in hypercalcemic patients with primary hyperparathyroidism (including parathyroid carcinoma) in whom curative parathyroidectomy is not possible or appropriate (Nemeth and Shoback, 2013). PAMs bind in the TMD of CaSR and stabilize the receptor in a more active state. Phenylalkylamine calcimimetics such as cinacalcet bind in the TMD in a cavity that overlaps a putative Ca^{2+} binding site and the extracellular loops (Leach et al., 2016). Calcilytics such as the amino alcohol NPS-2143 that are negative allosteric modulators also bind within the TMD and induce a more inactive conformation (Nemeth and Goodman, 2016). The pockets for cinacalcet and NPS-2143 overlap to an extent, with some of the receptor amino acids contacted being common and others not.

Activation of CaSR on parathyroid chief cells inhibits PTH synthesis and suppresses parathyroid secretion. CaSR-mediated change in PTH gene expression is the result of a change in PTH mRNA stability rather than in PTH gene transcription. High extracellular calcium recruits a degradation complex comprising both endo- and exoribonucleases to the 3′-untranslated region of the PTH mRNA to destabilize it (Naveh-Many, 2010). Extracellular calcium also exerts a posttranslational effect on PTH expression by promoting cleavage of intact PTH stored within secretory vesicles to yield fragments comprising the mid- and COOH-terminal regions, some of which are only truncated at the far NH_2-terminus (Kawata et al., 2005). There is evidence that the inhibition of CaSR downstream signaling is not just due to reversal or relaxation of CaSR activation, but rather that CaSR inhibition by hypocalcemia is an active process that requires the involvement of microRNAs and the proteins they control (Shilo et al., 2015).

With respect to ligand-bound CaSR inhibiting PTH secretion, activating Gq/11 is essential because mice with knockout of both these G proteins in the parathyroid gland have severe hyperparathyroidism similar to that present in mice homozygous for global knockout of *Casr* (Wettschureck et al., 2007). Confirmation that the Gq-coupled pathway may be important in part comes from the finding that transgenic mice specifically overexpressing a dominant-negative Gαq loop minigene in parathyroid chief cells had increased serum PTH as well as increased PTH mRNA and cellular proliferation (Pi et al., 2008). The abnormalities that reflected reduced sensitivity of the parathyroid gland to extracellular calcium were similar to those of heterozygous *Casr*-knockout mice (Ho et al., 1995). In humans, the parathyroid expresses predominantly *GNA11* rather than *GNAQ* (Nesbit et al., 2013a).

Downstream signaling pathways involved in extracellular calcium-regulated PTH release may include products of the 12- and 15-lipoxygenase pathways of arachidonate metabolism and/or $ERK_{1/2}$ that may be mediated by the interaction of CaSR and $G_{i/o}$ (Corbetta et al., 2002). A further downstream mechanism may involve rearrangement of the cytoskeleton to block access of PTH-containing secretory vesicles to the plasma membrane (Quinn et al., 2007).

The apparent link between parathyroid calcium-sensing and proliferative pathways as evidenced by marked parathyroid hyperplasia of mice with global knockout of *Casr* (Ho et al., 1995) suggested that somatic alterations in the *CASR* gene could be tumorigenic in sporadic parathyroid tumors. However, several studies have failed to document somatic mutation of the *CASR* gene as a significant factor in parathyroid tumorigenesis (Hosokawa et al., 1995; Thompson et al., 1995; Degenhardt et al., 1998; Cetani et al., 1999).

Familial hypocalciuric hypercalcemia

FHH is classically described as an autosomal dominant condition characterized by lifelong mild-to-moderate elevations of serum calcium concentrations in association with normal or mildly raised serum PTH concentrations and low urinary calcium excretion (Marx et al., 1981; Law et al., 1985; Marx, 2018). FHH is genetically heterogeneous and at present comprises three subtypes (FHH1−3). Two-thirds of FHH cases are the FHH1 subtype, which is due to heterozygous inactivating mutations affecting G-protein-coupled CaSR encoded by the *CASR* gene (3q13.3−21.1) (Pollak et al., 1993). FHH2 is due to heterozygous inactivating mutations of the G-protein alpha-11 subunit (Gα11) encoded by the *GNA11* gene (19p13.3) (Nesbit et al., 2013a). FHH3 is caused by mutations of the adapter-related protein complex 2 (AP2) sigma subunit (AP2σ) encoded by the *AP2S1* gene (19q13.3) (Nesbit et al., 2013b). Other FHH cases negative for *CASR*, *GNA11,* and *AP2S1* mutations have been described (Vargas-Poussou et al., 2016).

With respect to FHH1, individuals homozygous (or compound heterozygous) for *CASR* mutations present with NSHPT with marked parathyroid hypercellularity (Pollak et al., 1994), and the tumors constitute polyclonal growths rather than monoclonal neoplasms (Corrado et al., 2015). Almost 200 mutations in *CASR* have been identified in FHH1 and NSHPT patients (Hendy et al., 2009; Guarnieri et al., 2010; Hannan et al., 2012; Vargas-Poussou et al., 2016). In FHH1, lifelong hypercalcemia is accompanied by normal or elevated serum PTH levels as in mild sporadic primary hyperparathyroidism (PHPT). However, renal and skeletal manifestations of sporadic PHPT are generally absent. A family history and hypocalciuria—calcium-to-creatinine clearance ratios (< 0.01) that are low relative to the filtered load of calcium—are important in distinguishing FHH patients from those with a biochemical diagnosis of PHPT. With rare exceptions, subtotal parathyroidectomy in FHH cases does not achieve normocalcemia, and therefore surgical intervention is generally contraindicated. However, NSHPT is life-threatening and requires timely parathyroidectomy in newborns. The mutations are scattered throughout the CaSR protein sequence, although with some clustering in the extracellular domain at putative Ca^{2+}-binding sites and within parts of the TMD. Eighty-five percent of mutations are missense with some frameshift, nonsense, in-frame, and splicing mutations represented. Some mutations exert a dominant-negative effect on wild-type CaSR, and such cases may present in a more severe phenotype than loss-of-activity mutations. Calcimimetics have been used successfully in rare cases of FHH1 that present symptomatically to reduce serum calcium levels (Timmers et al., 2006). In addition, calcimimetics have provided clinical benefit in neonatal hyperparathyroid cases with heterozygous *CASR* mutations (Reh et al., 2011). However, calcimimetics are ineffective in NSHPT cases caused by biallelic deletion *CASR* mutations (Atay et al., 2014). In-depth views of the use of calcimimetics in patients harboring *CASR* mutations are available (Mayr et al., 2016; Marx, 2017).

With respect to FHH2, in 2013 Nesbit and colleagues (Nesbit et al., 2013a) reported the identification of heterozygous germline mutations in *GNA11* encoding Gα11 in affected members of a kindred with FHH2, and one unrelated FHH patient. *GNA11* was selected using a candidate gene approach because it is located at the locus of the FHH2 trait. Since that time, other FHH2 mutations have been identified (Gorvin et al., 2016, 2018), and some heterozygous activating mutations in autosomal dominant hypocalcemia type 2 (Mannstadt et al., 2013; Nesbit et al., 2013a; Li et al., 2014; Piret et al., 2016) have been identified, emphasizing the importance of Gα11 coupling for CaSR action. Somatic activating mutations of Gα11 cause uveal melanomas. Clinically, FHH2 patients present a milder phenotype than that of FHH1 patients, with a lower serum calcium concentration. In vivo administration of cinacalcet in an FHH2 patient harboring a *GNA11* inactivating mutation normalized the serum calcium concentration (Gorvin et al., 2018).

The FHH trait had also been mapped in two unrelated kindreds to a third locus distinct from that for FHH1 and FHH2. Ultimately, heterozygous germline mutations in the *AP2S1* gene were shown to underlie this subtype, FHH3 (Nesbit et al., 2013b). The *AP2S1* gene encodes the σ-subunit of the adaptor-related protein complex 2 critical for clathrin-mediated endocytosis of cell-surface proteins including GPCRs. AP2 is a heterotetramer of α-, β-. μ-, and σ-subunits and links clathrin to vesicle membranes by binding to tyrosine- and dileucine-based motifs of membrane-associated cargo proteins.

Exome capture and high-throughput sequence analysis of affected individuals of the FHH3 kindreds identified mutations of Arg15 in AP2σ. Further heterozygous alterations, all affecting Arg15 (Arg15Cys, Arg15His, and Arg15 Leu), were identified in subsets of unrelated FHH individuals (Nesbit et al., 2013b; Fujisawa et al., 2013; Hendy et al., 2014; Tenhola et al., 2015; Hannan et al., 2015; Vargas-Poussou et al., 2016). It is predicted that these FHH3-causing Arg15 mutations disrupt an interaction between the AP2 complex and the intracellular carboxyl terminus of CaSR, thereby impairing endocytosis of CaSR. Normally, CaSR coupled to G11/q proteins continues to be active, as the complex is endocytosed, and this activity is lost with the mutated AP2σ proteins that act in a dominant-negative manner (Gorvin, 2018). Administration of cinacalcet to FHH3 patients has been successful in lowering serum calcium concentration (Tenhola et al., 2015; Howles et al., 2016). This was the case for all three Arg15 mutations (Howles et al., 2016).

The few reported individuals with FHH2 appear to present with a milder phenotype than that of FHH1. More conclusive evidence of similarities and differences between FHH1 and FHH3 has been obtained by studying two relatively large FHH3 cohorts (Hannan et al., 2015; Vargas-Poussou et al., 2016). FHH3 patients present with higher mean levels of plasma calcium (and magnesium) than FHH1 patients despite having similar PTH levels and urinary calcium excretion. Mean renal tubular reabsorption levels are higher in FHH3 than in FHH1. In one study, a comparison was made with patients with mild PHPT, with the conclusion that plasma calcium levels were higher in FHH while PTH levels and urinary calcium excretion were lower (Vargas-Poussou et al., 2016). There was marked overlap between groups, emphasizing that diagnostic difficulties exist, as they do for FHH1 and for FHH3 versus non-FHH PHPT. This was also exemplified by the finding that in a separate study of five patients subsequently identified as FHH3, three had undergone unsuccessful subtotal parathyroidectomy (Hendy et al., 2014).

Hyperparathyroidism-jaw tumor syndrome

The syndrome of hereditary HPT-JT is a rare autosomal dominant disorder inherited with incomplete penetrance and characterized by early-onset recurrent parathyroid tumors (80%) and fibrous ossifying tumors of the mandibula or maxilla (30%). Less frequent renal lesions (10%) include Wilms' tumor, hamartomas, and polycystic kidney disease (Jackson et al., 1990; Chen et al., 2003). Uterine tumors include adenosarcoma, but benign adenofibromas and leiomyomas are more common (Bradley et al., 2005). While most resected parathyroid tumors in this syndrome are still benign, there is a heightened likelihood of progression to adenomas with atypical features and frank malignancy; parathyroid carcinoma occurs at increased frequency (15%−35%) in this syndrome (Mehta et al., 2014). In contrast to the multiglandular enlargement typically found at presentation in other classical forms of inherited hyperparathyroidism, a solitary, enlarged, and often cystic gland may be found in an HPT-JT patient, although multigland disease is sometimes present on initial presentation. Normocalcemia is often achieved after removal of the tumor(s); however, recurrence is well documented. In a large group of families, the HPT-JT trait was linked to 1q21-32 (Szabo et al., 1995; Hobbs et al., 2002). The responsible gene, HRPT2 at 1q31.2, was identified by positional cloning and mutation analysis and encodes parafibromin, a protein of 531 amino acids (Carpten et al., 2002). Consistent with a tumor-suppressor mechanism, many observed mutations within the gene would be predicted to cause loss of function (e.g., frameshifts, nonsense), and large gene deletions are also common (10%) in HPT-JT-affected individuals (Guarnieri et al., 2017) (Fig. 58.5). Parafibromin is expressed in a broad array of tissues, is highly conserved across species, and within the parathyroid gland it is reported in both the cytoplasmic and nuclear compartments (Woodard et al., 2005). Nuclear localization signals are present, and nucleolar location may have particular importance in its functions relevant to tumorigenesis (Panicker et al., 2010; Pazienza et al., 2013; Masi et al., 2014). Nuclear parafibromin has a proapoptotic activity (Lin et al., 2007). Transfection experiments have demonstrated the ability of parafibromin to inhibit cell proliferation and block cyclin D1 expression (Woodard et al., 2005). Experimental overexpression of wild-type parafibromin in transformed cell lines inhibits cell proliferation and induces G1-phase cell cycle arrest (Zhang et al., 2006). Parafibromin HPT-JT mutants act in a dominant-negative manner to abolish the ability of wild-type parafibromin to inhibit cell growth (Zhang et al., 2006). In mammalian cells, parafibromin is part of an RNA polymerase II−associated factor complex and has sequence homology to yeast Cdc73, a constituent of a protein multimer important for transcription initiation/elongation, histone methylation, and RNA processing (Rozenblatt-Rosen et al., 2005; Yart et al., 2005). In response, the human *HRPT2* gene was renamed *CDC73*. Parafibromin binds directly to the COOH-terminal part of β-catenin and transduces Wnt pathway signals into transcriptional initiation and elongation by RNA polymerase II (Mosimann et al., 2006). However, it is unclear how this or other proposed actions of parafibromin specifically relate to its role as a tumor suppressor. Initial studies in mouse models have tended to reinforce the key role of parafibromin loss in parathyroid neoplasia, with parathyroid-specific or conventional *Cdc73* knockout being reported to cause hypercalcemia and parathyroid proliferation (Wang et al., 2008; Walls et al., 2017).

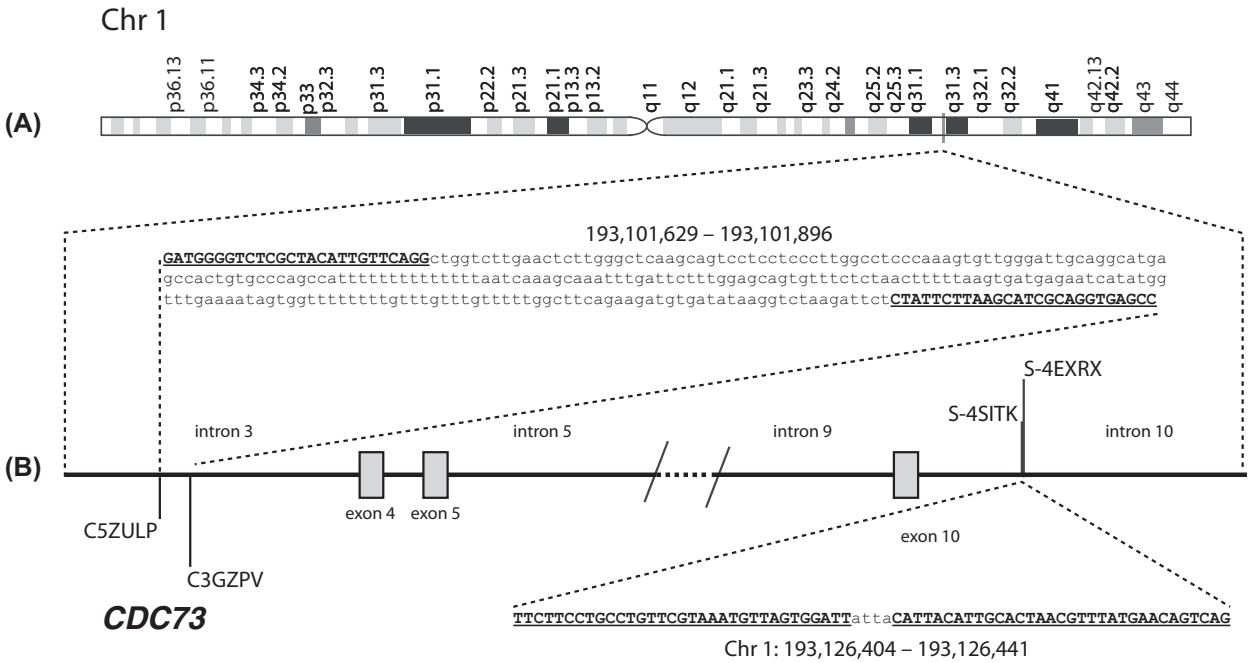

FIGURE 58.5 Intragenic deletion of *CDC73* is common in HPT-JT affected individuals, and one example is shown here. (A) SNP array analysis revealed an interstitial microdeletion of 0.25 Mb in band 1q31.2. (B) The hemizygous region was covered by 76 SNP array probes (from C-3GZPV to S−4S1TK) and encompassed part of the *CDC73* coding sequence from exons 4 to 10. The proximal (centromeric) breakpoint was located between the last present probe C-5ZULP (193,101,629 bp) and the first deleted probe C-3GZPV (193,101,895 bp), while the distal (telomeric) breakpoint was located between the last deleted probe S-4SITK (193,126,404 bp) and the first present probe S-4EXRX (193,126,441 bp) (see Guarnieri et al., 2017).

Familial isolated hyperparathyroidism

FIHP has been defined as hereditary primary hyperparathyroidism without the association of other disease or tumors. Although listed as a distinct genetic entity, some cases presenting as FIHP have been shown by gene mutation analysis to be variants of other monogenic diseases—FHH (Simonds et al., 2002; Warner et al., 2004), MEN1 (Carrasco et al., 2004; Pannett et al., 2003), and HPT-JT (Guarnieri et al., 2006; Kelly et al., 2006; Villablanca et al., 2004; Simonds et al., 2004). A personal or family history of parathyroid carcinoma in FIHP warrants strong consideration to determine germline *CDC73* (*HRPT2*) mutation status, which can lead to early detection and removal of potentially malignant parathyroid tumors (Kelly et al., 2006; Guarnieri et al., 2006). In addition, specific germline variants in the *GCM2* gene encoding the parathyroid-specific GCM2 transcription factor have been reported to be overrepresented in some autosomal dominant FIHP kindreds, especially those of Ashkenazi Jewish descent, as compared with their allelic frequencies in the general population (Guan et al., 2016, 2017). The penetrance of these variants and the contextual constraints in which they may contribute to the hyperparathyroid phenotype and thus have potential value in clinical management require further study. For most FIHP kindreds, the causative genes remain to be identified.

Molecular pathogenesis of parathyroid carcinoma

Mutation of the *CDC73* tumor-suppressor gene (formerly/also known as *HRPT2*) is a major driver in parathyroid carcinoma, whether in the context of familial or sporadic disease. Such mutations are detectable in up to 75% of unequivocally diagnosed parathyroid cancers (Shattuck et al., 2003a; Howell et al., 2003; Cetani et al., 2004; Gill, 2014; Pandya et al., 2017), with percentages varying among series probably due to relatively small sample sizes and differences in the selection of cases. Inactivating mutations in noncoding regions, and larger deletions in some series, would have escaped detection. Most such mutations in sporadic cases are somatic. In addition, about 20%−25% of patients with the clinical presentation of sporadic parathyroid carcinoma bear unsuspected germline mutations in *CDC73*/*HRPT2* (Shattuck et al., 2003). Such patients may represent de novo examples or lower penetrance variants of HPT-JT, and the opportunity for early diagnosis to prevent or cure parathyroid cancer in their family members established an important role for DNA testing in this circumstance.

Because of the impressive genetic evidence for *CDC73's* role, parafibromin immunostaining has been evaluated as a potential diagnostic test for parathyroid carcinoma (Tan et al., 2004; Gill et al., 2006; Juhlin et al., 2006). Several studies reported virtually complete loss of nuclear immunostaining in most parathyroid carcinomas in comparison with positive staining in benign parathyroid tumors. However, because of technical, case selection, and/or biological factors, not all studies yielded such uniform results (Juhlin et al., 2007), and parafibromin staining must be interpreted with caution in the clinical setting (Guarnieri et al., 2012b; Gill, 2014; Rosai et al., 2014; DeLellis et al., 2017; Lloyd et al., 2017).

Genetic evidence examining the relative frequency of clonal markers suggests that, in general, sporadic parathyroid carcinomas develop de novo as opposed to evolving from preexisting clinically apparent benign adenomas (Costa-Guda et. al., 2013b, 2014). However, parathyroid carcinomas that occur in the context of germline *CDC73* mutation may, in contrast, develop through a progression—i.e., from adenoma to atypical adenoma to carcinoma. Interestingly, adenomas and atypical adenomas in patients with germline *CDC73* mutations have been reported to be parafibromin negative and/or biallelically inactivated for *CDC73* (Kelly et al., 2006; Cetani et al., 2007), suggesting that loss of parafibromin is a crucial but not sufficient molecular genetic step in a parathyroid cell's acquisition of a frankly malignant phenotype in this context.

Additional insights have been gained using "next-generation" massively parallel sequencing technologies. Whole-exome sequencing and related methods not only confirmed the key role of *CDC73* inactivation but revealed a number of other recurrent gene alterations as putative or candidate drivers in the pathogenesis of parathyroid carcinoma (Kasaian et al., 2013; Yu et al., 2015; Pandya et al., 2017). These include mutations in well-established cancer genes not previously implicated in parathyroid carcinoma, such as *PIK3CA* and *MTOR*, and amplification of *cyclin D1* as well as novel candidate oncogenes like *ADCK1*. To the extent that some of these somatically mutated genes can be targeted by current or future cancer therapeutic agents, the findings provide a rationale for sequencing tumors from patients with surgically incurable parathyroid cancer and considering the use of such agents in appropriately selected cases.

Complementing the aforementioned finding of the extra copy number of *CCND1*, the cyclin D1 oncoprotein, overexpressed in 20%−40% of adenomas, appears to be even more frequently overexpressed in parathyroid carcinomas (Vasef et al., 1999; Hsi et al., 1996; Zhao et al., 2014). These observations strengthen the likelihood that cyclin D1 is a driver oncogene that contributes to the pathogenesis of parathyroid cancers and adenomas. As such, patients with metastatic disease and this tumor genotype might be considered for treatment with CDK4/6 inhibitors and/or eventual inclusion in clinical trials once novel anti−cyclin D1 therapies are developed. Evidence for the involvement of the Wnt signaling pathway provides additional leads toward pathogenetic mechanisms and potential therapeutic vulnerabilities (Svedlund et al., 2010; Juhlin et al., 2009; Pandya et al., 2017). *MEN1* mutations have been only rarely reported in parathyroid carcinoma and generally in series where inclusion did not require malignant clinical behavior of the tumor. Hints as to the chromosomal location of other, still unidentified, parathyroid cancer genes include the common loss of chromosome region 13q, which contains *RB* and *BRCA2* (Cryns et al., 1994b; Dotzenrath et al., 1996; Pearce et al., 1996; Kytola et al., 2000). However, the absence of detectable mutations in *RB* and *BRCA2* suggests that any major role for these genes would be indirect rather than as classical tumor suppressors (Shattuck et al., 2003b). Similarly, loss of putative tumor-suppressor genes in genomic regions including 1p, 3q, 4q, and 21q may be involved as significant factors in malignant parathyroid tumors (Cryns et al., 1995; Kytola et al., 2000; Agarwal et al., 1998). Specific chromosome regional gains, suggesting the involvement of oncogenes, have been found in parathyroid carcinomas by comparative genomic hybridization (Kytola et al., 2000; Agarwal et al., 1998), but the involved genomic locations show little consistency among the existing reports, and the results require confirmation by complementary methods. Identification of more genetic lesions that are highly specific for the malignant phenotype would be helpful in bringing molecular diagnostics to bear on this disease, which would aid in overcoming the well-known difficulties in distinguishing malignant versus benign parathyroid tumors histopathologically.

Ectopic secretion of parathyroid hormone

The ectopic secretion of PTH by nonparathyroid tumors is an extremely rare cause of hyperparathyroidism. The use of modern immunometric assays for PTH that show no cross-reactivity with PTH-related protein, the major cause of the hypercalcemia of malignancy, combined in some cases with molecular analysis using specific human *PTH* gene probes (Hendy et al., 1981; Vasicek et al., 1983), has suggested or confirmed the occurrence of this syndrome in several cases (see VanHouten et al., 2006 and references therein).

In one case of an ovarian carcinoma (Nussbaum et al., 1990), the molecular basis for the aberrant expression of PTH was determined. This involved a rearrangement (Fig. 58.6) and amplification of the PTH gene such that it was no longer under the control of upstream regulatory elements that may normally act to silence PTH gene expression in nonparathyroid tissue. This case provided strong documentation that the tumor was in fact the source of high circulating PTH levels and

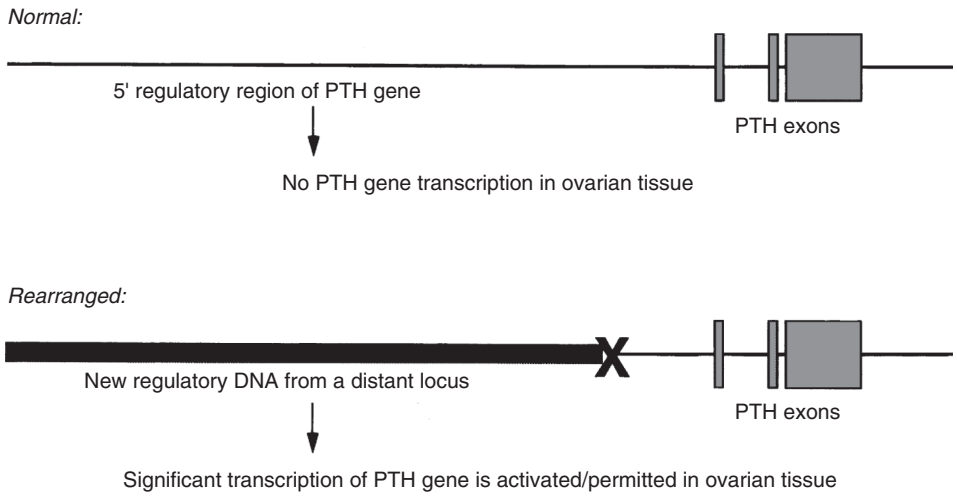

FIGURE 58.6 Molecular pathology of the ectopic production of PTH by an ovarian cancer. Schematic diagram of the normal PTH gene region (*top*) and the rearranged, amplified PTH gene region (*bottom*) in a PTH-secreting ovarian tumor. The bold **"X"** represents the breakpoint of the DNA rearrangement. *Reproduced with permission from Arnold, A. 1993. the patient's hypercalcemia. In a case of severe hyperparathyroidism resulting from ectopic PTH production by a pancreatic malignancy, a mechanism of transactivation of the PTH gene was suggested by the finding of hypomethylation of the PTH gene promoter in tumor tissue (VanHouten et al., 2006).

Chapter outline

Overview

$G_s\alpha$ is a ubiquitously expressed heterotrimeric G protein α subunit that couples cell surface receptors for hormones and other extracellular ligands to adenylyl cyclase and mediates receptor-stimulated intracellular cyclic adenosine monophosphate (cAMP) generation. Upon ligand binding, receptors promote the release of GDP and binding of GTP to $G_s\alpha$, leading to its activation. The "turn-off" mechanism is an intrinsic GTPase activity of $G_s\alpha$ that hydrolyzes bound GTP to GDP. Genetic defects involving $G_s\alpha$ are associated with a wide variety of human disorders, which are summarized in Table 59.1. Heterozygous inactivating $G_s\alpha$ mutations in the germ line usually lead to Albright hereditary osteodystrophy (AHO) and, less often, to progressive osseous heteroplasia (POH). Paternal transmission of these mutations leads to the AHO phenotype alone (pseudopseudohypoparathyroidism, PPHP), while maternal transmission leads to AHO plus obesity and multihormone resistance (pseudohypoparathyroidism type IA, PHPIA). The clinical differences between PHPIA and PPHP result from the fact that $G_s\alpha$ is imprinted in a tissue-specific manner, being primarily expressed from the maternal allele in specific hormone target tissues. $G_s\alpha$ is encoded by a complex imprinted gene (*GNAS*), which encodes gene products other than $G_s\alpha$. Patients with isolated renal parathyroid hormone (PTH) resistance without AHO (pseudohypoparathyroidism type IB, PHPIB) have a *GNAS* imprinting defect that presumably leads to tissue-specific $G_s\alpha$ deficiency. Endocrine tumors, fibrous dysplasia of bone (FD), and the McCune–Albright syndrome (MAS) result from gain-of-function, somatic mutations in $G_s\alpha$ that lead to constitutive adenylyl cyclase activation and cAMP signaling.

TABLE 59.1 Human diseases associated with *GNAS* gene defects.

GNAS gene defect	Disease
$G_s\alpha$ null mutations (maternal)	PHPIA (AHO + multihormone resistance and obesity PHPIA + POH
$G_s\alpha$ null mutations (paternal)	PPHP (AHO alone) POH
$G_s\alpha$ A366S mutation (maternal)	PHPIA + testotoxicosis
Loss of exon 1A maternal imprinting (sporadic or associated with *STX16* or NESP55 deletion) Paternal UPD of chromosome 20q $G_s\alpha$ ΔI382 mutation (maternal)	PHPIB
$G_s\alpha$-activating mutations (somatic)	GH-secreting pituitary tumors Thyroid adenomas, carcinomas Leydig cell tumors Pheochromocytoma Parathyroid adenoma ACTH-secreting pituitary tumor McCune–Albright syndrome Fibrous dysplasia Skeletal muscle myxomas Premature thelarche Intraductal papillary mucinous neoplasms of the pancreas

ACTH, adrenocorticotropic hormone; *AHO,* Albright hereditary osteodystrophy; *GH,* growth hormone; *PHPIA,* pseudohypoparathyroidism type IA; *PHPIB,* pseudohypoparathyroidism type IB; *POH,* progressive osseous heteroplasia; *UPD,* uniparental disomy.

$G_s\alpha$ structure and function

Like all heterotrimeric G proteins, G_s is composed of a specific α subunit ($G_s\alpha$) associated with tightly but noncovalently bound βγ dimers. These heterotrimeric complexes reside in the inner leaflet of the plasma membrane as well as in intracellular membranes. $G_s\alpha$ is ubiquitously expressed and couples a wide variety of seven-transmembrane receptors, including those for glycoprotein and peptide hormones, biogenic amines, and neurotransmitters, to the stimulation of adenylyl cyclase and generation of the intracellular second messenger cAMP (Weinstein et al., 2001, 2004). cAMP mediates many of its downstream effects by activating cAMP-dependent protein kinase (protein kinase A [PKA]), a serine/threonine protein kinase that phosphorylates many substrates, including enzymes involved in intermediary metabolism and transcription factors such as the cAMP-response element binding protein CREB (Montminy, 1997). cAMP also binds to and modulates the activity of other molecules (Richards, 2001), including ion channels (Sudlow et al., 1993; Wainger et al., 2001) and guanine nucleotide exchange factors for the small guanine nucleotide binding protein Rap1 (de Rooij et al., 1998; Kawasaki et al., 1998). While in many tissues cAMP is antimitogenic, in many neuroendocrine cell types it is mitogenic through activation of Rap1, which stimulates various mitogenic pathways, including B-Raf/mitogen-activated protein kinase, p70S6 kinase, and Akt (Miller et al., 1997; Vossler et al., 1997; Cass and Meinkoth, 1998; Mei et al., 2002; Wang et al., 2006).

$G_s\alpha$ may also be activated by tyrosine kinase (growth factor) receptors through tyrosine phosphorylation (Poppleton et al., 1996; Sun et al., 1997; Krieger-Brauer et al., 2000) and may activate other effectors, including cardiac Ca^{2+} channels (Yatani et al., 1988; Mattera et al., 1989) and Src tyrosine kinases (Ma et al., 2000). In addition to its role as a signal transducer at the plasma membrane, $G_s\alpha$ may also play a role in the control of intracellular membrane and vesicle trafficking (Bomsel and Mostov, 1992; Zheng et al., 2001).

Like all G proteins, G_s undergoes activation and deactivation through a "GTPase" cycle (Fig. 59.1). In the inactive state GDP is bound to $G_s\alpha$, which is localized to the inner leaflet of the plasma membrane associated with βγ. Ligand-bound receptors promote GDP release and binding of ambient GTP, allowing $G_s\alpha$ to attain an active conformation and to dissociate from βγ. Dissociation from βγ as well as depalmitoylation results in $G_s\alpha$ being released from the plasma membrane upon activation (Wedegaertner et al., 1996; Huang et al., 1999; Yu and Rasenick, 2002; Allen et al., 2005). GTP-bound $G_s\alpha$ directly binds to and activates its effectors, including adenylyl cyclase. The turn-off mechanism is an intrinsic GTPase activity that hydrolyzes bound GTP to GDP, allowing $G_s\alpha$ to reassociate with βγ.

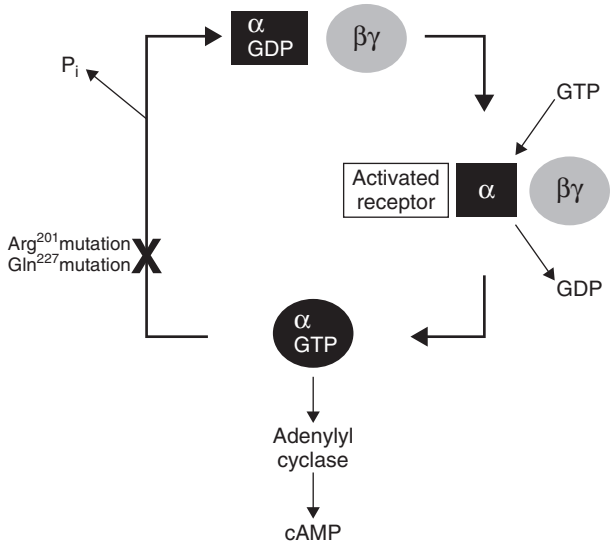

FIGURE 59.1 The G_s GTPase cycle. In the basal state $G_s\alpha$ has GDP bound to it and it associates with βγ to form a heterotrimer with GDP. Activated (ligand-bound) receptors promote the exchange of GTP for GDP on $G_s\alpha$, which allows $G_s\alpha$ to attain an active conformation and dissociate from βγ. GTP-bound $G_s\alpha$ directly activates adenylyl cyclase to generate cAMP. $G_s\alpha$ is deactivated through an intrinsic GTPase activity that hydrolyzes bound GTP to GDP, allowing $G_s\alpha$ to reassociate with βγ. Mutation of Arg^{201} or Gln^{227} leads to constitutive activation by disruption of the GTPase activity.

An RGS (regulator of G protein signaling) protein that stimulates the GTPase activity of $G_s\alpha$ has been identified (Zheng et al., 2001). Crystal structures have identified two highly conserved residues (Arg^{201} and Gln^{227} in the long form of $G_s\alpha$) that are critical for catalyzing the GTPase reaction (Graziano and Gilman, 1989; Landis et al., 1989; Coleman et al., 1994; Sondek et al., 1994), and mutation or posttranslational modifications of these residues lead to constitutive activation and human disease (see later). More recent work suggests that activating $G_s\alpha$ mutations may also activate the G protein via a mechanism other than impairment of GTPase activity (Hu and Shokat, 2018).

Like all Gα's, $G_s\alpha$ contains two structural domains, a Ras-like GTPase domain, which includes the sites for guanine nucleotide binding and effector interaction, and a helical domain (Sunahara et al., 1997; Tesmer et al., 1997). Alternative splicing leads to two long and two short forms of $G_s\alpha$ with helical domains of slightly differing length (Bray et al., 1986; Kozasa et al., 1988), which have only subtle biochemical differences between them (Jones et al., 1990; Seifert et al., 1998). Contacts between the helical and GTPase domains may be important for maintaining the binding of guanine nucleotide, which sits within a cleft between the two domains (Mixon et al., 1995; Warner et al., 1998). GTP binding leads to an active conformation by altering the positions of three regions (named switches 1, 2, and 3) within the GTPase domain (Noel et al., 1993; Lambright et al., 1994). In particular, switches 2 and 3 move toward each other and the active conformation is stabilized through mutual interactions between acidic and basic residues within these regions (Iiri et al., 1997; Li and Cerione, 1997; Warner et al., 1999). Interactions between switch 3 and helical domain residues may also be important for receptor-mediated activation (Grishina and Berlot, 1998; Marsh et al., 1998; Warner et al., 1998; Warner and Weinstein, 1999). The carboxy terminus is the major site of interaction with receptors (Sullivan et al., 1987; Simonds et al., 1989; Schwindinger et al., 1994; Conklin et al., 1996; Grishina and Berlot, 2000; Mazzoni et al., 2000).

The $G_s\alpha$ Gene *GNAS*

GNAS, the gene encoding $G_s\alpha$, is located at 20q13.2−q13.3 (Gejman et al., 1991; Levine et al., 1991; Rao et al., 1991). *GNAS* generates several gene products in addition to $G_s\alpha$ through the use of alternative promoters and first exons that splice onto a common exon (exon 2) (Fig. 59.2). In addition, *GNAS* is affected by genomic imprinting, an epigenetic phenomenon that leads to partial or complete suppression of gene expression from one parental allele (Reik and Walter, 2001). Allele-specific differences in gene expression are most likely the result of allele-specific differences in DNA methylation, which are observed in all imprinted genes. Primary imprinting centers are regions of differential methylation in which DNA methylation is erased in primordial germ cells, reestablished in either male or female gametes, and maintained in all tissues throughout development. Differential gene expression may result from differential methylation of gene promoters (with the silenced allele methylated) or may result from more indirect mechanisms.

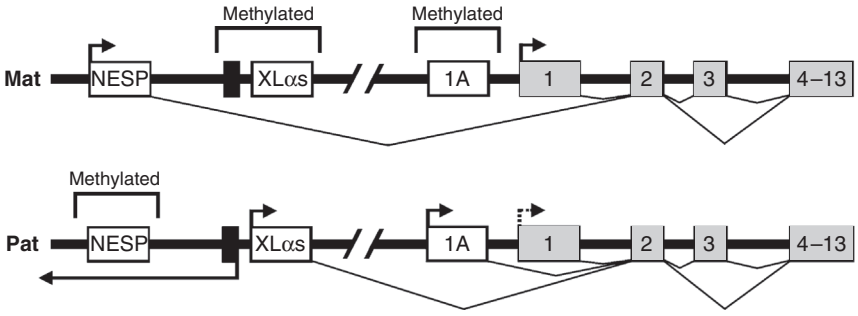

FIGURE 59.2 Organization and imprinting of *GNAS*. The maternal (*Mat*) allele is shown above and paternal (*Pat*) allele below (not to scale), indicating regions of DNA methylation, active promoters (*arrows*), and exon splicing. $G_s\alpha$ coding exons are depicted as *gray* boxes with exons 4–13 shown as a single box. Three other alternative first exons are shown as *white* boxes and the first exon of the antisense transcript is shown as a *black* box. The *dashed arrow* for the paternal $G_s\alpha$ promoter indicates that the promoter is silenced in a tissue-specific manner. Long and short forms of $G_s\alpha$ result from alternative splicing of exon 3. *NESP,* Neuroendocrine specific protein. *Reproduced from Weinstein, L.S., 2004. GNAS and McCune-Albright syndrome/fibrous dysplasia, Albright hereditary osteodystrophy/pseudohypoparathyroidism type 1A, progressive osseous heteroplasia, and pseudohypoparathyroidism type 1B. In: Epstein, C.J., Erickson, R. P. and Wynshaw-Boris, A. (Eds.), Molecular Basis of Inborn Errors of Development. Oxford University Press, San Francisco, pp. 849–866.*

$G_s\alpha$ mRNA transcripts are generated from the most downstream *GNAS* promoter and span 13 exons (Kozasa et al., 1988). Biologically active long and short forms of $G_s\alpha$ are generated by alternative splicing of exon 3, which encodes 15 amino acids within the helical domain (Bray et al., 1986; Kozasa et al., 1988). $G_s\alpha$ is imprinted in a tissue-specific manner, being primarily from the maternal allele in a few tissues (e.g., the pituitary, thyroid, and renal proximal tubules) and biallelically expressed in most tissues (Davies and Hughes, 1993; Campbell et al., 1994; Yu et al., 1998; Hayward et al., 2001; Weinstein et al., 2001; Germain-Lee et al., 2002; Mantovani et al., 2002; Liu et al., 2003). This imprinting is not associated with methylation of its promoter (Kozasa et al., 1988; Hayward et al., 1998; Peters et al., 1999; Liu et al., 2000). Rather, $G_s\alpha$ imprinting is controlled by a primary imprinting center located ~2 kb upstream of its promoter, which is methylated on the maternal allele (Liu et al., 2000, 2005; Williamson et al., 2004). This region contains a promoter and first exon (exon 1A or A/B), which splices to exon 2 to generate untranslated mRNA transcripts from the paternal allele (Fig. 59.2) (Ishikawa et al., 1990; Liu et al., 2000; Liu et al., 2000, 2000). Maternal imprinting (methylation) of the exon 1A region is absent in PHPIB patients, as discussed in greater detail later.

Alternative promoters and first exons located 46 and 35 kb upstream of the $G_s\alpha$ promoter generate transcripts that encode the chromogranin-like protein NESP55 and the alternative $G_s\alpha$ isoform XLαs, respectively (Hayward et al., 1998; Hayward et al., 1998; Kelsey et al., 1999; Peters et al., 1999) (Fig. 59.2). The NESP55 and XLαs promoter regions are oppositely imprinted: NESP55 is expressed only from the maternal allele and its promoter is methylated on the paternal allele, while XLαs is expressed only from the paternal allele and its promoter is methylated on the maternal allele. Both NESP55 and XLαs are expressed primarily in neuroendocrine tissues. NESP55 is unrelated to the Gα family and its coding sequence is restricted to its specific upstream exon. Its biological function is unknown and studies in mouse and humans suggest that loss of its expression leads to minimal phenotypic consequences (Liu et al., 2000; Plagge et al., 2005). Imprinting of NESP55 is not established until after implantation and is dependent upon a primary imprinting center located within the promoter region of a paternally expressed antisense transcript that traverses the NESP55 promoter from the opposite direction (Liu et al., 2000; Williamson et al., 2006). XLαs is a $G_s\alpha$ isoform in which the first 47 amino acids of $G_s\alpha$ are replaced with a long amino-terminal extension encoded by its specific first exon (Kehlenbach et al., 1994; Pasolli et al., 2000). XLαs is capable of signal transduction and activation of adenylyl cyclase (Klemke et al., 2000; Bastepe et al., 2002). Although XLαs is critical for postnatal feeding and metabolic regulation in mice (Plagge et al., 2004; Xie et al., 2006), its role in humans is less clear.

Albright hereditary osteodystrophy

Clinical presentation

Patients with AHO may present with one or more of the following clinical features: short stature, round face, broad body habitus, brachydactyly, subcutaneous ossifications, depressed nasal bridge, hypertelorism, low birth rate, and mental deficits or developmental delay (Fig. 59.3) (Ringel et al., 1996; Weinstein, 1998; Spiegel and Weinstein, 2001; Weinstein et al., 2001; Richard et al., 2013). None of these features are completely specific for this disorder, although subcutaneous ossifications are a fairly specific sign for AHO. The severity of the phenotype varies greatly, and some

patients who carry the genetic trait present with few or no clinical manifestations (Farfel and Friedman, 1986; Weinstein et al., 1990; Miric et al., 1993; Shore et al., 2002).

Ectopic ossifications in AHO (osteoma or calcinosis cutis) are often one of the earliest features of the disease (Gelfand et al., 2006; Poomthavorn and Zacharin, 2006) and can occur in any location. They present as punctate hard nodules or as subcutaneous calcifications on radiographs located within the dermis and subcutaneous tissue (Eyre and Reed, 1971; Prendiville et al., 1992; Goeteyn et al., 1999; Sethuraman et al., 2006) that occasionally enlarge to form more plate-like lesions but do not invade into deeper tissues. These lesions result from intramembranous, as opposed to endochondral, ossification and may be surrounded by inflammation (Riepe et al., 2005). They are caused by a primary cellular defect, rather than a defect in mineral metabolism, as they are absent in patients with primary hypoparathyroidism and are present in PPHP patients, who are normocalcemic and have no evidence for PTH resistance.

Brachydactyly refers to shortening and widening of the long bones in the hands and feet. Patients with AHO have a relatively specific pattern, which most often involves the distal thumb and third, fourth, and fifth metacarpals and is often asymmetric (Steinbach and Young, 1966; Poznanski et al., 1977; Graudal et al., 1986; Mantovani et al., 2004). Brachydactyly is generally not observed in early childhood but becomes apparent later in the first decade of life due to premature growth plate closure with coning of the epiphysis (Gelfand et al., 2006). Spinal cord compression occurs rarely, either from calcifications of longitudinal spinal ligaments (Yamamoto et al., 1997; Chen et al., 2005; Mak and Mok, 2005) or from spinal canal narrowing (Goadsby et al., 1991; Okada et al., 1994). Other musculoskeletal features that have been reported in AHO include carpal tunnel syndrome (Joseph et al., 2011), increased incidence of sleep apnea (Landreth et al., 2015), dental abnormalities (Reis et al., 2016), Madelung deformity (Rump et al., 2011; Sanchez et al., 2011), and acroscyphodysplasia (Mitsui et al., 2014).

Neurobehavioral abnormalities are also common in AHO patients, occurring in up to 50% of cases (Farfel and Friedman, 1986). There is no distinct neurocognitive syndrome associated with AHO, although psychomotor delay and mental retardation are relatively common. Some evidence suggests that these features are more prevalent in PHP1A than in PPHP (Mouallem et al., 2008). Psychiatric conditions and juvenile dementia have also been described in AHO patients (Maeda et al., 2005). In rare cases, basal ganglia calcification resulting from the hypoparathyroid biochemical state may lead to Parkinsonian symptoms.

In addition to the aforementioned physical features, AHO patients who inherit the disease from their mother (or have a de novo $G_s\alpha$ mutation on the maternal allele) also develop obesity and multihormone resistance, a condition known as PHPIA (Long et al., 1988; Davies and Hughes, 1993; Weinstein et al., 2001). In patients who inherit AHO from their father (or have a de novo mutation on the paternal allele) obesity and multihormone resistance are absent. This condition, in which patients present with only AHO, is also known as PPHP. Both PHPIA and PPHP often occur in the same kindred with the presentation of each case determined by parental inheritance. The multihormone resistance in PHPIA primarily involves PTH, thyroid-stimulating hormone (TSH), growth hormone-releasing hormone (GHRH), and the gonadotropins, all of which activate G_s pathways in their target tissues. There is no resistance, at least based upon clinical parameters, to other hormones that also activate G_s, such as glucagon (Levine et al., 1983; Brickman et al., 1986), adrenocorticotropic hormone (ACTH) (Levine et al., 1983; Faull et al., 1991), isoproterenol (Carlson and Brickman, 1983), and vasopressin (Moses et al., 1986; Faull et al., 1991).

PHPIA patients develop renal PTH resistance during early childhood but may initially present with acute symptoms of hypocalcemia (seizures, tetany, numbness) at any time of life, often during early adolescence. Generally, there is no evidence for PTH resistance at birth or even in the first year of life, but soon thereafter PTH levels rise followed by the development of hyperphosphatemia and finally hypocalcemia (Werder et al., 1978; Tsang et al., 1984; Barr et al., 1994; Yu et al., 1999; Riepe et al., 2005; Gelfand et al., 2006). Over time patients develop chronic features of biochemical hypoparathyroidism, including basal ganglia calcifications, cataracts, and calcifications at other sites, and on rare occasions may develop rickets. Some PHPIA patients have elevated PTH levels but remain eucalcemic (Balachandar et al., 1975; Drezner and Haussler, 1979; Breslau et al., 1980). The PTH signaling defect is primarily localized to the renal proximal tubule, and this results in hyperphosphatemia due to increased phosphate reabsorption and low or inappropriate normal serum 1,25-dihydroxyvitamin D ($1,25(OH)_2D$) levels (Lambert et al., 1980; Braun et al., 1981; Breslau and Weinstock, 1988; Miura et al., 1990). Because the defect is limited to the proximal tubules, the ability of the distal tubules to reabsorb calcium in response to PTH remains intact, and therefore PHP patients do not tend to develop hypercalciuria upon treatment as do patients with primary hypoparathyroidism. Consistent with the presence of a G_s defect, the acute PTH-stimulated urinary cAMP response is markedly blunted in PHPIA patients, while it is normal in PPHP patients (Chase et al., 1969; Levine et al., 1986). Although one bone sample from a PHPIA patient showed no defect in PTH−$G_s\alpha$ signaling (Ish-Shalom et al., 1996), the occurrence of secondary skeletal effects of chronically elevated PTH is lower in PHPIA than in PHPIB, perhaps due to partial $G_s\alpha$ deficiency in osteoblasts from these patients.

TSH resistance is present in virtually all PHPIA patients and is often the first observed manifestation, as TSH levels are generally elevated in neonatal screening (Levine et al., 1985; Weisman et al., 1985; Yokoro et al., 1990; Yu et al., 1999; Gelfand et al., 2006). TSH levels may normalize for several months before once again becoming elevated (Yu et al., 1999). Once TSH resistance is established, TSH levels are mildly or moderately elevated and thyroid hormone levels are normal or slightly low. As the defect is at the level of TSH signaling, which also stimulates thyroid growth, goiter is usually absent. Antithyroid antibodies are usually absent.

Female PHPIA patients often present with signs of clinical hypogonadism, including delayed or incomplete sexual maturation, oligomenorrhea, or infertility, associated with mildly low estrogen levels (Wolfsdorf et al., 1978; Shapiro et al., 1980; Levine et al., 1983; Shima et al., 1988; Namnoum et al., 1998; de Sanctis et al., 2003). Although it is assumed that these patients are resistant to gonadotropins, studies have not consistently demonstrated that they have elevated gonadotropin levels. It has been proposed that PHPIA patients may have a more subtle form of gonadotropin resistance that leads to an ovulatory defect due to a poor ovulatory response to the midcycle luteinizing hormone surge (Namnoum et al., 1998). Some PHPIA patients also have prolactin deficiency (Carlson et al., 1977; Brickman et al., 1981; Kruse et al., 1981; Levine et al., 1983; Faull et al., 1991; Schuster et al., 1993).

Many, although not all, PHPIA patients have growth hormone (GH) deficiency, presumably secondary to pituitary resistance to GHRH (Shima et al., 1988; Faull et al., 1991; Germain-Lee et al., 2003; Mantovani et al., 2003; de Sanctis et al., 2007). However, short stature in PHPIA does not correlate with GH deficiency and appears to result from a primary skeletal growth plate defect leading to premature maturation and closure. In fact, prior to puberty PHPIA patients often are tall for their biological age and have advanced bone ages. Severe early-onset obesity and primary insulin resistance (not accounted for by obesity) are also observed in PHP1A (Long et al., 2007; Muniyappa et al., 2013). Olfactory defects have also been described in PHPIA (but not PPHP) patients, although it is unclear whether this reflects a true sensory defect or a central neurological defect (Henkin, 1968; Weinstock et al., 1986; Ikeda et al., 1988; Doty et al., 1997).

Molecular genetics

AHO was initially shown to be associated with a G_s signaling defect by biochemical and cellular assays performed on membrane samples from various tissues (Farfel and Bourne, 1980; Farfel et al., 1980, 1981, 1982; Levine et al., 1980, 1986; Bourne et al., 1981; Mallet et al., 1982; Spiegel et al., 1982; Downs et al., 1983; Heinsimer et al., 1984; Ong et al., 1996). In these assays G_s signaling activity was similarly reduced by ~50% in tissues from both PHPIA and PPHP patients, suggesting that these patients have similar genetic G_s defects resulting from a genetic defect in one parental allele. Consistent with these findings, these patients were shown to have similar reductions in $G_s\alpha$ mRNA (Carter et al., 1987; Levine et al., 1988) and protein (Patten and Levine, 1990), and to have heterozygous $G_s\alpha$ loss-of-function mutations (Patten et al., 1990; Weinstein et al., 1990; Miric et al., 1993; Oude Luttikhuis et al., 1994; Shapira et al., 1996; Ahmed et al., 1998; Aldred et al., 2000; Aldred and Trembath, 2000; Ahrens et al., 2001; Spiegel and Weinstein, 2001; Linglart et al., 2002; de Sanctis et al., 2003; Rickard and Wilson, 2003; Weinstein, 2004; Thiele et al., 2007). All AHO patients within the same kindred (both those with PHPIA and those with PPHP) have identical mutations, confirming that AHO is an autosomal dominant disorder (Weinstein et al., 1990; Wilson et al., 1994; Fischer et al., 1998; Nakamoto et al., 1998; Walden et al., 1999; Yu et al., 1999; Mantovani et al., 2000). Whether an individual has PHPIA or PPHP is determined by parental inheritance, as discussed under "Pathogenesis."

$G_s\alpha$ mutations in AHO are spread throughout the coding exons and in the majority of cases are unique to each kindred, although some identical mutations or mutations affecting the same amino acid have been identified in more than one kindred (Miric et al., 1993; Iiri et al., 1994; Farfel et al., 1996; Ahmed et al., 1998; Aldred and Trembath, 2000; Ahrens et al., 2001). One 4-bp deletion in exon 7 has been identified in many families (Yu et al., 1995; Aldred and Trembath, 2000; Mantovani et al., 2000; Ahrens et al., 2001; Linglart et al., 2002; Shore et al., 2002; de Sanctis et al., 2003), as this site appears prone to de novo mutation due to pausing of DNA polymerase and slipped-strand mispairing (Yu et al., 1995). In most cases there is no genotype–phenotype correlation as the mutations completely disrupt $G_s\alpha$ mRNA expression (frameshift, nonsense, or splice junction mutations) or $G_s\alpha$ protein stability (Warner et al., 1997, 1998, 1999). Mutations in exon 1, which specifically encodes $G_s\alpha$, provide strong evidence that deficiency of $G_s\alpha$, as opposed to other *GNAS* gene products, underlies this disorder (Thiele et al., 2010). Mutation within the alternatively spliced exon 3 was associated with loss of expression of the long but not short form of $G_s\alpha$, leading to normocalcemic PHP1A with no obesity (Thiele et al., 2007).

Several missense mutations have specific effects on $G_s\alpha$ function. For example, mutations at the carboxy terminus uncouple $G_s\alpha$ from receptors (Schwindinger et al., 1994; Wu et al., 2001; Linglart et al., 2002, 2006). Mutation of either Arg^{231} within the switch 2 region or Glu^{259} within the switch 3 region leads to a receptor activation defect by destabilizing interactions between the two switch regions that are necessary to maintain the active conformation (Iiri et al., 1997; Warner et al., 1999). The Arg^{258}Trp mutation results in decreased GDP binding in the basal state as well as a receptor-activation defect due to increased GTPase activity (Warner et al., 1998; Warner and Weinstein, 1999). The Ala^{366}Ser mutation results in PHPIA plus male gonadotropin-independent precocious puberty (testotoxicosis) (Iiri et al., 1994). This mutation leads to increased GDP release in a temperature-sensitive manner. At core body temperature the mutant protein is thermolabile due to an inability to maintain GDP binding, which results in PHPIA. At the lower testicular temperature, the GDP binding defect is subtler, allowing the protein to remain stable. However, testotoxicosis results from constitutive activation of $G_s\alpha$ due to increased GDP/GTP exchange in the absence of receptor stimulation.

Diagnosis and management

Although PTH stimulation of urinary cAMP (Ellsworth–Howard test) is the classical test for confirming the presence of PTH resistance (Chase et al., 1969), the PTH analog is no longer clinically available, and with modern PTH assays the diagnosis can usually be made based on baseline hormonal measures once nutritional vitamin D deficiency and renal dysfunction are ruled out. Patients with a blunted urinary cAMP response to PTH are classified as having PHPI. PHPI is further subclassified as PHPIA or PHPIB based on the presence or absence of AHO and multihormone resistance, respectively. Rarely, patients have the PHPIA phenotype without evidence for a $G_s\alpha$ defect because the functional assay does not assess receptor–G protein coupling, and they are classified as PHPIC (Thiele et al., 2011). Patients who have a normal urinary cAMP response but a defective phosphaturic response to PTH are classified as PHP type II (Rao et al., 1985).

As many of the features of AHO (brachydactyly, obesity, neurobehavioral abnormalities) are nonspecific, the diagnosis should not be made based upon the presence of these features alone, especially in the absence of family history, multihormone resistance, or subcutaneous ossifications, which is a more specific feature of AHO. These features are also present in other known genetic syndromes (e.g., Prader–Willi, brachydactyly syndromes, Turner's syndrome, Rubinstein–Taybi syndrome) and have also been found in association with chromosomal deletion of 2q37 (Phelan et al., 1995; Wilson et al.,

1995). Therefore, to confirm the diagnosis of PHPIA or PPHP one must confirm the presence of a $G_s\alpha$ defect by biochemical or genetic studies. Acrodysostosis presents with severe generalized skeletal abnormalities, and hormone resistance is associated with mutations in the genes encoding PKA regulatory-1α subunit (Linglart et al., 2011) or phosphodiesterase 4D.

The most direct way to confirm the presence of a $G_s\alpha$ defect is by *GNAS* mutation screening, which is commercially available but has a sensitivity of only ~70%. Alternatively, one can assay for G_s signaling activity in an erythrocyte membrane sample, but this is available in only a small number of research laboratories and is more technically difficult. In at least some cases patients have been diagnosed as having PHPIC because a nonhydrolyzable GTP analog was used to stimulate G_s in the biochemical assay. As this bypasses the necessity for receptor stimulation, it will give a normal result even when the mutation produces a specific defect in receptor-stimulated signaling (Iiri et al., 1997; Linglart et al., 2002, 2006). For this reason, biochemical assays should be performed using a receptor ligand (e.g., isoproterenol) so that these $G_s\alpha$ biochemical defects are not missed.

There is no specific therapy for the physical and neurocognitive manifestations of AHO. Rarely the subcutaneous ossifications require surgical excision to relieve discomfort or disfigurement. PTH resistance in PHPIA (and PHPIB) patients should be aggressively managed with oral calcium and vitamin D (either 50−100,000 IU/day of ergocalciferol or cholecalciferol or 0.5−2 μg/day of calcitriol). The goal is to try to normalize calcium and PTH, if possible, to prevent the skeletal effects of chronically elevated PTH and the development of autonomous (tertiary) hyperparathyroidism. Treatment should be initiated when patients develop high PTH levels even if normocalcemic. If autonomous parathyroid tumors develop, surgical excision may be required to reverse hypercalcemia, but management of the underlying PTH resistance will still be required postoperatively. PHP patients generally do not develop hypercalciuria upon treatment because the PTH defect is localized to the renal proximal tubule and the distal tubules can still increase calcium reabsorption in response to circulating PTH (Mizunashi et al., 1990; Stone et al., 1993). However, patients still need to be periodically monitored for hypercalciuria while on therapy.

Levothyroxine should be prescribed to normalize TSH levels and hypogonadism can be managed with oral contraceptives in females and testosterone in males. GH testing should be performed in children with PHPIA and GH therapy may be instituted if GH deficiency is diagnosed (Germain-Lee et al., 2003; Mantovani et al., 2003; de Sanctis et al., 2007). The more general use of GH in AHO patients to maximize height is under investigation.

Pathogenesis

The first clue that *GNAS* imprinting may be important for the clinical variability of AHO (PHPIA vs. PPHP) came from the observation that maternal inheritance produces offspring with PHPIA, while paternal inheritance produces offspring with PPHP (Davies and Hughes, 1993; Wilson et al., 1994; Nakamoto et al., 1998). Molecular studies in mice and humans have confirmed that $G_s\alpha$ is imprinted in a tissue-specific manner, being expressed primarily from the maternal allele in pituitary, thyroid, gonads, and renal proximal tubules (Yu et al., 1998; Hayward et al., 2001; Germain-Lee et al., 2002; Mantovani et al., 2002; Liu et al., 2003). In these tissues mutation of the active maternal allele will result in $G_s\alpha$ deficiency and impaired hormone signaling, while mutation of the inactive paternal allele would have little effect on $G_s\alpha$ expression or hormone action (Fig. 59.4). Therefore $G_s\alpha$ imprinting in renal proximal tubules would account for the fact that PTH-stimulated urinary cAMP is markedly reduced in PHPIA but is normal in PPHP (Chase et al., 1969; Levine et al., 1986). In most other nonendocrine tissues $G_s\alpha$ is biallelically expressed (Campbell et al., 1994; Hayward et al., 1998; Hayward et al., 1998, 1998), which accounts for a similar ~50% reduction in $G_s\alpha$ expression being observed in erythrocytes and other tissues in both PHPIA and PPHP patients (Levine et al., 1986).

In renal proximal tubules PTH normally stimulates G_s/cAMP signaling pathways, which leads to decreased phosphate reabsorption and increased $1,25(OH)_2D$ production by induction of the 1α-hydroxylase gene. Therefore $G_s\alpha$ deficiency in PHPIA (and PHPIB) leads to decreased $1,25(OH)_2D$ production and hyperphosphatemia due to low urinary phosphate excretion. Hyperphosphatemia also acts to inhibit $1,25(OH)_2D$ production. Hypocalcemia results from the combined effects of hyperphosphatemia and low $1,25(OH)_2D$ levels, as the latter results in decreased intestinal calcium absorption and skeletal calcium mobilization (Drezner et al., 1976; Drezner and Haussler, 1979; Epstein et al., 1983). Hypocalcemia, hyperphosphatemia, and low $1,25(OH)_2D$ levels all contribute to secondary hyperparathyroidism. The onset of renal PTH resistance occurs in early childhood after the first year of life and may correlate to the onset of $G_s\alpha$ imprinting in the renal proximal tubule (Turan et al., 2014). Likewise, hypothyroidism, hypogonadism, and GH deficiency in PHPIA result from resistance to TSH, gonadotropins, and GHRH in their respective target tissues (thyroid, gonads, pituitary) (Mallet et al., 1982; Namnoum et al., 1998; Germain-Lee et al., 2003; Mantovani et al., 2003). $G_s\alpha$ is imprinted in all of these tissues and therefore maternal, but not paternal, $G_s\alpha$ mutation leads to $G_s\alpha$-deficiency hormone resistance.

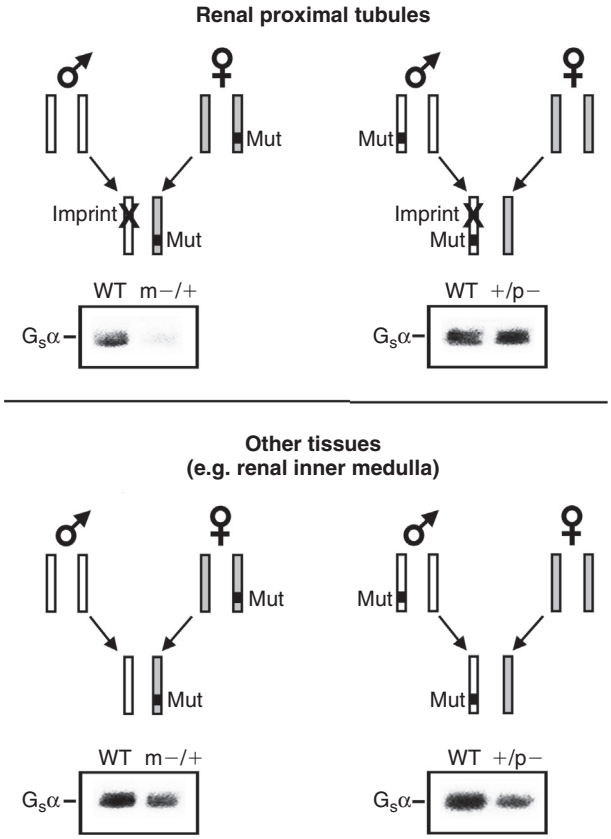

FIGURE 59.4 The role of tissue-specific $G_s\alpha$ imprinting in the pathogenesis of pseudohypoparathyroidism type IA and pseudopseudohypoparathyroidism. (Top) $G_s\alpha$ is paternally imprinted (denoted with an *X*) in renal proximal tubules and therefore mutation (*Mut*) of the active maternal allele (*gray*) results in loss of $G_s\alpha$ expression and parathyroid hormone resistance (left), while mutations in the inactive paternal allele (*white*) do not effect $G_s\alpha$ expression or hormone signaling (right), as shown below in immunoblots of renal cortical membranes from wild-type (*WT*) mice and mice with a $G_s\alpha$ mutation on the maternal or paternal allele (*m−/+* or *+/p−*, respectively) using a $G_s\alpha$-specific antibody (Yu et al., 1998). (Bottom) In other tissues $G_s\alpha$ is not imprinted and therefore maternal and paternal $G_s\alpha$ mutations both lead to ~50% loss of $G_s\alpha$ expression, as shown below in immunoblots of renal inner medullary membranes (Yu et al., 1998). *Reproduced from Weinstein, L.S., 2004. GNAS and McCune-Albright syndrome/fibrous dysplasia, Albright hereditary osteodystrophy/pseudohypoparathyroidism type 1A, progressive osseous heteroplasia, and pseudohypoparathyroidism type 1B. In: Epstein, C.J., Erickson, R. P. and Wynshaw-Boris, A. (Eds.), Molecular Basis of Inborn Errors of Development. Oxford University Press, San Francisco, pp. 849–866.*

A likely explanation for why PHPIA patients do not show clinical resistance to other hormones that also activate $G_s\alpha$ in their target tissues (e.g., ACTH or vasopressin) is that $G_s\alpha$ is not imprinted in these target tissues and therefore $G_s\alpha$ expression is reduced to only ~50% in these tissues (Weinstein et al., 2000). This partial $G_s\alpha$ deficiency may be insufficient to produce clinical hormone resistance, either because $G_s\alpha$ is not rate limiting for generating the cAMP second messenger or because the cAMP levels, while reduced, are still sufficient to elicit a normal physiological response (Carlson et al., 1985; Brickman et al., 1986; Weinstein et al., 2000). This would also explain why PTH resistance is evident in the renal proximal tubule, but not in the distal tubule or in the skeleton (Stone et al., 1993; Ish-Shalom et al., 1996).

Obesity is also a feature specific for PHPIA and therefore is also a consequence of severe $G_s\alpha$ deficiency in a tissue in which $G_s\alpha$ expression is normally affected by imprinting (Long et al., 1988). This is confirmed by mouse studies showing that germ-line disruption of $G_s\alpha$ expression on the maternal allele leads to severe obesity and insulin resistance, while disruption of the paternal allele leads to a much less severe metabolic phenotype (Chen et al., 2005). One potential mechanism for the pathogenesis of obesity in PHPIA would be $G_s\alpha$ deficiency in adipocytes, leading to decreased ability of sympathetic nervous system (SNS) activity and hormones to stimulate lipolysis in these cells, which has been documented in these patients (Kaartinen et al., 1994; Carel et al., 1999). Moreover, genetic manipulations in mice that increase or decrease cAMP or its downstream effectors can lead to a lean or obese phenotype, respectively (Cummings et al., 1996; Martinez-Botas et al., 2000; Valet et al., 2000). However, $G_s\alpha$ has been shown not to be imprinted in adipose tissue (Mantovani et al., 2004) and mice with adipose tissue-specific $G_s\alpha$ deficiency do not develop obesity (Li et al., 2016).

Genetically modified mouse models indicate that imprinting in the central nervous system underlies the obesity that is associated with $G_s\alpha$ and that these mutations impair the stimulation of SNS activity and energy expenditure by central melanocortins (Chen et al., 2009). More recently this parent-of-origin effect of $G_s\alpha$ mutations on energy expenditure was shown to be due to $G_s\alpha$ imprinting in the dorsomedial hypothalamus (Chen et al., 2017). This model is consistent with the finding of reduced serum norepinephrine levels and resting energy expenditure in PHP1A patients (Carel et al., 1999; Shoemaker et al., 2013; Roizen et al., 2016). The role of hyperphagia, if any, on the development of obesity in PHP1A requires further study. $G_s\alpha$ imprinting in brain probably explains why neurocognitive problems are more prevalent in PHP1A (Mouallem et al., 2008).

The other AHO features that are present in both PHPIA and PPHP patients are also most likely to be caused by $G_s\alpha$ deficiency rather than NESP55 or XLαs deficiency, as these gene products would be disrupted only by maternal or paternal mutations, respectively, and AHO is absent in PHPIB patients in whom NESP55 is not expressed due to biallelic methylation of its promoter (Liu et al., 2000). Brachydactyly is probably the result of $G_s\alpha$ deficiency in growth plate chondrocytes, which normally mediates the paracrine effects of PTH-related peptide (PTHrP) to inhibit hypertrophic differentiation of chondrocytes (Vortkamp et al., 1996; Kronenberg, 2003). Mice with disruption of the gene encoding PTHrP (Karaplis et al., 1994) or its receptor (Lanske et al., 1996; Jobert et al., 1998) develop severe skeletal dysplasia with stunted long bone growth resulting from accelerated chondrocyte differentiation. Other studies in mice have confirmed that $G_s\alpha$ deficiency in growth plate chondrocytes leads to a similar cellular and whole-animal phenotype (Bastepe et al., 2004; Sakamoto et al., 2005). Osteoma cutis appears to result from the fact that $G_s\alpha$ deficiency in mesenchymal cells promotes osteoblast differentiation, as discussed in more detail in the sections on POH and MAS/FD. The exact mechanisms by which some AHO patients develop mental deficits are not clear, but may also be related to $G_s\alpha$ deficiency, as cAMP and PKA are known to be important for learning and memory (Levin et al., 1992; Wu et al., 1995; Abel et al., 1997; Rotenberg et al., 2000) and for neurite outgrowth and differentiation (Vossler et al., 1997; Jessen et al., 2001).

Progressive osseous heteroplasia

Clinical features

POH is a more severe form of the ectopic ossification observed in AHO in which dermal and subcutaneous ossifications coalesce to form large plaques and invade deep connective tissues and skeletal muscle, leading to joint stiffness and bone deformity (Kaplan and Shore, 2000). Its onset is generally in early childhood, although one case of adult-onset POH has been reported in whom a $G_s\alpha$ mutation was not identified (Seror et al., 2007). POH may occur sporadically or in a familial manner. In many cases there are no other features of AHO, although POH has been reported to coexist with other features of AHO or multihormone resistance (Eddy et al., 2000; Gelfand et al., 2007). There is no specific therapy for the ossifications. A report on one case suggested that intravenous pamidronate may have slowed the progression of new lesions, although it did not affect the lesions that already had developed (Hou, 2006).

Genetics

In most cases POH is associated with heterozygous germ-line $G_s\alpha$ loss-of-function mutations that are similar, and in some cases identical, to those observed in patients with PHPIA and PPHP (Eddy et al., 2000; Yeh et al., 2000; Ahmed et al., 2002; Shore et al., 2002; Gelfand et al., 2007). Although it has been reported that POH occurs only with paternal inheritance of *GNAS* mutations (Shore et al., 2002), POH has been shown to occur upon maternal transmission of mutations in two cases, one of which also had features of PHPIA (Eddy et al., 2000; Ahmed et al., 2002). In one of these cases, the proband had POH, while his affected sister presented with PHPIA without POH (Ahmed et al., 2002). Moreover, another case showed features consistent with POH, AHO, and multihormone resistance (PHPIA) (Gelfand et al., 2007). Although neither parent had the mutation, the presence of hormone resistance in the proband strongly suggests that the mutation was on the maternal allele. In one family, paternal transmission of a $G_s\alpha$ mutation resulted in five cases of POH in one generation, while maternal transmission of the mutation resulted in AHO (PHPIA vs. PPHP not determined) in the next generation (Shore et al., 2002). Based on its often unilateral and segmental involvement, it has been suggested that POH is a segmental disorder caused by a somatic inactivating mutation of the wild-type allele at an early stage during development (Happle, 2016), and evidence for this hypothesis has been found in chick embryos with somatic disruption of *GNAS* (Cairns et al., 2013).

Pathogenesis

As in AHO, the ectopic ossifications in POH form by intramembranous ossification. Given that AHO and POH patients have similar mutations that completely disrupt $G_s\alpha$ expression, the severity of ectopic ossification in an individual patient is most likely determined by other factors, including differences in genetic background. Other genes that may modify the severity of ossification include those that may affect $G_s\alpha$ expression from the unaffected allele or those that encode other proteins involved in $G_s\alpha$ signaling or bone formation. It remains unclear why many POH patients do not also have other features of AHO. Although it has been reported that POH is associated with mutation only on the paternal allele (Shore et al., 2002), several reports have contradicted this conclusion (Eddy et al., 2000; Ahmed et al., 2002; Gelfand et al., 2007).

While activating $G_s\alpha$ mutations appear to inhibit osteoblast differentiation in FD, as discussed later, decreased $G_s\alpha$ expression promotes osteoblast differentiation in cultured cells with increased expression of the osteogenic transcription factor Cbfa1/RUNX2 and other osteoblast-specific genes (Lietman et al., 2005). The effect of reduced cAMP on cellular levels of Cbfa1/RUNX2 protein may be in part the result of reduced degradation (Tintut et al., 1999). This regulation may be bidirectional, as one study showed that Cbfa1/RUNX2 suppresses the expression of $G_s\alpha$ in a cultured osteoblastic cell line (Bertaux et al., 2006). $G_s\alpha$ deficiency in mesenchymal precursor cells may promote osteoblast differentiation, leading to ectopic ossification in AHO and POH. Consistent with this, Cbfa1/RUNX2 mRNA was shown to be expressed in dermal fibroblasts from a POH patient (Yeh et al., 2000). Work has shown that activation of Hedgehog signaling in progenitor cells with loss of $G_s\alpha$ plays a key role in ectopic ossification (Regard et al., 2013).

Pseudohypoparathyroidism type IB

Clinical features

PHPIB patients present with renal PTH resistance in much the same way as PHPIA patients, with diminished urinary cAMP response to administered PTH or its analogs, but do not exhibit the AHO phenotype or resistance to most other hormones (Levine et al., 1983). Consistent with the absence of AHO, G_s bioactivity is unaffected in erythrocyte membranes derived from PHPIB patients (Levine et al., 1983; Silve et al., 1986). About half of the patients show evidence of borderline TSH resistance, with slightly elevated TSH levels, which in some cases may be intermittent (Liu et al., 2003; Foppiani et al., 2006). PHP1B patients are born with higher than normal birth weights (Brehin et al., 2015) and rarely may develop GH deficiency (Fernandez-Rebollo et al., 2013; Sano et al., 2015).

Some PHPIB patients present with elevated serum alkaline phosphatase, cortical bone resorption, osteitis fibrosa cystica, or slipped capital femoral epiphysis, presumably due to skeletal effects of chronically elevated PTH levels (Kolb and Steinbach, 1962; Costello and Dent, 1963; Agarwal et al., 2006), and can rarely present with a rachitic picture. These complications seem to be relatively specific for PHPIB, as this is not a feature of PHPIA. Management of the PTH and TSH resistance is similar to that discussed for PHPIA, except that normalization of PTH levels may be more critical to prevent skeletal manifestations of elevated PTH levels and the development of autonomous (tertiary) hyperparathyroidism (Neary et al., 2012). Occasionally PHP1B patients (as defined by their molecular genetic defect) may have one or more AHO features, particularly brachydactyly (Mariot et al., 2008; Mantovani et al., 2010). In one kindred PHPIB was associated with increased urine uric acid excretion and hypouricemia (Laspa et al., 2004), while in another kindred the affected patients initially presented with paroxysmal dyskinesia (Mahmud et al., 2005).

Genetics

Most cases of PHPIB are sporadic, but some are familial. In familial cases the PTH resistance occurs only upon maternal transmission of the trait, similar to the inheritance pattern in PHPIA (Juppner et al., 1998). Those who inherit the trait paternally are asymptomatic carriers. Although mapping studies linked familial PHPIB to the vicinity of *GNAS* on 20q13 (Juppner et al., 1998), the presence of normal erythrocyte G_s function in PHPIB patients ruled out the possibility that the disease is due to mutations that directly disrupt the $G_s\alpha$ coding exons (Levine et al., 1983; Silve et al., 1986). Rather PHPIB is associated with a *GNAS* imprinting defect in which maternal-specific imprinting (methylation) of the exon 1A imprinting control region is absent in virtually all cases, resulting in a paternal-specific imprinting pattern (unmethylated) on both parental alleles (Liu et al., 2000, 2005; Bastepe et al., 2001a,b; Jan de Beur et al., 2003). In sporadic cases the upstream NESP55, XLαs, and antisense promoters are usually also abnormally imprinted with a maternal-specific methylation pattern on both alleles, while imprinting of these upstream regions is unaffected in most

familial cases (Liu et al., 2005). PTH resistance specifically correlates with loss of exon 1A maternal imprinting, and there is no phenotypic correlation with the imprinting status of NESP55, XLαs, or the antisense promoter (Linglart et al., 2007; Elli et al., 2014). Paternal uniparental disomy of chromosome 20 is another mechanism for the development of PHP1B as both *GNAS* alleles would have a paternal epigenotype (Bastepe et al., 2001a, 2011; Takatani et al., 2015). PHP1B with broad methylation changes across the *GNAS* locus is also rarely observed in patients with a broader imprinting abnormality affecting multiple imprinted genes (Court et al., 2013; Maupetit-Mehouas et al., 2013; Bakker et al., 2015; Rochtus et al., 2016; Sano et al., 2016).

Familial PHPIB in almost all cases is associated with a deletion within the linked *STX16* gene (Bastepe and Juppner, 2000; Linglart et al., 2005; Liu et al., 2005). Upon maternal transmission the deletion results in the loss of maternal exon 1A methylation and PHPIB, while paternal transmission has no effect on exon 1A imprinting as the region is normally unmethylated on this allele and does not produce a phenotype. Although this region is presumed to have one or more *cis*-acting elements required for the establishment or maintenance of exon 1A methylation, deletion of the orthologous region in mice did not result in the exon 1A methylation defect or PTH resistance (Frohlich et al., 2007). Less commonly familial PHP1B is associated with maternal deletions involving NESP55 (Bastepe et al., 2005; Richard et al., 2012; Rezwan et al., 2015) or NESPAS (Chillambhi et al., 2010) leading to a paternal epigenotype throughout the *GNAS* locus or with duplications within the *GNAS* upstream region (Perez-Nanclares et al., 2015). In another kindred PHPIB resulted from maternal, but not paternal, inheritance of a 3-bp deletion that removes the carboxy-terminal residue Ile^{382} in $G_s\alpha$ (Wu et al., 2001). The original report showed evidence that this mutation resulted in selective uncoupling of the G protein from the PTH/PTHrP receptor, but a subsequent study showed evidence that the mutation leads to uncoupling from other receptors as well (Linglart et al., 2006).

Pathogenesis

Loss of exon 1A imprinting in PHPIB strongly suggests that this region, which is a primary imprinting control center (Liu et al., 2000), is required for tissue-specific imprinting of $G_s\alpha$. A model has been proposed in which the exon 1A region contains one or more *cis*-acting regulatory elements that inhibit the activity of the $G_s\alpha$ promoter in a methylation-sensitive and tissue-specific manner (Weinstein et al., 2001). In the model shown in Fig. 59.5, the exon 1A region contains a silencer element that binds a *trans*-acting repressor protein that is expressed only in specific tissues such as renal proximal tubules. Normally the repressor binds to the paternal allele and inhibits the paternal $G_s\alpha$ promoter but is unable to bind to the maternal allele due to methylation, allowing the maternal $G_s\alpha$ promoter to remain active. In PHPIB both parental alleles are unmethylated and therefore the repressor can bind to and suppress $G_s\alpha$ expression from both alleles, resulting in renal PTH resistance. In most other tissues the repressor is not expressed and therefore $G_s\alpha$ is expressed from both parental alleles.

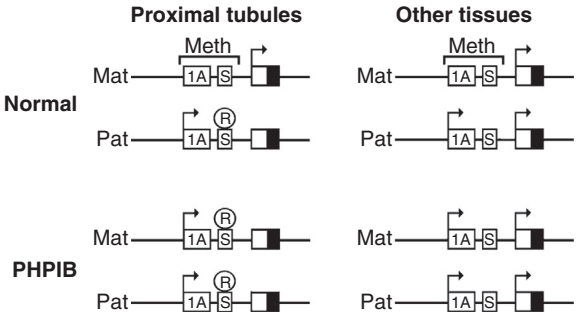

FIGURE 59.5 Model for tissue-specific $G_s\alpha$ imprinting and the pathogenesis of pseudohypoparathyroidism type IB. The model shown predicts that the exon 1A differentially methylated region has a *cis*-acting silencer element (*S*) that inhibits the paternal $G_s\alpha$ promoter (shown as *half-filled box*) in a tissue-specific manner by binding a repressor (*R*) that is expressed in a tissue-specific manner. In renal proximal tubules (left) the repressor can bind to and silence $G_s\alpha$ on the paternal (*Pat*) allele but is unable to bind to or silence $G_s\alpha$ on the maternal (*Mat*) allele as the binding site is methylated. In most other tissues (right) the repressor is not expressed and therefore $G_s\alpha$ is biallelically expressed. In pseudohypoparathyroidism type IB (*PHPIB*) methylation of the maternal allele is absent, allowing the repressor to bind to and silence $G_s\alpha$ from both alleles in renal proximal tubules, leading to $G_s\alpha$ deficiency and renal parathyroid hormone resistance. In most other tissues $G_s\alpha$ expression is unaffected because the repressor is not expressed. This would explain why PHPIB patients have normal $G_s\alpha$ expression in erythrocytes and why they do not develop Albright hereditary osteodystrophy. *Reproduced from Weinstein, L.S., 2004. GNAS and McCune-Albright syndrome/fibrous dysplasia, Albright hereditary osteodystrophy/pseudohypoparathyroidism type 1A, progressive osseous heteroplasia, and pseudohypoparathyroidism type 1B. In: Epstein, C.J., Erickson, R. P. and Wynshaw-Boris, A. (Eds.), Molecular Basis of Inborn Errors of Development. Oxford University Press, San Francisco, pp. 849–866.*

Moreover, the absence of the repressor would predict that loss of maternal exon 1A methylation in PHPIB patients would have no effect on $G_s\alpha$ expression, which is consistent with the fact that $G_s\alpha$ is unaffected in erythrocyte membranes from these patients. The absence of the AHO phenotype in PHPIB patients presumably is due to the fact that $G_s\alpha$ expression levels are unaffected in the vast majority of tissues where $G_s\alpha$ is normally expressed equally from both parental alleles. As $G_s\alpha$ is not imprinted in bone; this tissue would be expected to have normal $G_s\alpha$ levels and PTH responsiveness and therefore be prone to the adverse effects of chronically elevated PTH levels (Murray et al., 1993).

This model is supported by the observation that deletion of the exon 1A region from the paternal allele in mice leads to loss of tissue-specific $G_s\alpha$ imprinting (Williamson et al., 2004; Liu et al., 2005) and can reverse the effects of a $G_s\alpha$-null mutation on the maternal allele (Xie et al., 2008). In fact, these mice have markedly reduced circulating PTH levels presumably due to increased PTH sensitivity in renal proximal tubules due to $G_s\alpha$ overexpression. Borderline TSH resistance in PHPIB results from the fact that $G_s\alpha$ expression from the paternal allele is normally only partially suppressed (Liu et al., 2003). The occasional appearance of AHO features, particularly brachydactyly, in PHP1B patients may correlate with the extent of tissue-specific $G_s\alpha$ imprinting (Zazo et al., 2011).

Fibrous dysplasia of bone and the McCune–Albright syndrome

Clinical features

FD is a benign skeletal disorder with a broad spectrum of severity. It may involve a single bone (monostotic fibrous dysplasia, MFD), multiple bones (polyostotic fibrous dysplasia, PFD), or, in rare circumstances, the entire skeleton (panostotic fibrous dysplasia) (Lichtenstein and Jaffe, 1942; Bianco et al., 2003; Collins and Bianco, 2003; Collins, 2006; Boyce and Collins, 2015).

When FD is found in association with characteristic skin spots and hyperfunctioning endocrinopathies it is known as MAS (McCune, 1936; Albright Fuller et al., 1937). The skin lesions (café-au-lait macules) have a characteristic appearance of jagged borders (resembling the cartographic appearance of the coast of Maine), and tend to follow the developmental lines of Blaschko (Fig. 59.6). The hyperfunctioning endocrinopathies include gonadotropin-independent precocious puberty, thyroid nodules with hyperthyroidism, GH excess (acromegaly/gigantism), and/or adrenal hyperplasia with glucocorticoid excess (Cushing's syndrome). In each case the associated pituitary trophic hormones (gonadotropins, thyrotropin, ACTH) are undetectable, indicating a primary defect in each endocrine gland. Renal phosphate wasting leading to hypophosphatemia, rickets, and osteomalacia can also be present, and is usually seen in patients with extensive FD (Collins et al., 2001; Riminucci et al., 2003; Bhattacharyya et al., 2012). It is caused by the production of the phosphate- and vitamin D-regulating hormone fibroblast growth factor 23 (FGF23) by cells in FD lesions (Riminucci et al., 2003).

FD was described by Donovan McCune and Fuller Albright in association with café-au-lait spots and endocrine hyperfunction; Albright labeled the disease as osteitis fibrosa disseminata (McCune, 1936; Albright Fuller et al., 1937). This name was assigned because of the resemblance, at the histopathological level, to the bone disease of hyperparathyroidism, osteitis fibrosa cystica. In the original cases Albright described, the patients had extensive (disseminated) PFD, thus disseminata. It was Lichtenstein who labeled the disease FD (Lichtenstein, 1938), and Lichtenstein and Jaffe were the first to report extensively on the spectrum, radiographic appearance, and histopathology of

FIGURE 59.6 A typical café-au-lait spot in a patient with McCune–Albright syndrome. Note the relationship of the skin lesions to the midline, the jagged (coast of Maine) borders, and the relationship to the developmental lines of Blaschko. The linear patch at the nape of the neck is seen quite commonly, either in isolation or in association with the larger skin lesions.

FD (Lichtenstein and Jaffe, 1942). FD in the long bones usually presents in childhood as a limp, pain, or a pathologic fracture (DiCaprio and Enneking, 2005; Leet and Collins, 2007; Paul et al., 2014). FD in the skull may first appear as subtle facial asymmetry, or a "lump," and is sometimes associated with pain and dental complications (Riminucci et al., 2002; Burke et al., 2017). Fractures (especially low trauma, pathologic fractures) are more common in childhood, but can persist into adulthood (Leet et al., 2004). Pain, sometimes severe, even in the absence of fractures or trauma is a common feature of FD, particularly in adults (Kelly et al., 2008). The extent of the disease (skeletal disease burden score) can be quantified with the use of nuclear medicine bone scans (Collins et al., 2005), and the skeletal disease burden score directly correlates with fracture rate and number, but surprisingly not with the extent of pain. The skeletal disease burden score also has a direct correlation with the extent to which FD has a deleterious effect on the health-related quality of life (Kelly et al., 2005), with the predominant factor affecting quality of life being the extent to which the skeletal disease burden affects the ability to ambulate without assistance.

FD affects the spine commonly and can be associated with scoliosis (Leet et al., 2004; Berglund et al., 2018) (Fig. 59.7). The FD-associated scoliosis usually appears in childhood and can progress rapidly, even into adulthood, and can rarely be lethal. An uncommon finding in association with FD can be intramuscular myxomas, known as Mazabraud's syndrome (Mazabraud and Girard, 1957; Biazzo et al., 2017). Isolated intramuscular myxomas, in the absence of FD, are also caused by the same $G_s\alpha$ mutations (Okamoto et al., 2000). Rarely (<1% of cases), FD can undergo malignant transformation. Cancer will usually present as the rapid expansion of a preexisting FD lesion in association with pain. On imaging studies there will be a disruption of the cortex in association with a soft tissue mass. Bone cancers have been reported in 123 cases in two large case series (Schwartz and Alpert, 1964; Ruggieri et al., 1999) and in two large reviews (Yabut et al., 1988; Lopez-Ben et al., 1999), wherein it was found that approximately half of the cases of cancer arose in MFD and half in PFD. When one considers that MFD is more common, cancer is more likely to occur in PFD. The regions or bones most commonly involved are the craniofacial bones, the femur, and the tibia. In these series, the most commonly seen histological types were osteosarcoma, fibrosarcoma, and chondrosarcoma. There are reports suggesting that malignant transformation may be more common in patients with Mazabraud's syndrome (Lopez-Ben et al., 1999; Jhala et al., 2003). However, this is probably not the case, but rather represents an ascertainment bias, as the actual prevalence of intramuscular myxomas in association with FD may be more common than expected because most intramuscular myxomas are asymptomatic and go undetected.

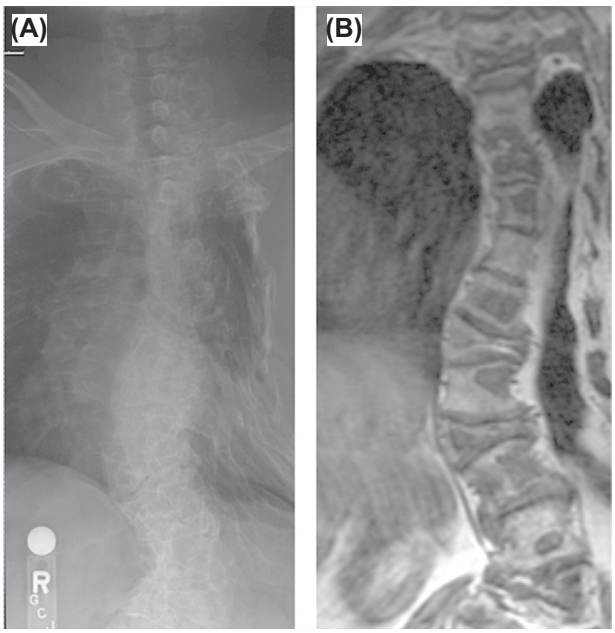

FIGURE 59.7 Scoliosis in FD. Scoliosis of the spine is demonstrated in (A) an X-ray and (B) magnetic resonance imaging (MRI) of the spine in a 54-year-old woman with FD. The extent of the involvement of the vertebral columns with FD is demonstrated in the MRI, where large parts of the vertebrae are shown to be replaced with FD. Surprisingly, and typically, the woman had neither pain nor any evidence of neurological compromise, despite extensive disease and multiple compression fractures.

Genetics

FD/MAS is the result of activating mutations in $G_s\alpha$ (Weinstein et al., 1991; Schwindinger et al., 1992). The vast majority of the mutations (>95% in our series, unpublished data, and 100% in a large published series, Lumbroso et al., 2004) occur at Arg^{201} and are divided roughly equally between either Arg^{201} to His or Arg^{201} to Cys. However, a 2007 report from a large series of patients with FD found three cases (5%) in which the patients had Gln^{227} to Leu mutations (Idowu et al., 2007). The lack of vertical transmission of FD or MAS, the fact that the skin lesions appear to roughly follow the developmental lines of Blaschko, and the fact that the skeletal lesions often tend to affect one side of the body has led to the widely held concept that FD and MAS are the manifestation of somatically acquired *GNAS* mutations and that patients are mosaics. The concept, first proposed by Happle (Happle, 1986), is that if germ-line, the *GNAS* mutations that cause FD and MAS would be lethal, and that the mutation "survives" only due to the somatic, mosaic nature of the mutation. The implication of this line of reasoning is that for a patient with MAS whose disease is manifested by, for example, café-au-lait skin spots (a tissue of ectodermal origin), FD of the long bones (a tissue of mesodermal origin), and hyperthyroidism (a tissue of endodermal origin), the mutation must have occurred very early in development at the inner cell mass stage, prior to the development of the three germ layers (Fig. 59.8). While the clinical data appear to support this model, it has yet to be proven experimentally. In fact, there is an animal model with transgenic expression of a typical $G_s\alpha$ mutation that survives and appears to model at least the FD aspect of MAS (Saggio et al., 2014). As $G_s\alpha$ is imprinted in a tissue-specific manner, the clinical presentation of individuals may also be affected by the parental allele that harbors the mutation, particularly with respect to the presence or absence of acromegaly (Mantovani et al., 2004).

Pathogenesis

FD is the result of $G_s\alpha$-activating mutations in bone marrow stromal cells, which are a subset of skeletal stem cells that gives rise to osteogenic cells, including chondrocytes, osteoblasts, and osteocytes, as well as bone marrow adipocytes and hematopoietic supportive stromal cells (Bianco and Robey, 1999, 2015). Lichtenstein was the first to speculate that FD is the result of the "perverted activity of the specific bone-forming mesenchyme" (Lichtenstein, 1938) and Bianco and colleagues were the first to prove that FD results specifically from bone marrow stromal cells harboring activating $G_s\alpha$ mutations (Riminucci et al., 1997; Bianco et al., 1998; Bianco and Robey, 1999). In addition, it has been shown that the ability of cells harboring the $G_s\alpha$ mutation to produce an FD lesion is dependent on the presence of both mutated and

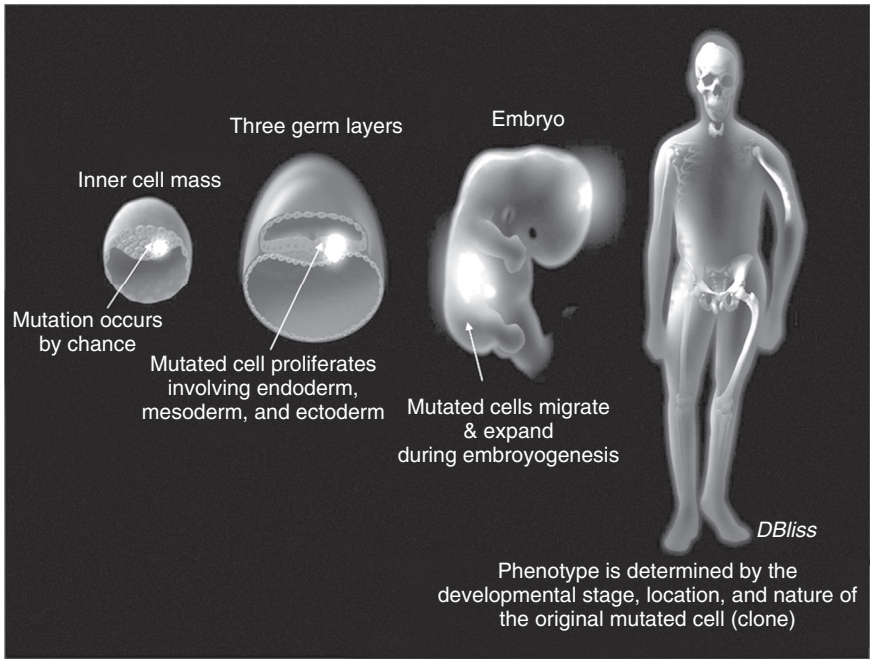

FIGURE 59.8 Developmental explanation for fibrous dysplasia of bone and McCune–Albright syndrome. For involvement of tissues that derive from all three germ layers (skin, bone, and thyroid, for example), the mutation must have occurred in the inner cell mass at the blastocyst stage. The clone in which the mutation occurs is propagated into the three germ layers and the cells migrate and proliferate, leading to the final phenotype.

nonmutated cells (Bianco et al., 1998). It is the fate of the original clone in which the mutation occurs that dictates the phenotype of an individual patient (Fig. 59.8). If the mutation occurs very early in development in a clone in the inner cell mass there will be widespread tissue involvement, perhaps involving all bones and multiple endocrine glands as well. If it occurs later in development, lateral to the midline, there may be only skeletal tissue on one side of the body involved. The "map" of affected tissue is established early in life, with the majority of FD lesions established by the age of 5 and with virtually no new lesions occurring after the age of 15 (Hart et al., 2007). Developmentally, the skeleton forms normally, in that all bones are present in the appropriate anatomical location and relative size, growth plates form normally, and the cortex of bones is intact and normal (at least initially). FD first appears in the bone marrow space of an anatomically normal bone. The fibroosseous tissue that makes up FD replaces the normal bone marrow. It can, and often does, expand within the bone marrow space, increasing the relative size of the bone marrow compartment, deforming the segment of the involved bone in an expansile fashion, and thinning the bone cortices. While entire bones, or even the entire skeleton, can be involved, the disease involves only the bone marrow compartment. Due to the fibrous nature of the tissue and the thinning of the cortex, the weight-bearing bones, especially the femurs, will often bow, giving rise to the "shepherd's crook" deformity of the proximal femur and the "windswept" deformity of the lower extremities (Fig. 59.9).

The genesis of an FD lesion, from a nascent, virtually undetectable collection of bone marrow stromal cells harboring the $G_s\alpha$ mutation and residing in the marrow of an as yet clinically unaffected young child to the full-blown, clinically significant lesion giving rise to the shepherd's crook or windswept deformity, is a complex process that involves all steps in bone development and maintenance, including modeling, bone deposition, mineralization, and remodeling (Riminucci et al., 2007). These processes give rise to a fibroosseous bone disease with a distinct and unique histopathology (Fig. 59.10). The details of the histopathology are complex and are detailed elsewhere (Riminucci et al., 1997, 1999, 2003, 2006, 2007; Bianco et al., 1998, 2000; Bianco and Robey, 1999), but the essentials include a bone marrow space that is replaced with a "fibrous" tissue that is composed of cells that express markers of osteogenic cells. The islands of bone within the fibrous tissue are abnormal in that they are immature, woven bone and have increased numbers of osteocytes. In some cases, the lesions may also include islands of chondrocytic cells. There are two hallmarks of FD histopathology: one is the presence of retracted, stellate-shaped osteoblastic cells, which is due to the effect of excess cAMP (Miller et al., 1976; Riminucci et al., 1997), and the second is the arrays of collagen bundles running perpendicular to the trabecular surface, known as Sharpey fibers (Riminucci et al., 1997), which are a normal feature at sites of tendon and ligament insertion into bone. In addition, FD, which is created by the intrinsic genetic defect in the bone marrow stromal cell, is further influenced by the abnormal extrinsic hormonal milieu that can exist as part of MAS.

It was an understanding of the signaling pathways in the involved endocrine tissues that led to the discovery of the molecular defect underlying FD. The realization that the hormonal hypersecretion was taking place in the absence of trophic hormones suggested that the defect was downstream of the cell surface receptors for these hormones and may

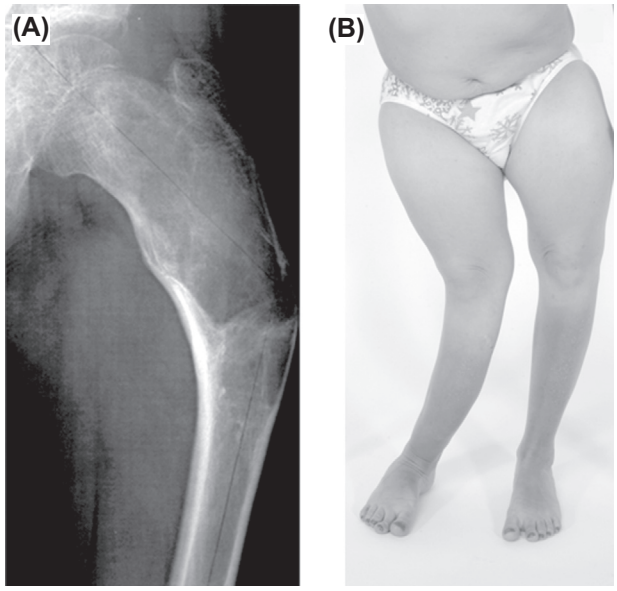

FIGURE 59.9 Classic deformities associated with fibrous dysplasia of bone. (A) The shepherd's crook deformity of the proximal femur and (B) the "windswept" deformity often seen in severe bilateral lower extremity disease are shown.

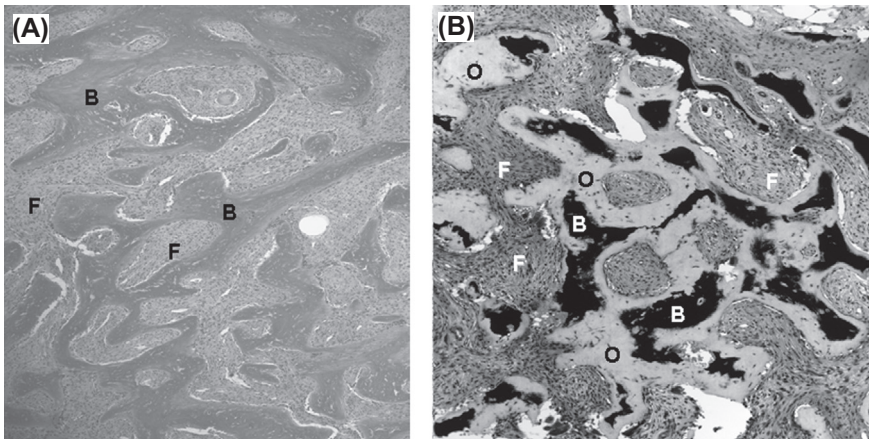

FIGURE 59.10 Histopathological appearance of fibrous dysplasia of bone. (A) Hematoxylin and eosin staining of a demineralized section of fibrous dysplasia of bone showing the classic "Chinese characters" made of trabecular bone (labeled *B*) with fibrous tissue interwoven between (labeled *F*). (B) Von Kossa stain of an un-demineralized, plastic-embedded section of bone, useful for inspecting the degree of mineralization, shows that the trabeculae of bone are composed of bone (*black*, labeled *B*) as well as osteoid (labeled *O*). The fibrous tissue is labeled (*F*). The presence of the unmineralized bone confirms the osteomalacic nature of the lesions.

involve the G proteins that are coupled to cell surface receptors in the generation of downstream signaling (Weinstein et al., 1991; Schwindinger et al., 1992). The activating mutations in $G_s\alpha$ that give rise to FD lead to ligand-independent generation of intracellular cAMP by inhibiting its intrinsic GTPase activity, leading to activation of downstream signaling pathways (Fig. 59.11) (Spiegel and Weinstein, 2004), and/or by allowing GDP-bound $G_s\alpha$ to interact with and activate adenylyl cyclase to generate cAMP (Hu and Shokat, 2018).

The endocrine organs involved, in order of prevalence, include the gonads, thyroid, pituitary (either somatotrophs or developmentally immature somatolactotrophs), and the adrenals (Danon and Crawford, 1987; Ringel et al., 1996; Collins and Shenker, 1999; Boyce and Collins, 2015). Parathyroid gland involvement has been reported to be part of the syndrome, but it is questionable if this is a feature of the disease. In the one reported case of hyperparathyroidism associated with FD/MAS in which a mutation in the hyperplastic gland was sought, it was not present. Some of the suspected cases of familial FD may represent hyperparathyroidism–jaw tumor syndrome, in which fibroosseous lesions (somewhat reminiscent of FD at the clinical, radiographic, and histopathological level) arise in the gnathic bones in association with hyperparathyroidism (Osundwa et al., 2001; Carpten et al., 2002).

Another metabolic syndrome that is commonly seen in association with FD is renal phosphate wasting (Collins et al., 2001; Bhattacharyya et al., 2012). It was originally thought that the phosphaturia and hypophosphatemia of FD were the result of activated $G_s\alpha$ in the kidney (Zung et al., 1995). However, it was subsequently demonstrated that phosphaturia is caused by oversecretion of the phosphate- and vitamin D-regulating FGF23 by FD bone cells (Riminucci et al., 2003). As such, the degree of renal phosphate wasting is directly correlated with the extent of the FD skeletal disease burden (Collins et al., 2005). Of the associated extrinsic endocrine/metabolic syndromes associated with FD, it is hypophosphatemia that probably has the most profound effect on FD. Hypophosphatemia will exacerbate the intrinsic hypomineralization that exists in FD lesions (Bianco et al., 2000; Corsi et al., 2003), and is associated with a greater degree of deformity and an increased number of fractures that occur at a younger age (Leet et al., 2004). GH excess worsens craniofacial fibrous dysplasia, leading to bone overgrowth, vision and hearing loss due to nerve compression (Cutler et al., 2006), and increased risk of malignancies (Uwaifo et al., 2001; Lee et al., 2002; Burke et al., 2017) (Fig. 59.12).

An involvement of the gastrointestinal tract with neoplasms harboring $G_s\alpha$ mutations has been found to be part of MAS. Findings range from small, asymptomatic luminal polyps to benign intraductal papillary mucinous neoplasms (IPMNs) in the pancreas, highly dysplastic luminal neoplasms, and pancreatic cancer (Gaujoux et al., 2014; Wood et al., 2017). This is not surprising, given that the same $G_s\alpha$ mutations that cause MAS have been found to be driver mutations in IPMNs (Wu et al., 2011).

Diagnosis and management

Clinically significant disease is usually diagnosed in childhood; the more significant, the earlier the presentation. The initial presentation of disease in the long bones is usually a limp, pain, or fracture through an FD lesion. Disease in the craniofacial region usually presents as a "lump." X-rays usually have a characteristic "ground glass" appearance

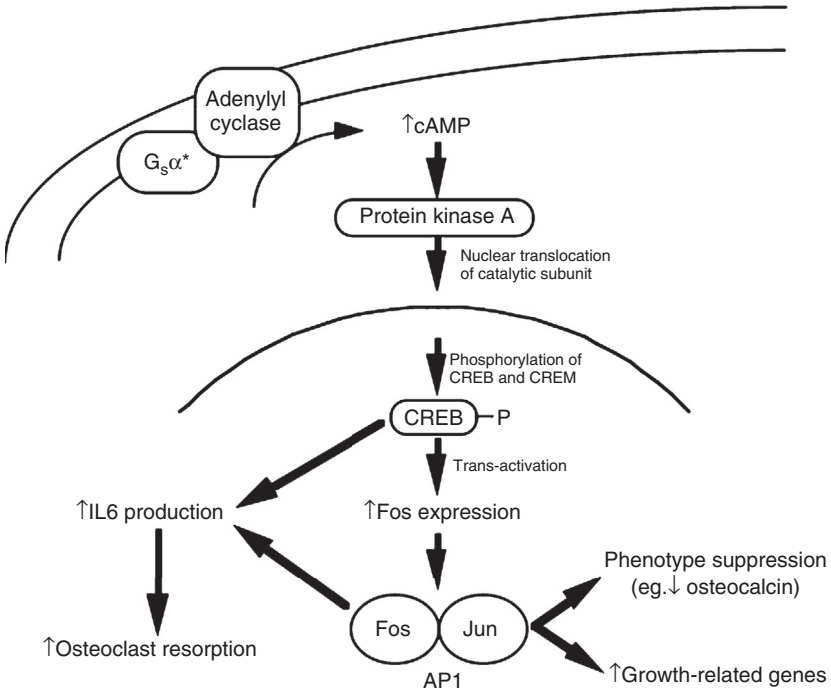

FIGURE 59.11 Possible mechanisms by which activated G_s in osteogenic cells may lead to fibrous dysplasia of bone. G_s activation increases the activity of the effector adenylyl cyclase, leading to increased intracellular cAMP levels. Binding of cAMP to the regulatory subunits of cAMP-dependent protein kinase (protein kinase A) allows release of its catalytic subunits, which translocate to the nucleus and phosphorylate proteins such as cAMP-responsive element binding protein (*CREB*) and cAMP-responsive element modulator (*CREM*). Phosphorylated CREB binds to promoters of cAMP-responsive immediate—early genes (e.g., c-*fos*) and increases their expression. Fos, the product of c-*fos*, binds with Jun to form activator protein 1 (*AP1*). AP1 is a transcription factor that increases the expression of growth-related genes and decreases the expression of osteoblast-specific genes, such as osteocalcin (phenotype suppression). Phosphorylated CREB and AP1 also stimulate the transcription of the interleukin-6 (*IL6*) gene. IL6 may be important in recruiting osteoclasts and stimulating osteoclastic bone resorption.

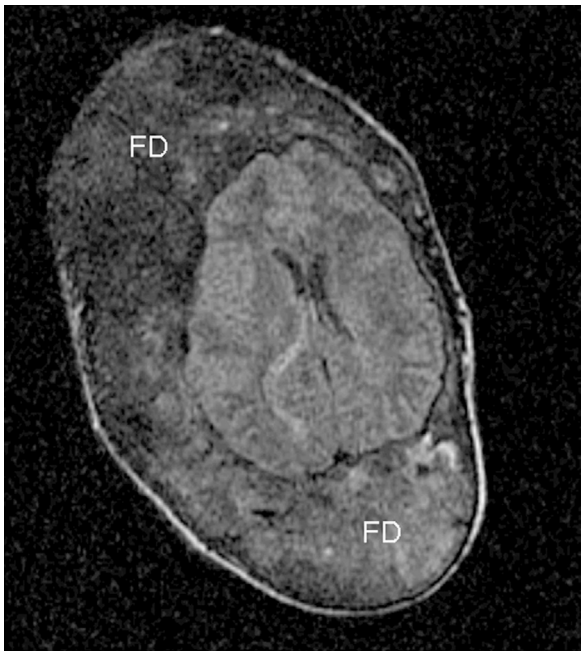

FIGURE 59.12 Craniofacial fibrous dysplasia of bone complicated by growth hormone excess. Areas of fibrous dysplasia of bone (*FD*) that have undergone massive expansion under the stimulation of excess growth hormone (GH)/insulin-like growth factor 1 in a patient with McCune—Albright syndrome are shown. The craniofacial bones are the only bones to undergo such expansion in patients with FD and GH excess.

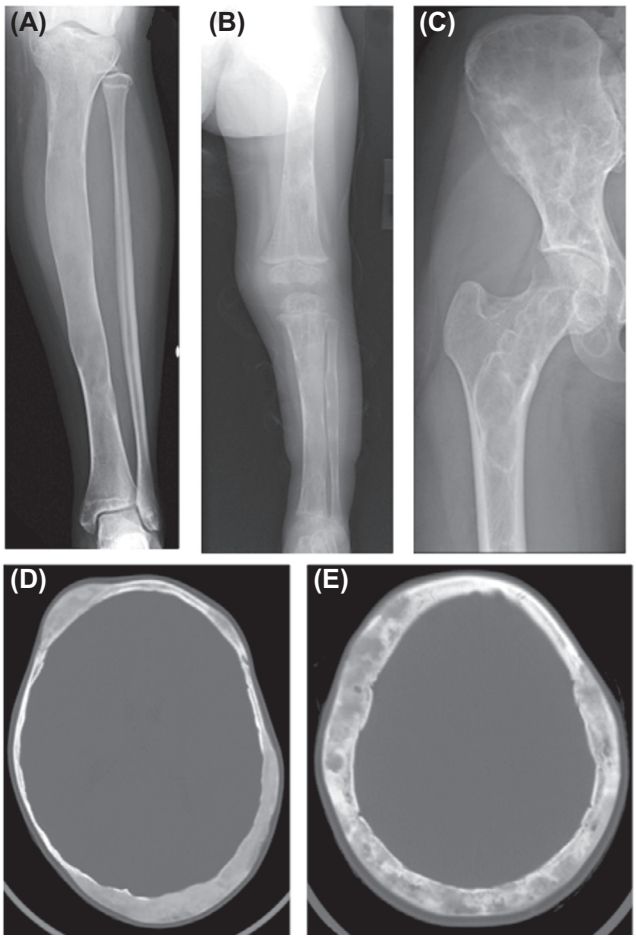

FIGURE 59.13 Radiographic appearance of fibrous dysplasia of bone. (A) The classic description of the radiographic appearance of fibrous dysplasia of bone (FD) is "ground glass," which is depicted in the tibia. (B) In very young children, there is more of a streaked appearance, and (C) in older patients with less active disease there is often a sclerotic rim around FD lesions. (D) On computed tomographic scanning in young children the appearance is, again, homogeneous and ground glass, but (E) with age, the appearance is inhomogeneous, mottled, and sometimes reported to be "cystic."

(Fig.59.13A). However, this classic ground glass appearance is age dependent. In fact, in very young children, FD is often not apparent on X-rays, and when detected has an inhomogeneous "streaked" appearance, rather than the typical ground glass appearance (Fig. 59.13B). This streaked appearance is sometimes mistaken for the "dripping candle wax" appearance of Ollier's disease. In older patients, sclerosis can appear at the edges of FD lesions, representing the reaction of the adjacent normal bone to the FD, and indicating less active disease (Fig. 59.13C). The same is true of FD in the craniofacial region. By computed tomography (CT), the modality of choice for imaging craniofacial FD, the appearance is homogeneous and ground glass in young children (Fig. 59.13D). With time, the lesions develop a mottled appearance, as they are an admixture of typical fibroosseous tissue with islands of what is essentially soft tissue (Fig. 59.13E). This appearance is often referred to as "cystic," which is a useful descriptor, but it must not be mistaken for true, fluid-filled cysts, which can also occur uncommonly in FD. Fluid-filled cysts, with pathognomonic fluid levels, which are best seen by magnetic resonance imaging, occur in $<5\%$ of cases of FD. These truly cystic lesions often behave aggressively, rapidly expanding into adjacent tissue, destroying cortex, and when they are adjacent to vital structures, especially in the skull, they can have significant morbidity (Diah et al., 2007). These lesions require immediate surgical attention. Fluid-filled cysts in the craniofacial region can be distinguished from soft tissue "cystic" lesions on CT scanning by measuring the Houndsfield units; fluid-filled lesions will be ≤ 10 HU, while cystic lesions will be > 10 HU (Collins and Bianco, 2006).

When FD lesions occur in the setting of either typical café-au-lait spots or hyperfunctioning endocrinopathies, the diagnosis is straightforward. However, if there is confusion, a biopsy demonstrating the typical histopathological changes cited earlier can aid in the diagnosis. Finally, if confusion still exists, mutation analysis on affected tissue can confirm the diagnosis if positive for a $G_s\alpha$ mutation. Another factor that can aid in the diagnosis is consideration of the bones involved

and/or the distribution of the disease. FD most commonly involves the proximal femur and skull base, and in polyostotic disease at least one of these two areas will always be involved. When multiple bones are involved, asymmetry is the rule, and the presence of bilateral, symmetric disease is suggestive of another process. In addition, measurement of skeletal disease burden by bone scan can quantify the extent of the disease and aid in prognostication in terms of potential future morbidity (Collins et al., 2005).

In evaluating and caring for patients with FD, it is important to screen for and treat associated endocrinopathies. The correlation between the extent of the skeletal disease and the extent of endocrine involvement is not high, so one cannot assume that minimal skeletal disease automatically excludes the presence of significant endocrine disease. A careful history, physical examination, evaluation of the growth chart, and focused laboratory testing are necessary. The evaluation should assess for precocious puberty, hyperthyroidism, hypophosphatemia (with a low serum $1,25(OH)_2D$ and renal phosphate wasting), and GH excess. Glucocorticoid excess can also occur, usually in the neonatal period. The altered phosphate and vitamin D metabolism is due to overproduction of the phosphaturic factor FGF23 by FD bone, so measurement of serum FGF23 can aid in the diagnosis (Collins et al., 2001; Riminucci et al., 2003). There is a direct correlation between the risk for hypophosphatemia and the FD skeletal burden, with FGF23-mediated renal phosphate wasting seen only in cases of fairly extensive FD.

Surgery remains the mainstay of treatment for FD of the appendicular skeleton. Yet, there is no consensus as of this writing as to the timing or indications and which techniques are best for which indication and at which age. There is an emerging consensus that, when their use is possible, intramedullary rods are better than side plates and screws (Ippolito et al., 2003; Stanton, 2006; Leet and Collins, 2007; Majoor et al., 2018). While bone grafting (filling FD lesions with grafting material, often bone bank, cadaveric bone) was at one time considered useful, a consensus is emerging, especially in children, that this is not the best practice (Ippolito et al., 2003; Leet et al., 2016).

The skull base, through which the optic nerves pass, is the most common site for FD involvement, and it was believed that optic nerve encasement was progressive and visual impairment the rule if untreated (Moore et al., 1985; Chen et al., 1997). For this reason, prophylactic decompression of the optic nerves was recommended. However, evidence has shown this not to be the case (Lee et al., 2002). In fact, the majority of patients with skull base FD, despite extensive disease, will have normal vision throughout their life. It has been further shown that the one group of patients who do suffer functional morbidity due to craniofacial FD (blindness and deafness) are the subgroup of patients with GH excess (Cutler et al., 2006; Amit et al., 2011; Boyce et al., 2013, 2016). This point emphasizes the importance for screening and treatment of GH excess in patients with craniofacial FD.

Another aspect of the disease that needs to be noted because of the possibility of significant morbidity, and even mortality, is that of scoliosis associated with FD of the vertebral column (Mancini et al., 2009). FD in the spine was thought to be an uncommon occurrence, probably because it is difficult to detect on plain radiographs. However, it has been shown that when the sensitive detection technique of ^{99}Tc−methylene diphosphonate bone scanning is used, FD in the spine can be seen in up to 63% of the patients, and that in 64% of the patients who had FD in the spine there was associated scoliosis (Leet et al., 2004a,b). Importantly, while scoliosis can be progressive and associated with significant morbidity and mortality, it is also amenable to surgical correction. Surgical correction is usually effective and lasting, more so than most other surgical interventions in FD.

Bisphosphonates are a useful adjuvant in the treatment of some patients with FD. Early reports contained great enthusiasm for the use of bisphosphonates having a significant effect on the natural history of the disease (Liens et al., 1994; Chapurlat et al., 1997; Zacharin and O'Sullivan, 2000; Parisi et al., 2001). However, subsequent studies and longer follow-up have not substantiated this benefit (Plotkin et al., 2003; Chan and Zacharin, 2006), including the only randomized, placebo-controlled study published as of this writing (Boyce et al., 2014). Yet, it is clear that bisphosphonates can be effective in the relief of pain associated with FD in some patients (Plotkin et al., 2003; Chapurlat, 2006; Lala et al., 2006). Pain is one of the most significant causes of disease-related loss of quality of life in FD (Kelly et al., 2005, 2008). The pain can often be debilitating and require the use of narcotic analgesics. Quite often this pain can be controlled with the use of high-dose intravenous bisphosphonates. However, it has been our experience that the pain of craniofacial FD is often less amenable to treatment with bisphosphonates. Other medical treatments have been tried, including calcitonin (Bell et al., 1970), glucocorticoids (Di Figlia, 1951), and external beam radiation (Tanner et al., 1961), but with no benefit. In fact, it has been demonstrated that external beam radiation is probably associated with an increased rate of sarcomatous transformation (Ruggieri et al., 1994).

More recently, case reports and small series suggest the anti-RANKL drug denosumab may be an effective treatment (Boyce et al., 2012; Benhamou et al., 2014; Ganda and Seibel, 2014). However, as with other high-turnover bone diseases, when denosumab is discontinued, there can be a dramatic increase in bone turnover and hypercalcemia (Boyce et al., 2012). Based on the finding of increased levels of interleukin-6 (IL-6) production by mutation-bearing FD bone cells in

preclinical in vitro models (Riminucci et al., 2003), anti-IL-6 therapy with the anti-IL-6 receptor drug tocilizumab has been undertaken with apparent benefit (Chapurlat et al., 2012).

In summary, FD is a complicated disease that results from somatic mutations in *GNAS* that occur early in embryogenesis and lead to a specific mosaic pattern of involved bones that is established early in development. The intrinsic genetic defect can be influenced by associated endocrine dysfunction that can occur as part of MAS, and highlights the need for screening and treatment of associated endocrine diseases. While a consensus on surgical treatment is lacking, progress has been made. As of this writing medical treatment appears to be palliative, with bisphosphonates offering significant benefit in terms of pain control. Denosumab and tocilizumab show promise for the future. Improvement in both medical and surgical care is needed, and given the relative rarity of the disease, will come only from multicenter, international cooperative studies.

Chapter outline

Introduction to chronic kidney disease

Chronic kidney disease (CKD) affects over 20 million individuals in the United States, and 752 million individuals worldwide (Bikbov et al., 2018). Progressive kidney disease that leads to the need for dialysis (end-stage kidney disease or ESKD) or transplantation affects over 700,000 individuals in the United States. CKD is defined as abnormalities of kidney structure or function present for >3 months, with stratification based on estimated glomerular filtration rate (eGFR) category and the magnitude of albuminuria (Group, 2013). The Kidney Disease: Improving Global Outcomes (KDIGO) group has updated the classification of CKD and changed the term "stage" to "grade," as not all kidney disease is progressive, and noted that the presence or absence of albuminuria can greatly influence prognosis (Levin and Stevens, 2014). There is considerable overlap between individuals identified with osteoporosis and CKD (KDIGO, 2009), and at every stage/grade of kidney disease, there is increased fracture risk (Moe and Nickolas, 2016), demonstrating the important contribution of CKD to bone fragility (Fig. 60.1).

The major causes of CKD are diabetes and hypertension, but there are many other causes of kidney disease, including genetic defects, glomerular lesions, and syndromes of tubular abnormalities. All forms of kidney disease are associated with bone and mineral abnormalities, but the specific causes of the kidney damage or treatments may have additional effects on bone. For example, cystic kidney diseases can be due to genetic alterations in cilia leading to cyst growth in the kidneys and also affect osteocyte function, at least in animal models (Xiao and Quarles, 2010). Patients with glomerulonephritis are often treated with steroids that may lead to steroid-induced osteoporosis. Some kidney tubular defects such as Fanconi's syndrome or the genetic defect Dent's disease lead to proximal tubule phosphate wasting and can lead to osteomalacia. Primary gonadal dysfunction is nearly universal in patients with ESKD, leading to the equivalent of

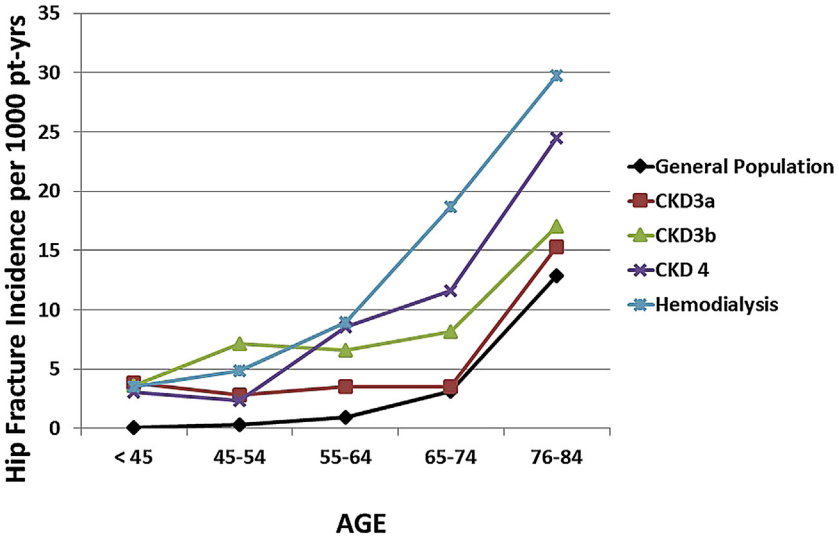

FIGURE 60.1 Hip fracture incidence increases with progressive CKD. As patients age in the general population there is a higher increased incidence of hip fracture. This incidence increases with progression of CKD. *CKD*, chronic kidney disease; *pt-yrs*, patient years. *Data from Alem et al. for dialysis patients and the general population from Olmstead, Minnesota (Alem, A.M., Sherrard, D.J., Gillen, D.L., Weiss, N.S., Beresford, S.A., Heckbert, S.R., Wong, C., Stehman-Breen, C., 2000. Increased risk of hip fracture among patients with end-stage renal disease. Kidney Int. 58, 396–399), Naylor et al. (2013) for CKD stages 3–4 (Naylor, K., Mcarthur, E., Leslie, W., Fraser, L., Jamal, S., Cadarette, S., Pouget, J., Lok, C., Hodsman, A., Adachi, J., Garg, A., 2013. 3-Year incidence of fracture in chronic kidney disease. Kidney Int.) courtesy of the Canadian Institute for Clinical Evaluative Sciences (ICES). Reprinted with permission from Moe, S.M., Nickolas, T.L., 2016. Fractures in patients with CKD: time for action. Clin. J. Am. Soc. Nephrol. 11, 1929–1931.*

postmenopausal osteoporosis or osteoporosis due to testosterone deficiency. Even with the best treatment possible for CKD, kidney transplant, the resulting kidney function is still impaired, and the prevention of transplant rejection with steroids can further increase the risk of bone abnormalities. Finally, CKD is more common in older individuals. Although there is some loss of GFR with normal aging, in patients with eGFR <60 mL/min/m^2 (grade 3–5 CKD) there is clearly loss of normal mineral homeostasis. As a result, there is considerable overlap between CKD and age-related/postmenopausal osteoporosis (Fig. 60.2). Thus, bone and mineral disorders in patients with CKD may be due to the underlying loss of kidney function, but also due to the underlying cause of the CKD and the treatments given.

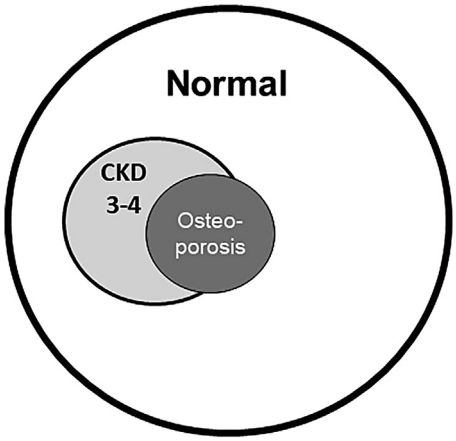

FIGURE 60.2 Overlap between osteoporosis and CKD stages 3–4. This graph shows the overlap between osteoporosis and CKD stages 3–4 in women from the United States, using data from the NHANES III survey. The kidney function was estimated using the Cockcroft–Gault equation, which results in a greater prevalence of CKD stages 3–4 than when other methods are used. *CKD*, chronic kidney disease; *NHANES III survey*, the Third National Health and Nutrition Examination Survey. *Reprinted with permission from Kidney Disease: Improving Global Outcomes, 2009. Clinical practice guidelines for the management of CKD–MBD. Kidney Int. 76, S1–S130.*

Chronic kidney disease–mineral bone disorder

Abnormalities of bone in patients with kidney disease were identified as early as the 1800s in isolated case reports (Ott, 2017). The magnitude of the problem was further illuminated with the onset of modern dialysis. The initial report of the first 16 patients on chronic hemodialysis noted that five had severe bone problems, including fractures (Pendras and Erickson, 1966). The term "renal osteodystrophy" was first used in 1942 to clearly denote that the abnormalities in bone were due to the presence of kidney disease (Liu and Chu, 1942). This term has continued to be used to describe the abnormalities of bone. However, since the beginning of the 21st century, there has been increasing research connecting abnormalities of bone and mineral metabolism to both skeletal and nonskeletal disorders, including cardiovascular disease, anemia, neuropathy, muscle weakness and impaired mobility, immune dysregulation, and altered mental status. The international organization KDIGO held a consensus conference in October 2005 to define and classify renal osteodystrophy. The conclusions of this expert panel of nearly 80 individuals from around the world was that the manifestations of mineral and bone abnormalities were so diverse, and included extraskeletal manifestations, that a new systemic disorder should be defined, called CKD–mineral and bone disorder (CKD–MBD; Table 60.1) (Moe et al., 2006). In contrast, the experts felt the term renal osteodystrophy should be reserved to define an alteration of bone morphology in patients with CKD, quantifiable by histomorphometry of bone obtained by biopsy. Renal osteodystrophy is one manifestation of abnormal bone of CKD–MBD. The goal of this new terminology is to provide consistency in the literature and raise awareness of the importance of these abnormalities in CKD.

The abnormalities that constitute CKD–MBD are interrelated. All three components of CKD–MBD are associated with increased morbidity and mortality in CKD patients and will be described in the following, with the major focus on the abnormalities of bone.

CKD–MBD: biochemical abnormalities

The four hormones parathyroid hormone (PTH), fibroblast growth factor-23 (FGF23), 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), and α-klotho regulate normal calcium and phosphorus levels in a series of feedback loops. In addition to the maintenance of normal extracellular and intracellular levels of calcium and phosphorus, the long-term goal is to ensure adequate availability of these ions for bone that is growing (modeling) or remodeling and minimize extraskeletal calcification in soft tissues and vasculature. The kidney is involved in all of these homeostatic loops, and thus, it is not surprising that homeostasis is disrupted in patients with CKD.

Abnormalities begin early in the course of CKD. The expression of α-klotho in the kidney is reduced by 50% in humans (Asai et al., 2012) and rodents (Moe et al., 2011) at eGFR near 60 mL/min/1.73 m^2. Similarly, at this level of GFR, levels of $1,25(OH)_2D$ are decreased and PTH and FGF23 increased (Fig. 60.3). In patients with an eGFR of less than 60 mL/min/1.73 m^2, over 50% have an elevated FGF23 level greater than 100 RU/mL and 25% have an elevated intact PTH greater than 65 pg/mL. In patients with eGFR <30 mL/min/1.73 m^2, over 90% have FGF23 levels >100 RU/mL, and 75% have an elevated PTH greater than 65 pg/mL (Isakova et al., 2011a). It is believed that with progression of CKD, the body attempts to maintain normal serum concentrations of calcium and phosphorus via increased PTH and FGF23. However, a recent study monitored serial FGF23 levels and found that the FGF23 levels remained stable in the majority of patients, but in those patients with rising levels, there was a marked increase in mortality (Isakova et al., 2017). It is

TABLE 60.1 Kidney Disease Improving Global Outcomes classification of CKD–MBD and renal osteodystrophy.

Definition of CKD–MBD
A systemic disorder of mineral and bone metabolism due to CKD manifested by either one or a combination of the following: • abnormalities of calcium, phosphorus, PTH, or vitamin D metabolism • abnormalities in bone turnover, mineralization, volume, linear growth, or strength • vascular or other soft tissue calcification
Definition of renal osteodystrophy • Renal osteodystrophy is an alteration of bone morphology in patients with CKD. • It is one measure of the skeletal component of the systemic disorder of CKD–MBD that is quantifiable by histomorphometry of bone biopsy.

CKD–MBD, chronic kidney disease–mineral bone disorder; *PTH*, parathyroid hormone.
From Moe, S., Drueke, T., Cunningham, J., et al., 2006. Definition, evaluation, and classification of renal osteodystrophy: a position statement from Kidney Disease: Improving Global Outcomes (KDIGO). Kidney Int. 69, 1945–1953.

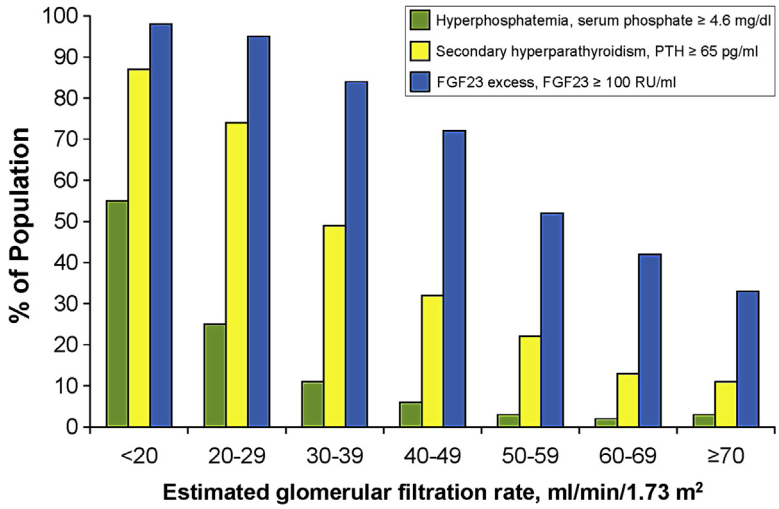

FIGURE 60.3 Prevalence of hyperphosphatemia, secondary hyperparathyroidism, and elevated FGF23 in relation to eGFR. Hyperphosphatemia was defined as serum phosphate ≥4.6 mg/dL, secondary hyperparathyroidism as parathyroid hormone (*PTH*) ≥65 pg/mL and fibroblast growth hormone-23 (*FGF23*) excess as FGF23 ≥ 100 RU/mL. *eGFR*, estimated glomerular filtration rate. *Reprinted with permission from Isakova, T., et al., 2011. Fibroblast growth factor 23 is elevated before parathyroid hormone and phosphate in chronic kidney disease. Kidney Int. 79, 1370−1378.*

presumed that the low expression of α-klotho creates an FGF23-resistant state in the kidneys, leading to increased FGF23 levels in kidney disease. The elevated FGF23 also leads to increased catabolism of both 25(OH)D and $1,25(OH)_2D$. Thus, as early as eGFR <60 mL/min/m^2, there is evidence of the biochemical abnormalities of CKD−MBD.

In contrast to the early rise in FGF23 and PTH and decrease in $1,25(OH)_2D$, serum levels of calcium and phosphorus are abnormal only when the eGFR is <30 mL/min/m^2. Thus, calcium and phosphorus levels do not reflect underlying hormonal derangements. There is decreased calcium absorption in the intestine that can be corrected with the administration of $1,25(OH)_2D$, which has been the practice for over 40 years. However, in CKD stages 3 and 4, there is also a marked reduction in urine calcium excretion. The mechanism by which this occurs is not well understood. It is possible that increased PTH leads to reabsorption; however, the urine calcium does not change in response to treatments with $1,25(OH)_2D$ or its analogs in which PTH is lowered by 30% (Coyne et al., 2006).

These decreases in calcium intestinal absorption and kidney excretion with CKD put patients at risk of positive calcium balance. Two recent calcium balance studies (Spiegel and Brady, 2012; Hill et al., 2012) have demonstrated positive calcium with oral intake from diet and supplements/binders of 800−1000 mg. The potential adverse consequences of positive calcium balance or excess calcium intake include suppression of bone remodeling rates and extraskeletal calcium deposition, at least in patients with ESKD (Barreto et al., 2008). Thus, indiscriminate use of calcium supplements in patients with CKD should be avoided.

Epidemiologic data have demonstrated that hyperphosphatemia in patients with both CKD and ESKD is associated with increased morbidity, and all-cause and cardiovascular mortality in patients with CKD (Kestenbaum et al., 2005; Isakova et al., 2009; Block et al., 2004). In patients with CKD stages 3−5 there are no data to support an increased risk of mortality or fracture with increasing serum calcium concentrations. However, similar to phosphate, there are several studies in dialysis patients demonstrating that hypercalcemia is associated with increased mortality (Block et al., 2004; Tentori et al., 2008). Similar to other biochemical measures of CKD−MBD, most observational studies have found an association of all-cause mortality with elevated levels of PTH; the mortality risk appears to increase at levels greater than 600 pg/mL (Block et al., 2004; KDIGO, 2009). In contrast, nearly all studies have identified an association with elevated FGF23 and adverse outcomes at all stages of kidney disease (Isakova et al., 2011b; Faul et al., 2011; Gutierrez et al., 2008, 2009; Isakova, 2012). Meta-analyses examining the risk of serum levels of calcium, phosphorus, PTH, and FGF23 in patients with CKD have demonstrated the strongest association with mortality with elevated phosphorus and FGF23 (Palmer et al., 2011; Krupp and Madhivanan, 2014). The reality is that none of these biochemical measures of CKD−MBD move in isolation. Thus it is not surprising that the combination of more than two abnormalities (for example, high phosphorus and high PTH) is associated with a greater risk of mortality than any single biochemical measure (Stevens et al., 2004; Tentori et al., 2008; Danese et al., 2015). Importantly, these data are all from observational studies and it is not yet clear that lowering these circulating biochemistries with interventions affects outcomes.

CKD–MBD: vascular calcification

In 1979, Ibels et al. demonstrated that both renal and internal iliac arteries of patients undergoing a renal transplant had increased atherogenic/intimal disease and increased calcification (detected by biochemical methods) compared with transplant donors. In addition, the medial layer was thicker and more calcified in uremic patients compared with the donors (Ibels et al., 1979). When coronary arteries from patients with ESKD who died from a cardiovascular event were compared with those of non-CKD patients who similarly died of a cardiovascular event, there was increased medial thickening, medial calcification, and calcification of intimal plaques in the patients with ESKD. However, the actual area of plaque was similar in the two groups (Schwarz et al., 2000). We examined the inferior epigastric artery of patients undergoing a kidney transplant, and demonstrated medial (nonatherosclerotic) calcification in 31% of patients with associated deposition of bone matrix proteins (Moe et al., 2002). We also identified upregulation of RUNX2 in areas of arteries with calcification, demonstrating that the vascular smooth muscle cells dedifferentiate to osteochondrocyte-like cells in vivo (Moe and Chen, 2008) (Fig. 60.4). These observations demonstrate that arterial calcification in arteries of patients with CKD is not just due to dystrophic (precipitation of calcium-phosphate salts) calcification, but rather to an active cell-mediated process. Hyperphosphatemia, present late in the course of CKD, can induce RUNX2 expression in vascular smooth muscle cells (Jono et al., 2000). However, the effect of uremic serum on calcification is greater than that of phosphorus alone (Moe et al., 2003), indicating that multiple uremic toxins can induce aberrant mineralization.

Coronary artery calcification can be detected with electron beam computed tomography (EBCT) or multislice CT scan. In 1996, Braun et al. first demonstrated by EBCT that coronary artery calcification increased with advancing age in patients on dialysis and that the calcification scores were 2 to 5-fold greater in dialysis patients than in age-matched individuals with normal renal function and angiographically proven coronary artery disease. The prevalence of detectable coronary disease is higher in CKD patients with diabetes than without, with an overall incidence of significant calcification of 47%–63% (Mehrotra et al., 2004). By the time patients reach the need for dialysis, significant coronary artery calcification is observed in over 80% of patients (Block et al., 2005).

There is an inverse relationship between bone mineralization and vascular calcification in patients on dialysis. London and colleagues evaluated hemodialysis patients who underwent bone biopsy with histomorphometry and assessment of vascular calcification by ultrasound with semiquantitative scoring. Those patients with lowest bone formation rates and decreased osteoblast surfaces had the greatest degree of peripheral artery calcification (London et al., 2004). Barreto found that patients on dialysis with low-turnover bone disease by biopsy, compared with high turnover, were more likely to have progression of coronary artery calcification over 1 year as assessed by serial multislice CT scan (Barreto et al., 2008). The mechanism by which turnover affects arterial calcification was studied by Kurz et al. These studies used radiolabeled calcium in CKD patients, demonstrating that in the setting of very-low-turnover bone, versus high-turnover bone, the calcium is not taken up into the bone (Kurz et al., 1994). However, as detailed later, bone disease is far more complex than just abnormal bone turnover.

CKD–MBD: bone abnormalities

The bone component of CKD–MBD consists of abnormalities in linear growth (Ingulli and Mak, 2014), fragility (increased fractures; Fig. 60.1), and abnormal pathology. The last, renal osteodystrophy, is one component of the skeletal outcomes that are associated with CKD–MBD and is defined as an alteration in bone morphology in patients with CKD; it can also be characterized as a global disorder of bone quality that encompasses abnormalities in bone turnover, collagen structure, cortical and trabecular microarchitecture, and/or mineralization (Moe et al., 2006).

Historical classification

Renal osteodystrophy was classified by bone biopsy with tetracycline double labeling and quantitative histomorphometry, and the underlying associated pathologies were categorized by the turnover or mineralization of bone (Table 60.2). This classification utilizes measures of unmineralized osteoid as a percentage of total bone area and quantified fibrosis. These two static measures in conjunction with dynamic measures of bone turnover (i.e., bone formation rate, activation frequency) were used to define the type of renal osteodystrophy.

Fig. 60.5 illustrates types of renal osteodystrophy based on the historical nomenclature. *Normal bone* is illustrated in Fig. 60.5A. *Osteitis fibrosa cystica* (i.e., high-turnover bone disease, hyperparathyroid bone disease) is illustrated in Fig. 60.5B. Sustained hyperparathyroidism results in high bone turnover, excessive numbers and activity of osteoblasts and osteoclasts, disordered collagen production (i.e., formation of woven bone), and accumulation of fibroblastic osteoprogenitors not in the osteoblastic differentiation program, resulting in peritrabecular bone marrow fibrosis. Excessive

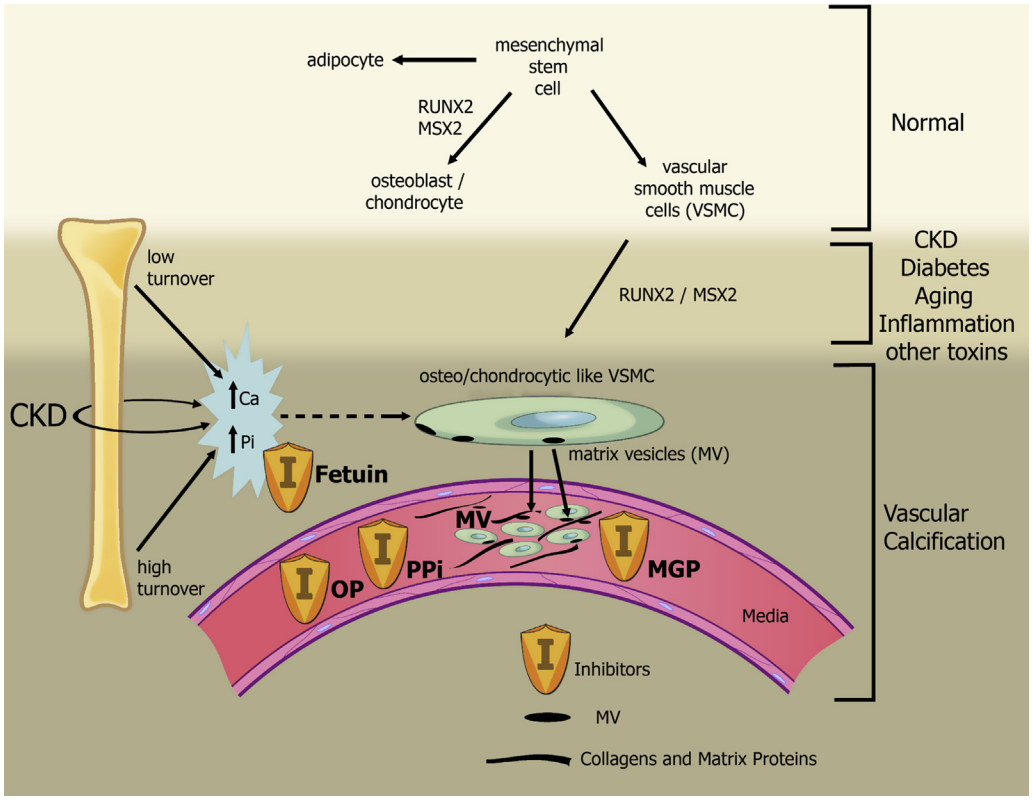

FIGURE 60.4 Overview of pathogenesis of arterial calcification in kidney disease. Normally, mesenchymal stem cells differentiate to adipocytes, osteoblasts, chondrocytes, and vascular smooth muscle cells (VSMCs). In the setting of chronic kidney disease, diabetes, aging, inflammation, and multiple other toxins, these VSMCs can dedifferentiate or transform into osteo/chondrocyte-like cells by upregulation of transcription factors such as RUNX2 and MSX2. These transcription factors are critical for normal bone development and thus their upregulation in VSMCs is indicative of a phenotypic switch. These osteo/chondrocyte-like VSMCs then become calcified in a process similar to bone formation. These cells lay down collagen and noncollagenous proteins in the intima or media and incorporate calcium and phosphorus into matrix vesicles to initiate mineralization and further mineralize into hydroxyapatite. The overall positive calcium and phosphorus balance of most dialysis patients feeds both the cellular transformation and the generation of matrix vesicles. In addition, the extremes of bone turnover in chronic kidney disease (low and high or adynamic and hyperparathyroid bone, respectively) will increase the available calcium and phosphorus by altering the bone content of these minerals. Ultimately, whether an artery calcifies or not depends on the strength of the army of inhibitors (*I*) standing by in the circulation (fetuin-A) and in the arteries (*PPI*, pyrophosphate; *MGP*, matrix Gla protein; *OP*, osteopontin, as examples). *From Moe, S.M., Chen, N.X., 2008. Mechanisms of vascular calcification in chronic kidney disease. J. Am. Soc. Nephrol. 19, 213–216, with permission.*

osteoblast activity is characterized by unmineralized osteoid. Excessive osteoclast activity is characterized by an elevated resorption surface and tunneling into individual trabecula. *Adynamic bone disease* is illustrated in Fig. 60.5C. The hallmark of adynamic bone disease is a profound decrease in or lack of bone turnover, with an absence of osteoblast and osteoclast activity, osteoid formation, and endosteal fibrosis. In contrast to osteomalacia, in adynamic bone there is no increase in

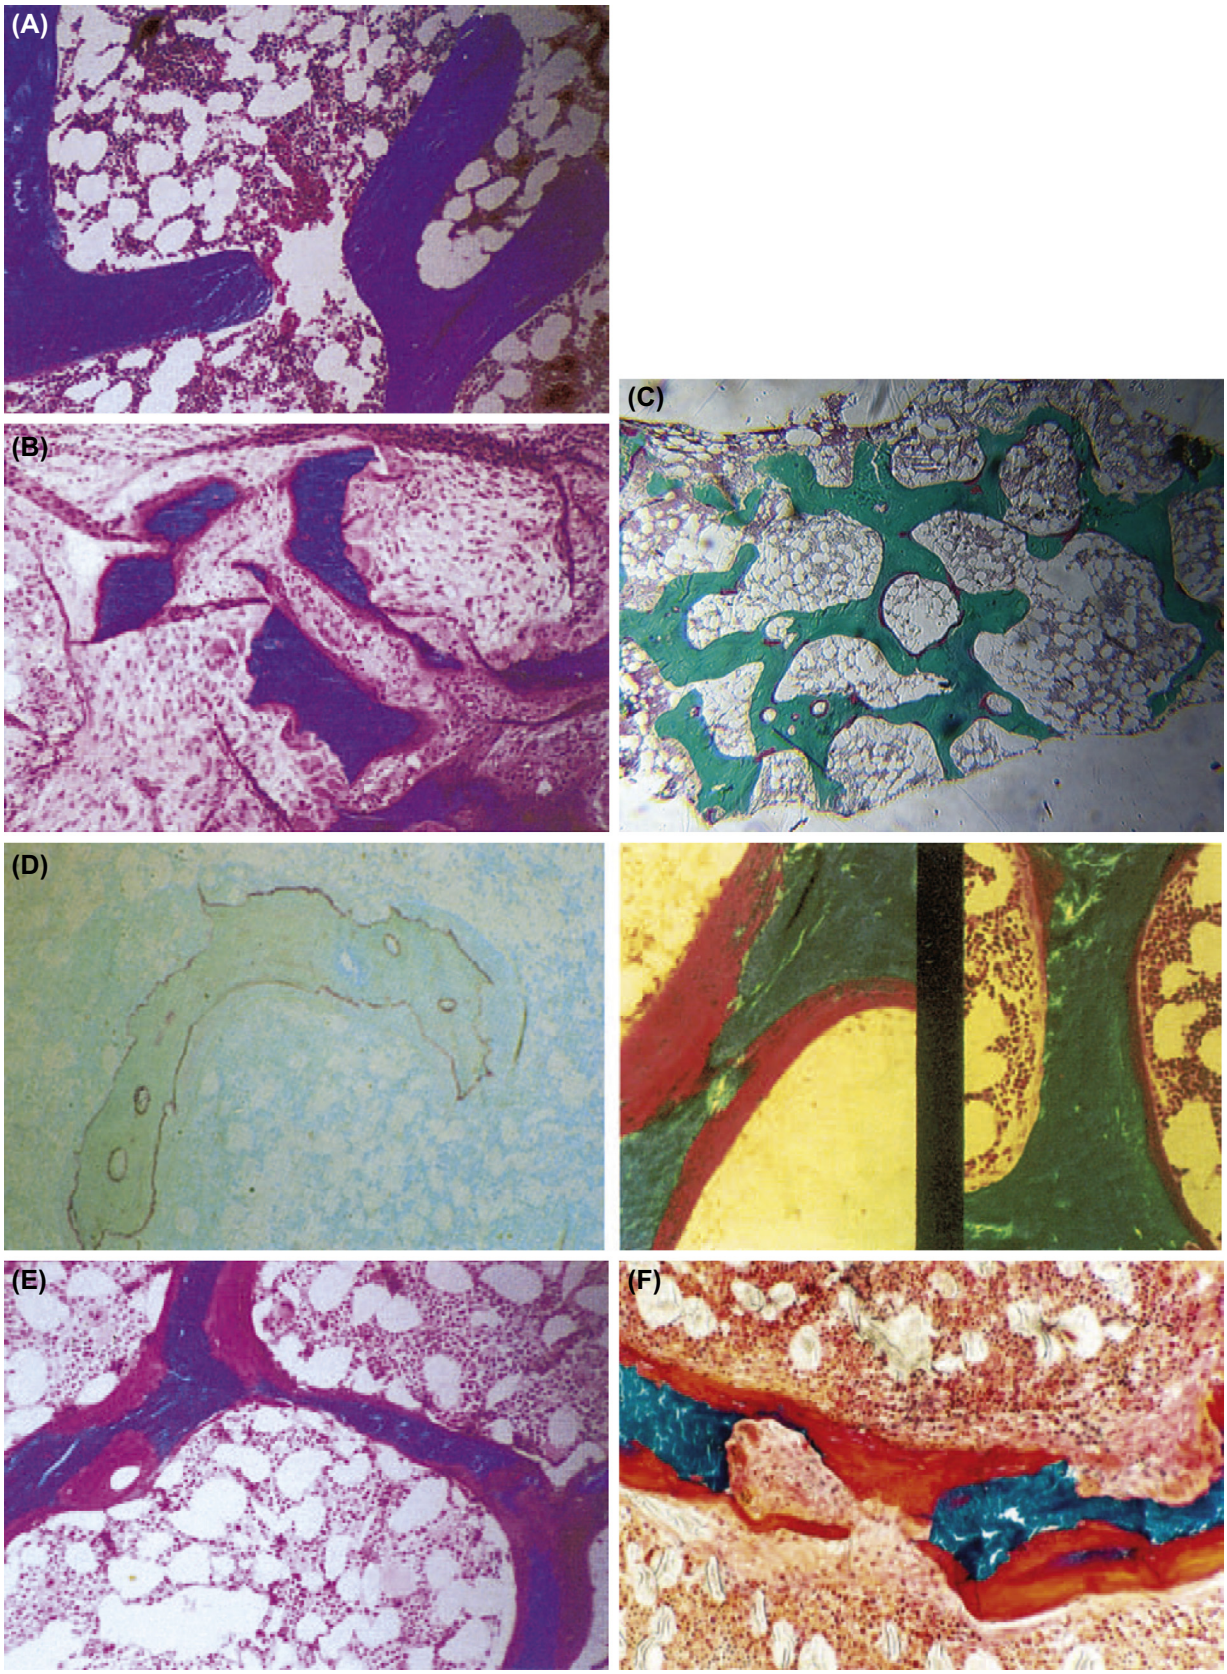

FIGURE 60.5 Bone histology categorized by historical classification system. (A) Normal bone. (B) Hyperparathyroid bone (increased osteoclast and osteoblasts and fibrosis). (C) Adynamic bone (no cellular activity and no osteoid). (D) Aluminum bone disease. (Left) Aluminum staining at mineralization front. (Right) Accumulation of osteoid (orange-red stain). (E) Osteomalacia (increased unmineralized osteoid in pink/red). (F) Mixed uremic osteodystrophy presence of increase osteoid (orange red) indicating mineralization defect, and increased osteoclast activity. ***A, B, D [right],*** *and* ***E,*** *Courtesy S.L. Teitelbaum, MD;* ***D [left],*** *Courtesy D. J. Sherrard, MD.*

osteoid. The majority of the bone surface is covered by lining cells, with few bone-forming and -resorbing cells. The bone structure is predominantly lamellar and the extent of the mineralizing surface is markedly reduced, with thin, single or no tetracycline labels present. Low-turnover bone disease was initially described as a complication of aluminum toxicity resulting from high aluminum content in dialysis water and aluminum-based phosphate binders. Aluminum bone disease (Fig. 60.5D) was histologically characterized by the presence of aluminum deposits at the mineralization front and was frequently associated with osteomalacia (Fig. 60.5E). Aluminum bone disease is now rarely reported due to monitoring of aluminum content in dialysis water and the extremely rare use of aluminum-based phosphate binders (Malluche et al., 2011). Low turnover also occurs in the absence of aluminum exposure; therefore, the etiology of adynamic/low-turnover bone disease is multifactorial. Major contributory factors include diabetes, older age, and malnutrition, along with factors that are unique to uremia (Andress, 2008) (see "Pathogenesis of abnormal bone"). *Mixed uremic osteodystrophy* is illustrated in Fig. 60.5F and describes bone that has features of both renal hyperparathyroidism and defects in mineralization. Therefore, there is excessive osteoblast and osteoclast activity, increased endosteal and peritrabecular fibrosis, and more osteoid than expected, and tetracycline labeling uncovers a mineralization defect.

TMV classification system

In 2009, the KDIGO committee proposed a new classification system, based on the three key histologic features of renal osteodystrophy, bone turnover, mineralization, and volume (TMV [turnover, mineralization, volume] system; Table 60.3), to better describe the bone abnormalities present in CKD and to assist with clinical decision-making. In this system, the histomorphometric abnormalities are reported using standard nomenclature as recommended by the American Society of Bone and Mineral Research (Parfitt et al., 1987). This shift in classification recognized that the historical definition could not accommodate advances in our understanding of the diverse and complex pathobiology of bone disease in CKD patients. For example, the historic renal osteodystrophy classification system relied on assessments of bone turnover and mineralization but was unable to appreciate the increasingly recognized and important role of bone volume as an indicator of bone disease and fracture risk in CKD (Barreto et al., 2006). The TMV classification system provides a clinically relevant description of the underlying bone pathology as assessed by histomorphometry, which in turn helps define the pathophysiology and thereby guide therapy. Fig. 60.6 compares the older classification of renal osteodystrophy based on turnover with the new TMV classification system.

Turnover reflects the rate of bone remodeling. In health, remodeling is a coupled process of bone resorption and formation and is measured on histomorphometry by dynamic measurements of osteoblast function using double tetracycline labeling. The bone formation rate and activation frequency represent parameters for assessing bone turnover. Bone turnover is influenced by hormones, cytokines, mechanical stimuli, and growth factors that influence the recruitment, differentiation, and activity of osteoclasts and osteoblasts. It is important to clarify that although bone formation rate is frequently similar to bone resorption rate, which cannot be measured directly, it is not always so. Imbalance in these processes can affect bone volume. For example, if resorption exceeds formation, negative bone balance and decreased bone volume result.

Mineralization reflects the degree and rate of calcium deposition on bone collagen. By histomorphometry, both static and dynamic parameters contribute to the assessment of mineralization. Static parameters include osteoid surface, which quantifies the percentage of cancellous surface with unmineralized osteoid, with and without osteoblasts, and osteoid thickness, which is the mean thickness of the osteoid on cancellous surfaces. Dynamic parameters, based on tetracycline double labeling, include the mineralizing surface, mineral apposition rate, and mineralization lag time. Causes of

TABLE 60.3 TMV classification system for renal osteodystrophy.

Turnover	Mineralization	Volume
Low	Normal	Low
Normal	Abnormal	Normal
High		High

From Moe, S., Drueke, T., Cunningham, J., et al., 2006. Definition, evaluation, and classification of renal osteodystrophy: a position statement from Kidney Disease: Improving Global Outcomes (KDIGO). Kidney Int. 69 (11), 1945–1953.

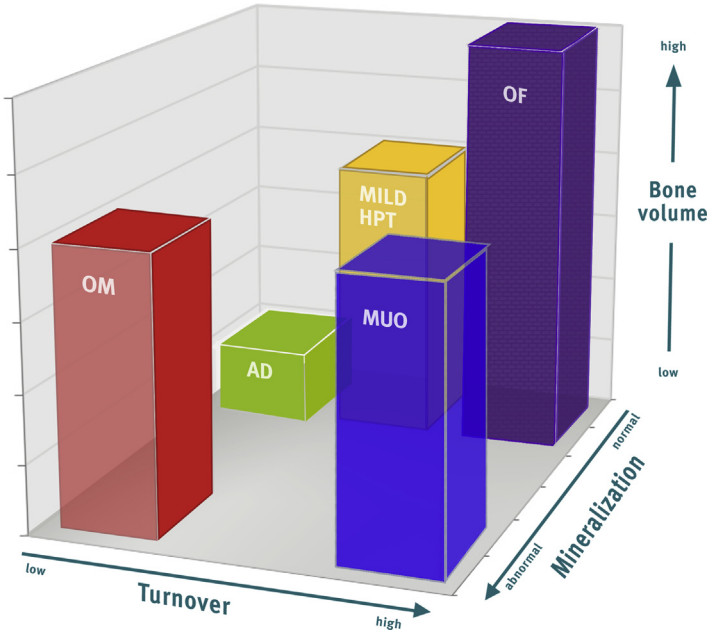

FIGURE 60.6 Comparison of older classification of renal osteodystrophy with TMV classification. The figure is a graphical example of how the TMV system provides more information than the present, commonly used classification scheme. Each axis represents one of the descriptors in the TMV classification: turnover (from low to high), mineralization (from normal to abnormal), and bone volume (from low to high). Individual patient parameters could be plotted on the graph, or means and ranges of grouped data could be shown. For example, many patients with renal osteodystrophy cluster in areas shown by the bars. The *red* bar (osteomalacia [*OM*]) is currently described as low-turnover bone with abnormal mineralization. The bone volume may be low to medium, depending on the severity and duration of the process and other factors that affect bone. The *green* bar (adynamic bone disease [*AD*]) is currently described as low-turnover bone with normal mineralization, and the bone volume in this example is at the lower end of the spectrum, but other patients with normal mineralization and low turnover will have normal bone volume. The *yellow* bar (mild hyperparathyroid [*HPT*]-related bone disease) and the *purple* bar (osteitis fibrosa [*OF*] or advanced HPT-related bone disease) are currently used distinct categories, but in actuality represent a range of abnormalities along a continuum of medium to high turnover and any bone volume depending on the duration of the disease process. Finally, the *blue* bar (mixed uremic osteodystrophy [*MUO*]) is variably defined internationally. In this graph, it is depicted as high-turnover, normal bone volume, with abnormal mineralization. In summary, the TMV classification system more precisely describes the range of pathologic abnormalities that can occur in patients with CKD. *From Moe, S., Drueke, T., Cunningham, J., et al., 2006. Definition, evaluation, and classification of renal osteodystrophy: a position statement from Kidney Disease: Improving Global Outcomes (KDIGO). Kidney Int. 69 (11), 1945–1953, with permission.*

mineralization defects in CKD include vitamin D deficiency, mineral abnormalities, metabolic acidosis, and aluminum and iron bone toxicity.

Volume reflects the amount of bone per unit volume and is the percentage total marrow area (including trabeculae) occupied by cancellous bone. Bone volume is determined by age, gender, race, genetic factors, nutrition, endocrine disorders, mechanical stimuli, toxicities, neurologic function, vascular supply, growth factors, and cytokines.

The spectrum of renal osteodystrophy in CKD

Renal osteodystrophy type may be based on the severity of kidney disease, demographic factors, genetics, exposure to medications that are toxic to the skeleton, and hormonal and metabolic abnormalities that are associated with CKD. Bone biopsy studies in CKD patients also demonstrate that renal osteodystrophy results in global abnormalities in both bone quality and strength; thus, renal osteodystrophy can be considered a form of osteoporosis as defined by the National Institutes of Health Consensus Conference on Osteoporosis.

Some data suggest that up to three-quarters of predialysis patients (CKD stages 3 and 4) have histologic evidence of renal osteodystrophy (Elder, 2002). Of 132 patients with CKD stages 3–5 (not on dialysis), Lehmann et al. (2008) reported that 68.8% patients had mild or full-blown osteitis fibrosa cystica (58.3% CKD stages 3–4; 72.8% CKD stage 5), 8.3% of patients had either adynamic bone disease or mixed uremic osteodystrophy, and 3.8% had osteomalacia (5.5% CKD stages 3–4; 3.1% CKD stage 5). Of 84 predialysis patients, Spasovski et al. (2003) reported that 23%, 38%, 9%, 15%, and 12% had adynamic bone disease, normal bone, hyperparathyroid bone disease, mixed osteodystrophy, and osteomalacia,

respectively. In a more recent analysis that reflects contemporary trends in management of CKD−MBD, Carvalho et al. (2016) compared histomorphometric findings between 16 and 15 patients who were either predialysis (CKD stages 3−5) or on dialysis, respectively, using the TMV system. The prevalence of turnover types differed by dialysis status: (1) for predialysis, 50% had normal turnover, 31% had high turnover, and 19% had low bone turnover, and (2) for dialysis, 50% had high turnover, 31% had low turnover, and 19% had normal bone turnover. Differences in mineralization based on dialysis status were not noted. However, they reported differences in cortical bone volume based on dialysis status: patients with more severe CKD had thinner and more porous cortices.

In patients undergoing dialysis, several recent studies have used the TMV classification system to describe contemporary trends in renal osteodystrophy and characterize tissue-level impairments in bone quality (Sprague et al., 2015; Malluche et al., 2011, 2012). Malluche et al. (2011) evaluated 630 bone biopsies from adult hemodialysis patients from Europe and the United States. For turnover, 58%, 25%, and 18% of patients had low, high, and normal turnover, respectively. There were clear racial differences in turnover: low bone turnover predominated in whites (62%) and normal or high turnover predominated in blacks (68%). For mineralization, defects were uncommon (3% of patients). For volume, low, normal, or high cancellous bone volume was equally distributed among whites, but high volume predominated in blacks. Furthermore, blacks had normal cortical thickness with higher porosity, but whites had an equal distribution of low or normal thickness with high or normal porosity. Trabecular microarchitecture was also examined, with trabecular thickness being low in 37% of patients, normal in 40% of patients, and high in 13% of patients. Trabecular separation was normal in most (78%) of the patients. Interestingly, both black and white patients with high bone turnover had increased porosity, and more than 80% of patients with low cancellous bone volume had thin trabeculae.

The KDIGO consortium (Sprague et al., 2015) evaluated 492 bone biopsies in adult hemodialysis patients from Brazil, Turkey, Venezuela, and Portugal. Similar to Malluche et al. (2011), the prevalence of low-turnover renal osteodystrophy predominated (59%), but only 17% compared with 25% had high turnover. In a smaller study of 35 hemodialysis patients, those with low bone turnover had more microstructural abnormalities (lower cancellous bone volume and thinner trabeculae) than those with high or normal turnover, while those with high turnover had reduced bone strength as measured by nanoindentation (Malluche et al., 2012). In this same study, mineralization defects were common. In children, defective mineralization (defined as increased in osteoid in combination with low mineralization rates) was present in as many as 29% of CKD stage 2 patients, 42% of CKD stage 3 patients, and 79% of patients with CKD stages 4 and 5 (Wesseling-Perry, 2015).

Pathogenesis of abnormal bone

The pathogenesis of abnormal bone in CKD is complex and multifactorial (Table 60.4). Clinically, the focus of treatment of renal osteodystrophy is to lower PTH with calcitriol, or its analogs, or calcimimetics. More recently, animal studies have led to an appreciation of non-PTH-mediated mechanisms.

Parathyroid hormone and decreased $1,25(OH)_2D_3$

The original "trade-off hypothesis," suggested by Bricker et al., deduced that as individual nephrons were lost, the trade-off for maintaining external solute balance for a given solute as renal disease advances would be the induction of one, or more, of the abnormalities of the uremic state (Bricker, 1972). Bricker and Slatopolsky noted from dog experiments that the compensatory response to loss of nephrons and the inability to excrete phosphorus was an increase in PTH secretion (Slatopolsky et al., 1971). The effect of phosphate and PTH increase on bone was detailed in these dogs in 1977 (Slatopolsky et al., 1977), providing the biologic rationale for treating renal osteodystrophy by suppressing PTH with phosphate restriction and $1,25(OH)_2D_3$ in animal models (Rutherford et al., 1977), and eventually in humans (Slatopolsky et al., 1984). Multiple studies demonstrated that low levels of $1,25(OH)_2D_3$ (Martinez et al., 1996) and decreased repression of the PTH gene transcription led to greater synthesis and secretion of PTH. As kidney disease progresses, the number of vitamin D receptors in the parathyroid glands decreases (Merke et al., 1987). These studies led to the primary approach to the treatment of secondary hyperparathyroidism with calcitriol or its analogs for over 40 years.

Interestingly, the data supporting the efficacy of calcitriol or its analogs on improving renal osteodystrophy in humans are limited. An initial study showed improvement in bone formation rate by bone biopsy in 11 patients on hemodialysis treated with intravenous calcitriol (Andress et al., 1989). Subsequent studies in patients with CKD not yet on dialysis demonstrated decreased bone turnover in 30%−50% of subjects treated with calcitriol or its analogs (Baker et al., 1989; Hamdy et al., 1995; Nordal and Dahl, 1988). A study in children undergoing treatment with peritoneal dialysis showed similar results (Salusky et al., 1987). Initially the increase in calcium as a result of calcitriol/analog therapy was presumed

TABLE 60.4 Contributions to the pathogenesis of renal osteodystrophy.

Decreased or aberrant hormones
Increased or decreased PTH
Decreased $1,25(OH)_2D_3$
Increased FGF23
Reduced gonadal hormones
Reduced growth hormone/IGF signaling in children
Abnormal mineralization
Hypocalcemia, or altered calcium-phosphate ratio or product
Decreased $1,25(OH)_2D_3$
Decreased mobility
Abnormal FGF23/klotho signaling in osteocytes
Abnormal cellular function
Decreased mesenchymal differentiation
Abnormal RANK/RANKL/OPG
Abnormal Wnt signaling (elevated sclerostin and Dkk-1)
Inflammation; increased cytokines
Increased TGFβ
Increased FGF23 and osteocyte dysfunction
Abnormal collagen
Increased advanced glycation end product formation
Oxidative stress
Inflammation

$1,25(OH)_2D_3$, 1,25-dihydroxyvitamin D_3; *Dkk-1*, Dickkopf-1; *FGF23*, fibroblast growth factor-23; *IGF*, insulin-like growth factor; *OPG*, osteoprotegerin; *PTH*, parathyroid hormone; *RANK*, receptor activator of NF-κB; *RANKL*, receptor activator of NF-κB ligand; *TGFβ*, transforming growth factor β.

to be favorable for bone mineralization. However, with the recognition of diffuse extraskeletal calcification and resulting cardiac morbidity and mortality, new analogs of calcitriol were developed to be "less calcemic." Unfortunately, human studies have failed to show differences in hypercalcemia (Coyne et al., 2006). Thus, therapy with calcitriol and its analogs, while efficacious in reducing PTH, does not uniformly correct bone turnover or mineralization (reviewed in Newman et al., 2016), suggesting additional non-PTH-mediated mechanisms.

The expression of the calcium-sensing receptor (CASR) is also downregulated in hypertrophied parathyroid glands in CKD (Sumida et al., 2013). Calcimimetics, allosteric activators of the CASR, are used clinically to lower PTH while lowering calcium, phosphorus, and FGF23 (Investigators et al., 2012; Parfrey et al., 2013; Moe et al., 2015c). Animal studies of the $5/6^{th}$ nephrectomy rat model showed improved volumetric cortical bone mineral density (BMD) and cortical stiffness but a nonsignificant lowering of bone formation rate (Wada et al., 1998). In a prospective, randomized controlled study, cinacalcet reduced bone formation rate and fibrosis in dialysis patients. In 77 patients treated with 6–12 months of the calcimimetic cinacalcet, there was a decrease in PTH and a reduction in bone formation rate, mineralization lag time, and osteoblast perimeter and a borderline decrease in osteoclast perimeter (Behets et al., 2015). In small studies, cinacalcet improved BMD (Lien et al., 2005; Tsuruta et al., 2013; Ishimura et al., 2011) but the effect was in general limited to cortical sites. In a study of 163 kidney transplant recipients, cinacalcet therapy (used to treat residual hyperparathyroidism) improved BMD of the hip despite lowering serum calcium levels (Cho et al., 2010). In a secondary analysis of the Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE) trial comparing cinacalcet with placebo on top of usual care (generally calcitriol and its analogs and phosphate binders), a reduction in cortical fractures was found, although the majority of efficacy was in patients older than 65 years of age (Moe et al., 2015a).

Thus, elevated PTH may explain some of the abnormalities of renal osteodystrophy, particularly the cortical porosity and thinning. However, studies have demonstrated that the incidence of age-adjusted hip fracture has actually increased over the past decades despite an intensive use of PTH-lowering therapies (Wagner et al., 2014; Wakasugi et al., 2013). However, bone is still abnormal in the absence of elevated PTH in patients with CKD (e.g., adynamic bone disease), supporting other factors in the pathogenesis of renal osteodystrophy.

Abnormalities in the fibroblast growth factor-23–klotho pathway

Both FGF23 and klotho are expressed in osteocytes, with a complex interrelationship (Rhee et al., 2011; Kaludjerovic et al., 2017a). Expression of FGF23 in osteocytes is markedly increased in early CKD (Wesseling-Perry and Juppner, 2013; Wesseling-Perry, 2010; Graciolli et al., 2017). This may be due to elevated PTH, but there is also decreased expression of the FGF23 regulatory proteins dentin matrix protein 1 and sclerostin in CKD (Pereira et al., 2009). In biopsies from children, the greater the osteocyte expression of FGF23, the greater the mineralization defect (Wesseling-Perry, 2015). Interestingly, klotho is also expressed in osteocytes and klotho-null animals have osteoporosis (Kuro-o et al., 1997), but it is not clear if this was due to klotho changes in bone or the myriad of other systemic abnormalities in mineral metabolism seen in these animals. Concomitant deletion of PTH receptors reverses this phenotype (Yuan et al., 2012). Targeted deletion of klotho from osteocytes in normal animals led to increased bone formation and bone volume, with enhanced osteoblast activity (Komaba et al., 2017). However, when these same animals were induced to have CKD through nephrectomies, the klotho expression was markedly downregulated and there was decreased mineralization and osteoblast activity (Komaba et al., 2017). In long bones, klotho stimulates FGF23 production in animal models of CKD (Kaludjerovic et al., 2017b). Similarly, the exogenous administration of soluble klotho markedly stimulates FGF23 production from bone. Unfortunately, this led to hypophosphatemia, osteomalacia, and fractures in animals (Smith et al., 2012). These studies exemplify the importance of the FGF23–klotho pathway in mediating kidney–bone abnormalities and suggest that downregulation of klotho in osteocytes in CKD, similar to the low expression in kidney and parathyroid glands, may be a factor in the pathogenesis of renal osteodystrophy.

Disordered osteoblast function or differentiation

When PTH is suppressed in the setting of CKD, there are low bone remodeling rates and, in some cases, a paucity of cells. The latter is often called adynamic or aplastic bone disease. The paucity of cells in true adynamic bone disease differs from simple suppression of bone turnover as is seen with, for example, bisphosphonates and indicates abnormal osteoblast differentiation. Studies of mesenchymal stem cell (MSC) differentiation have demonstrated impaired osteoblast differentiation of MSCs in the presence of uremic serum (Della Bella et al., 2017), perhaps due to cytotoxic effects of uremic toxins such as asymmetric dimethylarginine (Xiao et al., 2001). In our rat model of slowly progressive CKD, we found that low PTH and low bone remodeling were associated with decreased vascular endothelial growth factor A (VEGF-A), RUNX2, and Nrf2 (nuclear factor [erythroid-derived 2]-like 2), a master regulator of oxidative stress (Chen et al., 2015). The low VEGF-A and RUNX2 signaling would preferentially lead to adipocyte differentiation of MSCs instead of osteoblasts (Liu et al., 2012b). Adipocyte content of marrow is increased in bone with aging (Justesen et al., 2001), and we also found increased bone marrow fat in patients with CKD compared with matched controls (Moorthi et al., 2015). Taken together, these data support impaired osteoblast differentiation in CKD.

Impaired Wnt signaling

Sclerostin and Dickkopf-1 (Dkk-1) are circulating inhibitors that prevent LRP5/6 activation of Wnt signaling. Such signaling is known to inhibit osteoblastic bone formation and thus may play a role in the development of abnormal bone cell differentiation in CKD where levels of both inhibitors are elevated (Cejka et al., 2011a; Ferreira et al., 2013; Fang et al., 2014; Sabbagh et al., 2012). Sabbagh et al., using the jck mouse model of progressive CKD, identified an increase in sclerostin-positive osteocytes and corresponding reduction in Wnt/β-catenin target genes, indicating impaired osteoblast differentiation. These changes were observed despite increased osteoclastic-mediated bone remodeling and before major increases in PTH (Sabbagh et al., 2012). Parallel studies of human biopsies from patients with CKD showed increased sclerostin in osteocytes, with only slight attenuation in the setting of elevated PTH (Sabbagh et al., 2012). We further examined this pathway in our Cy/+ rat model of CKD and found that anti-sclerostin antibody treatment was effective in restoring bone volume and cortical geometry only in animals with PTH suppression and low bone turnover, and not in the high-PTH animals (Moe et al., 2015b). Even with improved bone volume, there was no improvement in biomechanical testing with the anti-sclerostin antibody as was seen in normal animals (Moe et al., 2015b).

Dkk-1 was examined in the LDL receptor knockout mouse with surgically induced CKD. Early in the course of CKD (stage 2), animals were given a monoclonal antibody against Dkk-1. The treatment stimulated bone formation rates, corrected the osteodystrophy, and prevented CKD-stimulated vascular calcification. The treatment also decreased the elevated levels of sclerostin, but not FGF23 (Fang et al., 2014). Moyses and colleagues (Ferreira et al., 2013) examined these Wnt antagonists in rats subjected to both nephrectomy and parathyroidectomy and then fed either a low- or a

high-phosphate diet. The result was low-turnover bone in both groups. However, when the animals were fed a high-phosphorus diet there was a decrease in bone volume, and higher sclerostin and Dkkl-1 gene expression compared with the normal phosphate diet—treated animals, suggesting phosphate may also regulate these pathways in a PTH-independent mechanism.

Transforming growth factor β family abnormalities

Expression of transforming growth factor β (TGFβ) is increased in bone biopsies from patients with CKD (Santos et al., 2003; Duarte et al., 2002), and TGFβ is known to regulate bone remodeling by enhancing osteoblast differentiation (Filvaroff et al., 1999; Erlebacher et al., 1998). A neutralizing antibody to TGFβ increased bone volume and suppressed bone turnover, with reduction in both osteoblasts and osteoclasts (Liu et al., 2014). Hruska and colleagues have found that there is increased circulating activin A, a TGFβ superfamily member, released into the circulation in the setting of kidney injury (Hruska et al., 2017). It is believed to be derived from peritubular myofibroblasts, where it stimulates fibrosis in the kidney. Activin A binds the activin type 2A receptor to stimulate osteoclasts (Williams et al., 2018; Sugatani et al., 2003) and in the presence of CKD leads to increased bone remodeling and bone loss. Blockade of this pathway with a ligand trap reversed these abnormalities (Sugatani et al., 2017).

Abnormalities of bone collagen

In addition to cellular abnormalities in bone, the abnormal bone quality seen by imaging studies is suggestive of abnormal collagen. Bone represents the largest collection of long-lived proteins in the body, principally collagen, and thus is highly susceptible to alteration. A major mechanism of collagen changes is through accumulation of advanced glycation end products (AGEs). In patients with CKD, regardless of the presence or absence of diabetes, there are increased circulating levels of AGE proteins (pentosidine and CML) compared with age-matched controls (Thornalley and Rabbani, 2009). AGE levels increase with progression of CKD (Misselwitz et al., 2002), probably due to increased oxidative stress and chronic inflammation (Small et al., 2012), which facilitate AGE formation. In vitro (Willett et al., 2013) and in human bone biopsy studies from patients with postmenopausal osteoporosis (Ural et al., 2015; Abraham et al., 2015), AGE accumulation is associated with reduced bone mechanical properties and impaired osteoblast activity (Gangoiti et al., 2013; Weinberg et al., 2014). In vitro, bone that is nonenzymatically glycated has reduced post-yield strain, a property that can be linked to brittle bone (Willett et al., 2013). We and others have found increased skeletal AGE levels in a CKD animal model, and we have shown these levels to be independent of PTH levels and bone turnover (Aoki et al., 2013; Allen et al., 2015). These and probably other abnormalities in collagen may impair bone quality in CKD.

Diagnostic tests for abnormal bone in CKD

Bone biopsy is the gold standard for assessing bone quality and strength and can inform treatment options for renal osteodystrophy based on the formation, resorption, and mineralization characteristics of bone measured by quantitative histomorphometry. However, bone biopsy's utility in the clinic is limited by its availability at only a few centers worldwide, invasiveness, cost, degree of patient discomfort, and long duration of time needed to process and analyze bone tissue. Noninvasive approaches to assess bone quality and strength in patients with renal osteodystrophy can be implemented in the clinic and can inform treatment decisions without the need for an invasive bone biopsy procedure. Areal BMD can be measured by dual-energy X-ray absorptiometry (DXA), and trabecular microarchitecture can be assessed with the trabecular bone score (TBS). Cortical and trabecular microarchitecture and mechanical estimation of bone strength can be quantified by high-resolution peripheral quantitative CT (HR-pQCT) or micro—magnetic resonance imaging (micro-MRI) with application of micro—finite element analysis (FEA). Finally, bone turnover and mineralization can be assessed by measuring calciotropic hormones and circulating markers of bone formation and resorption. Each of these tools will be discussed.

Bone density and the fracture risk assessment tool

DXA is the clinical standard to measure areal BMD and fracture risk in the general population and is integral to the World Health Organization's (WHO) definition of osteoporosis (T score ≤ -2.5) (Kanis et al., 1994). Historically the role of DXA to assess bone health and fracture risk in CKD was controversial because in small cross-sectional studies, DXA did not discriminate prevalent fractures, and measurements of areal BMD do not predict type of renal osteodystrophy.

However, longitudinal studies in patients across the spectrum of CKD have demonstrated that low areal BMD at the hip and forearm predict incident fractures (West et al., 2015; Iimori et al., 2012; Naylor et al., 2015; Yenchek et al., 2012). Furthermore, these studies reported that the WHO T scores performed similarly in patients with and without CKD for fracture prediction. Based on these studies, the KDIGO guidelines were revised in 2017 to recommend measurement of areal BMD by DXA in CKD patients to assess fracture risk when clinically indicated.

In the general population, the sensitivity of fracture prediction by DXA is improved by the addition of clinical risk factors to measures of areal BMD. The Fracture Risk Assessment (FRAX) tool was developed to provide 10-year absolute risk of major osteoporotic and hip fracture by including 10 clinical risk factors, with or without areal BMD of the femoral neck, into a fracture risk prediction model (Kanis et al., 2008). FRAX has been studied in CKD. In a study from the Canadian Multicentre Osteoporosis Study, 320 individuals with an eGFR <60 mL/min and 1787 with an eGFR ≥60 mL/min were followed for a mean of 4.8 years (Naylor et al., 2015). FRAX performed similarly in its ability to predict major osteoporotic fractures in patients with and without kidney disease. In a cross-sectional study of 353 patients with a mean eGFR of 28 mL/min (∼30% with prevalent fractures), FRAX with femoral neck BMD discriminated those with and without fractures, but was not superior to femoral neck BMD alone (Jamal et al., 2014). FRAX alone, FRAX with BMD, and BMD alone were better discriminants of fracture than age alone. In a study of 485 Japanese hemodialysis patients FRAX did not predict increased fracture risk over a 3.3-year median follow-up (Iimori et al., 2012). It is important to note that for all these studies, the follow-up time was short (with FRAX being validated in general population cohorts to predict fractures over 10 years), and fracture event data from administrative data sets may not have ascertained all fracture types (e.g., occult vertebral fractures). These studies suggest that more research is needed to determine the usefulness of FRAX in CKD. More specifically, some of the clinical factors included in current FRAX algorithms may not be relevant in CKD patients. CKD-specific fracture assessment tools need to be developed, which should incorporate CKD-specific predictors of fracture.

Bone quality imaging: TBS, QCT, HR-pQCT, and micro-MRI

An important limitation of DXA is that it does not assess the three-dimensional microarchitecture of trabecular bone; therefore, DXA cannot assess bone quality. TBS is a novel, widely available, gray-scale textural parameter developed to assess trabecular microarchitecture from lumbar spine areal BMD measures obtained by DXA. In patients without kidney disease, TBS has been shown to predict fracture (Pothuaud et al., 2009; Boutroy et al., 2013; Iki et al., 2014). TBS has been validated against both three-dimensional trabecular microarchitecture assessed by micro-CT in human cadaver vertebrae and two-dimensional transiliac bone biopsy from patients with idiopathic osteoporosis and low trauma fractures (Hans et al., 2011; Roux et al., 2013; Muschitz et al., 2015). We recently demonstrated that TBS was significantly associated with trabecular bone volume (BV/TV), trabecular width (Tb.Wi), trabecular spacing, cortical width on bone biopsy in patients on dialysis (Ramalho et al, 2018). In studies of patients with ESKD and after kidney transplantation, TBS measures were reported to be lower than in matched controls (Yavropoulou et al., 2017; Perez-Saez et al., 2017; Naylor et al., 2016a) and to predict fracture independent of BMD and clinical risk factors for fracture (Naylor et al., 2016a, 2016b). We (Luckman et al., 2017) reported that TBS measures correlated with both cortical and trabecular microarchitecture by HR-pQCT before kidney transplantation, and that changes in TBS measurements reflected changes in trabecular microarchitecture and failure load but not cortical microarchitecture 12 months after transplantation.

QCT has a resolution of 300 μm^3 and quantifies cortical and trabecular volumetric BMD and geometry. Studies using QCT have shown that in CKD cortical deficits predominated and discriminated and predicted future fractures (Jamal et al., 2006; Leonard, 2009; Denburg et al., 2013). HR-pQCT has a higher nominal resolution (60−82 μm^3), which measures trabecular number, thickness, and separation and cortical porosity at the distal radius and tibia. Micro-FEA applied to HR-pQCT data sets has been used to determine the mechanical competence (strength) of cortical and trabecular bone (Pistoia et al., 2004; Boutroy et al., 2008), and advances in image processing methods permit measurement of cortical porosity and trabecular rod and plate structure, which have been associated with bone strength (Nishiyama et al., 2010; Liu et al., 2011, 2012a). The utility of HR-pQCT to quantify cortical and trabecular microarchitecture at the distal radius and tibia to describe microarchitectural mechanisms that account for bone loss over time and to assess fracture risk has been investigated in patients with CKD. Trombetti et al. (2012) compared cortical and trabecular microarchitecture and FEA-calculated bone strength between 33 patients with ESKD and 33 age-matched controls. Patients, compared with controls, had cortices that were thinner and less dense, with higher degree of porosity, and lower trabecular number with higher trabecular network heterogeneity; these impairments were more severe in women than in men. We used HR-pQCT to describe the microarchitectural mechanisms of bone loss in a longitudinal study of 54 patients with CKD stages 2 to 5D. Mean annualized loss of areal BMD by DXA at the forearm was 2.9% (Nickolas et al., 2013). With HR-pQCT, we

identified microstructural mechanisms of the forearm bone loss detected by DXA; there was significant loss of cortical area (−2.9%), density (−1.3%), and thickness (−2.8%) and significant increases in cortical porosity (+4.2%). HR-pQCT discriminated and predicted fractures, defined abnormalities in bone quality that adversely affected bone strength, and identified microstructural abnormalities that accounted for reduced bone density as measured by DXA (West et al., 2015; Trombetti et al., 2012; Nickolas et al., 2010, 2011, 2013; Cejka et al., 2011b). We (Nickolas et al., 2010, 2011) reported that abnormalities in cortical and trabecular bone were more severe with longer duration and severity of CKD. Cortices were thinner and less dense at the radius and tibia, and trabeculae that were less dense, fewer in number, and, with greater network heterogeneity at the radius, highly discriminated predialysis CKD patients with and without fracture (Fig. 60.7) (Nickolas et al., 2010, 2011). Similarly, in a study of 74 hemodialysis patients with and without fracture, Cejka et al. (2011b) reported that patients with fractures had lower cortical and trabecular density, thinner cortices, and fewer trabecular that were more widely spaced apart. In a longitudinal study of 211 patients with CKD stages 3–5, West et al. (2015) reported that cortical measures from HR-pQCT predicted incident fractures.

Micro-MRI also measures bone microarchitecture, but studies of micro-MRI and fracture discrimination and prediction are lacking in CKD. Micro-MRI assessment of trabecular bone microarchitecture has been validated in general population cohorts (Majumdar, 1998; Wehrli et al., 1998). Technical limitations have made cortical bone assessment more difficult, but the development of reduced-acquisition pulse sequence protocols such as ultrashort echo time has made this possible (Seifert and Wehrli, 2016). These can measure the water content of cortical bone as a surrogate marker of cortical porosity,

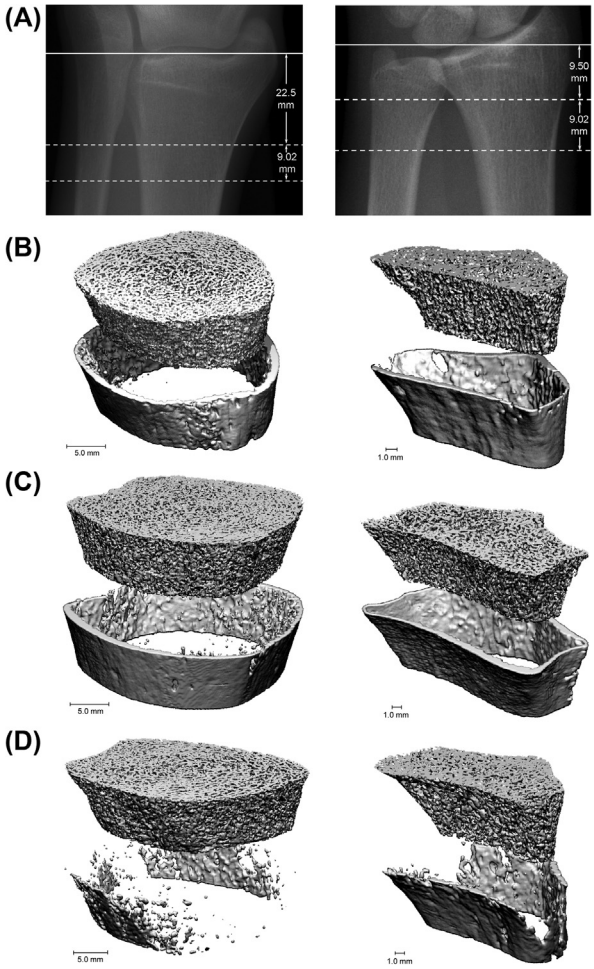

FIGURE 60.7 HR-pQCT provides detailed images of bone geometry and microarchitecture. The left represents the radius and the right the tibia. (C) Images from a predialysis female patient with CKD and without fracture. (D) Images from a predialysis female patient with CKD and with prevalent fracture. *From Nickolas, T.L., et al., 2010. Bone mass and microarchitecture in CKD patients with fracture. J. Am. Soc. Nephrol. 21, 1371–1380, with permission.*

and may provide fracture discrimination in addition to volumetric BMD (Techawiboonwong et al., 2008). In ESKD, Wehrli et al. (2004) reported that compared with age, gender, and body mass index-matched controls, ESKD patients had thinner cortices with lower cortical cross-sectional area. Furthermore, Rajapakse et al. (2012) reported that stiffness and failure load measured by micro-FEA applied to micro-MRI data sets are reduced over the first 6 months of kidney transplantation.

Calciotropic hormones and bone turnover markers

In patients with CKD, measuring calciotropic hormones and bone turnover markers provides mild to moderate accuracy in the noninvasive assessment of bone turnover and mineralization. However, the utility of measuring these markers in improving patient-related outcomes, such as fractures, remains unproven. Calciotropic hormones include PTH and 25-hydroxyvitamin D; markers of bone formation include bone-specific alkaline phosphatase (BSAP), total alkaline phosphatase (TAP), osteocalcin, and procollagen type 1 N-terminal propeptide (P1NP); and markers of bone resorption (osteoclast function) include tartrate-resistant acid phosphatase 5b (TRAP), C-terminal telopeptide of type 1 collagen (CTX), pyridinoline (PYD), and deoxypyridinoline (DPD). TAP has sometimes been used as a surrogate marker of BSAP, particularly in the absence of liver disease. However, total alkaline phosphatase has high biological variation (>20%) and a high BSAP can still result in a normal TAP level (Pagani and Panteghini, 2001; Tibi et al., 1991). Unfortunately, many of these markers are cleared by the kidney, leading to the possibility of falsely elevated values on standard assays; only alkaline phosphatase and TRAP are not cleared at all by the kidneys (Moorthi and Moe, 2013). The 2017 KDIGO guidelines recommend measuring PTH and BSAP to assess turnover type in patients with CKD and to inform treatment of the underlying bone disease when bone biopsy is not available (Ketteler et al., 2017).

PTH and BSAP are the most widely used bone turnover markers to assess bone turnover and BSAP, vitamin D, calcium, and phosphorus are the most common serologic markers to assess mineralization (Ketteler et al., 2017; Malluche et al., 2011; Sprague et al., 2015; Lehmann et al., 2008). Generally, extremes of PTH and BSAP identify bone turnover type based on gold standard bone biopsy. In a comprehensive analysis across the spectrum of CKD, Lehman et al. (Lehmann et al., 2008) studied the utility of PTH, BSAP, TAP, osteocalcin, TRAP, PYD, and DPD in 132 patients with CKD stages 3−5 (not on dialysis). For all patients, regardless of CKD stage, PTH measurements distinguished patients with low/normal versus high bone turnover with a sensitivity, positive and negative predictive value, and accuracy of 91%, 79%, 82%, and 80%, respectively. BSAP, TAP, and TRAP discriminated low/normal from high turnover in CKD stage 5; in contrast, TAP and TRAP did not discriminate in CKD stages 3 and 4.

The two largest studies as of this writing also found only a weak relationship with these biomarkers and bone histomorphometry. In 630 patients with CKD stage 5D (dialysis), Malluche et al. (2011) reported that low-turnover renal osteodystrophy was prevalent in the majority of patients (58%), while only a minority of patients (3%) had a defect in mineralization. Levels of PTH were lower in patients with low- compared with high-turnover renal osteodystrophy, but TAP did not differ between turnover types. Patients with, compared to without, defective mineralization had lower levels of calcium and higher levels of TAP and PTH. Similarly, the KDIGO consortium (Sprague et al., 2015) studied 492 patients on dialysis from four countries who had undergone bone biopsy and assessed the diagnostic accuracy of PTH, BSAP, and P1NP for turnover type. Correlations between bone biopsy−based bone formation rate/bone surface and PTH, BSAP, and P1NP were mild to moderate, ranging from ρ 0.21 for P1NP to ρ 0.52 for BSAP. Similar to Malluche et al. (2011), the prevalence of low-turnover renal osteodystrophy predominated (59%). PTH, BSAP, and P1NP all similarly discriminated low from nonlow and high from nonhigh turnover, with areas under the curve (AUCs) ranging from 0.650 for P1NP (low vs. nonlow) to 0.757 for BSAP (low vs. nonlow); combining biomarkers together did not improve their ability to discriminate turnover type. For PTH, the AUC, sensitivity, and specificity for discriminating low- versus nonlow-turnover renal osteodystrophy were 0.701%, 65%, and 67%, respectively, and for discriminating high- versus nonhigh-turnover renal osteodystrophy were 0.724%, 37%, and 86%, respectively. Combining PTH with BSAP did not improve accuracy, with AUCs of 0.718 for identifying both low- and high-turnover renal osteodystrophy (Sprague et al., 2015). Multiple other studies have evaluated bone biomarkers, reviewed in Moorthi and Moe (2013) and Evenepoel et al. (2017). Table 60.5 summarizes the associations of bone biomarkers with bone outcomes.

These data suggest that PTH and bone turnover markers may have high clinical utility in assessing bone quality and fracture risk in CKD, in particular when used in conjunction with bone imaging methods and as discussed in a recent review (Khairallah and Nickolas, 2018). For example, fracture risk can be measured by DXA. However, deciding on a treatment (vitamin D, calcimimetic, antiresorptive, anabolic) will need to consider the underlying turnover type. PTH and bone turnover markers can potentially be used to inform which pharmacologic agent is most appropriate. However, before bone turnover markers can be widely used to manage renal bone disease, several limitations need to be overcome. BSAP

TABLE 60.5 Association of bone biomarkers and bone outcomes in chronic kidney disease.

Biomarker	Cleared by the kidney	Predictor of histomorphometry for patients	Predictor of fractures	Predictor of bone loss
Marker of bone turnover				
Parathyroid hormone (PTH)	Yes	PTH levels are higher with increased bone turnover than in those with adynamic bone disease (Sprague et al., 2015; Malluche and Monier-Faugere, 2006; Barreto et al., 2008)	Inconsistent results for risk stratification between high or low PTH and fractures (KDIGO, 2009)	Predicted loss of cortical area and thickness in patients with CKD 3–5D (Nickolas et al., 2013)
		No consistent relationship between PTH and bone formation rates or bone volume (Sprague et al., 2015; Malluche and Monier-Faugere, 2006; Barreto et al., 2008)	Decreased fracture risk after parathyroidectomy (Isaksson et al., 2017)	
		Racial differences (Moore et al., 2009)		
Marker of bone formation				
Bone-specific alkaline phosphatase (BSAP)	No	BSAP levels are higher in patients with high turnover in CKD 5D (Sprague et al., 2015; Lehmann et al., 2008; de Oliveira et al., 2015; Coen et al., 1998; Urena et al., 1996)	Predicted fractures in patients on dialysis (Iimori et al., 2012)	Predicted loss of cortical area and thickness in patients with CKD 3–5D (Nickolas et al., 2013)
		Inconsistent discrimination in predialysis CKD (Bervoets et al., 2003; Salam et al., 2018)	No prospective data in patients with CKD 3–5	
Osteocalcin	Yes	Inconsistent discrimination in predialysis CKD (Bervoets et al., 2003; Lehmann et al., 2008; Salam et al., 2018)	No data in CKD	Predicted loss of cortical area and thickness in patients with CKD 3–5D (Nickolas et al., 2013)
Procollagen type 1 N-terminal propeptide (P1NP)	Yes, monomer; no, multimer	P1NP levels are higher in patients with high turnover in CKD 5D (Sprague et al., 2015)	No data in CKD	Predicted loss of cortical area and thickness in patients with CKD 3–5D
		P1NP levels discriminated low from nonlow and high from nonhigh turnover in patients with CKD 3–5D (Salam et al., 2018)		Predicted loss of total volumetric and cortical BMD in patients with CKD 5D (Malluche et al., 2014)
Markers of bone resorption				
C-telopeptide (CTX)	Yes	CTX levels discriminated low from nonlow and high from nonhigh turnover in patients with CKD 3–5D (Salam et al., 2018)	No data in CKD	Predicted loss of cortical area, density, and thickness in patients with CKD 3–5D (Nickolas et al., 2013)
Tartrate-resistant acid phosphatase 5b (TRAP5b)	No	TRAP5b levels discriminated low from nonlow and high from nonhigh turnover in patients with CKD 3–5D (Salam et al., 2018)	No data in CKD	Predicted loss of cortical area, density, and thickness in patients with CKD 3–5D (Nickolas et al., 2013)
		TRAP5b discriminated high from non-high in patients with CKD 5 (Lehmann et al., 2008)		Predicted loss of total volumetric BMD in patients with CKD 5D (Malluche et al., 2014)

Biomarker	Cleared by the kidney	Predictor of histomorphometry for patients	Predictor of fractures	Predictor of bone loss
Pyridinoline	Yes	Discriminated high from nonhigh in patients with CKD 3−5 (Lehmann et al., 2008)	No data in CKD	No data in CKD
Deoxypyridinoline	Yes	Discriminated high from nonhigh in patients with CKD 3−5 (Lehmann et al., 2008) and Patients on PD (de Oliveira et al., 2015)	No data in CKD	No data in CKD

BMD, bone mineral density; *CKD,* chronic kidney disease; *PD,* peritoneal dialysis. CKD 3−5 are patients with estimated glomerular filtration rate less than 60.

lacks a readily available automated assay and there are concerns of cross-reactivity with the liver isoenzyme; there are no validated reference ranges for bone turnover markers in patients with CKD; most bone turnover markers are cleared by the kidney (monomeric P1NP, osteocalcin, and CTX) and have high intra- and interassay variability and biological variability. Future research needs to address these issues and study their impact on hard clinical end points.

Conclusion

Bone disease is a major complication of CKD and is one manifestation of CKD−MBD. Renal osteodystrophy is an alteration of bone morphology in patients with CKD and is one measure of the skeletal component of the systemic disorder of CKD−MBD that is quantifiable by histomorphometry assessed on bone biopsy (Moe et al., 2006). The pathogenesis of renal osteodystrophy is complex. Traditionally, the primary focus on bone health in patients with CKD has been to control PTH with calcitriol or other vitamin D analogs and more recently with calcimimetics. Clearly secondary and tertiary hyperparathyroidism has a major role in stimulating bone remodeling, especially in inducing cortical porosity. Imaging studies are consistent with a primary cortical defect; however, overall bone microarchitecture is impaired when patients with CKD are examined by HR-pQCT. Recent data have demonstrated abnormalities in FGF23/klotho signaling in bone, mesenchymal differentiation of osteoblasts, and Wnt signaling. It is therefore no surprise that PTH alone is an insufficient biomarker for predicting bone histology, and thus future research needs to determine improved molecular signatures of various forms of renal osteodystrophy to optimize both diagnostic and treatment strategies. Such signatures, together with newer imaging modalities, should allow reduction of the ultimate adverse bone outcome: fractures.

Chapter 61

Osteogenesis imperfecta

David W. Rowe

Center for Regenerative Medicine and Skeletal Development, Department of Reconstructive Sciences, Biomaterials and Skeletal Development, School of Dental Medicine, University of Connecticut Health Center, Farmington, CT, United States

Chapter outline

Introduction

There has been a remarkable expansion in the complexity of the genetic mechanisms that result in a clinical diagnosis of osteogenesis imperfecta (OI). This genetic disorder continues to be the paradigm for understanding the molecular basis of heritable connective tissues and evaluating therapeutic strategies for disorders affecting the mineralized skeleton. Some advances are a consequence of the new DNA sequencing technologies, transgenic animal models, and precise clinical observation, while others reflect the concerted efforts of parent supports and collaborating clinical centers to develop multicenter observational studies and clinical trials. This chapter will attempt to convey why this is an exciting time for physicians and scientists, who are beginning to see significant progress in appreciating the complexities of the disease and developing treatments tailored for the specific individual.

While it is still useful to characterize the clinical severity of OI as nondeforming, progressively deforming, and perinatal lethal, this does not help in appreciating the diverse genetic causes of the bone disease, and it probably oversimplifies the clinical spectrum of any specific mutation. Specifically, the heterogeneity of clinical severity is remarkable for a similar type of mutation, even with the same mutation within the same family. This variability is evident in recent reviews of the genetic subtypes of OI, in which almost all are described as variable or mild to severe. The basis for this clinical appearance is termed phenotypic variance and ascribed to both environmental factors and genetic loci that can interact with dominantly inherited mutations. A recent example is demonstrated in a Wnt1 mutation in a three-generational family with different disease severity that was attributable to a small gene duplication unrelated to the location of Wnt1 (Alhamdi et al., 2018). Similar intrafamilial variability has been observed in other genetic forms of OI (Pollitt et al., 2016; Rauch et al., 2013; Galicka et al., 2005). A more detail discussion for the basis of genetic variation affecting phenotype is found in the genetic literature (Pai et al., 2015; Burrows et al., 2016), and its implications for OI will be discussed in the last section of this chapter.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00061-0

The major contribution to assessing the disease severity and natural history of OI has come from the interinstitutional collaborations that arose from the leadership of patient-support groups including the Osteogenesis Imperfecta Foundation (OIF, 2019), Children's Brittle Bone Foundation (CBBF, 2019), and the National Organization for Rare Disorders (NORD, 2019). The initial consortium, called the Linked Clinical Research Centers, demonstrated its ability to capture and analyze clinical data from 544 OI subjects. This accomplishment led to the formation of the Brittle Bone Disorders Consortium (BBDC) (BBDC, 2019) as a recognized part of the NIH-funded Rare Diseases Clinical Research Network (RDCRN, 2019). From these efforts, more comprehensive descriptions of disease severity, nonskeletal effects, and treatment outcomes are being to appear.

Clinical classification

Severe-deforming osteogenesis imperfecta

With the prenatal identification of OI using 3-D ultrasound and CT imaging (Ulla et al., 2011; Akizawa et al., 2012; Suzumori et al., 2011), infants that in the past would not have survived a vaginal delivery are now among those individuals with the most severe forms of skeletal deformity. The cranium is unusually soft and molded and may be fractured at birth. Intracranial bleeding may have occurred. The sclerae are deep blue. The limbs are deformed and short, raising the consideration of hypophosphatasia, achondrogenesis, and thanatophoric dwarfism in the diagnosis. Multiple fractures are seen on X-ray, and the extremities appear broad and crumpled. The critical problem is neonatal pulmonary insufficiency that may lead to death in the first postnatal week (Shapiro et al., 1989). Faulty thoracic musculoskeletal development also limits respiratory function in the majority of cases (LoMauro et al., 2018). Retrospective studies prior to (Shapiro, 1985) and after instituting advanced neonatal care (Folkestad, 2018) still find a higher rate of death in the first year of life than for a reference population, which persists through early childhood. The impact of drug intervention on these early disease processes is yet to be determined (Palomo et al., 2015).

Infants born with fractures and deformity who survive the perinatal period continue to experience multiple fractures with deformities and significant molding of the calvarium (Sinikumpu et al., 2015). Fractures may continue to occur during early childhood that may preclude a normal pattern of ambulation and require the assistance of a walker or wheelchair. Surgical intervention with limb straightening using expandable rods appears to improve ambulation (Franzone et al., 2017; Grossman et al., 2018; Ashby et al., 2018; Gardner et al., 2018), particularly when used in combination with antiresorptive therapy (Ruck et al., 2011, Anam, 2015). Deformity of the thoracic cage (pectus carinatum, pectus excavatum) may be present in early childhood and advance as scoliosis and vertebral compression increase (LoMauro et al., 2018). Vertebral compression, most commonly of the central or "codfish" type, begins shortly after birth and progresses relentlessly prior to puberty (Engelbert et al., 2003; Wallace et al., 2017). Although antiresorptive drugs increase vertebral bone density, they do not affect the progression of kyphoscoliosis. Surgical correction becomes necessary when lung mechanics are compromised (Liu et al., 2017; Piantoni et al., 2017; O'Donnell et al., 2017). Fortunately, the complication associated with the anesthesia needed for these orthopedic procedures is well appreciated and rarely experienced (Bojanic et al., 2011; Rothschild et al., 2018).

Young adults who reach skeletal maturity, many of whom have been treated with antiresorptives, still have short stature, usually in proportion to the severity of their skeletal deformities (Palomo et al., 2015; Germain-Lee et al., 2016; Jain et al., 2019). Dental abnormalities including malocclusion (Nguyen et al., 2017; Jabbour et al., 2018), tooth agenesis (Malmgren et al., 2017), and tooth degeneration requiring dental interventions (Thuesen et al., 2018), resulting in a low oral health-related quality of life (Najirad et al., 2018). Despite dental issues and enduring bone pain with or without an associated fracture (Zack et al., 2005; Folkestad et al., 2017; Tsimicalis et al., 2018), overall quality of life is remarkably positive (Dahan-Oliel et al., 2016; Hald et al., 2017; Tsimicalis et al., 2018; Bendixen et al., 2018). Developing better tools for assessing quality of life issues not currently appreciated by the medical community is a major focus of the BBDC (Swezey et al., 2019).

Issues that develop with increasing age for individuals with OI include cardiovascular, pulmonary, and neurological difficulties, which probably account for the modestly reduced life span of adults with the severer forms of OI (Folkestad, 2018). Beginning in childhood, evidence can be demonstrated of aortic root enlargement (Al-Senaidi et al., 2015; Rush et al., 2017) that can lead to valvular insufficiency (Migliaccio et al., 2009; Radunovic et al., 2011; Ashournia et al., 2015), heart failure (Radunovic et al., 2015; Folkestad et al., 2016), and reports of aortic dissection (Balasubramanian et al., 2019). In addition to structural deformities of the chest wall that compromise pulmonary function, primary pathology within the lung tissue, and skeletal muscle weakness, may also contribute to respiratory symptoms (Arponen et al., 2018; Tam et al., 2018). Because of molding of the base of the skull, subjects with severely compromised bone strength are at risk for developing basilar invagination (Janus et al., 2003; Khandanpour et al., 2012; Cobanoglu et al., 2018) that may

cause brain stem compression with both respiratory and neurological complications and sudden death (Janus et al., 2003; Kovero et al., 2006). Charnas reported communicating hydrocephalus in 17 out of 76 subjects with OI (Charnas et al., 1993). Brain stem compression requiring surgical decompression or reinforcement of the craniocervical junction is extremely complex, requiring mechanical support, transoral clivectomy, and decompression of the posterior fossa where respiratory center function is compromised (Cobanoglu et al., 2018).

Mild nondeforming osteogenesis imperfecta

Individuals who sustain an increased number of fractures that heal without deforming are considered to have type I OI. Despite their apparent normalcy, they are susceptible to complications that affect quality of life, particularly scoliosis and vertebral compression fractures (Ben Amor et al., 2013). A recent survey of 117 affected individuals demonstrated a smaller birth size, impaired adolescent growth spurt, and eventually lower height (Graff et al., 2017). Even during childhood and early adolescence, reduced measurements of gait strength, possibly reflecting muscle weakness (Veilleux et al., 2014; Pouliot-Laforte et al., 2015; Pavone et al., 2017) or ligamentous laxity, are evident by formal gait analysis (Garman et al., 2017). Because patients with type I OI do not benefit from antiresorptive drugs, there was little to offer this large segment of individuals with OI. However, recent studies show the promise of a significant response to anabolic agents such as PTH (Gatti et al., 2013; Orwoll et al., 2014; Leali et al., 2017) and antisclerostin (Glorieux et al., 2017; Nicol et al., 2018) that, if utilized as the skeleton is forming, might mitigate many of these complications.

Molecular classification

The previous edition of the chapter listed nine OI types, two of which were based on clinical phenotyping. In the past 2 years there have been five comprehensive review articles (Forlino et al., 2016; Kang et al., 2017; Lim et al., 2017; Marini et al., 2017; Morello, 2018) listing 18 recognized types and another 2 with OI features and a known genetic mechanism that have not joined the typing list. These review articles provide clear distinctions of the broad range of mutations that interfere with the formation of a stable type I collagen extracellular matrix, the major component of bone, skin, and tendons/ligaments. Rather than repeat the important contributions of these reviews, highlights of each type of molecular mechanism will be presented.

Primary mutations within type I collagen genes A1 and A2

By far, these mutations are the most common genetic cause of OI (Rauch et al., 2010; Zhang et al., 2012), but the location of the mutation has a large impact on clinical severity. The more severe forms (types II, III, and IV) usually result from a mutation in either gene that interferes with the formation of a stable collagen helix and its ability to interact with non-collagenous protein within the bone matrix (Marini et al., 2007). The mutations can be a single base change (usually glycine substitution) or the deletion of an internal segment of the gene. Efforts to associate disease severity with mutation location have been published (Marini et al., 2007; Bodian et al., 2009), but its utility as a predictor of individual skeletal health has not reached clinical fruition, in part due to variations in genetic background and the increasing use of drug interventions. Because these are dominant mutations, pedigrees with multiple affected individuals across generations are the rule. However, the occurrence of OI in a family without a prior history, particularly if more than one child is affected, raises the possibility of germinal mosaicism in one of the parents (Pyott et al., 2011). Thus, knowing the underlying mutation in the affected child is essential in genetic testing of the parents to distinguish germinal mosaicism from a recessive form of OI (see below). Qualified academic and commercial sites for obtaining mutation discovery are maintained on the Osteogenesis Imperfecta Foundation website (OIF-Testing, 2019).

Type I OI is clinically and molecularly distinct from types II, III, and IV. The molecular hallmark is half-normal production of a normal type I collagen molecule and an apparently normal extracellular matrix. The mutation is usually due to either single base change in the collagen type I, alpha 1 (Col1A1) gene that generates a premature stop codon or a splice site mutation that deletes an exon and places the downstream exons out of frame, bringing a stop codon in-frame. In either case, the affected Col1A1 transcript is destroyed by a cellular mechanism called nonsense-mediated decay (Lykke-Andersen et al., 2015). Although this haploid-insufficient mutation is inherited as dominant (Ben Amor et al., 2013), the phenotypic variation may omit family members that only present in later life with osteoporosis. This is another example of why knowing the mutation of affected family members is useful for detecting those who would be predisposed to early-onset osteoporosis (Arundel et al., 2015; Makitie et al., 2017) and might benefit from therapy to delay that outcome (see later).

Mutation of genes that modify the synthesis of type I collagen chains

The majority of these mutations are recessively inherited because they affect enzymes or other processing proteins that provide sufficient activity in the heterozygous state. These disorders usually appear as new disorders within families without previous skeletal abnormalities and point to the importance of mutation identification for predicting natural history and recurrence risk. A number of genes that encode the enzyme complexes that hydroxylate proline at the 3-OH (OI types VII-CRTAP, VIII-P3H1, and IX-PPIB; Barbirato et al., 2015) and 4OH positions (Cole—Carpenter syndrome, P4H1; Balasubramanian et al., 2018; Rauch et al., 2015), and lysine within the helical or telopeptide (Bruck syndrome, PLOD2; Lv et al., 2018; Leal et al., 2018), have been identified and have clinical features of the more severe forms of OI.

The hydroxylation steps occur within the Golgi system and are dependent on proper folding and transit through the system by specific chaperones (OI type X, SERPINH1— Song et al., 2018; Marshall et al., 2016 and OI type XI, FKBP10—Kelley et al., 2011). These mutations either slow transit of the assembly of normal collagen molecules through the rough ER or fail to detect and remove misfolded collagen molecules. The importance of the TMEM38B gene that encodes an ER calcium transport protein necessary for efficient processing and secretion of collagen was revealed by studying another rare recessive OI phenotype classified as OI type XIV (Volodarsky et al., 2013; Webb et al., 2017).

Mutations that control the level of differentiation of osteoblasts

The osteogenic lineage is first recognized as a migratory myofibroblast that enters the nonproliferative stage of enhanced production of extracellular matrix proteins and ends as an embedded osteocyte. Mutations of type I collagen disrupt this sequence of events, which can be recognized in primary cell culture by the low expression of genes that reflect full osteogenic differentiation. Thus, it would not be surprising that other genes controlling differentiation may result in an OI phenotype, although in these cases severity may be less because the extracellular matrix is not abnormal. The first example was the discovery of a heterozygous null mutation of Sp7/Osterix (OI type XIII; Lapunzina et al., 2010; Fiscaletti et al., 2018), a transcription factor required for progenitor cells to enter into and maintain osteogenic differentiation. Subsequently, homozygous null mutations of the Wnt 1 gene (OI type XV), which maintains the differentiated state of the osteoblast, were demonstrated to cause severe OI, while the heterozygous state presented as premature osteoporosis (Palomo et al., 2014; Panigrahi et al., 2018).

Additional mutations resulting in OI have directed attention to more complex and previously unappreciated mechanisms that impact the extent or tempo of osteogenic differentiation. OI type V is dominantly inherited and has the distinctive phenotype features of interosseous membrane calcification, hyperplastic callus formation at sites of bone fracture, and severe bimaxillary malocclusion in addition to bone fragility (Cheung et al. 2007, 2008; Retrouvey et al., 2018). The phenotype is linked to the IFITM5 gene, which encodes the BRIL protein strongly expressed in osteoblasts. The IFITM5 mutation either adds an additional five amino acids to the N-terminal of the protein or a point mutation in the body of the gene (Shapiro et al., 2013; Rauch et al., 2013; Fitzgerald et al., 2013; Brizola et al., 2015). In either case, enhanced osteogenic differentiation and excessive mineralization of the extracellular matrix in cultured cells and mouse models appears to be a consequence of this gene mutation (Rauch et al., 2018; Blouin et al., 2017). In contrast, OI type VI is recessively inherited and has the unusual history of mild to no skeletal abnormalities at birth followed by development of typical bone fractures with deformity during childhood. Histological analysis of bones revealed distorted and impaired matrix mineralization (Trejo et al., 2017). Null mutations in the SERPINf1 gene have been identified for this phenotype (Wang et al., 2017; Homan et al., 2011). This gene produces the well-characterized pigment epithelium-derived factor (PEDF) studied in other clinical settings for its antithrombotic and antivascular properties (Yamagishi et al., 2010; Michalczyk et al., 2018; Eslani et al., 2017). When a mouse model was created, a defect in osteoblast differentiation to a mature osteocyte was demonstrated. Currently, mechanisms dependent on PEDF interaction with Wnt signaling pathways that control differentiation and mineralization are being studied. Because PEDF is a circulating protein (Rauch et al., 2012), efforts to provide this factor using genetic tools are being explored in mouse models with equivocal results to date (Al-Jallad et al., 2015; Belinsky et al., 2016).

Mutation of genes that regulate the maturation of secreted procollagen into collagen fibril

Extracellular processing procollagen is required for helical domains to self-align into growing collagen fibril prior to interaction with the other noncollagenous proteins that embed the growth factors necessary for the regenerative properties of bone. The first example is loss of function of the BMP1 gene resulting in type XII OI (Xu et al., 2019; Pollitt et al., 2016;

Cho et al., 2015). The encoded protein is a metalloproteinase that not only cleaves the C-terminal propeptide of types I and III collagen but also is a protease for other proteins including prodecorin (Syx et al., 2015), lysyl oxidase, latent TGF-β1, BMP-2/4, GDF-8/11, and IGFs as well as the release of antiangiogenic fragments from parent proteins, all of which promote bone healing (Muir et al. 2014, 2016; Asharani et al., 2012; Jasuja et al., 2007; Ge et al., 2006). Another example of a collagen-interacting protein was found in homozygous base substitutions of the SPARC gene (OI type IV; Mendoza-Londono et al., 2015). Osteonectin is the encoded protein widely expressed in many connective tissues and in bone appears to influence both osteogenic differentiation and collagen cross-linking (Rosset et al., 2016).

Pathophysiology of osteogenesis imperfecta

The fundamental abnormality in OI is an inability to produce a bone matrix capable of providing the mechanical, remodeling, and regenerative properties of the axial, appendicular, and cranial skeleton. While most attention is focused on bone and dentin, other type I collagen–rich mineralizing tissues such as the enthesis, periodontal ligaments, and a fibrocartilaginous joint (the temporomandibular joint) are also likely to be affected. Two fundamental differences in the pathophysiologic mechanisms of OI influence how to conceptualize the disease process and eventually shape a therapeutic response. Type I OI and to a lesser extent types XIII (Sp7) and XV (Wnt) produce a normal collagen molecule, although of insufficient quantity to meet load requirements. In contrast, types II–XI produce an abnormal collagen molecule that has adverse effects on osteoblasts and the function of the extracellular matrix. Even though disease severity may merge between the clinical types, it is important to distinguish the cellular and regulatory differences of low production versus an abnormal collagen molecule.

Osteogenesis imperfecta secondary to production of an abnormal collagen molecule

Whether due to a primary mutation with the type I collagen gene or in genes that modify the formation of the triple helical molecule, the resulting consequences act at cellular and physiological levels (Fig. 61.1). The impaired processing of the mutant collagen through the rough ER adversely impedes the progression to full differentiation of the osteogenic lineage, possibly due to activation of ER stress responses (Scheiber et al., 2019; Mirigian et al., 2016; Lindert et al., 2015; Bateman et al., 2019). In vitro this effect can be observed as failure to achieve gene markers of full osteogenic differentiation (Fedarko et al., 1995; Kalajzic et al., 2002; Gioia et al., 2012), while in vivo there is an imbalance in the RANKL/OPG ratio indicative of a preponderance of early osteogenic linage cells (Li et al., 2010). During childhood when the need for matrix apposition and bone remodeling is the greatest, this primary abnormality of lineage progression is compounded by deposition of a defective bone matrix that sustains microfractures. Osteocytes, in response to changes in perceived load, may initiate additional sites of bone resorption/remodeling by the release of RANKL (Zimmerman et al., 2018). The combined result is high osteoclastic activity and a high bone turnover rate that cannot be compensated for by the osteoblast lineage. Clinically this high turnover state is assessed by the type I collagen cross-linking peptides (CTXs) and histologically by markers of high bone formation and bone erosion (Rauch et al., 2006). Intervention with inhibitors of osteoclast formation, either a bisphosphonate or anti-RANKL antibody, is effective in interrupting high turnover state and providing the osteogenic cells to enhance overall matrix accumulation (Palomo et al., 2015). Bone apposition does increase in spite of a suppression of osteogenic markers in growing children. However, once full somatic growth is achieved, the effect of osteoclastic suppression diminishes because bone remodeling is impacted, and the consequences of continued treatment can become evident (Nicolaou et al., 2012; Hegazy et al., 2016; Trejo et al., 2017; Andersen et al., 2019).

Anabolic therapies have generally been ineffective during the period of rapid growth, in part because the osteogenic lineage is fully taxed at this time. However, mouse model studies suggest these agents may play roles in enhancing matrix formation during somatic growth when used sequentially with an antiresorptive agent (Olvera et al., 2018). Another approach for stimulating bone anabolism is based on the known weakness of skeletal muscle in OI and the loading effect muscle has on maintaining bone mass. Because the myostatin D knockout mouse has a high skeletal muscle mass (McPherron et al., 1997), drug inhibition of this muscle mass regulator has been shown to increase bone mass in experimental mouse models (Lee et al., 2016). This logic appears to apply to OI also, as two different research groups have shown increases in bone and muscle mass in a mouse model of severe OI (DiGirolamo et al., 2015; Oestreich et al., 2016).

Left unexplained are the nonosseous features of the more severe forms of OI, which include pulmonary fibrosis and aortic root dilatation. These are features of Marfan's disease that have previously been associated with a chronic TGFβ-induced inflammatory state. A seminal paper reported that a similarly high TGFβ state exists in murine models of OI and that treatment with anti-TGFß antibodies both increased bone mass and reduced pulmonary inflammation (Grafe

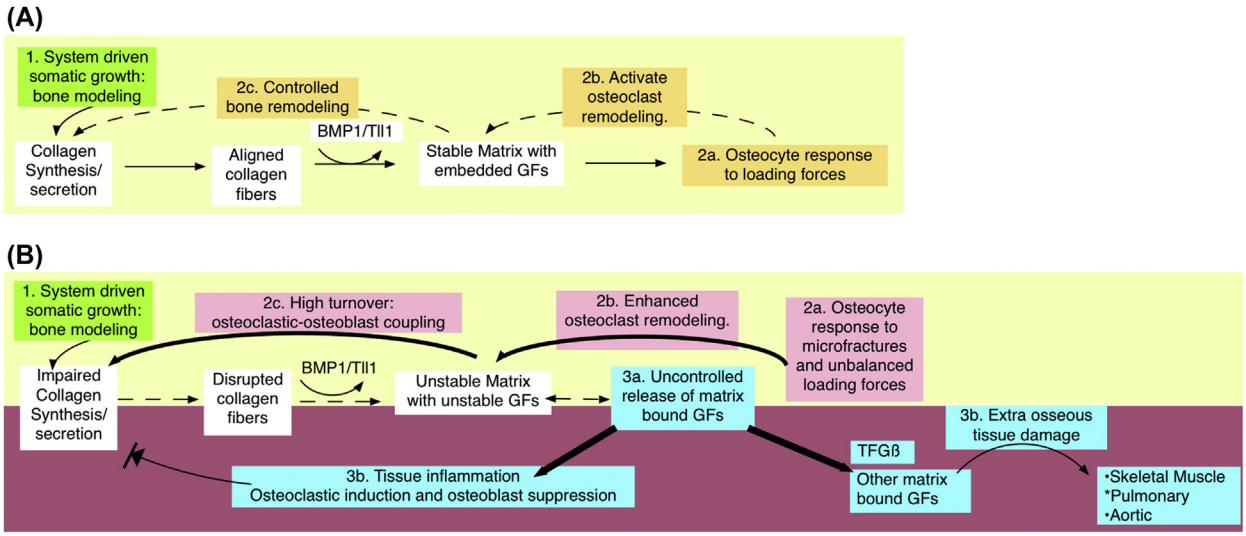

FIGURE 61.1 Pathophysiological dynamics in OI. (A) Normal physiological regulation. Osteoblasts have an exceptionally high production rate of extracellular matrix molecules including type I collagen. The secreted fibrils align into collagen fibrils, bind other matrix molecules and sequester a variety of local acting bone growth factors including TGFs, BMPs and IGFs. During somatic growth (1), systemic hormones drive osteoblasts to meet the need of the elongating bones and increasing body weight. This net accumulation of bone matrix is termed bone modeling. Additional loading forces, probably acting through osteocytes (2a), initiate the bone remodeling process in which osteoclasts resorb bone matrix and release bone growth factors (2b) that in turn activate the osteogenic lineage to proliferate and replace the resorbed bone matrix (2c). (B) Pathophysiological regulation of OI. The inherent inability of the osteogenic lineage to produce mature osteoblasts and the inefficient production/secretion of type I collagen in those cells that do achieve full differentiation reduce the amount of matrix that can be produced in a growing bone. Furthermore, the matrix formed is not normally aligned and probably does not properly bind matrix proteins and growth factors (1). Thus, during the bone modeling phase of skeletal growth, both the mechanical and regulatory function of the growing bone is compromised. (a) mechanical: The innumerable asymptomatic microfractures activate the osteocyte remodeling process (2a). Because the intensity of the osteoclastic activity (2b) drives the recruitment of the osteoblastic lineage (2c), the process is termed a high bone turnover state, but in this case the matrix produced is no better than what was removed. The unabated high remodeling state is associated with an extremely low bone mass, multiple fractures, bone pain and bone deformity. Thus, suppression of the osteoclast function breaks this cycle and allows for bone matrix accumulation particularly during somatic growth. (b) regulatory: Because the disordered matrix does not retain embedded growth factors adequately, the high turnover state releases more factors than usual (3a). The inflammatory growth factors (Fig. 61.2) can act locally by augmenting the myeloid precursor balance of macrophages to osteoclasts, while impeding the expansion of the osteoblast lineage. When these growth factors escape to the peripheral circulation, they can induce an inflammatory state in peripheral tissues. Thus, suppression of high bone turnover in children can lead to bone accumulation and possibly less peripheral inflammatory activity. However, in adults in which a moderately elevated rate of bone turnover is not a basis for osteoclast suppression, the released growth factors could lead to inflammatory tissue damage in OI target tissues. Such a mechanism argues for the use of pharamcologics that suppress the action of the released inflammatory growth factors.

et al., 2014). This systemic inflammatory state is also evident in hematopoietic tissues in mice (Matthews et al., 2017) and human subjects (Brunetti et al., 2016). What is the cause of this increase in circulating TGFβ? The mechanism in Marfan's disease is mutations in the fibrillin-1 gene that inactivate the ability of this protein to maintain TGBFβ in a latent inactive form (Ramirez et al., 2018). Perhaps the same mechanism exists in bone. Numerous growth factors including TGFβ, BMPs, and IGFs are contained with the bone matrix, and the loss of their regulated release, particularly in a high turnover state, may be another consequence of the disrupted bone matrix. Support for this circular mechanism for high bone resorption is the direct effect that TGFβ has on stimulating the macrophage-to-osteoclast lineage (Yasui et al., 2011; Omata et al., 2016) and the observation that anti-TGFß treated OI mice increased their bone mass by a suppression of osteoclast number and reduction in bone formation markers (Grafe et al., 2014). Furthermore, the increased bone mass observed in anti-myostatin D-treated mice resulted from the same combination of reduced osteoclast number and reduced markers of bone formation (DiGirolamo et al., 2015; Oestreich et al., 2016). Myostatin has additional effects on tissues other than muscle including promoting osteoclast differentiation (Dankbar et al., 2015), so the muscle-loading effect on bone may in part be attributable to suppression of the cell inflammatory process. The similarity of effect of anti-TGBß and antimyostatin/activin 2A receptor decoy therapy becomes clearer when the confluence of pathways that influence the SMAD 2/3 pathway in different types is examined (Fig. 61.2). Thus, blocking activation of this pathway using antibodies to ligands or solubilized receptor peptides may be an additional therapeutic strategy that can be tailored to specific forms of OI or stages of its natural history.

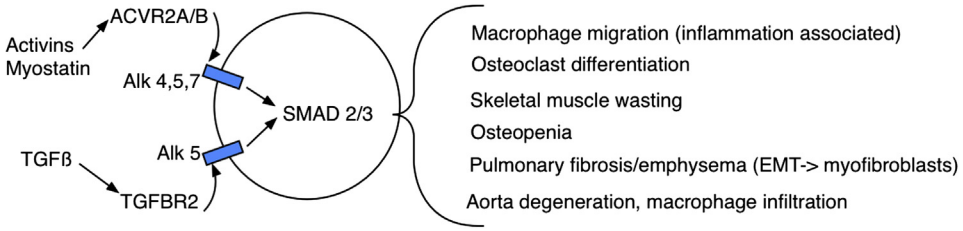

FIGURE 61.2 Inflammatory growth factors. Both activins/myostatin and TGFs can have an equivalent influence on the SMAD 2/3 pathway to activate the macrophage-driven inflammatory state as well as having primary effects on certain target tissues. The ligands bind to separate type 2 receptors (ACVR2A/B and TGBβR2) that in turn bind to different type I receptors (*blue* [gray in print version]) to activate the same SMAD pathway. The pathways can be interrupted either with antibodies to the ligands or soluble type 2 receptors that bind and inactivate the ligands.

Where these considerations may become important is with the use of therapeutics that suppress resorption or stimulate formation. Currently, CTXs are used to assess osteoclastic activity, but the use of additional blood studies that assess mediators or markers of chronic inflammation, as well as measures of bone matrix protein activity, may provide a better window into the balance of bone-intrinsic versus bone growth factor derived drivers of bone turnover (Nicol et al., 2019). Thus, states associated with bone modeling may facilitate a matrix that stabilizes the release of the bone-derived growth factors while high bone turnover in individuals who have achieved full somatic growth may favor the release of these factors. At this point it is unknown whether the suppression of osteoclastogenesis will have the effect of reducing the nonosseous complications of OI either directly, as with bisphonphonates and anti-RANKL drugs, or more systemically with drugs that act through activin−Smad2/3 pathways. Conversely, drugs that stimulate new bone formation may have different effects on nonosseous tissues depending on the balance of modeling versus remodeling achieved by their administration.

Osteogenesis imperfecta due to underproduction of a normal type I collagen molecule

The only mouse model of type I OI utilized a now disbanded genetic technique that shortened the life span of the line due to leukemia (Jacobsen et al., 2016; Jepsen et al., 1997). Thus, lacking a model that replicates this form of OI has hindered fully appreciating the pathogenesis and natural history effect of chronic underproduction of type I collagen. What is known from human fibroblast studies is that unlike the normal setting of twofold greater collagen chain production of α1(I) versus α2(I), equal production of α1(I) and α2(I) proteins results in the formation of a normal collagen heterotrimer, ($\alpha1(I)_2$ $\alpha2(I)_1$) (Rowe et al., 1985), while trimeric molecules composed of $\alpha1(I)_1$ $\alpha2(I)_2$ or $\alpha2(I)_3$ are unstable and degraded (Gauba et al., 2008; Kuznetsova et al., 2003). At this point, it is unclear whether this degradation process contributes to ER stress similar to that observed for cells exposed to a mutant collagen gene product. An additional complication for understanding the cellular environment are splice site mutations of the Col1A1 gene in which the resulting in-frame stop that normally would inactivate the transcript is alternatively skipped to create an in-frame deletion and a mutant Col1A1 chain (Bateman et al., 1999). Because the toxic effect of an abnormal collagen chain is strong, just a small proportion this product relative to total type I collagen produced in a type I OI mutation would contribute to a more severe clinical phenotype. Distinguishing the impact of low type I collagen accumulation alone versus a low product containing a small proportion of mutant molecules will be a challenge.

Inactivation mutations of the collagen type I, alpha 2 (Col1A2) gene would be expected to produce a heterotrimer of three alpha chains ($\alpha1(I)_3$) that lacks the stability of the heterotrimer and would be expected to cause a bone phenotype (Kuznetsova et al., 2003). A spontaneous mutation in the Col1A2 gene in mouse that precludes formation of a heterotrimer is one of the major murine models for studying OI pathogenesis and various therapeutic interventions. Human subjects with a similar mutation have a severe phenotype in proportion to the extent that heterotrimer formation is impeded (Pace et al., 2008). However, a human subject with an inactivating mutation of the Col1A2 gene has been identified who presented as Ehlers−Danlos and not OI (Schwarze et al., 2004). Reconciling these differences using murine models is likely to provide additional insights into cell and matrix factors that influence skeletal health.

Even less understood is the consequence of a diminished content of type I collagen−containing matrix in bone and other tissues relative the other matrix proteins that interact with this organizing molecule. Until shown otherwise, the underlying assumption is that increasing the type I collagen output should have a positive impact on skeletal health. The anabolic agents that enhance matrix production from osteoblasts and other type I collagen−producing cells needs to be explored, again using animal models prior to clinical trials. In contrast, OI-causing mutations that affect the progression of

osteogenic lineage will require a different therapeutic approach utilizing agents that enhance or block the pathways affected by the mutation. Many potential drug candidates are already available that will have to be personalized for the offending mutation. In all cases, including type I OI, initiating the intervention early in childhood when bone matrix is being accumulated will be important, and maintaining a lifestyle that is anabolic for the skeleton will have to be emphasized.

In summary, the pathophysiological basis for OI is extremely heterogeneous and cannot be anticipated by clinical presentation alone. Clearly, molecular diagnosis will provide some insight into the likely cell and matrix consequences, and improved testing for bone metabolic and inflammatory markers will further refine the underlying factors determining disease severity and nonosseous outcomes.

Therapeutic options

Although anti−bone resorptive agents have changed the natural history of the more severe forms of OI, particularly in children, the specific drugs, how they are used, and their durations of treatment are not uniformly applied in the different treatment centers in the United States and elsewhere. Thus, for the individual physician who encounters an individual with OI, it is probably wise to refer to one of the major treatment centers so that the individual can be enrolled in one of a number of multicenter trials and benefit from the best clinical experience available (Montpetit et al., 2015). The centers provide the additional health-supporting advantages of physical and occupational therapies, contact with other affected families, and the resources of the Osteogenesis Imperfecta Foundation. Agents approved or under evaluation can be divided into three classes: antiresorptive, anti-Tgfß and antiactivin, and anabolic.

Antiresorptive agents

Bisphosphonate in the form of short-acting pamidronate was the first agent successful in reducing fracture frequency in growing children. A major experience in using this drug was assembled by the Montreal treatment center (Glorieux et al., 1998; Arikoski et al., 2004) and was subsequently replicated at other centers (DiMeglio et al., 2004; Fleming et al., 2005). Most notable were a reduction in fractures, better formation vertebra, and improved linear growth. Because the drug requires intravenous administration that must be repeated 2−3 times each year, longer-acting forms such as zoledronate have received greater usage (Palomo et al., 2015; Tsimicalis et al., 2018). Oral forms such as alendronate and risedronate are also effective (Ward et al., 2011; Bishop et al., 2013) but have not become standard practice.

The introduction of the anti-RANKL drug denosumab provided an entirely different approach for inhibiting bone resorption. Unlike bisphosphonates that induce osteoclast death after full differentiation has been achieved, denosumab prevents osteoclast differentiation. It has the advantage of infrequent injections and a predictable therapeutic window, and it has proven effective in early clinical trials (Hoyer-Kuhn et al., 2016). However, it has not become the primary treatment as of 2019.

Anti-TGFß and anti-activin agents

Although there is strong data in mouse models of OI that these antibodies and soluble receptor peptides can be effective in suppressing osteoclastogenesis and potentially having other beneficial nonosseous effects (Grafe et al., 2014), a clinical trial is just being initiated through the BBDC.

Anabolic agents

The use of bone anabolic agents to overcome the severe osteopenia of OI has always been an attractive approach and was the basis of growth hormone treatment in growing children. However, the experience in humans was inconclusive (Wright, 2000), and its use is no longer recommended. Use of PTH, teriparatide, has shown promise in adults, but its expense and a lack of coverage by most insurance companies has limited its use. The recent introduction of a PthrP analog, Abaloparatide, not only is as effective as PTH in increasing bone anabolism (Makino et al., 2018), but costs significantly less. Studies from osteoporotic patients that use PthrP and an antiresorptive sequentially are particularly encouraging (Le et al., 2019; Hiligsmann et al., 2019) and are leading to similar ongoing trials in adults with OI.

Stimulating bone anabolism with antisclerostin antibodies shows significant positive effects in adults with OI. Markers of bone anabolism without an increase in bone turnover markers (Glorieux et al., 2017; Sridharan et al., 2018) suggest the modeling effect this drug is expected to deliver (Sinder et al., 2016; Sridharan et al., 2018). Although the initial application for osteoporosis was rejected by the FDA in 2017, this hurdle was cleared in 2019.

Cell and gene-therapy options

The high-profile announcements of stem cell and gene-correction possibilities for human disease have impacted potential treatment options for OI, particularly in young severely affected individuals. The rationale for either approach is the observation that parents with somatic mosaicism for a mutation that causes a severe form of OI in their child rarely have features of skeletal disfunction. The basis for this observation has not been directly tested, but it may reflect the superior competitive advantage that normal osteoblasts have for cell proliferation and matrix production relative to osteoblasts compromised by mutant collagen chains. It is possible that a degree of mosaicism sufficient to affect skeletal health could be achieved by either a cell-based or gene-therapy approach.

Initial reports of bone marrow and bone marrow mesenchymal cell transplantation were performed without solid animal studies demonstrating that osteoblast engraftment by this means would have a significant impact on disease severity (Horwitz et al. 1999, 2002, 2008). Subsequent studies using more sensitive GFP reporter-based methods in mouse models have clearly demonstrated that systemic administration of stem cells capable of osteogenic differentiation does not engraft trabecular bone (Wang et al., 2005; Boban et al., 2010; Otsuru et al., 2017). Despite this basic animal work (Featherall et al., 2018), infusion of marrow-derived stromal cells is still being performed on an experimental basis (Le Blanc et al., 2005; Westgren et al., 2015; Gotherstrom et al., 2014) without clear-cut animal data to show that it is effective for engraftment (Millard et al., 2015).

Direct introduction of mouse bone progenitor cells into the bone marrow cavity or an experimental defect space in mice leads to engraftment and integration with the host bone (Pauley et al., 2014; Gohil et al., 2016). In contrast, direct injection of whole bone marrow is not effective (Wang et al., 2005; Lee et al., 2019). Given the increasing success of drug interventions, this type of strategy would be limited as a supplement to orthopedic reconstructive procedures of the limb, vertebral, or basilar skull bones. However, this type of use will only be meaningful in the human clinical setting if the cells are isogenic with the individual subject. Claims that mesenchymal-derived cells are immune-privileged have not been validated for osteogenic engraftment (Bilic-Curcic et al., 2005). A possible solution to this problem is the use of patient-derived induced pluripotential stem cells (iPSCs). By engineering a correction of the underlying OI mutation using CRISPR/Cas9 technology, it should be possible to generate otherwise normal patient-specific progenitor cells that would generate normal bone matrix in the region of their application.

The molecular technologies to safely introduce a new gene into cells have improved to the point that they are now being applied in clinical trials for a number of hematopoietic disorders (Herrmann et al., 2018; Ahmed et al., 2018; Elsner et al., 2017). Animal studies are promising for other tissue types, particularly those that do not have a high level of cell turnover (Tabebordbar et al., 2016; Deverman et al., 2018). In the case of recessive forms of OI that result from a loss of enzymatic or chaperone function, gene replacement could be effective. The issue is the delivery method. While systemic administration is possible, the vast majority of osteogenic cells targeted would be mature cells that eventually would be replaced by nontargeted progenitors. However, it might be possible to transiently increase the progenitor cell number prior to administering the targeting vector to achieve a sufficient number of transformed cells to reach a mosaic threshold effect. While this might be an issue for children, bone-lining cells in adults may harbor the capacity for bone remodeling (Matic et al., 2016), making them an excellent target for genetic engineering.

All of these potentially attractive approaches require small animal testing, which provides exquisitely sensitive and relatively low-cost test platforms to identify the most positive candidate vectors and application strategies. Once identified, they will need to be validated in principle in larger animal models prior to a stepwise clinical safety and efficacy trial.

Use of induced pluripotential stem cells as a diagnostic tool

Given the increasing complexity of the various molecular forms of OI and the strong influence of background genes that further complicate disease pathogenesis, it is likely that animal models will never fully serve as models for specific individuals with OI. Because iPSCs express the genetic heterogeneity of their donor, they provide the opportunity for developing personalized therapeutic decisions (Kilpinen et al., 2017; DeBoever et al., 2017; Rowe et al., 2019). While obtaining primary osteoblastic cells from individual subjects is difficult, generation of iPSCs from peripheral blood provides the opportunity to direct these cells into the osteogenic lineage for detailed testing (Chen et al., 2013). Once a model for full osteogenic differentiation is achieved, protein and RNA expression studies can be initiated with best model in an in vivo setting for that specific subject (Xin et al., 2018). In this setting, not only can the effect of the mutation be assessed but also the identification of other genes whose products might interact with mutation becomes possible. To test the relative

impact of the candidate background gene to overall cellular phenotype, the CRISPR/Cas9 system can be used to revert the background gene to its wild-type form and determine whether this change improves the matrix production capability of the engineered osteoblasts (Xin, 2017, 2018). Knowing the contribution background gene may influence other combinatorial therapeutic options that are becoming available from osteoporosis/osteopenia research areas.

Chapter 62

Hereditary deficiencies in vitamin D action

Uri A. Liberman

Department of Physiology and Pharmacology, Sackler Faculty of Medicine, Tel Aviv University, Tel-Aviv, Israel

Chapter outline

Introduction

Hereditary deficiencies in vitamin D action can be caused by disturbances in the synthesis or degradation of the hormonal form of the vitamin 1,25-dihydroxyvitamin D (1,25$(OH)_2$D, calcitriol) or defects in the interaction of calcitriol and its target tissues.

Vitamin D derived from endogenous production in the skin or absorbed from the gut is transformed into its active form by two successive steps: (1) hydroxylation in the liver to 25-hydroxyvitamin D [25(OH)D] and (2) 1α-hydroxylation in the renal proximal tubule to 1,25$(OH)_2$D. Some other cells exhibit 1α-hydroxylase activity: placental decidual cells, keratinocytes, macrophages of various origins, and some tumor cells. The role of the extrarenal production of 1,25$(OH)_2$D is unknown, and under normal conditions it does not significantly contribute to circulating levels of the hormone. Hydroxylation at carbon 24, to produce 24, 25-dihydroxyvitamin D [24,25$(OH)_2$D] or 1,24,25-trihydroxyvitamin D is performed in a wide range of normal tissues and is believed to be important in the removal of vitamin D metabolites. All these enzymes are mitochondrial mixed-function oxidases containing cytochrome P450 and having ferredoxin- and heme-binding domains (CYP enzyme system). Cloning of cDNA for porcine 25-hydroxylase and the mouse, rat, and human 24- and 1-hydroxylase, as well as the genes for the latter two enzymes, has been reported (Akeno et al., 1997; Fu et al., 1997a; Jehan et al., 1998; Jones et al., 1999; Monkawa et al., 1997; Murayama et al., 1999; Ohyama et al., 1993; Shinki et al., 1997; Takeyama et al., 1997). Hereditary defects along the cascade of 1,25$(OH)_2$D synthesis or degradation lead to a deficiency in the vitamin D hormonal form—i.e., low to undetectable circulating levels of calcitriol. All patients with these

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00062-2

defects will experience complete cure of all clinical and radiological signs and symptoms of their hypocalcemic rickets as well as biochemical aberrations on high doses of vitamin D, and for the hereditary defects in calcitriol biosynthesis it could be achieved by physiological replacement doses of calcitriol—the hormonally active form of vitamin D. Continuous treatment is necessary to keep patients in remission. As far as bone deformities are concerned, they depend on the age when treatment is initiated. In view of the foregoing, it is suggested that the name allocated to this group of hereditary deficiencies more than 50 years ago, hereditary vitamin D–dependent rickets (HVDDR), should be retained, with an additional letter to denote the functional defect—i.e., HVDDR type A (HVDDR-A) to specify a defect in the 25-hydroxyvitamin D 1-alpha hydroxylase (CYP27B1); HVDDR-B to define a defect in the vitamin D 25-hydroxylase (CYP2R1), and HVDDR-C for defects causing increased degradation of calcitriol (CYP3R1).

Regarding defects in the interaction of calcitriol with its target tissue, as detailed elsewhere in this book, calcitriol effects are mediated via a high-affinity intracellular receptor, the vitamin D receptor (VDR). VDR acts as a ligand-modulated transcription factor that belongs to the steroid, thyroid, and retinoic acid receptors gene family (Baker et al., 1988; Burmester et al., 1988; Evans, 1988; Ozur et al., 1991). Thus, hereditary defects in the interaction of calcitriol and its target tissues could evolve from defects in hormone binding to VDR, defects in the heterodimerization with retinoid X receptor (RXR), the interaction of the receptor complexes with particular regions of DNA known as vitamin D–response elements (VDREs) that regulate the activity of vitamin D–responsive genes, or defects in translational or posttranslational modulatory functions. Patients with hereditary defects in the interaction of calcitriol and its target tissues have elevated to extremely high circulating levels of $1,25(OH)_2D$ (depending on previous treatment), and the majority of patients do not respond to treatment with any dose of vitamin D or its active 1-alpha hydroxylated metabolites. Based on the foregoing, it is suggested that this group of hereditary deficiencies in vitamin D be called hereditary calcitriol-resistant rickets (HCRR). All of these isolated deficiencies are very rare and usually autosomal recessive.

Though VDRs were demonstrated in most if not all tissues, leading to increased recognition of multiple target organs and actions of the hormone, it seems that most if not all clinical signs and symptoms associated with deficient vitamin D actions are caused by perturbations in mineral metabolism.

$1,25(OH)_2D$ is the most powerful physiological agent that stimulates active transport of calcium, and to a lesser degree phosphorus and magnesium, across the small intestine (DeLuca, 1984; Mayer et al., 1984). Thus, deficiencies in vitamin D action will lead to a decrease in the net flux of mineral to the extracellular compartment, causing hypocalcemia and secondary hyperparathyroidism. Hypophosphatemia will ensue as a result of both reduced absorption of phosphorus owing to deficient calcitriol action on the gut and increased renal phosphate clearance owing to secondary hyperparathyroidism. Low concentrations of calcium and phosphorus in the extracellular fluid will lead to defective mineralization of organic bone matrix. Defective bone matrix mineralization of the newly formed bone and growth plate cartilage will produce the characteristic morphological and clinical signs and symptoms of rickets, whereas at sites of bone remodeling, it will cause osteomalacia. Deficiencies in vitamin D action may impair the differentiation of osteoblasts and thus their functional capacity to mineralize bone matrix; this may be an additional mechanism leading to rickets and osteomalacia (Owen et al., 1991; Reichel et al., 1989).

Because all hereditary deficiencies in vitamin D action will lead to the same clinical, radiological, and histological aberrations as well as most biochemical ones, those common features will be discussed first.

Clinical features of rickets and osteomalacia

Children with hereditary deficiencies in vitamin D action appear normal at birth and usually develop the characteristic features of rickets within the first 2 years of life. Defects in bone mineralization are particularly evident in regions of rapid bone growth including, during the first year of life, the cranium, wrist, and ribs. Rickets at this time will lead to widened cranial sutures, frontal bossing, posterior flattening of the skull (craniotabes), bulging of costochondral junction (rachitic rosary), indentation of the ribs at the diaphragmatic insertion (Harrison's groove), and widening of the wrists. After the first year of life with the acquisition of erect posture and rapid linear growth, the deformities are most severe in the legs. Bow legs (genu varum) or knock-knee (genu valgum) deformities of varying severity develop as well as widening of the ends of long bones. If not treated, rickets may cause severe lasting deformities, compromise adult height, and increase susceptibility to pathological fractures.

The specific radiographic features of rickets reflect the failure of cartilage calcification and endochondral ossification and therefore are best seen in the metaphysis of rapidly growing bones. The metaphyses are widened, uneven, concave, or cupped, and because of the delay in or absence of calcification, the metaphyses could become partially or totally invisible (Fig. 62.1). In more severe forms or in patients untreated for prolonged periods, rarefaction and thinning of the cortex of the entire shaft, as well as bone deformities and greenstick fractures, will become evident.

FIGURE 62.1 Radiographs of wrists and hands of a patient with hereditary vitamin D–dependent rickets. Note the signs of severe rickets and demineralization.

The clinical features of osteomalacia are subtle and could be manifested as bone pain or low-back pain of varying severity in some cases. The first clinical presentation could be an acute fracture of the long bones, pubic rami, ribs, or spine. The radiographic manifestations could be mild—e.g., generalized, nonspecific osteopenia—or more specific, such as pseudofractures commonly seen at the medial edges of long bone shafts.

In hypocalcemic rickets and/or osteomalacia, as is the case in deficiencies in vitamin D action, radiographic features of secondary hyperparathyroidism such as subperiosteal resorption and cysts of the long bones may exist.

The characteristic histological feature of rickets and osteomalacia is deficiency or lack of mineralization of the organic matrix of bone. Because in clinical practice a bone specimen can be obtained only from the iliac crest, the histological picture is osteomalacia. Osteomalacia is defined as excess osteoid (hyperosteoidosis) and quantitative dynamic proof of defective bone matrix mineralization obtained by analysis of time-spaced tetracycline labeling (Parfitt, 1983; Teitelbaum and Bollough, 1979).

The biochemical parameters characterizing deficiencies in vitamin D action can be divided into those associated with vitamin D status, the primary disturbance in mineral homeostasis and the respective compensatory mechanisms, and changes in bone metabolism. Changes in mineral and bone metabolism will be similar in all states of deficient vitamin D action, whereas serum levels of vitamin D metabolites will characterize each of the two classes delineated in the introduction (Table 62.1).

TABLE 62.1 Biochemical features of hereditary vitamin D–dependent rickets (HVDDR) types A, B, and C and hereditary calcitriol-resistant rickets (HCRR).

	Serum concentrations					
	Calcium	Phosphorus	Alkaline phosphatase	iPTH	25(OH)D	$1,25(OH)_2D$
HVDDR						
Type A	↓	↓	↑	↑	N–↑	↓
Type B	↓	↓	↑	↑	↓	↓
Type C	↓	↓	↑	↑	↓	↓
HCRR	↓	↓	↑	↑	N–↑	↑

As previously discussed, deficiencies in vitamin D action will lead to hypocalcemia and secondary hyperparathyroidism. Thus, the characteristic biochemical features are low to low-normal concentrations of serum calcium (depending on compensatory parathyroid activity), low urinary calcium excretion, hypophosphatemia, increased serum parathyroid hormone (iPTH) levels, and decreased tubular reabsorption of phosphate (the last measure reflects the biological activity of elevated iPTH). Biochemical markers associated with increased osteoid production, such as bone-specific alkaline phosphatase and osteocalcin, will be elevated in states of rickets and osteomalacia (Cole et al., 1985). However, as $1,25(OH)_2D$ stimulates osteocalcin synthesis in vivo and in vitro, serum levels of this biochemical bone marker are unreliable measures in hereditary vitamin D–deficient states.

Hereditary vitamin D–dependent rickets

Genetic defects in the biosynthesis or degradation of 1,25-dihydroxycholecalciferol cause deficiencies in the biological active hormonal form of vitamin D. All of these patients will suffer from hypocalcemic rickets with the typical clinical and radiological signs and symptoms, as well as the classical aberrations in mineral homeostasis, as discussed previously. All patients with HVDDR could be completely cured by massive doses (50,000 IU/day or higher) of vitamin D. In patients with genetic defects in calcitriol biosynthesis, complete cure could be achieved as well by physiological replacement doses (0.25–2 μg/day) of calcitriol. Remission is dependent on continuous treatment as detailed above, thus the name vitamin D–dependent rickets. These defects in the activities of enzymes belonging to the CYP family system are the end result of mutations in different genes that encode the enzymes involved in the biosynthesis and catabolism of calcitriol:

a. kidney mitochondrial CYP27B1; it is suggested that the disease associated with such a defect be called HVDDR-A
b. liver microsomal enzyme CYP2R1; it is suggested that the disease caused by such a deficiency be called HVDDR-B
c. the enzyme that controls degradation of calcitriol and 25-hydroxy vitamin D (CYP3A4) increased activity; it is suggested that the hereditary disease caused by such activity be called HVDDR-C

Hereditary vitamin D–dependent rickets type A

HVDDR-A results from hereditary deficiencies in the biosynthesis of 1,25-dihydroxy vitamin D caused by mutations in the gene encoding the renal mitochondrial enzyme 25-hydroxy vitamin D 1-alpha hydroxylase (CYP27B1). This is a rare defect but may be more common in genetically isolated populations, a result of a founder effect, as is the case in some French-Canadian communities. Prader et al. (1961) were the first to describe two young children who showed all the usual clinical features of vitamin D deficiency despite adequate intake of the vitamin, thus coining the name "pseudovitamin D deficiency." Complete remission depended on continuous therapy with high doses of vitamin D, thus the term "vitamin D–dependent rickets." However, remission of the disease could be achieved by continuous therapy with physiological (microgram) doses of calcitriol or its active 1α-hydroxylated vitamin D metabolites (Delvin et al., 1981; Fraser et al., 1973; Miller, 2017).

Family studies have revealed that HVDDR-A is an autosomal recessive disease. Linkage analysis in a subset of French-Canadian families assigned the gene responsible for the disease to chromosome 12q13 (De Brackeleer and Larochell, 1991; Labuda et al., 1990). The gene encoding the 1α-hydroxylase of mouse kidney, human keratinocyte, and peripheral mononuclear cells was localized on chromosome 12q13.1-q13.3, which maps to the disease locus of HVDDR-A (Fu et al., 1997b; Kitanaka et al., 1998; Smith et al., 1999; St. Arnaud et al., 1997, Wang et al., 1998; Yoshida et al., 1998). There are no direct measures of the renal enzyme proving defective 1α-hydroxylase activity. This is virtually impossible to obtain because of both the difficulty in obtaining tissue and the low level of expression. There are, however, several indirect observations to support this etiology. First, circulating levels of 25-hydroxyvitamin D (25(OH)D) are normal or elevated, depending on previous vitamin D treatment. Second, serum concentrations of $1,25(OH)_2D$ are very low (see Table 62.1). Third, although massive doses (100–300 times the daily recommended dose) of vitamin D or 25(OH)D are required to maintain the remission of rickets, and physiological replacement doses of calcitriol are sufficient to achieve the same effect. Fourth, it was reported that cells isolated from the placenta of two women with this disease had deficient activity of the decidual enzyme 25(OH)D-1α-hydroxylase (Glorieux et al., 1995). It is noteworthy that human decidual cells do produce $1,25(OH)_2D$ and that this enzyme was regulated by feedback mechanisms (Delvin and Arabian, 1987; Diaz et al., 2000; Weisman et al., 1979). Finally, the 1α-hydroxylase gene from more than 100 families with HVDDR-A, and some of their first-degree healthy relatives were analyzed by direct sequencing, site-directed mutagenesis, and cDNA expression in transfected cells (Fu et al., 1997; Kitanaka et al., 1998–1999; Smith et al., 1999; St. Arnaud et al., 1997; Wang et al., 1998; Yoshida et al., 1998). All patients had homozygous mutations, whereas parents and other healthy siblings were

heterozygous for the mutation. Most patients of French-Canadian origin had the same mutation causing a frameshift and a premature stop codon in the putative heme-binding domain. The same mutation was observed in additional families of diverse origins (Smith et al., 1999). All other patients had either a base-pair deletion causing premature termination codon upstream from the putative ferredoxin and heme-binding domains, or missense mutations (Fu et al., 1997b; Kitanaka et al., 1999; Smith et al., 1999; Wang et al., 1998; Yoshida et al., 1998). No 1α-hydroxylase activity was detected when the mutant enzyme was expressed in various cells. The sequence of the human 1α-hydroxylase gene from keratinocytes and peripheral blood mononuclear cells has been shown to be identical with that of the renal gene (Fu et al., 1997b; Kitanaka et al., 1999; Smith et al., 1999; Wang et al., 1998; Yoshida et al., 1998), thus supporting the use of these accessible cells as a proxy to study the renal tubular enzymatic defect. Taken together, these observations support the notion that the etiology of this hereditary disease is a defect in renal tubular 25(OH)D-1α-hydroxylase activity.

The beneficial therapeutic effect of high serum concentrations of 25(OH)D in patients treated with massive doses of vitamin D while $1,25(OH)_2D$ levels remain low may have several possible explanations. First, high levels of 25-(OH)D may activate VDR, whose affinity for this metabolite is approximately two orders of magnitude lower than for $1,25(OH)_2D$. Second, a metabolite of 25(OH)D may act directly on target tissues. Finally, high levels of 25(OH)D may drive the local production of $1,25(OH)_2D$ via a paracrine−autocrine pathway, assuming that the tissue enzyme is controlled differently than the renal and decidual enzyme.

Hereditary vitamin D−dependent rickets type B

Serum concentrations of 25-hydroxy vitamin D [25(OH)D] reflect vitamin D status because 25(OH)D is the principal circulating form of vitamin D produced in the skin and ingested in the diet. It is an intermediate metabolite that serves as a reservoir for the highly regulated kidney production of the active hormonal form of vitamin D (calcitriol, $1,25(OH)_2D$). Some human enzymes possess vitamin D-25 hydroxylase activity, but current evidence indicates that the liver microsomal cytochrome P450 enzyme CYP2R1 is the principal vitamin D 25-hydroxylase in humans. A possible genetic defect in 25-hydroxylase as a cause of hereditary rickets was first reported in 1994 in two brothers of Nigerian descent (Casella et al., 1994). Both children had rickets associated with low 25(OH)D circulating levels at baseline. Relatively high doses of vitamin D restored serum levels of 25(OH)D toward normal, but somewhat lowering vitamin D intake caused a recurrent reduction in 25(OH)D levels. The authors concluded that the children had an inherited defect in 25(OH)D synthesis from parent vitamin D. In the last few years, additional reports and studies, including DNA sequencing of children with hereditary familial hypocalcemic rickets with low serum levels of 25(OH)D and no response to physiological doses of vitamin D, were published (Al Mutair et al., 2012; Thacher et al., 2015; Thacher and Levine, 2017; Miller, 2017). Most of these children were of Nigerian origin except for one family of Saudi Arabian descent (Al Mutair et al., 2012). Genomic DNA from 39 Nigerian children with rickets was extracted, amplified, and sequenced. The subjects included children with sporadic rickets and 12 children with one or more first-degree relatives having a history compatible with rickets in the past—so-called familial rickets. Of the 12 patients with familial rickets, 2 families had missense mutations in the gene encoding CYP2R1 (the main 25-hydroxylase enzyme). One mutation caused a substitution of proline for leucine at position 99 of the encoded pattern (L99P). Leucine is a conserved amino acid in the CYP2R1 of humans, mouse, and rat. It is predicted that this mutation impairs CYP2R1 folding. The patients with rickets were homozygous for this mutation. As was previously reported in an unrelated child of Nigerian origin with rickets, heterozygous patients did not have rickets. In the second family, including three children with rickets who were heterozygous to the L99P mutation, a second missense mutation originating from the mother was revealed. In this mutation, lysine in position 242 of the enzyme was replaced by asparagine. This mutation is predicted to impair the interaction of CYP2R1 with its substrate (vitamin D). No mutation was observed in the Nigerian children with sporadic rickets. The Saudi children were found to have compound heterozygous mutations of CYP2R1. One mutation, inherited from the father, was in a highly conserved splice down sequence that controls mRNA slicing. This mutation is predicted to lead to a truncated CYP2R1 protein or unstable mRNA. The second mutation, inherited from the mother, was a thymine insertion in exon 3 that is predicted to produce a truncated CYP2R1 protein.

Various functional activities were measured in vitro in transfected cells and revealed the relationship between the mutation and biological−biochemical effects.

Hereditary vitamin D−dependent rickets type C

Two unrelated female patients from nonconsanguineous families with early-onset rickets were recently described (Roizen et al., 2018). Both patients had detectable serum vitamin D but low circulating concentrations of 25-hydroxy vitamin D and

1,25-dihydroxy vitamin D that increased only after administration of very large doses of vitamin D and declined rapidly thereafter. There was no family history of rickets and all available first-degree relatives had normal circulating vitamin D metabolites as well as serum levels of calcium, phosphorous, PTH, and alkaline phosphatase. Targeted sequencing did not reveal mutations in any gene that is involved in vitamin D biosynthesis or action. Whole-exome sequencing analysis performed in the patients and their parents revealed recurrent de novo gain-of-function missense mutation in CYP3A4, a P450 enzyme that metabolizes many xenobiotics and drugs. An identical heterozygous single-nucleotide change that results in replacement of isoleucine by threonine at codon 301 was found only in the two patients and not in any available relative who was unaffected. Isoleucine 301 is highly conserved and forms a critical position of substrate recognition site 4 that determines CYP3A4 substrate selectivity. Replacement of isoleucine by threonine in position 301 substantially increases oxidation of 25-hydroxy vitamin D and 1,25-dihydroxy vitamin D. In vitro, the mutant CYP3A4 oxidized $1,25(OH)_2D$ with 10-fold greater activity than the wild-type CYP3A4 and twofold greater activity than CYP24A1, the principal inactivator of vitamin D metabolites. The CYP3A4 mutant may have changes in activity for other substrates not connected to vitamin D.

This is a third form of HVDDR, suggested to be called HVDDR-C. Similar to the other forms, it is caused by a deficiency in the hormonal form of vitamin D ($1,25(OH)_2$ vitamin D), it could be cured by high doses of vitamin D or its active metabolites, and remission is dependent on continuous treatment. However, as distinct from HVDDR-A and HVDDR-B, in which the deficiency of the hormone is caused by defects in biosynthesis, HVDDR-C is the end result of high degradation rates of calcitriol and its precursor. These findings raise an interesting possible function of vitamin D catabolism as a regulator of vitamin D status.

Diagnosis and treatment

The differential diagnosis of the various forms of hereditary hypocalcemic rickets is based on serum concentrations of $1,25(OH)_2$ vitamin D and 25(OH) vitamin D; the changes in serum concentration of these metabolites following a bolus administration of vitamin D, and the response to treatment with vitamin D or its active metabolites. The active metabolites include calcitriol and/or a synthetic 1-alpha hydroxylated form of vitamin D that requires hepatic 25-hydroxylation (not tightly controlled) to become fully active.

Based on etiology and pathogenesis, the various forms of hereditary hypocalcemic rickets just discussed include defects in the biosynthesis of calcitriol (HVDDR-A and HVDDR-B), its degradation (HVDDR-C), and defects in the vitamin D receptor–effector system, suggested to be called hereditary calcitriol-resistant rickets, or HCRR, discussed later in this manuscript (Table 62.2).

Circulating levels of $1,25(OH)_2$ vitamin D are low to undetectable in HVDDR-A and HVDDR-C and may be low to normal in HVDDR-B. However, normal serum levels of $1,25(OH)_2D$ could be considered inappropriately low in face of the marked secondary hyperparathyroidism recorded in these patients. In all patients with HCRR, serum concentrations of

TABLE 62.2 Response to treatment of patients with hereditary vitamin D–dependent rickets (HVDDR) types A, B, and C and hereditary calcitriol-resistant rickets (HCRR).

	Vitamin D		1α-Hydroxylated active vitamin D metabolites	
	Physiological	Pharmacological	Physiological	Pharmacological
HVDDR				
Type A	2	1	1	Toxic
Type B	2	1	1	Toxic
Type C	2	1	2	1
HCRR	2	1 or 2	2	1 or 2

Note. Physiological doses are those recommended or being used as replacement therapy. Pharmacological doses are 100 times or more than physiological doses (see details in text).
1—a positive response; a "positive response" means complete remission of skeletal signs and symptoms as well as aberrations in mineral metabolism.
2—no response.

$1,25(OH)_2D$ are high to very high (the highest values one can measure in a biological system), usually when the patients are on very high doses of vitamin D and its active 1-alpha hydroxylated metabolites.

Circulating levels of 25(OH) vitamin D are low to undetectable in HVDDR-B and HVDDR-C and normal to elevated in HVDDR-A (depending on previous or concomitant therapy with vitamin D). Serum 25(OH)D levels in patients with HCRR reflect vitamin D therapy and usually are high. One has to keep in mind that in HCRR there is no defect in vitamin D metabolism, and serum levels reflect drugs administered or secondary changes in mineral homeostasis.

A vitamin D loading test is not used very often. It consists of the administration of a high bolus dose, usually 50,000 IU of vitamin D_3 or D_2, followed by measuring the serum levels of 25(OH) vitamin D from the third day. In HVDDR-B and HVDDR-C, baseline values of 25(OH) vitamin D are low and the response is blunted. In HVDDR-A and HCRR, it is supposed to be normal.

The diagnostic possibility of a form of HVDDR or HCRR must be considered in patients with the clinical and radiological signs and symptoms, and biochemical aberrations, compatible with early-onset hypocalcemic rickets with no history of vitamin D deficiency and no response to vitamin D administration in doses recommended for vitamin D–deficiency rickets.

Response to treatment is measured by changes in clinical and radiological signs and symptoms of rickets, normalization of biochemical aberrations in mineral and bone metabolism, and catch-up growth in the long run.

High to very high doses of vitamin D will completely cure all patients with HVDDR, with remission dependent on continuous treatment. Patients with HVDDR-A and HVDDR-B could be cured and maintained in remission by physiological replacement doses (0.25–2 μg/day) of the active hormonal form of vitamin D ($1,25(OH)_2$ vitamin D) or its synthetic 1-alpha hydroxylated metabolite (not available in the USA) in doses of 1–3 μg/day. Less than 50% of patients with HCRR will respond to any treatment with very high doses of vitamin D or its active 1-alpha hydroxylated metabolites. Patients with HVDDR-C (only two patients with this defect were reported) were cured by very high doses of vitamin D (50,000 IU/day) or its 1-alpha hydroxylated metabolites.

Needless to say, the aim of treatment in patients with hereditary hypocalcemic rickets, as in all patients with hypocalcemic rickets, is to keep extracellular calcium and phosphorous concentrations in a range that enables normal mineralization of newly formed organic bone and matrix. Thus, there is a need to provide calcium supplementation in doses adapted individually depending on age, rate of mineralization, existing osteoid, etc.

Treatment with high doses of vitamin D or its 1-alpha hydroxylated active metabolites in some patients, as well as calcium supplementation, needs close monitoring of serum calcium, phosphorous, PTH, and bone biochemical markers as well as measurements of 24-hour urinary calcium and creatinine excretion. This is aimed to follow the response to treatment and possible side effects related to high serum calcium concentration or hypercalciuria. The frequency of clinical and biochemical monitoring after the patient stabilizes, and the achievement of bone cure could be reduced accordingly.

A similar syndrome has been described and studied in a mutant strain of pigs, where the mode of inheritance and clinical and biochemical features are similar to those of the human disease (Fox et al., 1985; Harmeyer et al., 1982). Piglets affected by the disease have rickets, elevated 25(OH)D with low or undetectable $1,25(OH)_2D$ serum concentrations, normal specific tissue-binding sites for tritiated $1,25(OH)_2D$, and no detectable activity of 25(OH)D-1α-hydroxylase in renal cortical homogenates. Thus, there is strong evidence that the disease state in the pig is caused solely by an inherited defect in the renal enzyme.

Hereditary defects in the vitamin D receptor–effector system, or hereditary calcitriol-resistant rickets

Introduction

This is a rare disorder, and less than 100 patients have been reported (Balsan et al., 1983; Bear et al., 1981; Brooks et al., 1978; Castells et al., 1986; Chen et al., 1984, 2003; Clemens et al., 1983; Cockerill et al., 1997; Eil et al., 1981; Feldman et al., 1982; Fraher et al., 1986; Fujita et al., 1980; Griffin and Zerwekh, 1983; Hawa et al., 1996; Hewison et al., 1993; Hirst et al., 1985; Hochberg et al., 1984; Liberman et al., 1980, 1983b; Lin and Uttley, 1993; Lin et al., 1996; Malloy et al., 1997, 1999, 2001, 2002, 2002a, 2004, 2010, 2012; Marx et al., 1978, 1984; Mechica et al., 1997; Nguyen et al., 2002, 2006; Rosen et al., 1979; Saijo et al., 1991; Simonin et al., 1992; Sockalosky et al., 1980; Takeda et al., 1986, 1987, 1989; Tauchiya et al., 1980; Yagi et al., 1993; Whitfield et al., 1996; Zhu et al., 1998; and personal communications).

Brooks et al. (1978) described an adult patient with hypocalcemic osteomalacia and elevated serum concentration of $1,25(OH)_2D$. Treatment with vitamin D, causing a further increase in serum calcitriol levels, cured the patient. The term vitamin D–dependent rickets type II was suggested to describe this disorder. However, reports on additional patients,

slightly more than half of whom did not respond to any vitamin D therapy, as well as in vivo and in vitro studies to be discussed later, seem to prove that vitamin D dependency is a misnomer. The term hereditary defects in the vitamin D receptor–effector system, or hereditary calcitriol-resistant rickets (the abbreviation HCRR is suggested), is therefore more appropriate to describe the etiology and pathogenesis of this syndrome.

Clinical and biochemical features

General features

The clinical, radiological, histological, and biochemical features (except serum levels of vitamin D metabolites) are typical of hypocalcemic rickets and/or osteomalacia as previously discussed. Notable exceptions are two unrelated patients with hyperphosphatemia despite elevated serum levels of iPTH (Liberman et al., 1980; Yagi et al., 1993), which can be the end result of long-standing and severe hypocalcemia that paradoxically inhibits the phosphaturic response to PTH or represents an additional hereditary renal tubular defect.

In HCRR, there is no history of vitamin D deficiency and no clinical or biochemical response to physiological doses of vitamin D or its 1α-hydroxylated active metabolites. Serum levels of 25(OH)D are normal or elevated (depending on previous vitamin D therapy); $1,25(OH)_2D$ concentrations are markedly elevated before or during therapy with vitamin D preparations; and 24,25-dihydroxyvitamin D ($24,25(OH)_2D$) circulating levels, when measured, are inappropriately low (see Table 62.1).

The disease manifests itself as an active metabolic bone disease in early childhood. However, late onset at adolescence and adulthood was documented in several sporadic cases including the first reports by Brooks et al. (1978) and Fujita et al. (1980). These patients represented the mildest form of the disease and had complete remission when treated with vitamin D or its active metabolites. It is unclear whether the adult-onset patients belonged to the same hereditary entity because no further studies on their VDR status have been published.

Ectodermal anomalies

A peculiar clinical feature of HCRR patients, appearing in approximately half of the subjects, is total alopecia or sparse hair (Fig. 62.2). Alopecia usually appears during the first year of life, and in one patient at least, has been associated with additional ectodermal anomalies (Liberman et al., 1980). It seems that alopecia is a marker of a more severe form of the disease as judged by the earlier onset, severity of clinical features, proportion of patients who do not respond to treatment with high doses of vitamin D or its active metabolites, and extremely elevated levels of serum $1,25(OH)_2D$ recorded during therapy (Marx et al., 1984, 1986). Though some patients with alopecia could achieve clinical and biochemical remission of their bone disease, none have shown hair growth. The notion that total alopecia is probably a consequence of a defective vitamin D receptor–effector system is supported by the following: alopecia has only been associated with hereditary defects in the VDR system—i.e., with end-organ resistance to the action of the hormone—and has not been recorded with hereditary deficiency in $1,25(OH)_2D$ synthesis (i.e., low circulating levels of the hormone); alopecia is present in kindreds with different defects in VDRs; high-affinity uptake of tritiated $1,25(OH)_2D_3$ in the nucleus of the outer root sheath of the hair follicle of rodents has been demonstrated by autoradiography (Strumpf et al., 1979); and the epidermis and hair follicle contain a calcium-binding protein that is partially vitamin D–dependent (Marx et al., 1984). Finally, alopecia develops in homozygote VDR knockout mice (Li et al., 1997; Yoshizawa et al., 1997). Taken together, it could be hypothesized that an intact VDR–effector system is important for differentiation of the hair follicle in the fetus unrelated to mineral homeostasis.

Vitamin D metabolism

Serum concentrations of $1,25(OH)_2D$ range from upper normal to markedly elevated values before therapy, but on vitamin D treatment may reach the highest levels found in any living system (100 times and more than the upper normal range) (Marx et al., 1986). These values may represent the end results of four different mechanisms acting synergistically to strongly stimulate renal 25(OH)D-1α-hydroxylase. Three of the mechanisms are hypocalcemia, secondary hyperparathyroidism, and hypophosphatemia. The fourth mechanism may be a failure of the negative feedback loop by which the hormone inhibits the renal enzyme activity caused by the basic defect in the VDR–effector system. This was demonstrated in two patients with HCRR in remission (normal serum levels of calcium, phosphorus, and PTH) in whom a load of $25(OH)D_3$ caused a marked increase in serum $1,25(OH)_2D_3$ concentration (Balsan et al., 1983; Marx et al., 1984; Nguyen et al., 2006). It was reported that 1α-hydroxylase gene expression was not suppressed by $1,25(OH)_2D_3$ in renal tubular cells

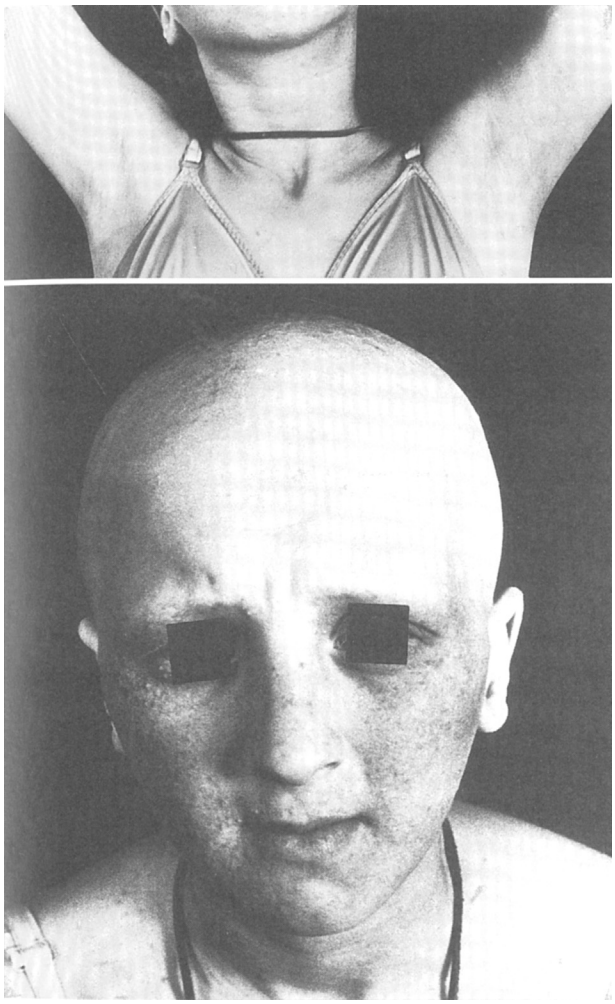

FIGURE 62.2 A patient with hereditary calcitriol-resistant rickets with total alopecia. Note: no scalp and axilla hair as well as no eyebrows and eyelashes.

from VDR knockout mice, whereas it was suppressed in cells with normal VDR or heterozygote for the null mutation (Murayama et al., 1999; Takeyama et al., 1997).

$1,25(OH)_2D$ is a potent inducer of the enzyme 25(OH)D-24-hydroxylase in vivo and in vitro. Serum levels of $24,25(OH)_2D$ have been very low or inappropriately low in the face of the elevated concentrations of the hormone in patients with HCRR (Castells et al., 1986; Fraher et al., 1986; Liberman et al., 1980; Marx et al., 1984). This probably reflects defective stimulation of $24,25(OH)_2D$ production owing to the basic deficiency in VDR activity. This assumption is supported by the observation that in mutant mice lacking VDR, expression of 24(OH)-hydroxylase was reduced to undetectable levels, and normal induction of the enzyme by $1,25(OH)_2D_3$ was not obtained (Takeyama et al., 1997).

Mode of inheritance

In approximately half of reported kindreds, parental consanguinity and multiple siblings with the same defect suggest an autosomal recessive mode of inheritance (Marx et al., 1984). Parents of patients who are expected to be obligate heterozygotes have been reported to be normal—i.e., no bone disease or alopecia, and normal blood biochemistry. However, studies on cells (cultured dermal fibroblasts, Epstein–Barr transformed lymphoblasts, and mitogen-stimulated lymphocytes) obtained from the parents of affected children revealed decreased bioresponse, decreased normal VDR protein and its mRNA, and a heterozygote genotype exhibiting both normal and mutant DNA alleles (Malloy et al., 1989, 1990; 1999, 2002; Nguyen et al., 2006; Ritchie et al., 1989; Takeda et al., 1990). There is a striking clustering of patients around the Mediterranean, including patients reported from Europe and America who originated from the same area.

A notable exception is a cluster of some kindreds from Japan (Fujita et al., 1980; Tauchiya et al., 1980, 1986, 1987, 1989; Yagi et al., 1993).

Cellular and molecular defects

Methods

The near ubiquity of a similar if not identical VDR–effector system among various cell types, including cells originating from tissues easily accessible for sampling, made it feasible to study the nature of intracellular and molecular defects in patients with HCRR. The cells used were mainly fibroblasts derived from skin biopsies (Balsan et al., 1983; Castells et al., 1986; Chen et al., 1984; Clemens et al., 1983; Eil et al., 1981; Feldman et al., 1982; Fraher et al., 1986; Griffin and Zerwekh, 1983; Hirst et al., 1985; Hughes et al., 1988; Liberman et al., 1983b; Malloy et al., 1989, 1990, 1997; 1999, 2002, 2004, 2010; Marx et al., 1984; Nguyen et al., 2002, 2006; Ritchie et al., 1989; Takeda et al., 1989) and peripheral blood mononuclear (PBM) cells (Koren et al., 1985; Ritchie et al., 1989; Takeda et al., 1986, 1990; Yagi et al., 1993). PBM cells contain high-affinity receptors for $1,25(OH)_2D_3$ that are expressed constitutively in monocytes and induced in mitogen-stimulated T lymphocytes and Epstein–Barr (EB)-transformed lymphoblasts. All cells have been used to assess most steps in $1,25(OH)_2D_3$ action, from cellular and subcellular uptake of the hormone to bioresponse, as well as to elucidate molecular aberrations in VDR protein, RNA, and DNA levels.

The hormone–receptor interaction has been analyzed by several methods including the binding characteristics of [3H] $1,25(OH)_2D_3$ to intact cells, nuclei or high-salt cellular soluble extracts, so-called cytosol (Balsan et al., 1983; Castells et al., 1986; Chen et al., 1984; Clemens et al., 1983; Eil et al., 1981; Feldman et al., 1982; Fraher et al., 1986; Hirst et al., 1985; Hochberg et al., 1984; Hughes et al., 1988; Koren et al., 1985; Liberman et al., 1983a,b; Malloy et al., 1989, 1990; Marx et al., 1984; Ritchie et al., 1989; Sone et al., 1990; Takeda et al., 1986; Yagi et al., 1993), measurements of VDR protein content by monoclonal antibodies with radiological immunoassay or Western blot analysis (Malloy et al., 1990; Ritchie et al., 1989), immunocytochemical methods in whole cells (Barsony et al., 1990), and characterization of the hormone–receptor complex on continuous sucrose gradient and nonspecific DNA-cellulose columns (Balsan et al., 1983; Chen et al., 1984; Clemens et al., 1983; Eil et al., 1981; Feldman et al., 1982; Hirst et al., 1985; Hochberg et al., 1984; Hughes et al., 1988; Liberman et al., 1983a,b; Malloy et al., 1989; Marx et al., 1984; Sone et al., 1990).

The cloning and nucleotide sequencing of the human VDR gene made it feasible to study molecular defects in patients with HCRR. The methods used included, among others, the isolation of genomic DNA that encodes the structural portion of the human VDR, PCR amplification, screening, and sequencing of the amplified DNA fragments (Hughes et al., 1988; Kristjansson et al., 1993; Malloy et al., 1990; Ritchie et al., 1989; Sone et al., 1990; Yagi et al., 1993); cloning and sequencing of VDR cDNA produced from isolated fibroblast total RNA by reverse transcription and PCR amplification (Rut et al., 1994; Saijo et al., 1991; Weise et al., 1993); and recreation of the mutant receptor in vitro by introducing the appropriate base change in normal VDR cDNA by site-directed mutagenesis that was transfected into cells that do not express endogenous VDR. Posttranscriptional action of $1,25(OH)_2D$ was tested in cells originating from patients or in cells cotransfected with VDR (either mutant or wild-type fused to a promotor containing VDRE) (Hewison et al., 1993; Hughes et al., 1988; Malloy et al., 1990, 1999; 2002, 2004; Nguyen et al., 2002, 2006; Ritchie et al., 1989; Sone et al., 1990; Yagi et al., 1993).

Types of defects

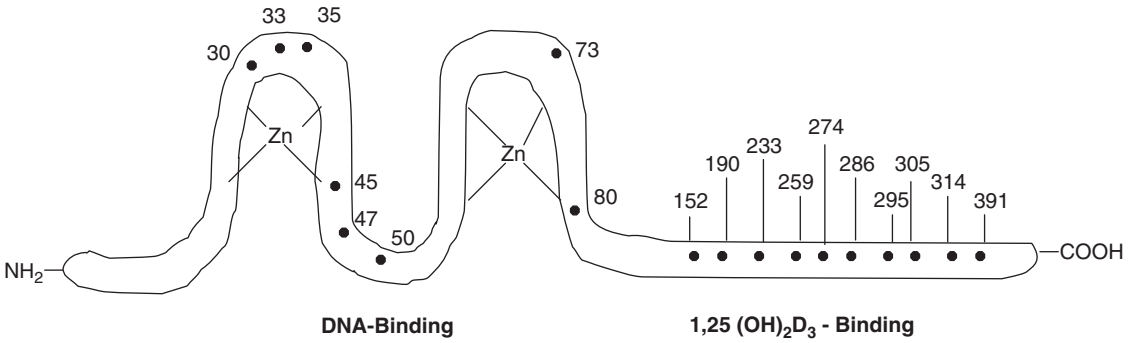
Studies with the above-mentioned methods in cells originating from a variety of patients with HCRR revealed heterogeneity of the cellular and molecular defects in the VDR–effector system. Based on the known functional properties of VDR, different classes of defects could be identified.

Defects in the hormone-binding region (including heterodimerization)

Deficient hormone binding

There are three subgroups in this class:

(i) No hormone binding. This is the most common abnormality observed and is characterized by the unmeasurable specific binding of [3H]$1,25(OH)_2D_3$ to intact cells, nuclei, or cell extracts (Balsan et al., 1983; Chen et al., 1984; Cockeril et al., 1997; Feldman et al., 1982; Fraher et al., 1986; Hawa et al., 1996; Koren et al., 1985; Kristjansson et al., 1993; Liberman et al., 1983a,b; Malloy et al., 1990, 2001; Marx et al., 1984; Mechica et al.,



Normal	Mutant	Normal	Mutant
30 Arg (CGA)	Stop (TGA)	152 Gln (CAG)	Stop (TAG)
33 Gly (GGC)	Asp (GAC)	190 Cys (TGT)	Trp (TGG)
35 His (CAC)	Gln (CAG)	233 Leu (GTC)	fs (GTG)
45 Lys (AAA)	Glu (GAA)	259 Gln (CAG)	Pro (CCG)
47 Phe (TTC)	Lle (ATC)	274 Arg (CGC)	Leu (CTC)
50 Arg (CGA)	Gln (CAA)	286 Trp (TGG)	Arg (CGG)
73 Arg (CGC)	Stop (TGA)	295 Tyr (TAC)	Stop (TAA)
73 Arg (CGG)	Gln (CAA)	305 His (CAC)	Gln (CAG)
80 Arg (CGG)	Gln (CAG)	314 Lle (ATC)	Ser (AGC)
		391 Arg (CGC)	Cys (TGC)

FIGURE 62.3 Schematic presentation of the homozygous mutation in the VDR protein in some patients with hereditary calcitriol-resistant rickets. The asterisks depict sites of amino acid substitutions owing to point mutations and codon changes using the numbering system of Baker et al. (1988).

1997; Nguyen et al., 2002; Ritchie et al., 1989; Sone et al., 1989). Studies in several kindreds with this defect (including an extended kindred with eight patients studied) revealed undetectable levels of VDR by immunoblots on an immunoradiometric assay in most kindreds (Kristjansson et al., 1993; Malloy et al., 1990; Nguyen et al., 2002; Ritchie et al., 1989; Weise et al., 1993). DNA from these affected subjects exhibited a single base mutation in each kindred resulting in (1) conversion of a normal amino acid codon into a premature termination codon in the coding sequence of the VDR protein and (2) a frameshift in translation resulting in a premature stop codon. The truncated VDRs that were produced lacked hormone binding or both hormone-binding and DNA-binding domains (Fig. 62.3) (Cockeril et al., 1997; Hawa et al., 1996; Mechica et al., 1997; Weise et al., 1993). The recreated mutant VDR cDNA was expressed in mammalian cells, and the resulting mutant VDR was demonstrated to be the truncated protein that exhibited no specific hormone binding. Steady-state VDR mRNA levels were decreased or undetectable in patient cells from one kindred (Malloy et al., 1990; Ritchie et al., 1989). An immunoradiometric assay for VDR did not detect the 148- and 291 amino acid—long mutant VDR, though this portion of the receptor included both epitopes required for recognition (Weise et al., 1993). These observations may indicate an unstable transcript and/or increased turnover. In cells cultured from parents of some patients expected to be obligate heterozygotes, the binding of [3H]1,25$(OH)_2D_3$, VDR protein, and mRNA content of cells ranged from the lower limit of normal to about half the normal level.

In one patient representing a kindred with no hormone binding, a missense mutation resulted in the substitution of the hydrophobic basic arginine-274 by the hydrophilic nonpolar leucine in the hormone-binding region (Kristjansson et al., 1993) (see Fig. 62.3). In this patient, normal transcription in a transfection assay could be elicited by 1000-fold higher concentrations of calcitriol than needed for the wild-type receptor. However, no in vivo or in vitro stimulation of 25(OH)D-24-hydroxylase could be obtained by high concentrations of 1,25$(OH)_2D_3$.

Two siblings without alopecia and with no response to any dose of 1,25$(OH)_2D$ in vivo and in vitro had a missense mutation that caused a substitution of tryptophan by arginine at amino acid 286 of VDR (see Fig. 62.3) (Nguyen et al., 2002). This substitution in a normal-size VDR completely abolished the binding of 1,25$(OH)_2D$ to its receptor. The tryptophan in this position is critical for the positioning of calcitriol in VDR as was unveiled by the three-dimensional arrangement of VDR and its ligand based on its crystal structure (Rochel et al., 2000).

(ii) Defective hormone binding capacity. In a patient representing one kindred, the number of binding sites in nuclei and high-salt soluble cell extracts was 10% of control with an apparent normal affinity (Balsan et al., 1983; Liberman et al., 1983a,b; Sone et al., 1989).

Recently, a boy with total alopecia, severe rickets, and growth retardation was found to have two heterozygote-different molecular defects in the ligand-binding domain (Nguyen et al., 2006). The patient's VDR had a low hormone-binding capacity, 10%−30% of controls, with normal affinity and markedly deficient stimulation of 25(OH)D_3-24-hydroxylase. The recreated mutations, each one tested separately in vitro, also showed deficient heterodimerization and different transactivation of two gene promotors. This patient, similar to another one described more than 20 years ago, could be completely cured by very high doses of 25(OH) vitamin D, 250 μg/day initially followed by 100 μg/day and then 75 μg/day as a maintenance dose continuing for years, plus modest calcium supplementation. In both patients, it could be shown that during remission (normocalcemia, normophosphatemia, normal iPTH), 1,25$(OH)_2$D production is driven by the substrate—i.e., 25(OH) vitamin D concentrations.

(iii) Defective hormone binding affinity. Binding affinity of tritiated calcitriol was reduced 20- to 30-fold, with normal capacity, in high-salt soluble dermal fibroblast extracts from one kindred (Castells et al., 1986). An additional patient, representing a different kindred, had a modest decrease of VDR affinity when measured at 0°C (Malloy et al., 1997). No studies on the molecular defect were performed in patients with the last two defects.

Deficient nuclear uptake

Hormone−receptor−nuclear interaction in this defect is characterized by normal or near-normal binding capacity and affinity of [^{3}H]1,25$(OH)_2D_3$ to high-salt soluble cell extracts with low to unmeasurable hormone uptake into the nuclei of intact cells (Eil et al., 1981; Hewison et al., 1993; Liberman et al., 1983b; Takeda et al., 1989; Whitfield et al., 1996). These features were demonstrated in skin-derived fibroblasts in all kindreds, in cells cultured from a bone biopsy of one patient (Liberman et al., 1983b), and in EB-transformed lymphoblasts of one patient (Hewison et al., 1993). Occupied VDR obtained from high-salt fibroblast extracts of two kindreds demonstrated normal binding to nonspecific DNA cellulose (Liberman et al., 1986). Immunocytological studies in fibroblasts of a patient with this defect showed that immediately after 1,25$(OH)_2D_3$ treatment, VDR accumulated along the nuclear membrane with no nuclear translocation (Barsony et al., 1990). Patients with this defect included a kindred with normal hair and several kindreds with total alopecia. Finally, almost all patients responded with complete clinical remission to high doses of vitamin D and its active 1α-hydroxylated metabolites.

Attempts to characterize the molecular defect were carried out in six kindreds. In three of them, no mutation in the coding region of the VDR gene was observed (Hewison et al., 1993; personal communication). Studies in two kindreds revealed a normal molecular mass and quantitative expression of VDR as judged by immunoblotting (Whitfield et al., 1996). Complete sequencing of the VDR-coding region revealed a different single-nucleotide mutation in each kindred: ATC to AGC (isoleucine-314 to serine) in one kindred, CGC to TCG (altering arginine-391 to cysteine) in the second kindred, and CAG to CCG (altering glutamine-259 to proline) in the third kindred (see Fig. 62.3) (Cockeril et al., 1997; Whitfield et al., 1996), This region is considered to play a role in heterodimerization of VDR with RXR, and thus it has been suggested that these patients' receptors have defects that compromise RXR heterodimerization, which is essential for nuclear localization and probably for recognition of the vitamin D−responsive element as well. The fact that no mutation in the VDR-coding region was observed in three additional kindreds with the same phenotypical defect may suggest that the genetic defect affects another component of the receptor−effector system that is essential for VDR's function as a nuclear transcription factor. It has been shown that coactivation complexes are essential for the ligand-induced transactivation of VDR (Freedman, 1999). It is worthwhile to note that in one kindred originally described with this defect (Takeda et al., 1989) a missense mutation at position 140 in exon 3, encoding the DNA-binding domain, was observed (Saijo et al., 1991).

Concerning deficient coactivators of the calcitriol−VDR complex, a patient with HCRR without alopecia was described (Malloy et al., 1999). Sequencing of VDR-DNA revealed a missense mutation in the ligand-binding domain that caused a substitution of glutamic acid to lysine at amino acid 120 (see Fig. 62.3). This receptor exhibits many normal properties including calcitriol binding, dimerization, and binding to vitamin D−response elements in DNA but a marked impairment in the binding of coactivators essential for transactivation of the hormone−receptor complex and the initiation of physiological response.

Defects in the DNA-binding region

Deficient binding to DNA—cell preparations derived from patients with this defect demonstrate normal or near-normal binding capacity and affinity for [3H]1,25$(OH)_2D_3$ to the nuclei of intact cells and high-salt soluble cell extracts, as well as normal-molecular-size VDR of 48−50 kDa, as analyzed by immunoblot. Hormone−receptor complexes, however,

have decreased affinity to nonspecific DNA (peak elution from DNA-cellulose columns at 0.1 M KCl compared with 0.2 M in normals) (Hirst et al., 1985; Hughes et al., 1988; Liberman et al., 1986; Saijo et al., 1991; Yagi et al., 1993). A single-nucleotide missense mutation within exon 2 or 3, encoding the DNA-binding domain of VDR, was demonstrated in genomic DNA isolated from dermal fibroblasts and/or EB-transformed lymphoblasts from 10 unrelated kindreds (Hughes et al., 1988; Lin et al., 1996; Malloy et al., 1989, 1994; Mechica et al., 1997; Rut et al., 1994; Sone et al., 1990; Saijo et al., 1991; Yagi et al., 1993). Eight different single-nucleotide mutations were found in the 10 kindreds (see Fig. 62.3). Two apparently unrelated kindreds share the same mutation (Saijo et al., 1991; Sone et al., 1990).

All point mutations caused a single substitution of an amino acid that resides in the region of the two zinc fingers of the VDR protein that are essential for the functional interaction of the hormone−receptor complex with DNA. Interestingly, all these altered amino acids are highly conserved in the steroid receptor superfamily and seem to concentrate in three regions: the tip of the first zinc fingers (three mutations), the "knuckle" region—the C-terminal of the first zinc fingers (three mutations), and the C-terminal side of the second zinc fingers (two mutations). All of these single−amino acid residue substitutions are associated with charge changes and thus affect hydrogen bonding. These aberrations, as well as changes in hydrophobicity, will have a deleterious effect on the interaction of the hormone−receptor complex with DNA.

Each mutant was recreated by introducing the appropriate base change into the normal VDR cDNA and then transfecting the mutated cDNA into mammalian cells. The functional properties of the resultant VDR-expression product were indistinguishable from mutant DNA—i.e., normal hormone binding and deficient binding to nuclear extracts and nonspecific DNA (Hughes et al., 1988; Saijo et al., 1991; Sone et al., 1990). Studies on cells obtained from the parents of some of these patients revealed, as expected, a heterozygous state—i.e., expression of both normal and defective forms of VDR as well as normal and mutant gene sequences (Hughes et al., 1988; Malloy et al., 1989) but without any clinical or biochemical abnormalities.

In vitro posttranscriptional and transcriptional effects of *1,25(OH)$_2$D$_3$*

The in vitro bioeffects of the hormone on various cells in patients with HCRR have been assayed mainly by two procedures, induction of 25(OH)D-24-hydroxylase and inhibition of mitogen-stimulated PBM cells.

1,25(OH)$_2$D$_3$ induces 25(OH)D-24-hydroxylase activity in skin-derived fibroblasts (Balsan et al., 1983; Castells et al., 1986; Chen et al., 1984; Clemens et al., 1983; Feldman et al., 1982; Fraher et al., 1986; Gamblin et al., 1985; Griffin et al., 1983; Hewison et al., 1993; Hirst et al., 1985; Hughes et al., 1988; Liberman et al., 1983b; Malloy et al., 1990; Ritchie et al., 1989; Rut et al., 1994; Sone et al., 1990; Yagi et al., 1993), mitogen-stimulated lymphocytes (Takeda et al., 1990), and cells originating from bone (Balsan et al., 1986) in a dose-dependent manner. In cells from normal subjects, maximal and half-maximal induction of the enzyme was achieved by 10-8 and 10-9 M concentrations of 1,25(OH)$_2$D$_3$, respectively. Dermal fibroblast and PBM cells from HCRR patients with no calcemic response to maximal doses of vitamin D or its metabolites in vivo did not show any 25(OH)D-24-hydroxylase response to very high concentrations of 1,25(OH)$_2$D$_3$ in vitro, whereas dermal fibroblasts from patients with a calcemic response to high doses of vitamin D or its metabolites in vivo showed inducible 24-hydroxylase with supraphysiological concentrations of 1,25(OH)$_2$D$_3$—i.e., a shift to the right in vitro. Physiological concentrations of 1,25(OH)$_2$D$_3$ partially inhibit mitogen-induced DNA synthesis in peripheral lymphocytes, with half-maximal inhibition achieved at 10-10 M hormone (Koren et al., 1985; Takeda et al., 1986). Mitogen-stimulated lymphocytes from several kindreds with defects characterized as no hormone binding or deficient binding to DNA, with no calcemic response to high doses of vitamin D and its metabolites in vivo, showed no inhibition of lymphocyte proliferation in vitro with concentrations of up to 10-6 M 1,25(OH)$_2$D$_3$ (Fig. 62.4). Additional methods for measuring the bioeffects of 1,25(OH)$_2$D$_3$ on various cells in vitro were carried out in only a few patients and included the inhibition of dermal fibroblast proliferation (Clemens et al., 1983), induction of osteocalcin synthesis in cells derived from bone (Balsan et al., 1986), a mitogenic effect on dermal fibroblasts (Barsony et al., 1989), and stimulation of cGMP production in cultured skin fibroblasts (Barsony and Marx, 1988). It is noteworthy that in all assays mentioned, without exception, each patient's cells showed severely deficient responses.

With elucidation of the molecular defects in HCRR, the transactivation abilities of naturally occurring mutant or recreated mutant VDRs were evaluated in a transcriptional activation assay. The human osteocalcin gene promoter fused to chloramphenicol acetyltransferase (CAT) gene reporter plasmid was transfected into patients or normal fibroblasts (Hewison et al., 1993; Hughes et al., 1988; Malloy et al., 1990; Ritchie et al., 1989; Saijo et al., 1991; Sone et al., 1989; Yagi et al., 1993). Treating normal transfected cells with 1,25(OH)$_2$D$_3$ caused a concentration-dependent induction of transcription as measured by increased CAT activity. No induction of transcription was observed in cells originating from patients with defects characterized as no hormone binding (Kristjansson et al., 1993; Malloy et al., 1990; Ritchie et al., 1989) or deficient binding to DNA (Hughes et al., 1988; Saijo et al., 1991; Sone et al., 1990; Yagi et al., 1993). Moreover,

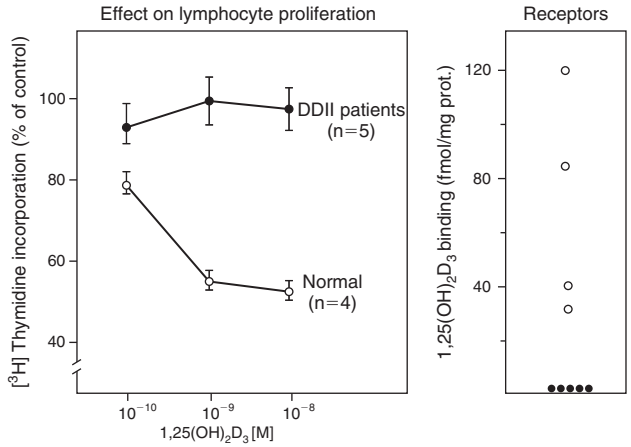


FIGURE 62.4 Effect of increasing concentrations of $1,25(OH)_2D_3$ on mitogen-induced lymphocyte proliferation from patients with hereditary calcitriol-resistant rickets (HCRR) and normal controls. The numbers of specific $[^3H]1,25(OH)_2D_3$-binding sites are depicted (right) in the same cell populations. HCRR patients tested here are with the defect characterized as no hormone binding.

in a cotransfection assay, the addition of a normal human VDR cDNA expression vector to the transfected plasmid that directed synthesis of a normal VDR restored the hormone responsiveness of resistant cells.

Finally, a 2 year-old girl with alopecia, hypocalcemic rickets, high circulating levels of $1,25(OH)_2$ vitamin D, and no response to recommended doses of vitamin D was characterized as having a deficient nuclear uptake defect; no mutation was identified within the coding region of the VDR gene, and no induction of 25(OH)D-24-hydroxylase activity by up to 10-6 M $1,25(OH)_2D_3$ was observed in cultured skin fibroblasts (Hewison et al., 1993). Cotransfection studies performed subsequently (Chen et al., 2003) showed that patient cells suppressed basal and hormone-induced transactivation by wild-type VDR. Electrophoretic mobility shift assays and western/southwestern blot analysis indicated that the suppressive effect was due to the overexpression of a nuclear protein that interacts specifically with a DNA response element known to bind RXR−VDR heterodimers. This dominant, negative-acting element belongs to the heterogenous nuclear ribonucleoproteins (hnRVP) family of nucleic acid binding proteins. Several members of this family, most notably hnRVPA1, were able to suppress calciferol-induced luciferase activity. The ability of hnRVPs to attenuate steroid hormones receptor genes transactivation also has been demonstrated in studies in New World primates known to have partial resistance to vitamin D and steroid hormones. These observations raise a few interesting questions. Are these proteins that interact with the DNA of the calciferol response element a part of the physiological control system of vitamin D and mineral homeostasis? The patient discussed has HCRR but with normal $1,25(OH)_2$ D receptors. The underlying cause for calcitriol resistance in this patient is overexpression of a response element binding protein that interacts with the DNA of the vitamin D−response element to block its biological activity. Most patients with HCRR have different defects within the coding region of VDR. As discussed, this patient, although being similar in clinical, radiological, and biochemical changes as well as dermal signs, has a different etiology and pathogenesis and therefore may deserve a different title such as HCRR type B. This patient had a complete cure of her rickets and normalization of all biochemical aberrations on treatment with high doses of $1,25(OH)_2$ vitamin D_3 (12 μg/day) plus 1 g/day of elemental calcium.

Cellular defects and clinical features

Normal hair was described with most phenotypes of the cellular defects, the exception being patients with deficient hormone-binding capacity and affinity, but this could be because only very few kindreds were described per subgroup. Normal hair is usually associated with a milder form of the disease as judged by the age of onset, severity of clinical features, and usually complete clinical and biochemical remission on high doses of vitamin D or its metabolites. Notable exceptions are two patients, from two separate kindreds, with normal hair that displayed resistance both in vivo (no clinical remission on a circulating calcitriol level of up to 100 times mean normal adult values) and in vitro—i.e., no induction of 25(OH)D-24-hydroxylase activity in dermal fibroblasts by up to 10-8 M $1,25(OH)_2D_3$ (Fraher et al., 1986; Malloy et al., 2002). Only about half of patients with alopecia have shown satisfactory clinical and biochemical remission in response to high doses of vitamin D or its active 1α-hydroxylated metabolites, but the dose requirement is 10-fold higher than in patients with normal hair (Marx et al., 1986).

It seems that patient defects characterized as deficient hormone-binding affinity and deficient nuclear uptake achieve complete clinical and biochemical remission on high doses of vitamin D or its active 1α-hydroxylated metabolites. Most patients with other types of defects could not be cured with high doses of vitamin D or its metabolites. However, it should be emphasized that not all patients received treatment for sufficiently long periods and at sufficiently high doses (see "Treatment").

Diagnosis

Clinical features of early-onset rickets with no history of vitamin D deficiency, total alopecia, parental consanguinity, additional siblings with the same disease, serum biochemistry of hypocalcemic rickets, elevated circulating levels of $1,25(OH)_2D$, and normal to high levels of 25(OH)D (see Table 62.1) support the diagnosis of HCRR. The issue becomes more complicated when clinical features are atypical—i.e., late onset of the disease, sporadic cases, and normal hair. Failure of a therapeutic trial with physiological replacement doses of vitamin D or its active metabolites plus calcium supplementation may support the diagnosis, but final direct proof requires the demonstration of a cellular, molecular, and functional defect in the VDR−effector system.

Based on clinical and biochemical features, the following additional disease states should be considered: (1) extreme calcium deficiency—a seemingly rare situation described in a group of children from a rural community in South Africa who consumed an exceptionally low-calcium diet of 125 mg/day (Pettifor et al., 1981). All had severe bone disease with histologically proven osteomalacia, biochemical features of hypocalcemic rickets with elevated serum levels of $1,25(OH)_2D$, and sufficient vitamin D. Calcium repletion caused complete clinical and biochemical remission. Nutritional history and the response to calcium supplementation support this diagnosis; (2) severe vitamin D deficiency—during initial stages of vitamin D therapy in children with severe vitamin D−deficiency rickets, the biochemical picture may resemble HCRR (i.e., hypocalcemic rickets with elevated serum calcitriol levels). This may represent a "hungry bone syndrome"—i.e., high calcium demands of the abundant osteoid tissue becoming mineralized. This is a transient condition that may be differentiated from HCRR by a history of vitamin D deficiency and the final therapeutic response to replacement doses of vitamin D.

Treatment

In about half of the kindreds with HCRR, the bioeffects of $1,25(OH)_2D_3$ were measured in vitro (see earlier). An invariable correlation (with one exception) was documented between the in vitro effect and the therapeutic response in vivo—i.e., patients with no calcemic response to high levels of serum calcitriol showed no effects of $1,25(OH)_2D_3$ on their cells in vitro (neither induction of 25(OH)D-24-hydroxylase nor inhibition of lymphocyte proliferation) and vice versa. If the predictive therapeutic value of the in vitro cellular response to $1,25(OH)_2D_3$ could be substantiated convincingly, it might eliminate the need for time-consuming and expensive therapeutic trials with massive doses of vitamin D or its active metabolites. In the meantime, it is mandatory to treat every patient with HCRR irrespective of the type of receptor defect.

An adequate therapeutic trial must include vitamin D at a dose sufficient to maintain high serum concentrations of $1,25(OH)_2D_3$, as patients can produce high hormone levels if supplied with enough substrate (Brooks et al., 1978; Marx et al., 1978). If high serum calcitriol levels are not achieved, it is advisable to treat with 1α-hydroxylated vitamin D metabolites in daily doses of up to 6 μg/kg, or a total of 30−60 μg, and calcium supplementation of up to 3 g of elemental calcium daily; therapy must be maintained for a period sufficient to mineralize the abundant osteoid (usually 3−5 months). Therapy may be considered a failure if no change in the clinical, radiological, or biochemical parameters occurs during continuous and frequent follow-up while serum $1,25(OH)_2D$ concentrations are maintained at 100 times the mean normal range.

In some patients with no response to adequate therapeutic trials with vitamin D or its active 1-alpha hydroxylated metabolites, a remarkable clinical and biochemical remission of their bone disease, including catch-up growth, was obtained by treatment with large amounts of calcium. This was achieved by long-term (months) intracaval infusions of up to 1000 mg of calcium daily (Balsan et al., 1986; Bliziotes et al., 1988; Weisman et al., 1987). Another way to increase calcium input into the extracellular compartment is to increase net gut absorption, independent of vitamin D, by increasing calcium intake (Sakati et al., 1986). This approach is limited by dose and patient tolerability and was used successfully in only a very few patients.

Several patients have shown unexplained fluctuations in response to therapy or in presentation of the disease. One patient, after a prolonged remission, became completely unresponsive to much higher doses of active 1α-hydroxylated vitamin D

metabolites (Balsan et al., 1983), and another patient seemed to show amelioration of resistance to $1,25(OH)_2D_3$ after a brief therapeutic trial with $24,25(OH)_2D_3$ (Liberman et al., 1980). In several patients, spontaneous healing occurred in their teens (Hochberg et al., 1984) or rickets did not recur for 14 years after the cessation of therapy (Takeda et al., 1989).

Animal models

Some New World primates (marmosets and tamarins) that develop osteomalacia in captivity are known to have high nutritional requirements for vitamin D and maintain high serum levels of $1,25(OH)_2D$, thus exhibiting a form of end-organ resistance to $1,25(OH)_2D$ (Adams and Gacad, 1988; Liberman et al., 1985; Shinki et al., 1983; Takahashi et al., 1985). Cultured dermal fibroblasts and EB-virus-transformed lymphoblasts have shown deficient hormone-binding capacity and affinity (Adams and Gacad, 1988; Liberman et al., 1985). It has been observed that marmoset lymphoblasts contain a soluble protein of 50–60 kDa that binds $1,25(OH)_2D_3$ with a low affinity but high capacity and thus may serve as a sink that interferes with hormone binding and its cognate receptor (Gacad and Adams, 1993). The same group described another protein present in the nuclear extract of these cells capable of inhibiting normal VDR-RXR binding to the vitamin D–response element (Arbelle et al., 1996).

It is of interest that these New World primates also exhibit a compensated hereditary end-organ resistance to true steroid hormones including glucocorticoids, estrogens, and progestins (Lipsett et al., 1985). This of course raises the interesting possibility that the defect in the hormone–receptor–effector system involves an element shared by all members of this superfamily of ligand-modulated transcription factors.

VDR knockout mice have been created by targeted ablation of the first or second zinc finger (Li et al., 1997; Yoshizawa et al., 1997). Only homozygotic mice were affected. Though phenotypically normal at birth, after weaning they become hypocalcemic and develop secondary hyperparathyroidism, rickets, osteomalacia, and progressive alopecia. Female mice with ablation of the first zinc finger are infertile and show uterine hypoplasia and impaired folliculogenesis. Otherwise, both VDR cell-mutant mice show clinical, radiological, histological, and biochemical features identical to those of the human disease HCRR. Supplementation with a calcium-enriched diet can prevent or treat most disturbances in mineral and bone metabolism in these animal models except alopecia (Delling and Demay, 1998). It is of interest that targeting the expression of human VDR to the keratinocytes of VDR-null mice prevented alopecia (Chen et al., 2001).

Concluding remarks

Hereditary deficiencies in vitamin D action are rare disorders. The importance of studying these diseases stems from the fact that they represent a naturally occurring experimental model that helps to elucidate the function and importance of vitamin D and the VDR–effector system in humans in vivo.

VDRs are abundant and widely distributed among most tissues studied, and multiple effects of calcitriol are observed on various cell functions in vitro. Yet the clinical and biochemical features in patients with HVDDR and HCRR seem to demonstrate that the only disturbances of clinical relevance are perturbations in mineral and bone metabolism. This demonstrates the pivotal role of $1,25(OH)_2D$ in transepithelial net calcium fluxes. Moreover, the fact that calcium infusions correct the disturbances in mineral homeostasis and cure the bone disease in patients with extreme end-organ resistance to calcitriol may support the notion that defective bone matrix mineralization in HVDDR and HCRR is secondary to disturbances in mineral homeostasis. Characterization of the molecular, cellular, and functional defects of the different natural mutants of human VDR in HCRR demonstrates the essentiality of VDR as the mediator of calcitriol action and the importance and function of its different domains. Furthermore, to function biologically, VDR must associate with additional partners—i.e., $1,25(OH)_2D$, an RXR isoform, a specifically defined DNA region, and coactivators and corepressor complexes. This notion has been based primarily on in vitro-created point mutations and in vitro functional assays. However, the acid test for the relevance of the structure–function relationship is the demonstration of in vivo effects in general and deficient function under pathological conditions in particular. Thus, studies in patients with hereditary deficiencies in vitamin D action are the essential link between molecular defects and physiologically relevant effects.

Chapter outline

Identification of fibroblast growth factor 23

Serum phosphate level is maintained within a narrow range by intestinal phosphate absorption, proximal tubular phosphate reabsorption, and equilibrium between extracellular phosphate and that in bone or the intracellular space. Parathyroid hormone (PTH) reduces serum phosphate by suppressing proximal tubular phosphate reabsorption. In addition, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$) works to increase serum phosphate by enhancing intestinal phosphate absorption. In addition to these hormones, the presence of some other humoral factor regulating serum phosphate level was postulated by analysis of hypophosphatemic diseases. Tumor-induced osteomalacia (TIO) is one of the paraneoplastic syndromes. Patients with TIO show hypophosphatemia with impaired proximal tubular phosphate reabsorption (Minisola et al., 2017). Hypophosphatemia usually enhances $1,25(OH)_2D$ production and increases serum $1,25(OH)_2D$ (Fukumoto, 2014). However, $1,25(OH)_2D$ is low to low normal in patients with TIO. In addition, serum calcium and PTH are usually normal in patients with TIO. TIO can be cured and biochemical abnormalities corrected by complete removal of the responsible tumors, indicating that some humoral factor produced by the tumors is causing hypophosphatemia and rather low $1,25(OH)_2D$. X-linked hypophosphatemic rickets (XLH) is the most prevalent cause of inherited hypophosphatemic rickets. Patients with XLH show biochemical features similar to those in subjects with TIO. The responsible gene for XLH was identified by positional cloning and named phosphate-regulating gene with homologies to endopeptidases on the X chromosome (*PHEX*) (The HYP Consortium, 1995). There is a murine model of XLH called the *Hyp* mouse. This mouse was shown to have a deletion in the *Phex* gene (Beck et al., 1997). Parabiosis experiments suggested that biochemical abnormalities in the *Hyp* mouse are caused by some humoral factor (Meyer et al., 1989). However, it was not clear whether biochemical abnormalities in TIO and *Hyp* are caused by the same humoral factor.

FGF23 was identified as a responsible gene for autosomal dominant hypophosphatemic rickets (ADHR) by positional cloning (ADHR Consortium, 2000). Patients with ADHR show clinical features similar to those in subjects with XLH. In addition, *Fgf23* was cloned by homology to *Fgf15* in mice (Yamashita et al., 2000). Furthermore, fibroblast growth factor

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00063-4

23 (FGF23) was identified as a responsible humoral factor for TIO (Shimada et al., 2001). FGF23 was later shown to be produced by bone, especially by osteocytes/osteoblasts (Liu et al., 2003), and to be the responsible humoral factor in XLH and *Hyp*.

Actions of fibroblast growth factor 23

The human *FGF23* gene encodes a protein of 251 amino acids. There is a signal peptide of 24 amino acids and a secreted FGF23 protein consists of 227 amino acids. A part of the FGF23 protein is proteolytically cleaved into inactive fragments between ^{179}Arg and ^{180}Ser before secretion by an enzyme that recognizes the ^{176}Arg−X−X−^{179}Arg motif (Shimada et al., 2001). While PHEX protein was originally postulated to mediate this processing of FGF23 protein, this hypothesis was later denied (Linglart et al., 2014).

FGF23 was shown to reduce the expression of type IIa and IIc sodium−phosphate cotransporters expressed in the brush border membrane of renal proximal tubules (Larsson et al., 2004; Shimada et al., 2004a). These cotransporters are physiological mediators of phosphate reabsorption. In addition, FGF23 suppresses the expression of *CYP27B1*, which encodes cytochrome P450 family 27, subfamily B member 1 (Shimada et al., 2004a). This enzyme converts 25-hydroxyvitamin D (25(OH)D) to 1,25$(OH)_2$D and is responsible for the production of 1,25$(OH)_2$D. FGF23 also enhances the expression of *CYP24A1* coding cytochrome P450 family 24, subfamily A member 1 (Shimada et al., 2004a). This enzyme converts 1,25$(OH)_2$D to 1,24,25- trihydroxyvitamin D and also 25(OH)D to 24,25-dihydroxyvitamin D. From these effects on vitamin D-metabolizing enzymes, FGF23 works to reduce the serum level of 1,25$(OH)_2$D. Because 1,25$(OH)_2$D is a hormone enhancing intestinal phosphate absorption, FGF23 reduces serum phosphate by suppressing intestinal phosphate absorption via reduction of serum 1,25$(OH)_2$D and also by inhibiting proximal tubular phosphate reabsorption (Fig. 63.1). In contrast, *Fgf23*-knockout mouse shows hyperphosphatemia with enhanced proximal tubular phosphate reabsorption and high 1,25$(OH)_2$D level (Shimada et al., 2004b; Sitara et al., 2004). These results indicate that FGF23 is a physiological humoral factor regulating phosphate and vitamin D metabolism and inspired the concept that bone works as an endocrine organ (Fukumoto and Martin, 2009).

Regulation of fibroblast growth factor 23 level

The regulatory mechanisms of FGF23 level are not fully elucidated. FGF23 levels can be regulated by changes in both *FGF23* expression and posttranslational processing of FGF23 protein as discussed later. A high-phosphate diet increases FGF23 levels in both rodents and humans (Ferrari et al., 2005; Perwad et al., 2005). However, it is not entirely clear how a high-phosphate diet causes high FGF23 levels. 1,25$(OH)_2$D and PTH were shown to enhance FGF23 production

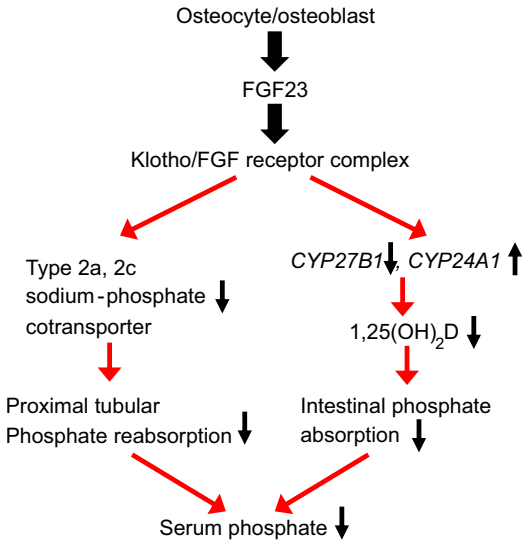

FIGURE 63.1 Actions of fibroblast growth factor 23 in kidney. Fibroblast growth factor 23 (FGF23) reduces serum phosphate by suppressing intestinal phosphate absorption via reduction of serum 1,25-dihydroxyvitamin D (1,25$(OH)_2$D and also by inhibiting proximal tubular phosphate reabsorption. *CYP24A1*, cytochrome P450 family 24, subfamily A member 1; *CYP27B1*, cytochrome P450 family 27, subfamily B member 1.

(Fan et al., 2016; Saito et al., 2005). Conversely, FGF23 reduces $1,25(OH)_2D$ level as previously mentioned. Furthermore, FGF23 was shown to inhibit PTH production and secretion (Ben-Dov et al., 2007). There seem to be negative feedback systems among PTH, $1,25(OH)_2D$, and FGF23.

PTH regulates serum calcium, and an increase in calcium activates the calcium-sensing receptor (CaSR) in parathyroid cells and suppresses PTH secretion (Brown et al., 1993). Therefore, there is a negative feedback between serum calcium and PTH via the CaSR. By an analogy to the relationship between calcium and PTH, it is suggested that serum phosphate affects FGF23 level. However, it is not known how serum phosphate is sensed in our body and whether serum phosphate can directly modulate FGF23 level.

A receptor for fibroblast growth factor 23

FGF23 belongs to the FGF family. FGF family members have an FGF homology region with a β-trefoil structure. FGF23 has an FGF homology region in the N-terminal portion of the processing site between ^{179}Arg and ^{180}Ser. FGF23 family members are divided into several subfamilies (Itoh and Ornitz, 2004). FGF23 belongs to the FGF19 subfamily together with FGF19 and FGF21. The prototypical FGF family members, such as FGF1 (acidic FGF) and FGF2 (basic FGF), work as autocrine/paracrine factors. These FGF family members have high affinity for heparin or heparan sulfate proteoglycan. Heparin or heparan sulfate proteoglycan enhances the affinity of FGF ligands to FGF receptors. In addition, because of this high affinity for heparin or heparan sulfate proteoglycan, these FGF family members are trapped in the extracellular matrix around cells producing these growth factors. This explains why some FGF family members work as local factors. In contrast, FGF23 is produced by bone and works in kidney and parathyroid glands. This means that FGF23 is a systemic factor. Actually, FGF19 subfamily members were shown to have a low affinity for heparin, explaining how these members work as systemic factors (Goetz et al., 2007). There are four FGF receptor genes, and alternative splicing from these genes produces several FGF receptor subtypes. The expression of most of these FGF receptors is not tissue specific. In vitro experiments showed that dissociation constants between FGF23 and these FGF receptors are much higher than the circulatory FGF23 level (Yu et al., 2005). These results indicate that FGF receptors alone cannot explain tissue-specific effects of FGF23.

Klotho was identified as a binding protein for FGF23 in kidney (Urakawa et al., 2006). *Klotho* was originally cloned as a gene whose expression is severely reduced in the genetically engineered *Klotho* mouse (Kuro-o et al., 1997). This mouse shows several phenotypes resembling aging, such as skin atrophy, infertility, emphysema, and reduced bone mass (Kuro-o et al., 1997). This mouse also shows high phosphate and $1,25(OH)_2D$ levels, like the *Fgf23*-knockout mouse, suggesting the involvement of Klotho in FGF23 signaling (Yoshida et al., 2002).

In vitro experiments showed that the Klotho−FGF receptor complex works as a specific receptor for FGF23 (Urakawa et al., 2006; Kurosu et al., 2006). Klotho is expressed in few tissues, such as kidneys and parathyroid glands. This tissue-specific expression of Klotho is considered to explain the target organs of FGF23. Klotho was shown to be expressed mainly in the renal distal convoluted tubules (Kuro-o et al., 1997). However, a 2012 study indicated that Klotho is also expressed in the proximal tubules (Andrukhova et al., 2012). It is postulated that a protein similar to Klotho, called β-Klotho, is necessary for the actions of FGF19 and FGF21 (Moore, 2007).

In contrast, there are several reports of Klotho-independent, FGF receptor−dependent actions of FGF23, such as suppression of PTH secretion and cardiac hypertrophy (Faul et al., 2011; Olauson et al., 2013). However, it has not been shown how FGF23 activates FGF receptors in a Klotho-independent way.

Hypophosphatemic diseases caused by excessive actions of fibroblast growth factor 23

After the cloning of *FGF23*, several kinds of hypophosphatemic diseases have been shown to be caused by excessive actions of FGF23 (Table 63.1). Establishment of assays for FGF23 helped to identify these hypophosphatemic diseases (Jonsson et al., 2003; Yamazaki et al., 2002). Circulatory FGF23 was shown to be high in hypophosphatemic patients caused by excessive actions of FGF23. In contrast, FGF23 is rather low in hypophosphatemic from other causes such as vitamin D deficiency and Fanconi syndrome (Endo et al., 2008). These results indicate that FGF23 level is regulated by serum phosphate or other associated metabolic changes, while it is not known how phosphate modulates FGF23 level as mentioned earlier. Chronic hypophosphatemia causes rickets and osteomalacia characterized by impaired mineralization of bone matrix. Rickets develops before the closure of growth plates. Growth retardation and bone deformities are major clinical problems in patients with rickets. In contrast, muscle weakness and bone pain are important symptoms of adult patients with hypophosphatemic osteomalacia.

TABLE 63.1 Diseases caused by aberrant actions of FGF23

Hypophosphatemic disease caused by excessive actions of FGF23	Responsible gene
Autosomal dominant hypophosphatemic rickets: ADHR	*FGF23*
X-linked hypophosphatemic rickets: XLH	*PHEX*
Autosomal recessive hypophosphatemic rickets 1: ARHR1	*DMP1*
Autosomal recessive hypophosphatemic rickets 2: ARHR2	*ENPP1*
Hypophosphatemia, dental anomalies and ectopic calcification	*FAM20C*
Jansen-type metaphyseal chondrodysplasia	*PTH1R*
McCune-Albright syndrome/Fibrous dysplasia of bone	*GNAS1*
Hypophosphatemia, skin and bone lesions	*HRAS, KRAS, NRAS*
Hypophosphatemic rickets and hyperparathyroidism	Translocation with a breakpoint adjacent to *Klotho*
Tumor-induced osteomalacia: TIO Hypophosphatemia by iron polymaltose, saccharated ferric oxide or ferric carboxymaltose Biliary atresia	
Hyperphosphatemic disease caused by impaired actions of FGF23	
Hyperphosphatemic familial tumoral calcinosis	*GALNT3, FGF23, Klotho*

DMP, dentin matrix protein 1; *ENPP1,* ectonucleotide pyrophosphatase/phosphodiesterase 1; *FAM20C,* family with sequence similarity 20, member C; *FGF23,* fibroblast growth factor 23; *GALNT3,* polypeptide N-acetylgalactosaminyltransferase 3; *GNAS1,* guanine nucleotide-binding protein, α stimulating;,*PHEX,* phosphate-regulating gene with homologies to endopeptidases on the X chromosome; *PTH1R,* parathyroid hormone 1 receptor.

Autosomal dominant hypophosphatemic rickets

Heterozygous mutations in *FGF23* cause ADHR. Mutations in patients with ADHR replace ^{176}Arg or ^{179}Arg with other amino acids, destroying the recognition site of ^{176}Arg−X−X−^{179}Arg by the processing enzyme (ADHR Consortium, 2000). This makes the mutant FGF23 proteins resistant to the processing. However, this resistance to the processing alone cannot explain the excessive actions of FGF23 in patients with ADHR. It is known that clinical presentation, including biochemical abnormalities, can wax and wane with time in patients with ADHR (Imel et al., 2007). This indicates that some patients can maintain serum phosphate level with mutations in *FGF23*. Even if the mutant FGF23 protein is resistant to the processing, these patients may be able to maintain FGF23 and phosphate levels by regulating the expression of *FGF23*.

Iron deficiency was shown to affect FGF23 level in patients with ADHR (Imel et al., 2011). Iron deficiency enhances *FGF23* expression and also processing of FGF23 protein, resulting in normal FGF23 and phosphate levels in healthy controls. In contrast, it is postulated that enhanced *FGF23* expression results in high FGF23 and hypophosphatemia in subjects with ADHR because the mutant FGF23 protein is resistant to the processing. However, it is not completely clear how iron deficiency affects FGF23 expression and processing. It is also possible that factors other than iron deficiency can modulate FGF23 level in patients with ADHR.

X-linked hypophosphatemic rickets

FGF23 is high in patients with XLH, suggesting that FGF23 is the humoral factor inducing hypophosphatemia in patients with XLH (Jonsson et al., 2003; Yamazaki et al., 2002). *Fgf23* was also shown to be overexpressed in bones of the *Hyp* mouse (Liu et al., 2003). *Phex* deletion in bone indicated that deficient Phex function in osteocytes/osteoblasts alone can explain *Hyp* phenotypes (Yuan et al., 2008). There are more than 300 kinds of *PHEX* mutations reported and assembled in a database (http://grch37.ensembl.org/Homo_sapiens/Gene/Variation_Gene/Table?db=core;g=ENSG00000102174;r=X:22050559-22269427). These mutations are considered to be inactivating ones. *PHEX* mutations were reported to change the expression of several proteins, including 7B2, resulting in high FGF23 (Yuan et al., 2013). However, it was not shown how deficient actions of PHEX cause decreased expression of 7B2. Furthermore, it is possible that there are other mechanisms for how inactivating mutations of *PHEX* cause elevated FGF23 levels.

Autosomal recessive hypophosphatemic rickets

Autosomal recessive hypophosphatemic rickets (ARHR) 1 and ARHR2 are caused by inactivating mutations in dentin matrix protein 1 (*DMP1*) and ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*), respectively (Feng et al., 2006; Levy-Litan et al., 2010; Lorenz-Depiereux et al., 2006, 2010). Enhanced expression of FGF23 in bone is considered to cause these diseases, while, again, the mechanisms of this overexpression of FGF23 are not completely understood. In vitro experiments showed that externally added DMP1 inhibits the production of FGF23 (Samadfam et al., 2009). However, the detailed mechanism of this inhibition of FGF23 production by DMP1 protein is not known. ENPP1 is an enzyme that hydrolyzes pyrophosphate. Pyrophosphate is a potent inhibitor of calcification, and inactivating mutations in *ENPP1* were shown to cause generalized arterial calcification of infancy (GACI) (Lorenz-Depiereux et al., 2010). GACI is usually fatal soon after birth. However, some surviving patients with mutations in *ENPP1* were shown to have hypophosphatemic rickets/osteomalacia with high FGF23.

Other hypophosphatemic diseases with known genetic causes

Mutations in family with sequence similarity 20, member C (*FAM20C*), cause hypophosphatemic disease with high FGF23, dental anomalies, and ectopic calcification (Rafaelsen et al., 2013). FAM20C is a Golgi serine/threonine protein kinase that phosphorylates secretory pathway proteins. Inactivating mutations in *FAM20C* have been shown to cause Raine syndrome, a neonatal osteosclerotic dysplasia (Simpson et al., 2007). This disease is usually fatal early in life. However, again, some surviving patients were shown to have hypophosphatemic rickets/osteomalacia with high FGF23. FAM20C can phosphorylate small integrin-binding ligand N-linked glycoproteins (SIBLINGs), including osteopontin and DMP1. It is likely that phosphorylation of these SIBLINGs affects mineralization of bone in patients with Raine syndrome. In addition, it is possible that deficient phosphorylation of DMP1 causes high FGF23, because inactivating mutations in *DMP1* result in ARHR1 (Kinoshita et al., 2014).

Activating mutations in PTH1 receptor (*PTH1R*) and guanine nucleotide-binding protein, α stimulating (*GNAS1*), cause hypophosphatemic disease with high FGF23, suggesting that FGF23 production is stimulated by the cyclic AMP pathway (Brown et al., 2009; Riminucci et al., 2003). In addition, there are several reports indicating that signals from FGF receptor regulate FGF23 production (Wohrle et al., 2011). Some activating mutations in FGF receptor 1 (*FGFR1*) were shown to cause hypophosphatemia with high FGF23 in patients with osteoglophonic dysplasia (White et al., 2005). FGF23 is high in hypophosphatemic patients with somatic mutations in *HRAS, KRAS* or *NRAS* (Lim et al., 2014), and there is a report of a hypophosphatemic patient with a de novo translocation with a breakpoint adjacent to the *Klotho* gene (Brownstein et al., 2008).

Acquired fibroblast growth factor 23-related hypophosphatemic disease

In addition to TIO, FGF23 is high in hypophosphatemic patients with iron-deficiency anemia treated with intravenous iron preparations (Schouten et al., 2009; Shimizu et al., 2009). Some patients treated with intravenous iron for a long time can present with severe hypophosphatemic osteomalacia. As discussed earlier, iron deficiency enhances both *FGF23* expression and processing of FGF23 protein. Therefore, it is possible that administration of intravenous iron preparations prevents the processing of FGF23 protein. However, it is not known how intravenous iron preparations affect the processing of FGF23 protein. High FGF23 level and hypophosphatemia are not reported with oral iron administration.

Hypophosphatemic rickets with high FGF23 was reported in some patients with biliary atresia (Wasserman et al., 2016). FGF23 was expressed in the liver of a patient. It is not known what triggers the expression of FGF23 in liver in this disease.

Treatment of fibroblast growth factor 23-related hypophosphatemic diseases

TIO can be cured by complete removal of the responsible tumors. Hypophosphatemia caused by intravenous iron preparations improves by stopping the drug. Other hypophosphatemic patients, including those with TIO, whose responsible tumors cannot be removed or found are usually treated with neutral phosphate and active vitamin D. However, these medications have limitations in both their effects and adverse events (Carpenter et al., 2011). Several methods to inhibit excessive FGF23 actions have been reported (Fukumoto, 2016). Of these, humanized anti-FGF23 blocking antibody has been tested in several clinical trials for patients with XLH and TIO. This antibody increases serum phosphate and

$1,25(OH)_2D$, and improves radiographic findings of rickets (Carpenter et al., 2014; Imel et al., 2015; Carpenter et al., 2018). The antibody was approved for patients with XLH in several countries in 2018.

Hyperphosphatemic diseases caused by impaired actions of fibroblast growth factor 23 (Table 63.1)

In contrast to hypophosphatemic diseases caused by excessive actions of FGF23, deficient actions of FGF23 result in hyperphosphatemic familial tumoral calcinosis. This disease is characterized by hyperphosphatemia with enhanced proximal tubular phosphate reabsorption and high $1,25(OH)_2D$ level (Lyles et al., 1988). These biochemical changes are also observed in *Fgf23*-knockout and *Klotho* mice. Patients with this disease have ectopic calcification and calcified mass, especially around large joints. These tumors can cause pain and white discharge from the skin.

There are three genes known to be responsible for hyperphosphatemic familial tumoral calcinosis. These are *GALNT3*, *FGF23*, and *Klotho* (Benet-Pages et al., 2005; Ichikawa et al., 2007; Topaz et al., 2004). *GALNT3* encodes a protein called UDP-*N*-acetyl-α-D-galactosamine:polypeptide *N*-acetylgalactosaminyltransferase 3 (GalNAc-T3). This enzyme attaches *N*-acetylgalactosamine to a Ser or Thr residue as an initial sugar of mucin-type O-linked glycosylation. There are 20 members of the GalNAc-Ts (Hurtado-Guerrero, 2016). While these 20 enzymes seem to have redundant substrate specificity, homozygous inactivating mutations in *GALNT3* cause hyperphosphatemic familial tumoral calcinosis, indicating that other GalNAc-Ts cannot compensate for the impaired actions of GalNAc-T3 in phosphate metabolism. FGF23 protein has three O-linked glycans at ^{171}Thr, ^{178}Thr, and ^{200}Thr. GalNAc-T3 was shown to initiate the O-linked glycosylation at ^{178}Thr, just before the processing site between ^{179}Arg and ^{180}Ser (Frishberg et al., 2007; Kato et al., 2006). This O-linked glycosylation at ^{178}Thr prevents the processing of FGF23 protein.

There are two kinds of assays for FGF23. The intact assay uses two kinds of antibodies that recognize the N-terminal and C-terminal portions of the processing site of FGF23. This assay measures only full-length biologically active FGF23 (Yamazaki et al., 2002). On the other hand, the C-terminal assay adopts two kinds of antibodies recognizing the C-terminal portion of FGF23. This C-terminal assay detects both full-length FGF23 and the processed C-terminal fragment of FGF23 (Jonsson et al., 2003). FGF23 levels in patients with mutations in *GALNT3* are very high by the C-terminal assay, but low to low normal by the intact assay (Frishberg et al., 2007). These results indicate that quite a lot of processed C-terminal fragment of FGF23 is present in the circulation of these patients, while there is only a little full-length FGF23. These clinical data also support the notion that deficient O-linked glycosylation at ^{178}Thr makes the FGF23 protein susceptible to the processing.

Patients with hyperphosphatemic familial tumoral calcinosis caused by mutations in *FGF23* also show similar FGF23 levels, high by C-terminal assay and rather low by full-length assay (Araya et al., 2005). The mutant FGF23 protein was shown to be trapped in the Golgi apparatus in in vitro experiments, while the detailed mechanism of the secretion of the processed C-terminal fragment is not known (Benet-Pages et al., 2005). On the other hand, it was also reported that the mutant protein can bypass the endoplasmic reticulum/Golgi quality control system and be secreted (Shawar et al., 2016). Further studies are necessary to clarify the mechanism of the impaired actions of FGF23 in patients with mutations in the *FGF23* gene.

There is a report of a patient with hyperphosphatemic tumoral calcinosis caused by a mutation in the *Klotho* gene (Ichikawa et al., 2007). FGF23 levels were high by both full-length and C-terminal assays in this patient. Because Klotho works as a coreceptor for FGF23, this hyperphosphatemic disease caused by a mutation in the *Klotho* gene is considered to be caused by resistance to FGF23. There is also a report of a patient with acquired hyperphosphatemic tumoral calcinosis caused by FGF23 autoantibodies (Roberts et al., 2018).

Treatment of hyperphosphatemic familial tumoral calcinosis

Surgery may be necessary for painful calcified masses. Dietary phosphate restriction and phosphate binders are used for hyperphosphatemia. There are a couple of reports suggesting the utility of acetazolamide for this condition (Lammoglia and Mericq, 2009; Yamaguchi et al., 1995). Theoretically, recombinant FGF23 can ameliorate hyperphosphatemia in patients with mutations in either *GALNT3* or *FGF23*.

Fibroblast growth factor 23 and chronic kidney disease–mineral and bone disorder

FGF23 is high in patients with chronic kidney disease (CKD) and can be extremely high in subjects with end-stage renal disease (Weber et al., 2003). FGF23 is also involved in the development of CKD–mineral and bone disorder. FGF23 starts

to increase in patients with CKD stage 2 during the progression of CKD before the increase in PTH or phosphate (Isakova et al., 2011). There is no clear abnormality in mineral metabolism when FGF23 begins to increase. It is not known what triggers this increase in FGF23 in patients with early CKD. However, this increase in FGF23 is considered to enhance urinary phosphate excretion and work to prevent the development of hyperphosphatemia. In vivo experiments showed that the inhibition of FGF23 activity by anti-FGF23 antibodies reduces urinary phosphate excretion and increases serum phosphate level in a rat model of early CKD (Hasegawa et al., 2010). On the other hand, FGF23 decreases $1,25(OH)_2D$ level and this reduced $1,25(OH)_2D$ may increase PTH synthesis. While FGF23 was shown to inhibit the synthesis and secretion of PTH (Ben-Dov et al., 2007), it is also reported that FGF23 is an inducer of parathyroid cell proliferation and PTH secretion (Kawakami et al., 2017). With the progression of CKD, the expression of Klotho in kidney and parathyroid glands decreases and FGF23 cannot work on these tissues in patients with end-stage renal disease (Koh et al., 2001; Komaba et al., 2010).

High FGF23 levels have been shown to be associated with various adverse events, especially in subjects with CKD. High FGF23 levels were reported to be associated with higher mortality, cardiovascular events, left-ventricular hypertrophy, arterial calcification, impaired vasodilation, decreased bone mineral density, fractures, progression of CKD, and so on (Fukumoto and Shimizu, 2011). Some of these associations were also reported in community-dwelling subjects. However, the reasons for these associations are not entirely clear. It was reported that FGF23 can induce left-ventricular hypertrophy by acting on cardiomyocytes (Faul et al., 2011). FGF23 was also shown to impair neutrophil recruitment and chemotaxis (Rossaint et al., 2016; Yang et al., 2017), and promote inflammation by acting on hepatocytes (Singh et al., 2016). Because Klotho is not shown to be expressed in these tissues, it is unknown at this writing how FGF23 induces these effects. In addition, it is not clear whether these direct actions of FGF23 in various tissues underlie the association between high FGF23 levels and all the reported adverse events. Further studies will clarify whether FGF23 has roles other than just working as a phosphotropic hormone and how FGF23 works in tissues without Klotho expression.

Chapter outline

Background

Tumor-induced osteomalacia (TIO), also known as oncogenic osteomalacia, is a rare paraneoplastic syndrome of abnormal phosphate and vitamin D metabolism caused by small tumors (phosphaturic mesenchymal tumors, PMTs) that secrete the phosphate- and vitamin D-regulating hormone fibroblast growth factor 23 (FGF23) (Jan de Beur, 2005; Drezner, 2001; Folpe et al., 2004; Jiang et al., 2012; Chong et al., 2011a; Minisola et al., 2017a; Florenzano et al., 2017). Biochemical hallmarks of the disorder are elevated or inappropriately normal blood FGF23 levels that cause renal phosphate wasting and hypophosphatemia, and impaired generation of 1,25-dihydroxyvitamin D. Low or inappropriately normal levels of 1,25-dihydroxyvitamin D can lead to secondary hyperparathyroidism, worsening renal phosphate wasting. Clinically, patients complain of bone pain and muscle weakness, and often present with pathologic fractures due to hypophosphatemic osteomalacia. When the disease occurs in children prior to growth plate fusion, it causes rickets. Rarely, TIO can be caused by multiple, synchronous PMTs (Peterson et al., 2010; Higley et al., 2015; Arai et al., 2017).

While "phosphatonins" other than FGF23 have been proposed to cause TIO (Schiavi and Moe, 2002; Bresler et al., 2004; Carpenter et al., 2005), the direct evidence to support their pathogenesis in TIO is weak, and there are no well-documented cases of TIO in which, when examined, FGF23 blood levels were not abnormally elevated. The time from onset of symptoms to diagnosis is often long, in large part due to lack of familiarity with the disease, combined with the fact that blood phosphorus levels are not routinely measured. As a result of delayed diagnosis, patients frequently present with significant morbidity, including multiple fractures, height loss, and a generalized debilitated status. If the condition develops before growth plate closure, linear growth is impaired, children fall below their previously established growth curve, and rickets is present.

There are patients with a TIO-like syndrome in whom a tumor is never found. Whether this is due to the inability to find the tumor or represents a separate syndrome is not known. Generally, patients with an acquired form of FGF23-mediated hypophosphatemia in which all causes of nontumorous FGF23-mediated hypophosphatemia have been excluded (see later) are considered to have TIO due to a tumor that has not been identified. It may take years to identify the tumor, and patients such as this should continue to undergo periodic testing to locate a tumor.

A TIO-like syndrome can also be seen in association with other diseases such as prostate cancer, oat cell cancer, hematologic malignancies, neurofibromatosis, cutaneous skeletal hypophosphatemia syndrome (CSHS), and polyostotic

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00064-6

fibrous dysplasia of bone (FD) (Nakahama et al., 1995; Konishi et al., 1991; Taylor et al., 1984; Carey et al., 1986; Reese and Rosen, 1997; Rao et al., 1987; Dent and Gertner, 1976; Saville et al., 1955; Ivker et al., 1997; Collins et al., 2001; Riminucci et al., 2003). In these cases, the primary disease is usually obvious, and the goal is treatment of the underlying disease. However, when the underlying disease is not amenable to cure or adequate treatment, as is the case in CSHS and FD, for example, medical treatment of the hypophosphatemic syndrome is the same as in cases of TIO caused by PMTs (see later).

Robert McCance is often credited with reporting the first case of TIO. In 1947, he reported a patient with manifestations of what was clearly TIO (McCance, 1947). The patient had pain, weakness, gait abnormalities, and low phosphorus levels. She was treated with high doses of vitamin D, but her symptoms did not completely resolve until a tumor in her femur was resected. McCance attributed her cure to the high-dose vitamin D therapy, not the tumor resection, and believed her disease was due to vitamin D resistance. At the time, vitamin D resistance was believed to be the mechanism of the disease that would eventually come to be understood as the FGF23-mediated phosphate wasting disorder X-linked hypophosphatemia (XLH) (Albright et al., 1937; Winters et al., 1957).

The first person to clearly recognize that the disease was the result of a "rachitogenic substance" was Andrea Prader. In 1959 he described an 11½-year-old girl who developed severe hypophosphatemic rickets over the course of a year (Prader et al., 1959). Her evaluation showed decreased tubular phosphate reabsorption but otherwise normal studies of kidney function. A tumor, classified as a giant cell granuloma, was identified in a rib and resected with resultant healing of her rickets. Prader made the association between resection of the tumor and cure of her rickets and posited that the granuloma was secreting a rachitogenic substance.

FGF23 was eventually identified as the rachitogenic substance causing TIO in 2003 (Jonsson et al., 2003). Approximately 500 cases of TIO have been reported in the English literature since Prader's original case (reviewed in Folpe et al., 2004; Chong et al., 2011a; Minisola et al., 2017a). The fact that over 300 of these cases have been reported since 2009 indicates a growing recognition of this disease. This recognition has paralleled the identification of FGF23 as the phosphaturic agent (White et al., 2001; ADHR, 2000). The discovery of FGF23 has not only paved the way toward a better understanding of the pathophysiology and treatment of TIO, but also provided a window into areas of mineral metabolism physiology that for years had been unexplained.

Phosphaturic mesenchymal tumors

There has been steady progress in elucidating the histopathology, cell biology, and molecular genetics of PMTs since Andreas Prader's first recognition in 1957 that a syndrome of TIO was caused by a "giant cell tumor." Weidner was the first to systematically characterize tumors that cause a TIO syndrome as distinct histopathological entities (Weidner and Santa Cruz, 1987). In 1991, Weidner et al. reviewed the literature of approximately 60 cases of TIO that had been described at that time (Weidner, 1991). They were the first to propose a classification system based on the histological findings and designated the tumors as "phosphaturic mesenchymal tumors." They subdivided PMTs into four categories: mixed connective tissue variant (PMTMCT), osteoblastoma-like variant, nonossifying fibroma-like variant, and ossifying fibroma-like variant. The first group, PMTMCT, comprised neoplasias containing primitive stromal cells, prominent vessels, and osteoclast-like giant cells. Osseous metaplasia and poorly formed cartilage-like areas with dystrophic calcification were also present. They noted that these tumors typically occurred in soft tissue and were almost invariably benign. The remaining three groups, also usually benign, tended to occur in bone.

In 2004, Folpe et al. reviewed the clinicopathological features of 32 new cases of TIO, re-reviewed all of the previously published cases, and made the assertion that virtually all of the cases fell into the category of PMTMCT (Folpe et al., 2004). The prototypical PMTMCT contains neoplastic cells that are spindled to stellate in shape, normochromatic, with small nuclei and indistinct nucleoli. The nuclear grade is low, and mitotic activity is usually absent or very low. The cells are typically embedded within a myxoid or myxochondroid "grungy matrix" that can resemble chondroid or osteoid. Osteoclast-like giant cells are often present and numerous; mature fat and even lamellar bone may also be seen. A prominent feature is an elaborate microvasculature with a mixture of vessel size and vascular pattern (Folpe et al., 2004). The most common diagnosis for these tumors prior to the moniker of PMTs was hemangiopericytoma, but it has also included hemangiomas, sarcomas, ossifying fibromas, granulomas, giant cell tumors, and osteoblastomas (Drezner, 2001; Folpe et al., 2004; Weidner, 1991). Typical features of PMTs are shown in Fig. 64.1.

Antigen expression was first evaluated in two immunohistochemical studies by Weidner et al. In their first study, tumors were negative for factor VIII (FVIII)-related antigen (endothelial marker), S-100 (epidermal marker), and cytokeratin (epithelial marker) (Weidner et al., 1985). The second study revealed only vimentin immunoreactivity (mesenchymal marker), in some cases within the tumor cells. All other antibodies, including desmin (mesenchymal

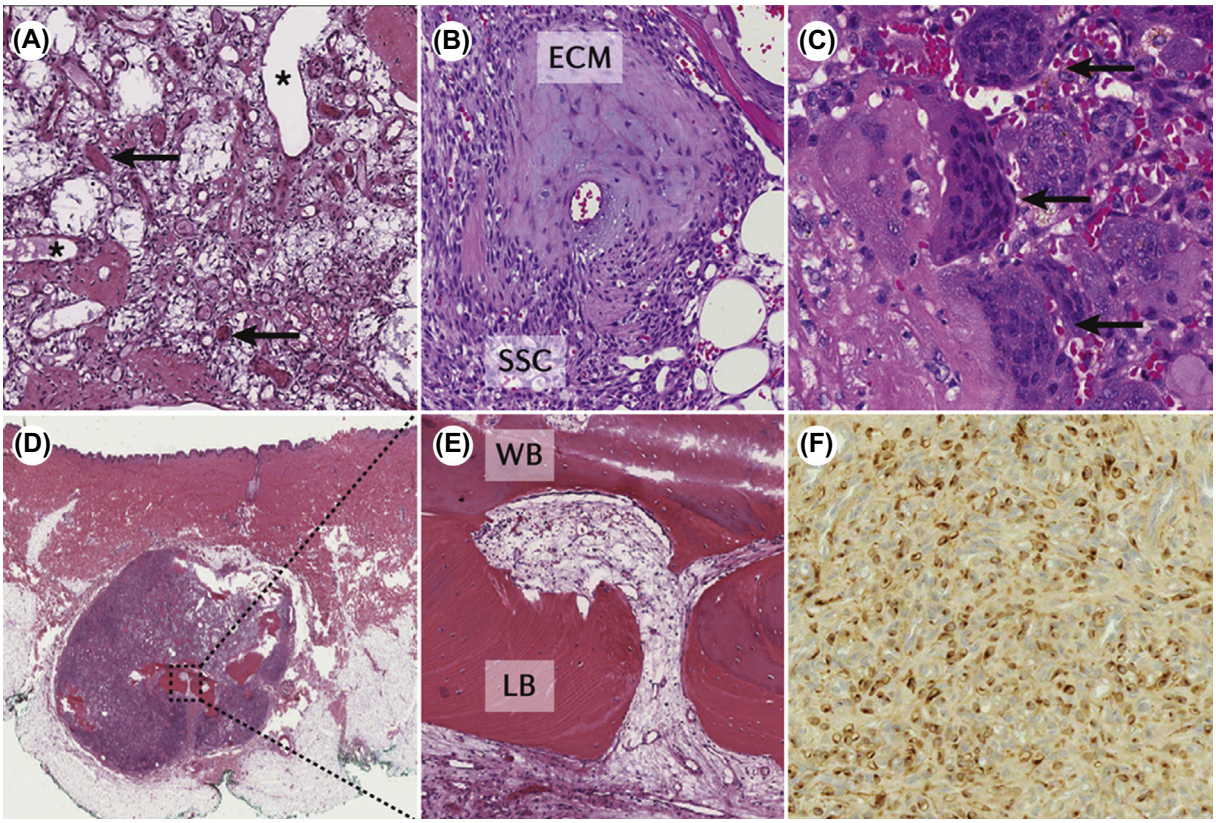

FIGURE 64.1 Histological features of phosphaturic mesenchymal tumors. (A) Low-power view demonstrates the marked vascularity of phosphaturic mesenchymal tumors (PMTs) (*arrows*, collections of fibroblast growth factor 23 (FGF23)-secreting tumor cells; *asterisks*, blood vessels). (B) The small spindle-shaped cells that predominate in PMTs often produce an abundant, "grungy" chondroid matrix. *ECM*, extracellular matrix; *SSCs*, spindle-shaped cells. (C) Multinucleated giant cells (*arrows*) are commonly seen in PMTs, and are often associated with the collagen-rich matrix, as in this case. (D and E) Low- (D) and high-power (E) views, respectively, of a small subcutaneous PMT (*dotted line* in D) that contained, as is sometimes the case in PMTs, both woven (*WB* in E) and lamellar bone (*LB* in E). (F) Immunohistochemical staining with a fibroblast growth factor 23 (FGF23)-specific polyclonal antibody demonstrates that it is the small spindle cells that predominate in the tumor that are the source of the FGF23. *Adapted from Minisola, S., Peacock, M., Fukumoto, S., Cipriani, C., Pepe, J., Tella, SH., et al., 2017. Tumour-induced osteomalacia. Nat. Rev. Dis. Primers. 3, 17044. Epub 2017/07/14.*

marker), leu-M1 and leukocyte common antigen (hematologic markers), and chromogranin and neuron-specific enolase (neuroendocrine tumor markers), were negative (Weidner et al., 1985). In their most recent series, Folpe et al. (Folpe et al., 2004) performed a series of immunohistochemical staining including pan-cytokeratin, desmin, S-100, smooth muscle actin, CD34, and FGF23, and with the exception of smooth muscle actin, which they found reactive in three cases, and FGF23, which was positive in about 70% of all the cases, all markers were negative. In terms of FGF23 staining, it was seen in the proliferating cells within the tumor. An example can be seen in Fig. 64.1.

In terms of ultrastructural features, Stone et al. described features consistent with a neuroendocrine tumor in a PMTMCT from a 33-year-old woman (Stone et al., 1992). Neurosecretory granules were also found in the case described by Wilkins et al. (Wilkins et al., 1995). However, immunostaining for S-100, neuron-specific enolase, chromogranin, and synaptophysin, typical markers of neurosecretory tumors, was negative, as was staining for actin, cytokeratin, and epithelial membrane antigen and FVIII. The only positive finding was vimentin, confirming what had already been described by Weidner at al. An additional case communicated by Shelekhova et al. also showed similar neurosecretory granules (Shelekhova et al., 2006). Somatostatin receptor expression is also a common feature of PMTs and accounts for the utility of imaging studies that utilize somatostatin receptor analogs, e.g., OctreoScan and DOTA-based scans (see later) (Seufert et al., 2001; Houang et al., 2013). However, the somatostatin receptors do not appear functional as far as regulating FGF23 expression, given that somatostatin analogs are not effective in treating TIO (Ovejero et al., 2017).

A potentially important recent finding is the identification of epithelial components in PMTs that arise from the maxilla and mandible (Wu et al., 2019). These tumors appear to have a much more aggressive clinical course and are perhaps more prone to metastasizing. Tumors that arise from the maxilla or mandible should be approached with greater care, assessing

for the presence of epithelial components and, if present, giving consideration to a more aggressive surgical approach, making sure to create wide margins. While the vast majority of tumors are benign, malignant transformation and metastases can occur (Harvey et al., 1992; Ogose et al., 2001; Rico et al., 1986; Uramoto et al., 2009; Wyman et al., 1977), a feature hard to predict from the benign histological appearance of even metastatic tumors (Bergwitz et al., 2011). While metastases are rare, benign tumors are not encapsulated, and infiltration into surrounding connective tissue is often present. This has significant implications for surgical management and emphasizes the importance of wide surgical margins to avoid persistence or recurrence. This is an important point that needs to be emphasized to surgeons caring for patients with TIO.

The most important recent finding in understanding the genetic and molecular pathophysiology of PMTs is the identification of fibronectin−FGF receptor 1 (FN1−FGFR1) translocations, that could be present in up to 60% of PMTs (Lee et al., 2015; Lee et al., 2016). Subsequent investigations of a larger group of tumors suggested that the percentage of tumors harboring FN1-FGFR1 translocations may be lower, and that other genetic abnormalities, such as fibronectin-FGF1 translocations, may be present (Lee et al., 2016). It is likely that additional genetic/molecular changes will be identified. There may be direct clinical implications for some of these genetic/molecular changes, as can be seen for FN1−FGFR1 translocations (see later).

To summarize, PMTMCTs are a group of tumors with a spectrum of histopathological findings that includes a background of spindle/stellate cells with low nuclear and mitotic activity. This is true even in cases of metastatic disease. Prominent vascularity is common and includes vessels of different sizes and patterns, consistent with the fact that they were historically most commonly classified as hemangiopericytomas. Osteoclast-like giant cells are frequently seen, and woven and/or lamellar bone can be present as well. Cytoplasmic FGF23 staining is a consistent feature. It is important to note that histopathological diagnosis of malignant disease is difficult to make, as even in clinically proven metastatic disease cellular features appear benign.

Clinical presentation and diagnosis

TIO typically presents with symptoms of chronic hypophosphatemia that include bone pain, muscle weakness, and fractures (Jan de Beur, 2005; Chong et al., 2011a). However, given the lack of specificity of the symptoms, diagnosis is often delayed, and patients are frequently misdiagnosed with several other more common rheumatologic, neurological, or psychiatric conditions, including osteoporosis, somatic syndrome, intervertebral disc herniation, and spondyloarthritis (Feng et al., 2017). Delay in diagnosis is not only due to nonspecific symptoms, but also the fact that blood phosphate levels are typically not checked as part of an initial panel of blood tests (El-Maouche et al., 2016). If left untreated, significant disability and deformity often develop, especially height loss due to vertebral compression fractures, which are common (Chong et al., 2011a). Patients can present at any age, including uncommonly in childhood (Chong et al., 2011a; Crossen et al., 2017; Jung et al., 2010), but are most often diagnosed between 40 and 45 years of age (Florenzano et al., 2017). What distinguishes the diagnosis of TIO in childhood from XLH, which is the most common form of genetic hypophosphatemia, is that in XLH the clinical presentation is early, usually appearing with weight-bearing ambulation. In TIO, the diagnosis is usually later, following a period of normal growth and development. And unlike autosomal dominant (ADHR) and autosomal recessive hypophosphatemic rickets (ARHR), rarer causes of familial hypophosphatemia that often present later in childhood, the signs and symptoms of hypophosphatemia in TIO are usually more profound and the FGF23 levels significantly higher than in ARHR or ADHR (Jan de Beur, 2005; Minisola et al., 2017a).

The characteristic biochemical findings of TIO include hypophosphatemia, renal phosphate wasting, low or inappropriately normal 1,25-dihydroxyvitamin D, and elevated or inappropriately normal FGF23 levels (Chong et al., 2011a; Florenzano et al., 2017; Gonzalez et al., 2017). The presence of renal phosphate wasting is confirmed by calculating either the tubular reabsorption of phosphate (TRP) or the ratio of the renal tubular maximum phosphate reabsorption rate to glomerular filtration rate (TmP/GFR). TmP/GFR is the most accurate reflection of renal phosphate reabsorption; however, TRP is simpler and more convenient (Minisola et al., 2017a). Both calculations require simultaneous urine and serum phosphate and creatinine measurements, but TmP/GFR requires fasting values at peak phosphate absorption, usually taken from a second morning void, while TRP can be calculated from random collections (Chong et al., 2011a). For accurate results, patients must have stopped phosphate supplementation and care should be taken to use consistent units when using either formula (Chong et al., 2011a). Online calculators and downloadable applications are available for the calculation of either of these values. Both TmP/GFR and blood phosphate levels vary with age, and care should be taken to use the appropriate age-specific normal ranges. Age-specific normal reference ranges for TmP/GFR are noted in Table 64.1. Under normal physiologic conditions, 85%−95% of filtered phosphate is reabsorbed by the proximal tubule. A TRP less than

TABLE 64.1 Normal ranges for ratio of renal tubular maximum phosphate reabsorption rate to glomerular filtration rate.

Age	Male, mg/dL (mmol/L)	Female, mg/dL (mmol/L)
Newborn	5.7–8.1 (1.27–2.59)	5.7–8.1 (1.27–2.59)
1 month–2 years	3.6–5.4 (1.15–1.73)	3.6–5.4 (1.15–1.73)
2–12 years	3.8–5.0 (1.22–1.60)	3.8–5.0 (1.22–1.60)
12–16 years	3.4–4.6 (1.09–1.47)	3.4–4.6 (1.09–1.47)
16–25 years	3.33–5.9 (1.07–1.89)	3.18–6.41 (1.02–2.05)
25–45 years	3.09–4.18 (0.99–1.34)	2.97–4.45 (0.95–1.42)
45–65 years	2.78–4.18 (0.89–1.34)	2.72–4.39 (0.87–1.40)
65–75 years	2.47–4.18 (0.79–1.34)	2.47–4.18 (0.79–1.34)

From Chong, W.H., Molinolo, A.A., Chen, C.C., Collins, M.T. 2011. Tumor-induced osteomalacia. Endocr. Relat. Cancer. 18(3), R53–R77.

85%–95% in the setting of hypophosphatemia or a TmP/GFR lower than the reference range is indicative of renal phosphate wasting.

Subsequent laboratory testing in patients with confirmed renal phosphate wasting should include serum calcium, 25-vitamin D, 1,25-dihydroxyvitamin D, parathyroid hormone (PTH), FGF23, and alkaline phosphate (see Fig. 64.2) (Minisola et al., 2017a). Vitamin D deficiency (25-vitamin D) must be corrected before making the diagnosis of TIO, as the frank or subtle secondary hyperparathyroidism associated with vitamin D deficiency can confound the determination of TRP or TmP/GFR. Patients with FGF23-mediated hypophosphatemia present with elevated (or inappropriately normal) FGF23 levels. It should be noted that an FGF23 value in the upper part of the normal range in the setting of hypophosphatemia is abnormal and consistent with TIO. 1,25-Dihydroxyvitamin D levels are low or inappropriately in the lower end of the normal range in TIO. Hypophosphatemia is considered to raise 1,25-dihydroxyvitamin D levels, so low levels of 1,25-dihydroxyvitamin D in the setting of hypophosphatemia are consistent with TIO. Alkaline phosphatase levels are generally elevated in TIO, and the degree of elevation reflects the degree of osteomalacia. In contrast, hypophosphatemia in the setting of low FGF23 and elevated 1,25-dihydroxyvitamin D levels would suggest an alternative etiology, such as an acquired or inherited Fanconi syndrome or, depending on the presentation, hereditary hypophosphatemic rickets with hypercalciuria. Calcium levels are typically normal in TIO. PTH levels can be normal or elevated. Patients with TIO commonly develop secondary hyperparathyroidism due to chronically low 1,25-vitamin D and the physiologic drive to maintain eucalcemia. Tertiary hyperparathyroidism can develop in longstanding disease, especially with prolonged phosphate supplementation (Jan de Beur, 2005; Chong et al., 2011a). C-terminal FGF-23 assays are commercially available, although at the time of this writing the more accurate intact FGF23 assay is available only for research purposes.

Familial causes of rickets, such as XLH, ADHR, and ARHR, can present with biochemical findings identical to TIO, and need to be considered in the differential diagnosis of hypophosphatemia (Chong et al., 2011a). As stated before, XLH usually presents in early childhood, especially when children begin to walk, at which time the legs begin to bow with weight bearing. However, XLH can have a broad phenotypic spectrum and diagnosis can be missed in childhood in patients with a subtler phenotype. Therefore, XLH should be considered even in adults. Clues to the diagnosis of XLH in adulthood that set it apart from TIO are short stature relative to predicted parental height, and a history of significant dental abnormalities, especially as a child, including enamel hypoplasia and dental abscesses. Certainly, a family history of hypophosphatemia and/or consanguinity suggests an inherited form of phosphate wasting and should suggest performing genetic testing. McCune–Albright syndrome, which consists of fibrous dysplasia, café-au-lait macules, and hyperfunctioning endocrinopathies, can also be associated with FGF23 hypersecretion from boney lesions, but the phosphate wasting in McCune–Albright syndrome occurs only in patients with extensive bone disease and the diagnosis is seldom confused with TIO (Boyce et al., 1993).

Tumor localization

After establishing the diagnosis of TIO, the next step in management is to determine the source of FGF23 (Fig. 64.3) (Minisola et al., 2017a). PMTs are typically small, slow-growing tumors that are notoriously difficult to locate

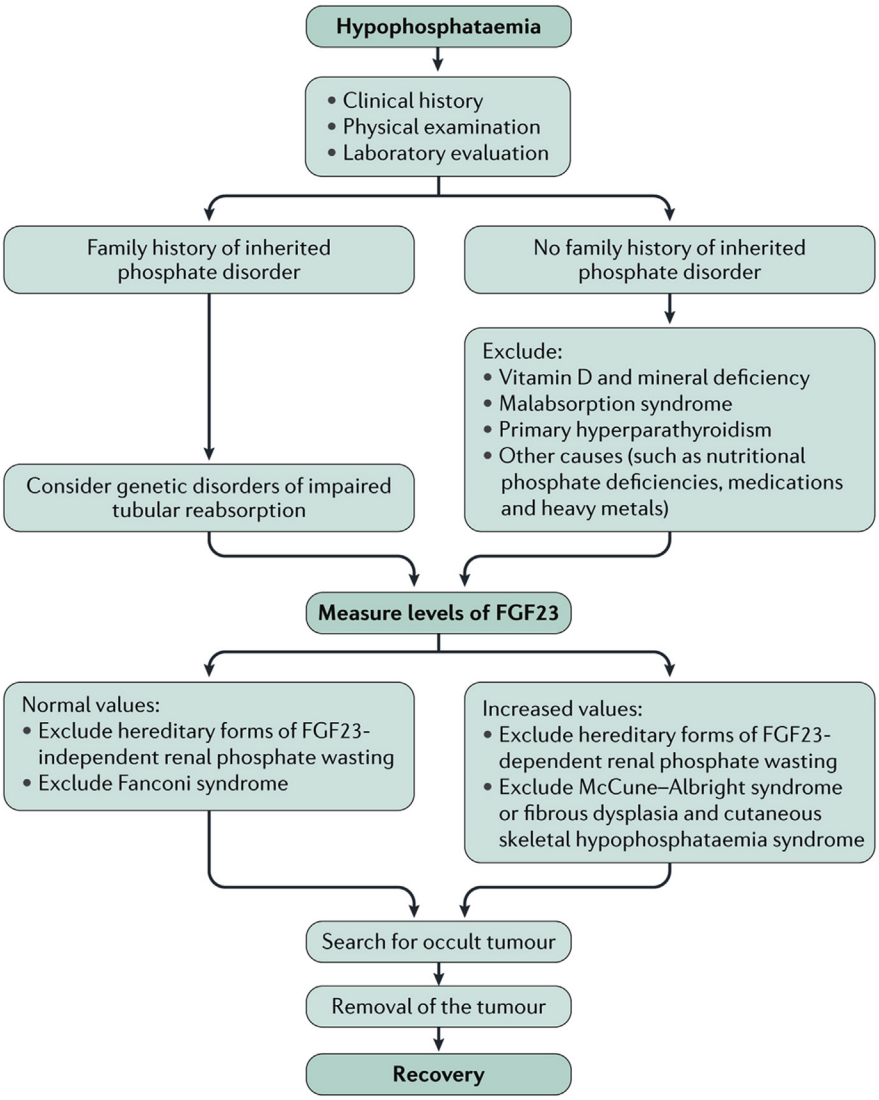

FIGURE 64.2 Diagnostic algorithm for tumor-induced osteomalacia. The clinical history should emphasize possible growth abnormalities and dental diseases (i.e., delayed dentition, previous dental abscesses). Physical examination is important for detecting limb abnormalities, which, in cases of inherited phosphate disorders, are more evident in the lower limbs. In adults, physical examination should attempt to detect small growths, including in the oral cavity, and assess any new lumps and bumps. Radiological investigations may be important, for example, for disclosing osteophytes or calcified entheses in patients with X-linked hypophosphatemic rickets or osteomalacia. *FGF23*, fibroblast growth factor 23. *Adapted from Minisola, S., Peacock, M., Fukumoto, S., Cipriani, C., Pepe, J., Tella, SH., et al., 2017. Tumour-induced osteomalacia. Nat. Rev. Dis. Primers. 3, 17044. Epub 2017/07/14.*

(El-Maouche et al., 2016). Surgical excision can result in cure, which is the gold standard treatment for TIO. A stepwise approach to localization is recommended and starts with a thorough medical history and physical examination. Occasionally tumors can be identified on physical examination. Asking the patient if there is a lump or bump that has arisen in the past several years, including in the oral cavity, and thoroughly examining the patient from head to toe can sometimes identify innocuous-appearing lesions that may be the offending tumor (Fig. 64.4) (Chong et al., 2011a) (Minisola et al., 2017a; Chong et al., 2013).

The three most effective functional imaging modalities at localizing PMTs, in order of accuracy, are DOTA-based positron emission tomography−computed tomography (PET/CT) studies, OctreoScan with single-photon emission CT (OctreoScan SPECT/CT), and [^{18}F]fluorodeoxyglucose PET/CT (FDG−PET) (El-Maouche et al., 2016). DOTA-based studies and OctreoScan both utilize analogs of somatostatin and target somatostatin receptors, which are highly expressed on PMTs. FDG−PET takes advantage of the increased metabolic activity of PMTs. DOTA is a chelator that is combined with positron emitter ^{68}Ga-labeled somatostatin analogs similar to octreotide. These can be ^{68}Ga PET/CT scans

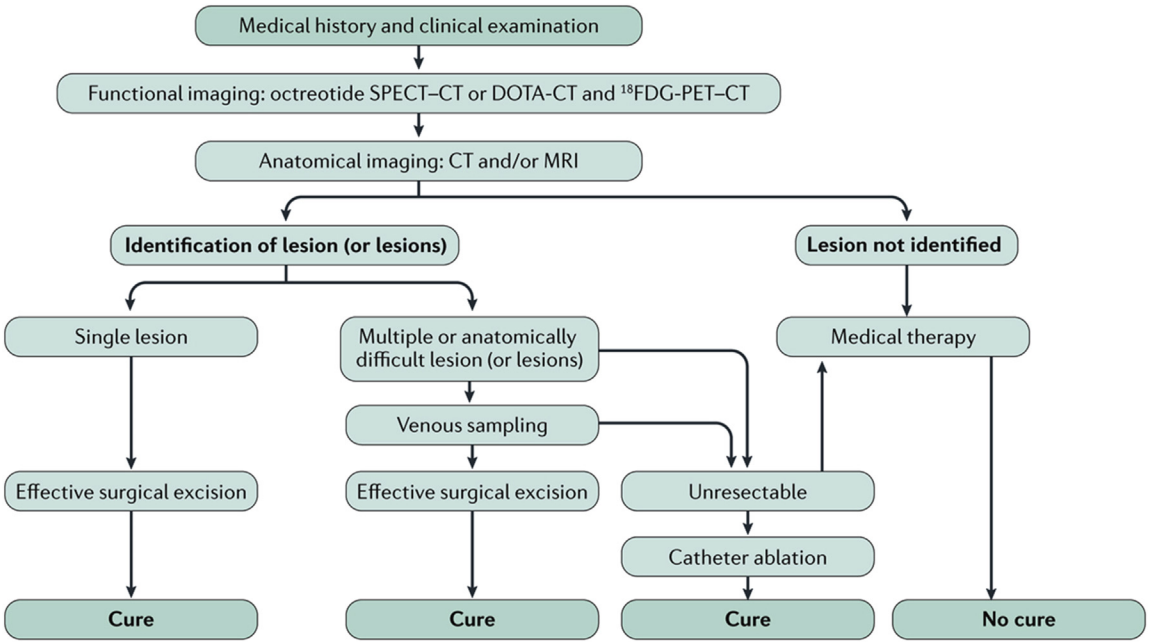

FIGURE 64.3 Localization algorithm. A suggested algorithm for the approach to tumor localization in a patient with a phosphaturic mesenchymal tumor. *DOTA−CT*, DOTA-chelated, ^{68}Ga-labeled somatostatin analog TATE, NOC, or TOC computed tomography (*CT*); *^{18}F-FDG−PET−CT*, ^{18}F-labeled fluorodeoxyglucose positron emission tomography/CT; *octreotide SPECT−CT*, octreotide scan with single-photon emission CT; *MRI*, magnetic resonance imaging. *Adapted from Minisola, S., Peacock, M., Fukumoto, S., Cipriani, C., Pepe, J., Tella, SH., et al., 2017. Tumour-induced osteomalacia. Nat. Rev. Dis. Primers. 3, 17044. Epub 2017/07/14.*

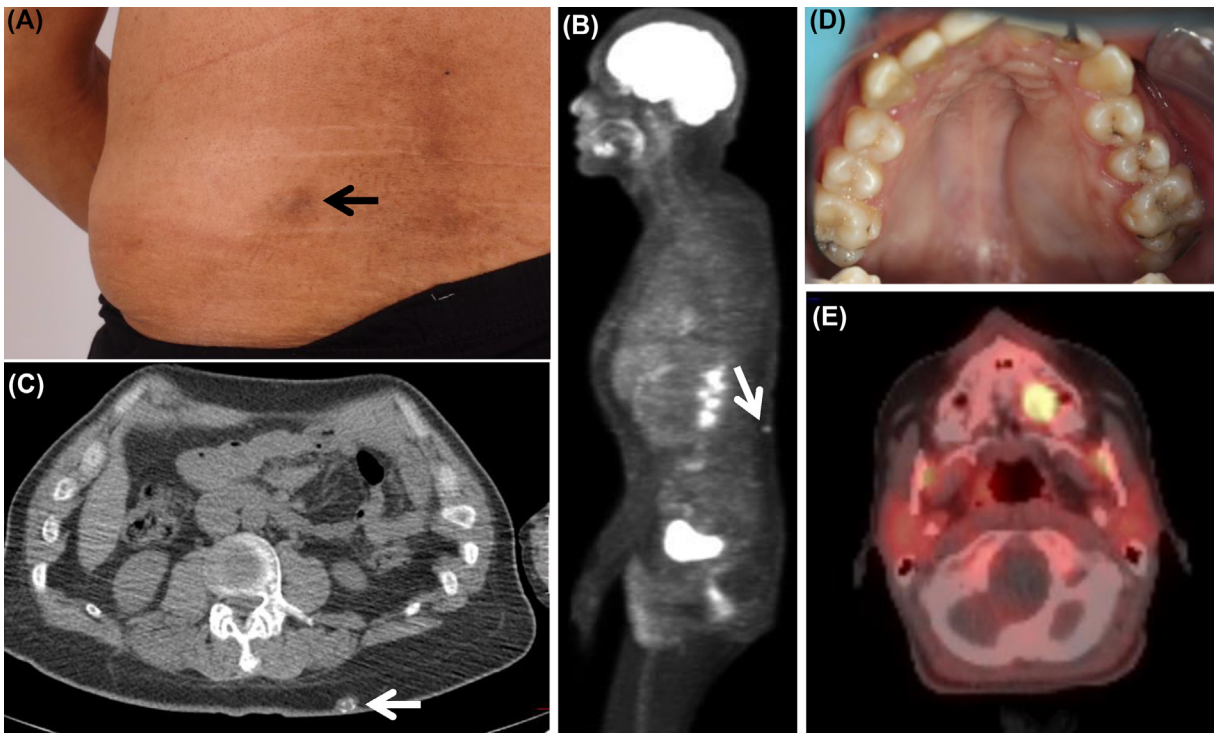

FIGURE 64.4 Tumors identified on physical examination. (A−C) The patient had a small, mobile, subcutaneous lesion on his back that he had noticed within the past several years (A, *arrow*). It showed marked metabolic activity on positron emission tomography/computed tomography (PET/CT) scan (B, *arrow*), and on CT windowing (C, *arrow*) it showed areas of calcification, which are often seen in phosphaturic mesenchymal tumors. (D and E) A 17-year-old girl was noted to have a mass in the roof of her mouth that she had noticed within the past several years (D). On merged ^{68}Ga-DOTA PET/CT scan (E) it was noted to have a high uptake of ^{68}Ga-DOTA, consistent with tumor-induced osteomalacia. In both cases, resection of the tumors led to complete remission.

with DOTA−TATE, DOTA−NOC, or DOTA−TOC. TATE, NOC, and TOC have been shown to have varying degrees of specificity for different somatostatin receptor subtypes, but as to whether these in vitro differences translate to varying degrees of clinical sensitivity or specificity remains to be seen. OctreoScans utilize pentetreotide conjugated with indium-111 and can be combined with SPECT/CT to produce 3D images. Full-body OctreoScan SPECT/CT can be time consuming, requiring 5−6 h of scanning over several days to optimize the diagnostic ability of this study, which may not be feasible in many centers (El-Maouche et al., 2016). It is important to note that cases have been identified wherein tumors were identified on FDG−PET, but were negative on somatostatin-based imaging studies. Therefore, if somatostatin receptor−based studies are negative, FDG−PET is the next imagining modality to perform (El-Maouche et al., 2016). Given that these tumors are often small, and all functional imaging studies have areas of false positive tracer uptake, there can be complementarity between somatostatin-based and FDG-based imaging that often make performing both of utility. Since tumors can be anywhere from head to toe, all scans must encompass the entire body, including the arms and hands (Chong et al., 2011b).

If a lesion is identified with functional imaging, the next step is to perform anatomical imaging of the area with contrast CT and/or magnetic resonance to assist with surgical planning. In cases with multiple suspicious lesions or a single lesion in a surgically challenging area, selective venous sampling is recommended to identify or confirm the location of the culprit lesion prior to surgery (Fig. 64.5) (Andreopoulou et al., 2011). Based on a cohort of nine subjects, a minimum ratio of FGF23 concentration gradient of 1.6 was identified as the cutoff between levels in venous drainage of the tumor bed and the general circulation (Andreopoulou et al., 2011). Venous sampling in the absence of pretest suspicious lesions has not been shown to be effective and is not recommended (Andreopoulou et al., 2011). Biopsy is generally discouraged due to the potential for tumor seeding; however, it may be required for tumor confirmation in rare cases prior to what might be a highly morbid surgery (Florenzano et al., 2017). Patients whose tumor cannot be localized even after extensive investigation can be treated medically (see later) with repeat attempts at localization periodically (Chong et al., 2011a; Florenzano et al., 2017).

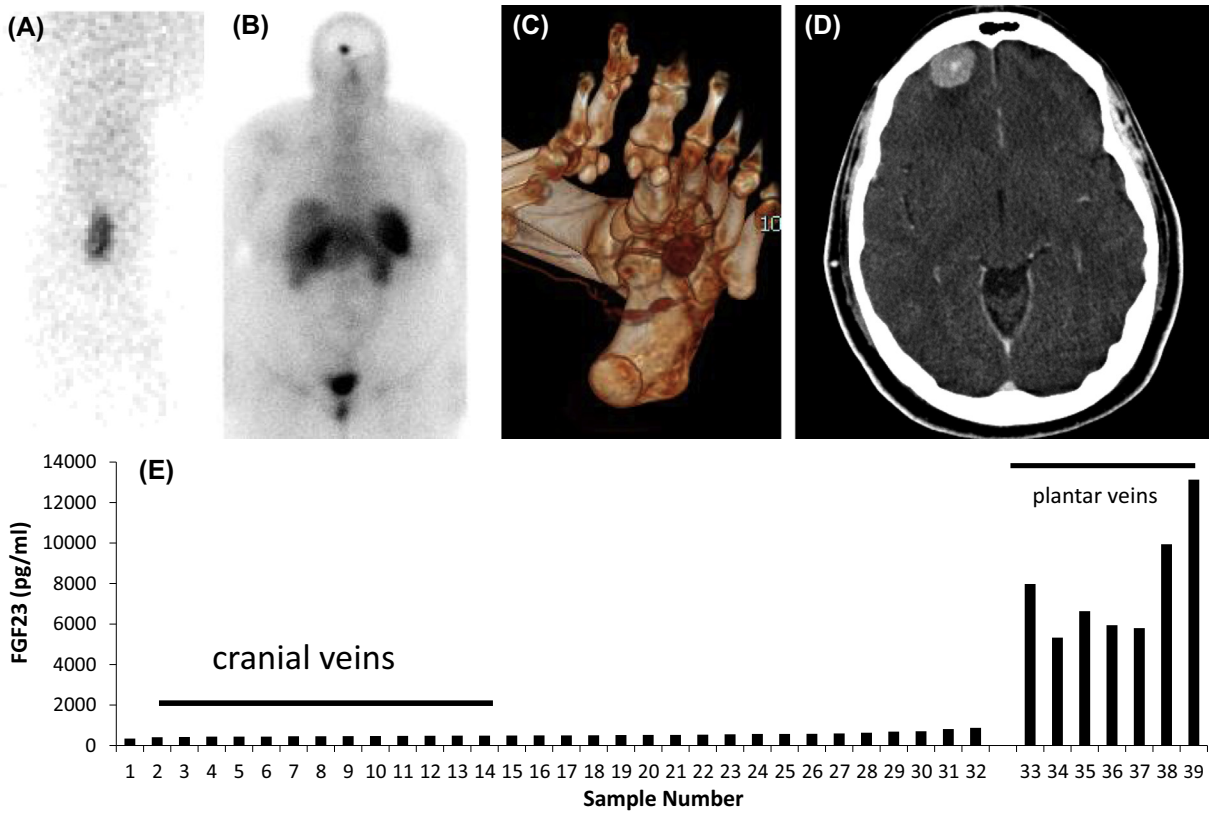

FIGURE 64.5 Utility of venous sampling in distinguishing between multiple foci. (A and B) A 43-year-old woman was noted to have tracer uptake in the foot and in the skull on OctreoScan. (C and D) On anatomic imaging (computed tomography) calcified masses were detected in both, either of which could represent a phosphaturic mesenchymal tumor. (E) Venous sampling revealed a clear step up in the plantar veins draining the foot, and not the skull, which suggested the lesion on the foot was the tumor. The lesion on the plantar surface of the foot was resected, and complete remission followed. *FGF23*, fibroblast growth factor 23.

Treatment

Surgical treatment

Surgery is considered the only definitive and curative treatment of TIO (Chong et al., 2011a; Minisola et al., 2017a), and therefore is the current standard of care. It is of utmost importance to aim for complete resection of the tumor with a wide margin of excision, as local recurrences have been reported (Chong et al., 2011a; Clunie et al., 2000), including cases that later developed malignant characteristics (Uramoto et al., 2009). When the tumor is located in soft tissue, as they are in about 50% of the cases, wide excision is less difficult, but not trivial, as the tumors are often not encapsulated and margins not immediately evident. Excision of tumors located in bone is more challenging. Distinction between tumor-bearing and normal bone is nearly impossible intraoperatively. While these tumors are often small and not locally aggressive, they are not encapsulated and tend to be locally infiltrative, especially along the trabeculae of bone. The preferred approach to ensure surgical cure of tumors located in bone is to completely resect the region of the bone in which the tumor is located (Florenzano et al., 2017). A more conservative surgical approach that entails curettage of the region in which the tumor resides is prone to persistence or recurrence. Despite an aggressive surgical approach, some patients require multiple interventions to remove the entire tumor (Sun et al., 2015). Postoperative radiotherapy for margin-positive tumors has been reported, but data on its utility are limited (Minisola et al., 2017a; Minisola et al., 2017b; Tarasova et al., 2013).

After complete resection, there is a rapid clinical recovery, with serum phosphorus and intact FGF23 returning to normal range within the first 5 days in most patients (Chong et al., 2013). In contrast, normalization of alkaline phosphatase, which reflects healing of osteomalacia, may take several weeks to months. Interestingly, serum 1,25-dihydroxyvitamin D levels begin to rise rapidly in the postoperative period, with levels elevated even above the normal range and a progressive decline toward normal during the second postoperative week (Chong et al., 2013).

Minimally invasive treatment

For many patients, surgery is not an option. Tumors may be located in areas difficult to access surgically, in which excision would likely cause significant morbidity. Operative morbidity may also be high in patients with poor performance status due to comorbid conditions (Florenzano et al., 2017; Tutton et al., 2012; Hesse et al., 2007). Ablative procedures include external beam radiation, radiofrequency ablation, and cryoablation, with or without prior embolization (Hesse et al., 2007; Jadhav et al., 2014; Tella et al., 2017). Multimodality, image-guided ablation with radiofrequency or cryoablation is a promising alternative for this group of patients. It has shown to be a technique with little morbidity and short hospital stays. Although surgery remains the treatment of choice, image-guided ablation may be an effective, less invasive, and safe treatment for patients with a difficult-to-remove tumor or who are poor surgical candidates (Tella et al., 2017). However, long-term efficacy of these modalities has not been demonstrated.

Conventional medical treatment

During the process of identifying the location of the culprit tumor, and in cases in which it is not possible to detect and/or completely resect the tumor, medical treatment is indicated. Phosphate plus active vitamin D (calcitriol or alfacalcidol) supplementation is the mainstay of treatment, with the goal of improving symptoms and healing osteomalacia. Biochemically, the goal is to maintain euphosphatemia, with blood phosphate in the lower end of the normal range, and PTH and urine calcium in the normal range (Tables 64.2 and 64.3) (Minisola et al., 2017a). The treatment regimen includes 15−60 mg/kg per day of elemental phosphorus (typically 1−3 g/day) divided into three to six doses and calcitriol or alfacalcidol 15−60 ng/kg per day (Chong et al., 2011a). Complications of medical therapy can include nephrocalcinosis and/or nephrolithiasis with an increased risk of reduced kidney function and/or secondary or tertiary hyperparathyroidism. Secondary hyperparathyroidism can also be seen at presentation as a consequence of decreased 1,25-dihydroxyvitamin D levels and reflects an appropriate physiological response to maintain eucalcemia (Florenzano et al., 2017). Secondary hyperparathyroidism can also develop as a consequence of treatment, especially if the dose of active vitamin D is not adequate and/or if there is insufficient dietary calcium to keep up with the rapid remineralization of the skeleton that occurs at the outset of treatment (Huang et al., 2000). Phosphorus supplementation is also thought to induce secondary hyperparathyroidism and parathyroid gland hyperplasia by an unclear mechanism (Huang et al., 2000; Reid et al., 1987). Prolonged secondary hyperparathyroidism can lead to the development of tertiary hyperparathyroidism with frank hypercalcemia (Huang et al., 2000). Active vitamin D (calcitriol or alfacalcidol) is used to prevent or treat secondary hyperparathyroidism. Addition of calcium supplements or increases in active vitamin D are indicated for difficult-to-normalize PTH, very low urinary calcium, or hypocalcemia. Secondary hyperparathyroidism can occur at the outset of

TABLE 64.2 Phosphorus supplements.

Phosphorus source	Amount of elemental phosphorus
Neutra-Phos	8 mmol (248 mg) per capsule/packet
Neutra-Phos-K	8 mmol (248 mg) per capsule/packet
K-Phos Neutral	8 mmol (248 mg) per tablet
K-Phos Original	3.68 mmol (114 mg) per tablet
Fleet Phospho-Soda	4.15 mmol (128.65 mg)/mL
Joulie's Solution	1.35 mmol (41.85 mg)/mL

TABLE 64.3 Medical treatment of tumor-induced osteomalacia.

Goal of therapy:	Low end of normal for age-appropriate normal range of phosphorus
Medication	**Dosing**
Phosphorus	15–60 mg/kg/day (approximately 1–3 g/day for adults) Dose should be divided four or five times/day to improve tolerance
Calcitriol or alfacalcidiol	15–60 ng/kg/day (approximately 0.75–3 μg/day for adults) Start 1.5 μg/day and titrate; dose can be divided two or three times/day
Monitoring	
Renal ultrasound to rule out nephrolithiasis and nephrocalcinosis at baseline. Repeat if concerning symptoms arise or persistent increase in urinary calcium.	
Serum calcium, phosphorus, and parathyroid hormone (PTH) every 3 months - If phosphorus below target, increase phosphorus supplements - If calcium below target, add/increase calcium supplements - If PTH elevated, increase calcitriol	
Urinary calcium (UCa) and creatinine (UCr) every 3 months (second morning void) - If UCa/UCr $\geq$ 0.2, check for urinary hemoglobin. Also check 24-h urinary calcium and creatinine with goal of normal-range urinary calcium. Decrease calcitriol dose if positive urinary hemoglobin or elevated 24-h urinary calcium. - If UCa/UCr $\leq$0.2, and serum phosphorus and PTH are okay, continue current regimen

treatment of severe cases of osteomalacia as the skeleton begins to mineralize at a high rate (Florenzano et al., 2017). Treatment with active vitamin D can induce the development of hypercalciuria and increase the risk for nephrocalcinosis/nephrolithiasis (Chong et al., 2011a). Given the described risk of significant side effects of medical therapy, monitoring with serum phosphorus, calcium, PTH, urinary calcium, and renal ultrasound should be routinely performed and treatment adjusted to meet therapeutic goals while avoiding complications (Chong et al., 2011a) (Table 64.3). In patients with more severe disease, doses of phosphate and vitamin D can be quite high at the outset of treatment. After the skeleton has healed significantly, the phosphate and vitamin D requirements decrease, and the doses of phosphate, and especially vitamin D, need to be lowered. Failure to do so can lead to renal calcification and impaired renal function. As is the case with XLH, some patients with mild disease may be treated with active vitamin D alone (Costa et al., 1981).

An adjuvant to conventional therapy with phosphate salts and active vitamin D is the calcimimetic cinacalcet (Geller et al., 2007). Its mechanism of action is based on the fact that FGF23 action is dependent on the presence of PTH for its full phosphaturic effect (Gupta et al., 2004). For this reason, lowering PTH with cinacalcet has been shown to decrease phosphaturia, reduce the need for phosphate and calcitriol supplements, and bring about bone healing (Geller et al., 2007). The main side effect of the use of cinacalcet is the development of hypercalciuria, thus requiring monitoring of 24-h urine calcium periodically and possibly requiring the use of a thiazide to prevent hypercalciuria. An even more dramatic approach along this line of thinking is total parathyroidectomy as a treatment for TIO (Bhadada et al., 2013). While this

approach may control blood phosphate, it will have other deleterious mineral homeostasis complications (e.g., hypercalciuria) and not address the underlying etiology of the disease, the PMT, which will still be in place with the potential to grow and/or metastasize.

Considering the presence of somatostatin receptors on PMTs, the somatostatin analog octreotide has been proposed as a potential treatment for TIO (Seufert et al., 2001). However, the preponderance of data to this point, albeit based on small, uncontrolled studies, is that octreotide is ineffective in treating TIO (Ovejero et al., 2017; Paglia et al., 2002). Likewise, the use of potentially tumoricidal treatment with lutetium-177 DOTATATE has failed to show a significant beneficial effect on tumor burden (Nair et al., 2017).

Future directions

Progress has been made and will continue to be made in the delineation of the underlying molecular/genetic pathophysiology, diagnosis, and treatment of TIO. Improvement in tumor molecular diagnostics in cancer biology can be directly applied to PMTs and will reveal novel molecular and genetic changes that underlie the development of PMTs beyond the FGFR changes that account for, at most, only about 40% of the cases of PMT. Data suggest a connection between the hypoxia-inducible factor/erythropoietin signaling pathway and the physiologic regulation of FGF23 production (Farrow et al., 2011; Toro et al., 2018; Hanudel et al., 2018). This points to another area of the physiological regulation of FGF23 that may be susceptible to pathophysiologic derangement and account for some cases of TIO, especially those in which a PMT cannot be identified.

DOTA-based imaging, which derives its utility from the fact that PMTs express somatostatin receptors, has significantly improved the localization of PMTs, allowing for the identification of tumors <2 cm in diameter. It is unlikely there will be significant progress in somatostatin receptor-based imaging, but it is possible that there are other epitopes expressed on PMTs that may lead to another avenue of tumor localization technologies.

The application of an array of ablative techniques, less invasive than surgery, in part enabled by the improvement in tumor localization, has opened the door for potentially lower morbidity treatment. It will be important going forward to be assured that the durability of remission brought about by these techniques is long lasting and that later recurrence, with or without metastatic spread, is not an issue.

The development of the anti-FGF23 humanized monoclonal antibody, burosumab (Kyowa Hakko Kirin, Tokyo, Japan, and Ultragenyx Pharmaceutical, Novato, CA, USA), which was recently approved for treatment of XLH (Carpenter et al., 2018; Insogna et al., 2018), opens a promising option for the treatment that will probably be applicable to patients with TIO. Burosumab is a blocking antibody that inhibits the formation of the FGF23−klotho receptor complex (Aono et al., 2011). Preliminary evidence shows that it significantly increases serum phosphate and 1,25-dihydroxyvitamin D in subjects with TIO (Carpenter et al., 2016). Here too, though, it should be noted that the PMT, the underlying cause of the disease with some potential for malignant transformation, is still in place and that medical treatment does not reflect cure, the primary goal.

The identification of aberrant FGFR expression/signaling in TIO has led to the study of drugs that target the FGF pathway (BGJ398) (Wohrle et al., 2011, 2013) and is currently an area of active investigation that may hold promise for patients with TIO.

Taken together, the future of the study and treatment of TIO is full of promise for both learning more about the biology of FGF23 and, most importantly, treating the patients who suffer from this debilitating disease.

Chapter 65

Osteopetrosis

Antonio Maurizi and Anna Teti
Department of Biotechnological and Applied Clinical Sciences, University of L'Aquila, L'Aquila, Italy

Chapter outline

Introduction

In 1904, Albers-Schönberg described a patient with extremely dense but fragile bones (Albers-Schönberg, 1904). This phenotype matches what is now called autosomal dominant osteopetrosis (ADO) and was named Albers-Schönberg or marble bone disease (Hill and Charlton, 1965). The term "osteopetrosis" (osteo + *petra*, stone, + *osis*, condition) was coined to better highlight the density of the bones, as opposed to osteoporosis, in which there is a reduction of bone mass, also leading to bone fragility. The disease is caused by abnormalities of osteoclasts, the cells deputed to the resorption of the bone matrix, described in detail in Chapter 17. Bone resorption is fundamental for harmonic bone accrual, the excavation of the bone cavities, and balanced bone remodeling, in concert with the bone formation implemented by osteoblasts (Teti, 2011; Cappariello et al., 2014).

In osteopetrosis, bone fragility is determined by the lack of bone renewal, with preservation of primary non-remodeled bone featuring persistent mineralized cartilage within the bone trabeculae (Rucci and Teti, 2016) (Fig. 65.1). This altered mineralized tissue does not retain the mechanical properties, losing resistance and fracturing with low energy. In this chapter we will describe the clinical, genetic, phenotypic, and molecular aspects of osteopetrosis and will provide information on existing and experimental therapies that we hope will cure in the future all forms of the disease.

Clinical features

Clinically, osteopetrosis is classified as lethal, intermediate, and mild forms. Lethal osteopetrosis has an autosomal recessive inheritance and is also called infantile or malignant osteopetrosis, or *autosomal recessive osteopetrosis* (ARO). A few cases have been demonstrated to have an X-linked inheritance and this group is called *X-linked osteopetrosis* (XLO). ARO and XLO are fatal within the first years of life. ARO has a prevalence of 1:250,000 live births (Whyte, 2013; Sobacchi et al., 2013, Teti and Econs, 2017), while the exact prevalence of XLO is unknown. Rarely, patients survive for the first decade, whereas most of them die within 2 years of birth (Whyte, 2013; Sobacchi et al., 2013; Teti and Econs, 2017). Symptoms include severe bone marrow failure signified by grave anemia, pancytopenia, impaired blood clotting, and susceptibility to infections, including osteomyelitis, and hepatosplenomegaly due to ectopic hematopoiesis. Patients also show hypocalcemia, hyperparathyroidism, stunted growth, pain, multiple atraumatic fractures affecting mostly the appendicular skeleton, cranial nerve compression syndromes leading to impaired vision and hearing, obstructive hydrocephalus due to overgrowth of the foramen magnum, nystagmus, frontal bossing, nasal sinus abnormalities, and impairment of tooth eruption (Schinke et al., 2009; Whyte, 2013; Sobacchi et al., 2013; Teti and Econs, 2017) (Table 65.1).

Mental retardation is generally not seen in this form, although cerebral hemorrhage can occur due to thrombocytopenia. However, some osteopetrotic subtypes show primary neurodegeneration severely impairing neural functions (Kornak et al., 2001; Chalhoub et al., 2003).

Intermediate osteopetrosis has an autosomal recessive inheritance as well and presents with symptoms similar to those of the lethal forms, but less severe. It is also called *intermediate recessive osteopetrosis* (IRO) and its symptoms include renal tubular acidosis, cerebral calcification, and mental retardation, not seen in other types of osteopetrosis. Its prevalence is very low and not quantified, with about 50 cases described in the literature (Ohlsson et al., 1986; Bolt et al., 2005).

Mild osteopetrosis has an autosomal dominant inheritance and is generally called benign osteopetrosis. This definition is misleading as there are cases showing high morbidity and, rarely, early death, although generally patients achieve adulthood and have a normal life span. Mild osteopetrosis is also known as Albers-Schönberg disease to honor the very first publication on osteopetrosis by Albers-Schönberg (1904). Currently, the most accepted name of this form is ADO, which was previously classified as type 1 and type 2 (Bollerslev and Andersen, 1988). In the section describing the genetics of osteopetrosis we will highlight that ADO type 1 (ADO1) is not an osteoclast disease (Van Wesenbeeck et al., 2003) and that this syndrome should be reclassified as high bone mass (HBM) as it affects the function of osteoblasts rather than that of osteoclasts. ADO type 2 (ADO2) is instead a genuine osteoclast disease, so its current classification is correct, although there is some debate as to whether this should be called ADO or ADO2. In this chapter we will call it ADO2 as this is the most acknowledged name for this form.

ADO2 has a prevalence of 1:20,000 live births and an incomplete penetrance (66%), therefore more than 30% are healthy carriers who do not develop the syndrome (Waguespack et al., 2007; Bollerslev et al., 2013). The affected individuals have mild to rarely lethal outcome, frequently with high morbidity, especially due to multiple low-energy fractures that in some patients occur tens of times during their life. High bone density is observed especially at the skull base, in the vertebral bodies, and in the pelvis, and these observations are pathognomonic of ADO2 (Bénichou et al., 2000; Waguespack et al., 2007; Del Fattore et al., 2006; Bollerslev et al., 2013). Patients may also frequently suffer from anemia, mandibular osteomyelitis, dental problems, pain, hypovision, and hypoacusis (Bénichou et al., 2000; Del Fattore et al., 2006; Waguespack et al., 2007). Severe forms are seriously debilitating, with a very poor quality of life. These patients are often wheelchair bound and need life-long assistance. Very few cases are reported to exhibit cognitive failures (Del Fattore et al., 2006).

Radiographic features

Even though we are in the third millennium and many new sophisticated imaging diagnostic tools are available, the best method to diagnose osteopetrosis is still by radiography. Bones appear dense and medullary cavities are reduced or obliterated. Diffuse sclerosis is observed in the entire skeleton in ARO, XLO, and IRO, while ADO2 is characterized by a

TABLE 65.1 Radiographic and clinical features of osteopetrosis.

Type of osteopetrosis	Acronym	Radiographic features	Clinical features

Autosomal recessive	ARO	• Dense bone with reduced or obliterated medullary cavity
		• Diffuse sclerosis
		• Bone-in-bone appearance
		  ■ Spine
		  ■ Pelvis
		  ■ Long bones
		• Misshapen metaphysis
		• Incomplete dentition
		• Hypertelorism with "hair-on-end" appearance of the calvaria bone
			• Bone marrow failure
			• Anemia
			• Pancytopenia
			• Thrombocytopenia
			• Impaired blood clotting
			• Susceptibility to infections
			• Osteomyelitis
			• Hepatosplenomegaly
			• Hypocalcemia
			• Hyperparathyroidism
			• Stunted growth
			• Pain
			• Multiple low-energy fractures
			• Impaired vision and hearing
			• Obstructive hydrocephalus
			• Nasal sinus abnormalities
			• Impairment of tooth eruption

Intermediate	IRO	• Similar to ARO but less severe	• All ARO symptoms but less severe • Renal tubular acidosis • Cerebral calcification • Mental retardation

Autosomal dominant	ADO2	• Focal sclerosis
		  ■ Skull basis
		  ■ Vertebral bodies
		  ■ Pelvis
		• Sandwich vertebrae
		• Rugger-jersey spine
			• Multiple low-energy fractures
			• Anemia
			• Mandibular osteomyelitis
			• Dental problems
			• Pain
			• Hypovision
			• Hypoacusis
			• Cognitive failures (rare cases)

focal sclerosis of the skull basis, vertebral bodies, and pelvis (Bénichou et al., 2000; Waguespack et al., 2007; Del Fattore et al., 2006; Bollerslev et al., 2013). Specifically, the vertebral bodies present with dense bone tissue at their sub−end plates and for this feature they are called "sandwich vertebrae," while the entire spine is called "rugger-jersey spine" due to the prominent sub−end plate sclerosis of multiple contiguous vertebrae that produce alternating sclerotic−lucent−sclerotic areas (Bénichou et al., 2000; Waguespack et al., 2007; Del Fattore et al., 2006; Bollerslev et al., 2013). This aspect makes the diagnosis of ADO2 rather easy.

Osteopetrotic bones, especially in the most severe cases, show the so-called "bone-in-bone" appearance (Williams et al., 2004), which indicates a bone that has another bone inside, like a miniature version, seen in spine, pelvis, and long bones. Furthermore, long bones may present with alternating radiolucent and radiodense metaphyseal lines, which represent growth-arrest bands (Yao and Seeger, 1997; Bénichou et al., 2000; Waguespack et al., 2007; Del Fattore et al., 2006; Bollerslev et al., 2013). The metaphysis also appears misshapen, with an expanded funnel-like appearance. The length of bones is reduced for age, demonstrating stunted growth, confirmed by the short stature of patients. Mandibles present a triangular opacity due to calcification of the secondary condylar ossification center. Dentition is incomplete, with defective enamel formation and predisposition to caries. Patients may show hypertelorism, malformed calvariae with an expanded diploic space, which shows the so-called "hair-on-end" appearance. This consists of thin vertical striations resembling hairs due to the diploe trabecular pattern perpendicular to the curvature of the cranial vault (Azam and Bhatti, 2006).

Genetic features

The very first gene found in 1983 to affect osteopetrotic patients is called *CAII* and encodes carbonic anhydrase type II (Sly et al., 1983). This is a member of the large family of carbonic anhydrases that accelerate the spontaneous hydration of carbon dioxide. The resulting carbonic acid represents an efficient source of protons especially in cells that largely acidify the extracellular environment, including gastric parietal cells, renal tubular cells, and osteoclasts (Fig. 65.2). *CAII* was found to be mutated in the form of IRO now classified as OPTB3 osteopetrosis (Table 65.2), clinically recognizable for its intermediate severity, renal acidosis, and mental retardation (Sly et al., 1983, 1985). Given the significant spontaneous carbonic acid formation occurring in osteoclasts, some bone resorption is still possible in these patients, which explains the intermediate course.

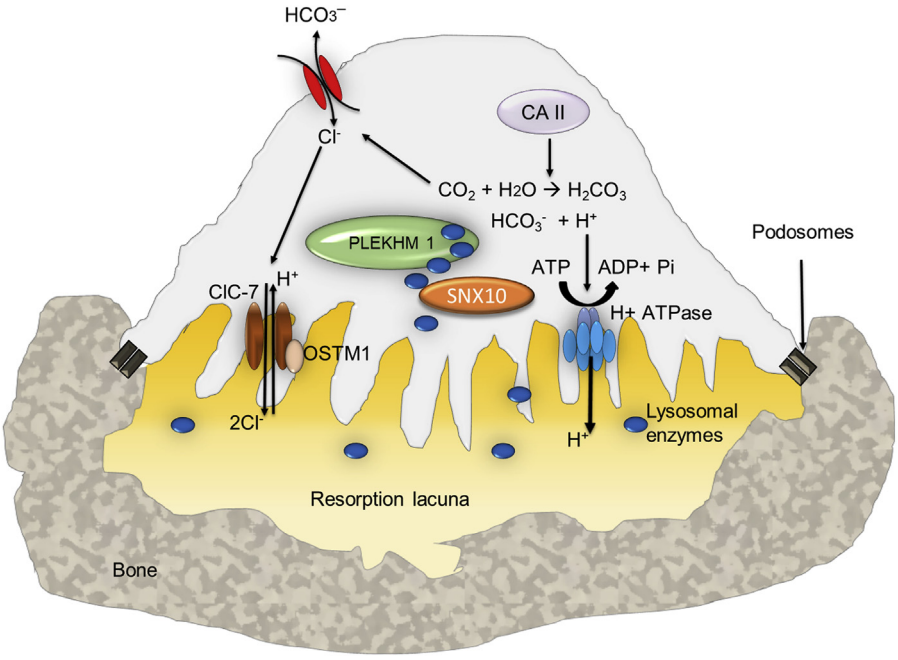

FIGURE 65.2 Osteoclast molecular mechanisms altered in osteopetrosis. Cartoon illustrating a polarized osteoclast in the process of bone resorption. The indicated proteins are mutated in the forms of osteopetrosis described in the text and in Table 65.2. *CAII*, carbonic anhydrase type II; *ClC-7*, chloride channel 7; *OSTM1*, osteopetrosis-transmembrane protein 1; *PLEKHM1*, pleckstrin homology domain-containing, family M (with RUN domain) member 1; *SNX10*, sorting nexin 10.

TABLE 65.2 Genetics of osteopetrosis.

Classification	OMIM number	Mutated gene	Encoded protein	Protein function	Osteopetrosis acronym	Frequency
OPTA1	607634	*LRP5*	LRP5	Induces bone formation	ADO1	Unknown
OPTA2	166600	*CLCN7*	ClC-7	Charge balances lysosomes and resorption lacunae	ADO2	70% of ADO
OPBT1	259700	*TCIRG1*	a3 subunit of the vacuolar H^+-ATPase	Acidifies lysosomes and resorption lacunae	ARO	50% of ARO
OPBT2	259710	*TNFS11*	RANKL	Induces osteoclastogenesis	ARO	5% of ARO
OPBT3	259730	*CAII*	Carbonic anhydrase II	Accelerates hydration of CO_2 in H_2CO_3	ARO	Unknown
OPBT4	611490	*CLCN7*	ClC-7	Charge balances lysosomes and resorption lacunae	ARO	10% of ARO
OPBT5	259720	*OSTM1*	OSTM1	Allows subcellular localization of ClC-7	ARO	5% of ARO
OPBT6	611497	*PLEKHM1*	PLEKHM1	Regulates vesicular trafficking	ARO	Unknown
OPBT7	612301	*TNFRS11A*	RANK	Induces osteoclastogenesis	ARO	5% of ARO
OPBT8	615085	*SNX10*	SNX10	Regulates endosome homeostasis	ARO	4% of ARO
-	300301	*NEMO*	NEMO	Regulates NF-κB activity	XLO	Unknown

The second gene found to affect osteopetrotic patients was identified 17 years later (Frattini et al., 2000). Building on the spontaneous osteopetrotic mouse model oc/oc, largely investigated to understand the molecular basis of bone resorption and identify the mechanisms inducing its impairment in osteopetrosis, Frattini et al. (2000) recognized the human homolog of the *atp6i* gene to be altered in about 50% of patients affected by ARO. This is now classified as OPTB1 (Table 65.2) osteopetrosis and the gene involved is called *TCIRG1*. This gene encodes the a3 subunit of the vacuolar H^+-ATPase (V-ATPase), a multimeric complex made up of a transmembrane V_0 domain transporting protons and a cytosolic V_1 domain representing the catalytic ATPase activity (Finbow and Harrison, 1997; Frattini et al., 2000) (Fig. 65.3). V_1 includes eight subunits, A−H, of which B, C, E, and G are tissue specific. For instance, mutations of the B1 isoform induce distal tubular acidosis and impair hearing (Karet et al., 1999). V_0 includes six subunits, a, d, c, c′, c″, and e. Subunits a and d are tissue specific, and biallelic loss-of-function mutations of the a3 isoform induce OPTB1 osteopetrosis. The a3 subunit is largely expressed in osteoclasts and in gastric parietal cells, where V-ATPase acidifies the extracellular environment: the resorption lacunae and the gastric lumen, respectively. In osteoclasts, V-ATPase is expressed in the lysosomal membrane and in the ruffled border membrane (Fig. 65.2). The latter derives from the fusion of lysosomes with the plasma membrane (Stenbeck, 2002); therefore, lysosomes contribute to inserting V-ATPase into this site and to modifying the resorption lacuna environment by releasing their acidic hydrolases (Baron et al., 1985; Stenbeck, 2002). Therefore, one can imagine the resorption lacuna as a giant modified lysosome. In fact, like lysosomes, this lacuna has a pH below 5 and contains lytic enzymes (Fig. 65.2). The low pH is essential to solubilize the hydroxyapatite crystals (Blair et al., 1986) and liberate the organic matrix underneath. This acidic environment is permissive for acidic enzymes that attack the organic matrix, especially type I collagen, which represents 95% of the matrix proteins and has been found to be sensitive to the proteolytic activity of cathepsin K (Zaidi et al., 2001). Mutations of cathepsin K do not disrupt the release of hydroxyapatite but prevent the hydrolysis of collagen, giving rise to a syndrome called pycnodysostosis or "Toulouse-Lautrec" disease (Motyckova and Fisher, 2002). The impairment of the acidification of the resorption lacunae disturbs bone resorption as is seen in OPTB1 osteopetrosis. OPTB1 affects at least 50% of ARO patients (Frattini et al., 2000) who are reported to harbor a severe disease. Given the expression of the a3 V-ATPase subunit in the gastric parietal cells as well, patients also present with high gastric pH that disturbs the absorption of calcium (Schinke et al., 2009; Barvencik et al., 2014). As a result, the

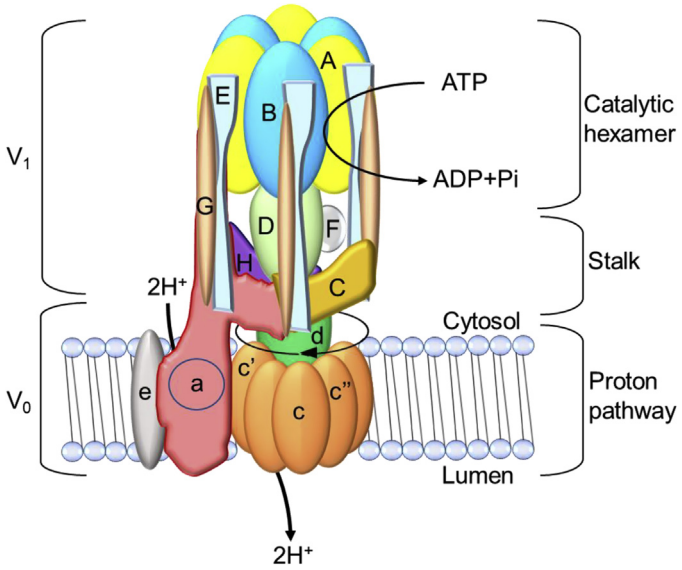

FIGURE 65.3 Molecular structure of the vacuolar H^+-ATPase. Osteoclasts express isoform 3 of the a subunit (a3) of the V_0 domain (*circle*).

bone matrix cannot mineralize properly. In fact, histopathologically, OPTB1 presents with unmineralized osteoid, reminiscent of rickets or osteomalacia. Therefore, this form of osteopetrosis has been proposed to be called osteopetrorickets or osteopetromalacia (Barvencik et al., 2014).

The second most frequent form of ARO is called OPTB4 and is caused by biallelic loss-of-function mutations of the *CLCN7* gene (Table 65.2). It affects about 10% of ARO patients. A peculiar phenotype of OPTB4 is a primary neurodegeneration, especially of the retina, hippocampus, and cerebral and cerebellar cortices (Kasper et al., 2005; Steward, 2003) (Fig. 65.4). For reasons yet to be elucidated, the penetrance of this symptom is incomplete, and some patients do not suffer from severe neurodegeneration. The *CLCN7* gene encodes a 2 chloride/1 proton antiporter (chloride channel 7; ClC-7) necessary to charge balance the electrogenic proton transport by V-ATPase (Cappariello et al., 2014). Like V-ATPase, it is inserted into the lysosomal membrane and transferred to the ruffled border membrane by an exocytosis process (Fig. 65.2). The source of chloride is through a chloride/bicarbonate exchanger located in the osteoclast basolateral membrane (Cappariello et al., 2014) (Fig. 65.2). This anion countertransporter effluxes the bicarbonate generated by the dissociation of the carbonic acid, whose formation is catalyzed by carbonic anhydrase type II, while influxing the chloride

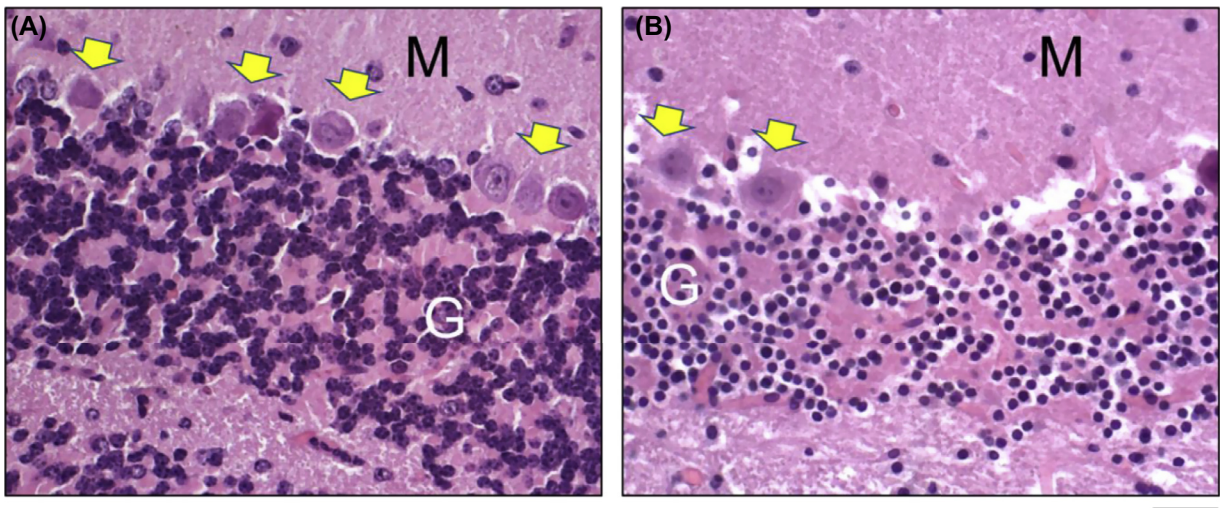

FIGURE 65.4 Histopathology of mouse cerebellar cortex. Histological sections of C57BL/6 mouse cerebellar cortex stained with hematoxylin and eosin. (A) One-month-old wild-type mouse. (B) One-month-old *Clcn7*^{G213R} ADO2 mouse. from the extracellular environment (Cappariello et al., 2014). Chloride is then released into the lysosomes or into the resorption lacuna by the ClC-7 protein (Fig. 65.2).

Associated with ClC-7 there is OSTM1, which is currently classified as the ClC-7 β subunit (Fig. 65.2). The role of OSTM1, encoded by the homonym gene, is to correctly subcellularly localize the ClC-7, contributing to the proper trafficking of the protein. Loss-of-function mutations of *OSTM1* induce OPBT5 osteopetrosis (Table 65.2), whose phenotype is very similar to that of OPTB4 osteopetrosis, albeit with a constant severe neurodegeneration (Pangrazio et al., 2006; Chalhoub et al., 2003). OPBT5 is even rarer than OPBT4, accounting for about 5% of patients (Pangrazio et al., 2006).

OPBT8 osteopetrosis (Table 65.2) is caused by mutations of the *SNX10* gene (Aker et al., 2012). The gene encodes a member of the sorting nexin protein family, involved in intracellular trafficking (Aker et al., 2012) (Fig. 65.3). The protein regulates endosome homeostasis and its mutations affect about 4% of ARO patients (Pangrazio et al., 2013). In this form of osteopetrosis, few and small osteoclasts are observed (Aker et al., 2012). In agreement with the role of the SNX10 protein, these osteoclasts show impairment of vesicular trafficking and endocytosis. They also show impaired extracellular acidification and altered ruffled border (Aker et al., 2012). In mice, SNX10 is not unique to osteoclasts. It is expressed in the stomach, where the phenotype is very similar to that induced by alteration of the *TCIRG1* gene: high pH and reduced calcium solubilization (Ye et al., 2015). In fact, the *SNX10*-coded protein contributes to the correct V-ATPase subcellular localization and is probably involved in the sorting of this complex to the ruffled border (Ye et al., 2015). In line with these alterations, the *SNX10* global knockout mouse skeleton is affected by osteopetrorickets or osteopetromalacia. In contrast, osteoclast-specific knockout mice show osteopetrosis but not rickets or osteomalacia (Ye et al., 2015).

The *PLEKHM1* gene, encoding the pleckstrin homology domain-containing, family M (with RUN domain) member 1 protein, is implicated in OPBT6 osteopetrosis (Table 65.2). This is another form of ARO in which the vesicular trafficking is altered (Fig. 65.2). It is milder than the other ARO forms, although the skeletal phenotype is still largely compromised (Van Wesenbeeck et al., 2007). PLEKHM1 functions as a multivalent adapter for the small GTP-binding protein Rab-7. It regulates Rab-7-dependent vesicular trafficking as well as lysosome−autophagosome fusion through interaction with the homotypic fusion and protein sorting complex (McEwan and Dikic, 2015), which associates the autophagic pathway with endocytic trafficking (McEwan and Dikic, 2015). Given the relevance of vesicular trafficking in the activity and cellular distribution of lysosomes and in their involvement in the formation of the osteoclast ruffled border, it is not difficult to imagine that the cellular impairment induced by PLEKHM1 loss-of-function mutations impairs bone resorption (Van Wesenbeeck et al., 2007). Through its interaction with Rab-7, PLEKHM1 also impairs the endocytic transport from early to late endosomes (McEwan and Dikic, 2015), also relevant for lysosome homeostasis (McEwan and Dikic, 2015). The literature on this form of ARO is scanty and the frequency of the mutation of this gene is not known. Interestingly, an R714C variant of PLEKHM1 has been found to induce a skeletal phenotype not related to osteopetrosis, characterized by osteopenia associated with focal osteosclerosis (Del Fattore et al., 2008), in which osteoclasts retained low tartrate-resistant acid phosphatase (TRAcP) intracellular activity, probably caused by exacerbated extracellular release of this lysosomal enzyme. Released TRAcP was observed to stimulate osteoblast activity, suggesting an increased osteoclast−osteoblast coupling potentially explaining the focal osteosclerosis seen in this patient (Del Fattore et al., 2008).

All the aforementioned ARO forms of osteopetrosis are defined as "osteoclast-rich" for their normal or high content of osteoclasts (Villa et al., 2009). The cellular nature of these AROs is related to the inability of osteoclasts to resorb bone, while the pattern of osteoclast differentiation remains unaltered (Villa et al., 2009). In several osteoclast-rich ARO patients (Villa et al., 2009), osteoclastogenesis is even increased, with no enhancement of osteoclast activity because of the alterations of genes involved in matrix reabsorption. This increase is thought to be due to the hypocalcemic phenotype caused by the lack of bone resorption, which stimulates the release of parathyroid hormone (PTH) from the parathyroid glands (Jacome-Galarzaet al., 2011; Hendy and Canaff, 2016). PTH is known to stimulate osteoclastogenesis by inducing the osteoblast expression of osteoclastogenic cytokines, including receptor activator of NF-κB ligand (RANKL) (Pierroz et al., 2009). In fact, in line with this hypothesis, osteoclast-rich ARO patients show high serum PTH concentration (Villa et al., 2009).

Two other forms of ARO do not show mature osteoclasts in their bone biopsies and are grouped as "osteoclast-poor" osteopetrosis. This histological feature is observed in two forms known as OPBT2 and OPBT7. OPBT2 is induced by loss-of-function mutations of the *TNFS11* gene encoding the osteoclastogenic protein RANKL (Table 65.2), while OPBT7 is caused by loss of function of the *TNFRS11A* gene encoding the RANKL receptor, RANK (Table 65.2; Fig. 65.5). OPBT2 and OPBT7 mutations affect 5% of ARO patients each. OPBT2 mutations are not osteoclast autonomous because the *TNFS11* gene is expressed by a variety of cell types, including lymphocytes and osteoblasts, but not by osteoclasts or their precursors (Pangrazio et al., 2012). However, osteoclasts are primarily affected by *TNFS11* gene mutations. In fact, RANKL is a member of the tumor necrosis factor family (Takahashi et al., 1999) and a proosteoclastogenic cytokine that

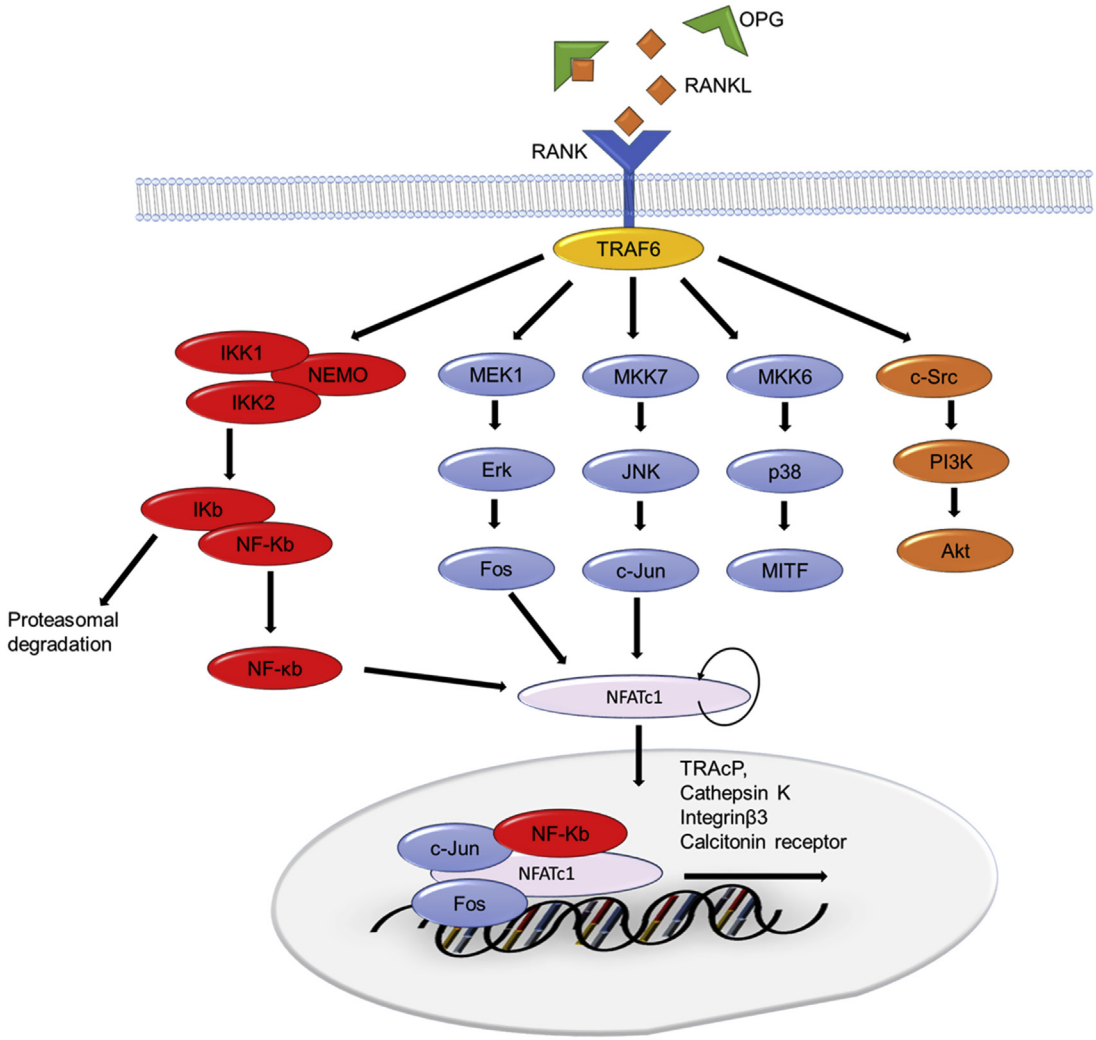

FIGURE 65.5 Osteoclastogenic receptor activator of NF-κB ligand (*RANKL*)/*RANK* intracellular signaling pathway. Cartoon illustrating the intracellular signaling pathway triggered by the RANKL/RANK axis, and the induced osteoclastogenic gene transcription. The pathway is physiologically antagonized by osteoprotegerin (*OPG*), which functions as a soluble RANKL decoy receptor.

binds its receptor RANK, expressed by osteoclast precursors, promoting their late differentiation. This event culminates in mononuclear precursor fusion into giant cells, which then polarize, maturate, and resorb bone (Takahashi et al., 1999). RANKL is also a prosurvival factor regulating osteoclast life span. The cytokine has many other roles in other cell types, especially in immune cells, such as dendritic cells and lymphocytes. In fact, an overall feature of *TNFS11* mutants is defective B and T differentiation and impaired immune response (Dougall et al., 1999). RANKL is also implicated in the development of the lobuloalveolar structure of the mammary gland (Asselin-Labat et al., 2010). Although severe, at variance with the osteoclast-rich osteopetrosis, this osteoclast-poor ARO form presents with a longer survival and a nonfibrotic bone marrow tissue (Sobacchi et al., 2007; Teti, 2012).

Phenotypically very similar to OPBT2, OPBT7 is caused by mutations in the RANKL counterpart (Table 65.2). In fact, the gene implicated, *TNFRS11A*, encodes the RANKL receptor RANK, expressed by osteoclast precursors (Guerrini et al., 2008). Therefore, dysfunctions are osteoclast autonomous although, as for the *TNFS11* gene mutations, also in this form of ARO there are lymphocyte deficiencies and impaired immune response. OPBT7 shares pathological features with OPBT2, but with an important therapeutic implication that will be described in the section on therapy.

So far, no other AROs are described in the literature. However, another lethal condition is the only XLO known, as of this writing, which is part of the complex syndrome called osteopetrosis, lymphedema, hypohidrotic ectodermal dysplasia and immunodeficiency (OL-HED-ID). OL-HED-ID is caused by mutations in the NF-κB essential modulator (*NEMO*)

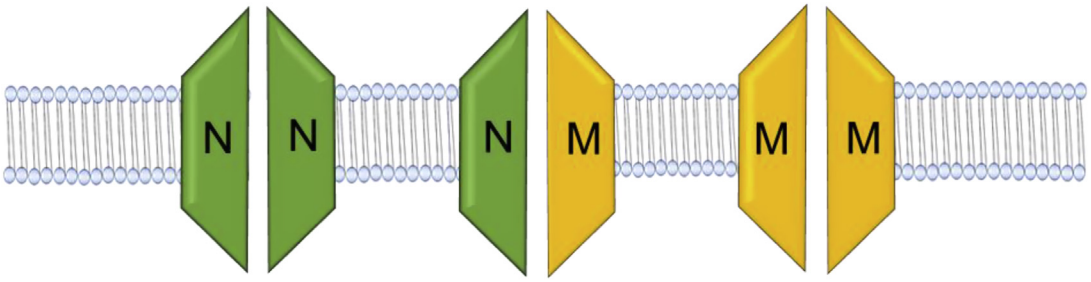

FIGURE 65.6 Assortment of chloride channel 7 (ClC-7) dimers in OPTA2 ADO2 osteopetrosis. Cartoon illustrating the potential ClC-7 subunit dimerization in OPTA2 osteopetrosis. Normal homodimers (*N/N*) are expressed together with mutated homodimers (*M/M*) and *N/M* heterodimers that are believed to be nonfunctional or malfunctional in their $Cl^-/2H^+$ exchange process.

gene (Table 65.2). This gene is also known as *IKKγ* or *IKBKG*, and its protein product exhibits a regulatory role in the IκB kinase (IKK) complex (Darwech et al., 2009). NEMO is an activator of the IKK complex, which is upstream of NF-κB and induces NF-κB translocation to the nucleus, where it functions as a proosteoclastogenic and pro-immune response transcription factor (Darwech et al., 2009) (Fig. 65.5). Given that NF-κB is also implicated in ectodermal tissue formation, including skin, hair, teeth, and sweat glands (Döffinger et al., 2001), its mutations cause alterations in these tissues as well, explaining the complexity of the disease. The bone histological phenotype of these patients is unknown, but the disease is assumed to be osteoclast poor given that the NF-κB pathway is involved in osteoclast differentiation. OL-HED-ID has the OMIM number 300301 (Table 65.2), but it is not classified with an OPBT number and the involved gene mutations have unknown frequency.

In addition to ARO and XLO, ADO patients have also received genetic diagnosis. As mentioned before, ADO1 is not an osteopetrosis but should be better classified as an HBM syndrome due to the involvement of exacerbated bone formation rather than impaired bone resorption (Van Wesenbeeck et al., 2003). This is not a trivial detail, as it has important clinical implications, because the HBM syndrome is characterized by strong bones that are not prone to fracture (Boyden et al., 2002; Van Wesenbeeck et al., 2003), while one relevant hallmark of osteopetrosis is bone fragility despite the increased bone mass (Teti and Econs, 2017). Nevertheless, OMIM lists ADO1 within the osteopetrotic disease family, where it is denominated OPTA1 (Table 65.2). Consistent with the HBM syndrome, the gene implicated in OPTA1 is *LRP5*, encoding a membrane receptor, low-density lipoprotein receptor–related protein 5 (LRP5), which, with its coreceptor Frizzled4, responds to members of the Wnt family of factors, affecting cell growth, adhesion, migration, and many other activities (Komiya and Habas, 2008). The pathway is highly conserved (Komiya and Habas, 2008) and was first identified in *Drosophila*, in which mutations impair segmentation (Wodarz and Nusse, 1998). LRP5 plays roles in the development of retina, inner ear, and bone. The Wnt/LRP5/Frizzled4 complex promotes bone formation, contributing to the regulation of bone mineral density and bone quality (Johnson, 2012), and is antagonized by specific inhibitors, including Dickkopf-1 (Niehrs, 2006) and sclerostin (Li et al., 2005). Some inactivating mutations of LRP5 induce juvenile primary osteoporosis, whereas many others cause osteoporosis–pseudoglioma syndrome. This is a very severe disease with extremely low bone mineral density, severe bone fragility, and eye abnormalities (Gong et al., 2001). Autosomal dominant *LRP5* mutations enhance bone mass, intensifying Wnt signaling or reducing the antagonistic effect of their inhibitors (Boyden et al., 2002). These mutations affect the first "B-propeller" module of LRP5 and may induce clinically recognizable HBM syndrome (Pangrazio et al., 2011). In line with this, a group of single-allele LRP5 mutations was identified in clinically diagnosed ADO1 patients, which should now be referred as a very mild form of HBM.

The only ADO form that is a genuine osteopetrosis disease is classified as OPTA2 (Table 65.2) and is caused by dominant negative mutations of the *CLCN7* gene (Cleiren et al., 2001), encoding the ClC-7 protein (Fig. 65.2) already described for OPBT4 ARO osteopetrosis. OPTA2 corresponds to the ADO2 phenotype and is caused mostly by single amino acid substitutions that alter the ClC-7 conformation. The frequency of these gene mutations accounts for about 70% of ADO2 cases, the remaining 30% still lacking a genetic diagnosis. Given that the ClC-7 protein is a homodimer, it is thought that OPTA2 patients express an assortment of mutated homodimers, normal homodimers, and heterodimers with one normal and one mutated subunit (Perdu et al., 2012) (Fig. 65.6). This condition reduces, but does not abolish, the chloride transport. The clinical result is a milder form of osteopetrosis, generally not lethal, but very heterogeneous in terms of penetrance, symptoms, and sufferance (Bénichou et al., 2000; Waguespack et al., 2007; Del Fattore et al., 2006; Bollerslev et al., 2013).

Current therapies

The turning point of the therapy of osteopetrosis was when the hematogenous and circulating origin of osteoclast precursors was discovered (Marks Jr and Walker, 1981) and when osteopetrosis was cured in mice by parabiosis (Walker, 1973) and by bone marrow transplantation (Walker, 1975). This was followed by the first osteopetrotic infant treated by bone marrow transplantation in 1980 (Coccia et al., 1980). Since then, hundreds of kids have been subjected to hematopoietic stem cell transplantation (HSCT) (Teti and Schulz, 2013), with outcomes that improved over the years (Driessen et al., 2003; Teti and Schulz, 2013). This therapy is not without limitations: (1) it is suitable only for ARO; (2) although most ARO patients can be treated, OPBT5 (*OSTM1* gene mutations) has severe neurodegeneration that HSCT cannot cure; (3) OPBT4 (*CLCN7* gene mutations) must be carefully evaluated neurologically before HSCT is performed due to the high likelihood of severe neurodegeneration in these patients as well; (4) OPBT2 (*TNFS11* gene mutations) is not osteoclast autonomous and cannot benefit from replacement of the osteoclast lineage by HSCT; (5) dwarfism and impaired vision and hearing do not improve if symptoms are already present at the time of HSCT; (6) lethal complications intrinsic to the procedure do not make HSCT suitable for intermediate osteopetrosis and ADO, such as OPTB3 (*CAII* mutations) and OPTA2 (*CLNC7* dominant negative mutations), respectively. Despite these limitations, HSCT is the only effective therapy that may provide patients an acceptable quality of life, especially in cases with no mental retardation (Teti and Schulz, 2013; Schulz et al., 2015).

Unfortunately, so far, other therapies have failed to substantially alleviate the osteopetrotic symptoms. Analgesics and antibiotics can treat pain and infections (Saigal et al., 2015). Calcium and vitamin D_3 supplementation and treatment with PTH, attempted in the far past, were not successful (Glorieux et al., 1981; Blazar et al., 1984; Key Jr et al., 1993; Askmyr et al., 2009). Interferon-γ has contradictory effects on osteoclast generation (Takayanagi et al., 2000; Gao et al., 2007) and induces several important adverse effects, although it delays the disease progression and improves hematopoiesis to some extent (Key et al., 1992, 1995). Erythropoietin and glucocorticoids are also used to improve hematopoiesis (Meletis et al., 1995). Furthermore, some patients are subjected to blood transfusions (Teti and Econs, 2017). However, these treatments are palliative and in general they are used while waiting for HSCT to be available or in cases that are not suitable for HSCT or in which HSCT failed. ARO patients with no options for HSCT will not be healed by any of these therapies, but they can be subjected to surgery to reduce fractures, decompress nerves, or treat hydrocephalus (Hwang et al., 2000).

No cure is available for ADO2 patients. The most harmful symptoms are pain and multiple fractures prone to developing osteomyelitis, which are treated with analgesics, surgery, and antibiotics, respectively (Landa et al., 2007; Saigal et al., 2015). HSCT is not performed given the intrinsic risky complications, unless symptoms are so severe as to become life threatening (Teti and Econs, 2017), which is a rare condition in ADO2. A phase II safety clinical trial has recently been completed, using an interferon-γ formulation, but results showed no efficacy (Imel et al., 2019). It is clear, though, that advanced research must be performed to overcome these bottlenecks and provide patients with effective therapeutic options.

Future therapeutic scenarios

Research does not arrest, and we are now in a phase of flourishing investigations on new therapies, also taking advantage of recent discoveries in other fields. Certainly, there is a substantial general progress in the HSCT technology under the pressure of medical needs for more frequent diseases, such as hematological cancers (Norkin and Wingard, 2017). These improvements are proving beneficial for the ARO forms suitable for HSCT as well, now infused also with hematopoietic stem cells (HSCs) donated by mismatched donors. Furthermore, the better understanding of the disease, the ease in finding useful information through certified websites, and the availability of genetic tests make early diagnosis of osteopetrosis more readily available also in nonspecialized centers. This is a *conditio sine qua non* for HSCT to be successful and to prevent irreversible symptoms, such hypovision and hypoacusis (Driessen e al., 2003). So, the HSCT field is already projected into the future also for osteopetrosis.

However, there is still very much that must be done for those conditions that have no cure at all. Gene therapy is under investigation for several diseases and could be a substantial advantage versus HSCT as it would allow the use of genetically modified patient HSCs instead of donor HSCs (Sessa et al., 2016). Gene therapy is being successfully employed for some congenital immunodeficiencies using lentivirus-transduced cells (Sessa et al., 2016). These studies have allowed important adverse effects noted in previous pioneer studies to be overwhelmed, making the therapy safe and effective (Sessa et al., 2016). Furthermore, there is great interest nowadays in the CRISPR/Cas9 genome editing technology, which is opening new doors to innovative genetic manipulations to cure diseases (Niu et al., 2016). One of these diseases could certainly be osteopetrosis, facilitated by its hematological etiology.

Gene therapy can also be associated with cell therapy and the paradigm for this innovation is the induced pluripotent stem cell (iPSC) technology (Neri et al., 2015; Fields et al., 2016). Autologous iPSCs could theoretically be genetically manipulated to replace the mutant gene and reinoculated into the patient, with the ultimate goal to engraft the bone marrow and provide corrected osteoclast lineage. Unfortunately, this procedure is still in its infancy and presents with a series of important drawbacks difficult to tackle: (1) reprogramming somatic cells requires transduction of several genes of pluripotency; (2) reprogramming technology is a long procedure during which osteopetrosis symptoms are likely to progress and become irreversible; (3) injected into experimental animals, iPSCs develop teratomas that are incompatible with safety; (4) hypothetically, corrected iPSCs could be predifferentiated and selected in vitro prior to their use in vivo: the inoculation of preosteoclasts into osteopetrotic mice has provided a proof of principle that the osteopetrotic phenotype could be improved, but the data has not yet demonstrated its efficacy as a therapy (Wakkach et al., 2008; Cappariello et al., 2010). However, given the great interest in the use of corrected iPSCs in medicine and the successful outcomes in local applications, such as in retinal disease (Fields et al., 2016), this therapy holds promise for future development.

As mentioned earlier, RANKL deficiency is not an osteoclast-autonomous disease, which prevents the employment of HSCT in OPBT2 (*TNFS11* gene mutations). These patients can receive only palliative interventions and are expected to die within their first decade of life. Two approaches could be anticipated for OPBT2: (1) pharmacological treatment with recombinant RANKL and (2) skeletal mesenchymal stem cell transplantation (SK-MSCT). Neither approach is available as of this writing, and research in these fields is experiencing important limitations. RANKL administration has been attempted in a mouse model of RANKL deficiency (Lo Iacono et al., 2012), with successful rescue of hematopoiesis, lymphopoiesis, and bone phenotype in mice treated for 1 month with soluble RANKL (Lo Iacono et al., 2012). Unfortunately, the study unveiled overdose complications causing expansion of lymphoid aggregates present in the lungs leading to respiratory impairment and death (Lo Iacono et al., 2012). The means to prevent accumulation of overdose over time can be investigated, for instance, by dose titration followed by dose scaling down at the time when the bone phenotype is normalized. An important limitation of this approach is the need for corporate interest to develop a pharmacological therapy for an extremely rare condition, estimated to affect only 5:25,000,000 live births.

SK-MSCT is very promising as a cure not only for osteopetrosis but also for other connective diseases. RANKL-producing cells, such as osteoblasts and osteocytes (Nakashima and Takayanagi, 2011), originate from SK-MSCs; therefore heterologous or corrected autologous SK-MSCs could be employed to provide patients with a source of RANKL, which could replenish the defective cytokine. Research on SK-MSCT has been ongoing for many years, but there are no substantial results yet supporting its therapeutic employment (Zhao and Liu, 2016). Therefore, a challenge for the future would be to optimize SK-MSCT and make it suitable for therapy. However, alternative approaches could be the subcutaneous implantation of devices incorporating RANKL-producing cells, which could exert a systemic effect, releasing soluble RANKL into the circulation. Calvarial osteoblasts have been used with this aim, implanted in diffusion chambers used long ago to investigate in vivo bone metabolism under controlled conditions (Gundle et al., 1995). Osteoblasts were cultured on hydroxyapatite supports functionalized to adsorb the catalytic domain of metalloproteinase-14, known to cleave the soluble domain of RANKL, which was then released into the circulation (Cappariello et al., 2015). Osteoclastogenesis was observed in RANKL-null mice receiving such devices, providing a proof of principle for future developments. Compared with pharmacological treatment with soluble RANKL, this method could prevent overdose, given that osteoblasts are physiologically regulated to produce RANKL, for instance, by PTH (Cappariello et al., 2014). Furthermore, caged into diffusion chambers, donor cells remain segregated from the host immune system, which should prevent or at least attenuate the immune response. Finally, donor cells could be engineered to express soluble RANKL in a controlled manner, theoretically improving efficacy while preventing overdose effects.

Most relevant is the lack of significant therapies for ADO2. The disease is generally nonlethal, but a large portion of patients live with debilitating symptoms, one being multiple and difficult to repair fractures. A 2015 approach resuscitated the interferon-γ therapy with a new indication for ADO2 (Alam et al., 2015). The approach was promising in ADO2 mice, in which interferon-γ improved the bone phenotype over an 8-week treatment. The reduction in bone volume induced by the treatment was approximately halfway between wild-type mice and ADO2 mutant mice. Therefore, although significant, the phenotypic rescue was unfortunately incomplete. However, based on these results and given that interferon-γ is approved for other diseases, such as chronic granulomatosis and ARO, a phase II safety clinical trial has recently been completed, unfortunately with negative results (Imel et al., 2019).

In an innovative perspective, because of its dominant negative nature, ADO2 is thought to be a target for RNA interference therapy. Our laboratory has been engaged for many years in this field and has patented a mutation-driven approach that proved effective in ADO2 mice in a variety of treatment regimens (Capulli et al., 2015; Maurizi et al., 2018). *Clcn7*^{G213R}

represents the mouse homolog of the most frequent human ADO2 mutation, and *Clcn7*^{G213R} heterozygous mice (Alam et al., 2014) have been challenged with *Clcn7*^{G213R}-specific small interfering (si) RNA proven to be effective in silencing the mutant, but not the normal, *Clcn7* mRNA (Capulli et al., 2015; Maurizi et al., 2018). The *Clcn7* gene is haplosufficient, as demonstrated by the normal phenotype of heterozygous carriers of *Clcn7* loss-of-function mutations. Therefore, we have created a condition of pseudohaplosufficiency that systemically rescued the bone phenotype upon 4 weeks of administration in young mice and 12 weeks in adult mice. Given that this siRNA complements the human *CLCN7*^{G215R} as well, and that the therapy is patented, corporate interest is expected to be in line with that for therapeutic siRNA developments in the search to cure other diseases (Chakraborty et al., 2017).

Conclusions

Over time, osteopetrosis moved from being an experiment of Nature to a family of, at least in part, treatable diseases. Instrumental to understanding the mechanisms of osteoclastogenesis and bone resorption, basic research has set the platform for genetic diagnosis and therapeutic approaches to osteopetrosis, which has given hope to patients and their families. The way to go is still demanding, but the results so far are encouraging and a tight interaction between basic and clinical scientists is anticipated to provide innovative solutions for the well-being of patients.

Chapter 66

Hypophosphatasia: nature's window on alkaline phosphatase function in humans

Michael P. Whyte[1,2]

[1]*Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children - St. Louis, St. Louis, MO, United States;* [2]*Division of Bone and Mineral Diseases, Department of Internal Medicine, Washington University School of Medicine at Barnes-Jewish Hospital, St. Louis, MO, United States*

Chapter outline

Introduction

Alkaline phosphatase (ALP) was discovered by Robert Robison, PhD, in 1923 (Robison, 1923). During the next decade, he and his coworkers would advance his hypothesis that this phosphomonoester phosphohydrolase functioned importantly in skeletal calcification, emphasizing the liberation of inorganic phosphate (Pi), perhaps from hexosephosphoric ester substrate. Liberation of Pi to bind with calcium (Ca^{++}) would allow for hydroxyapatite (HA) crystal formation and growth. However, by 1932 Robison had concluded that some additional unknown factor conditioned this process (Robison, 1932). As I will review, this proved to be the ALP natural substrate and inhibitor of biomineralization, inorganic pyrophosphate (PPi).

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00066-X

In the 1930s, physicians began to appreciate the important clinical insight that derives from quantitation of ALP activity in serum. Elevated levels (*hyper*phosphatasemia) usually denoted skeletal or hepatobiliary disease. In contrast, *hypo*-phosphatasemia usually went ignored (Wolf, 1978). Quantitation of serum ALP activity soon became the most frequently performed enzyme assay (McComb et al., 1979; Siller and Whyte, 2018).

In 1948, implication of the ubiquitously expressed "tissue nonspecific" (bone/liver/kidney) isoenzyme of ALP (TNSALP) as essential for skeletal mineralization began with the discovery by John C. Rathbun, MD, of hypophosphatasia (HPP) (Rathbun, 1948). In 1988, HPP was confirmed to be an inborn error of metabolism, as it was caused by loss-of-function mutation of the *ALPL* gene that encodes TNSALP (OMIM, 171760). The defective skeletal mineralization of HPP had been shown in the 1960s to involve deficient hydrolysis of PPi by TNSALP (Weiss et al., 1988a; Whyte, 1994). We now understand that ALPs are ubiquitous in nature (McComb et al., 1979; Harris, 1990; Moss, 1992; Whyte, 1994), yet there is uncertainty about the purpose of the three additional ALP isoenzymes in humans (Millán, 2006; Millán and Whyte, 2016).

In this chapter, I provide a brief history of the discovery of ALP, discuss the proposed function(s) of ALP in humans, and review the molecular and biological chemistry of the ALPs. Subsequently, HPP is described in some detail, and I summarize the most significant revelations about ALP from this "experiment-of-nature." Advances and refinements concerning the role of TNSALP revealed by mouse models of HPP are discussed (Millán, 2006; Millán and Whyte, 2016). Finally, the multinational approval in 2015 of asfotase alfa, a TNSALP-replacement therapy that restores "hard tissue" mineralization in HPP, returns us "full circle" concerning ALP.

History and proposed physiological roles of alkaline phosphatase

A 1923 publication by Robert Robison, PhD (Fig. 66.1**),** reported abundant phosphatase activity in bone and cartilage extracts from rats and rabbits, especially those with rickets. Thus, he hypothesized that the new enzyme acted in skeletal mineralization, perhaps by hydrolyzing a hexosephosphoric ester to increase the concentration of Pi available locally to bind with calcium (Ca^{++}) for HA crystal formation and growth (Robison, 1923). In 1924, he and Katherine Soames, PhD, reported that this phosphatase precipitated mineral into rachitic rat bone when monophosphate esters were the only source of Pi. In their laboratory, the enzyme became detectable using a distinctly alkaline pH optimum (Robison and Soames, 1924). However, Robison knew this pH was not physiological and called the enzyme "bone phosphatase" (Robison, 1932). The term "alkaline phosphatase" was introduced in the 1930s by others to distinguish it from a recently identified "acid phosphatase" that was becoming implicated in certain metastatic bone diseases (Siller and Whyte, 2018). However, concerns were emerging that challenged Robison's hypothesis (McComb et al., 1979). ALP activity was abundant not only in the skeleton but also in tissues that normally did not calcify (e.g., liver, intestine, and placenta). Furthermore, Robison had not identified its physiological substrate(s) (Neuman and Neuman, 1957).

FIGURE 66.1 Robert Robison, PhD, DSc, FRS (1883−1941), the discoverer of alkaline phosphatase in 1923. *Reproduced with permission from the Godfrey Argent Studio, as published in Obituary Notices of Fellows of The Royal Society, Vol. 3, 1941, p. 929.*

Then in the 1960s, electron microscopy rejuvenated Robison's hypothesis when the earliest site of HA crystal deposition in the skeleton was discovered by H. Clark Anderson, MD, to be within unique extracellular structures called "matrix vesicles" (MVs) (Anderson, 1969). MVs seem to be buds of the plasma membrane of chondrocytes and osteoblasts. They contain many enzymes including pyrophosphatase (PPi-ase) and ATPase (Anderson, 1992) and are especially rich in ALP (Ali, 1986). During the initial ("primary") phase of skeletal mineralization, HA crystals appear and then grow within MVs. When they rupture the MV, "secondary" mineralization features HA crystal growth for their deposition into the organic matrix of the skeleton (Ornoy et al., 1985). In 1975, nucleoside phosphate released from dying cells was proposed as the ALP substrate for Pi necessary to fulfill Robison's hypothesis (Majeska and Wuthier, 1975).

Further evidence that ALP functions in skeletal mineralization came from reports that used stereospecific inhibitors of ALP activity, such as L-tetramisole, which blocked calcification in vitro (Fallon et al., 1980). However, it was later shown that stereoisomers that did not block ALP activity would also impair mineralization (Whyte, 1994). In the clinic, it had been known for decades that circulating ALP activity correlated with the severity of disorders that involve accelerated bone formation (McComb et al., 1979), such as Paget bone disease (Kanis, 2002).

By the 1990s, many biological roles had been proposed for ALP (McComb et al., 1979; Harris, 1990; Moss, 1992; Whyte, 1989, 1994) and included provision of the nonphosphate moiety, transferase action in the synthesis of phosphate esters, regulation of Pi metabolism, maintenance of phosphoryl metabolite levels, and action as a phosphoprotein phosphatase (McComb et al., 1979; Alpers et al., 1990; Harris, 1990; Muller et al., 1991; Simko, 1991; Moss, 1992; Whyte, 1994; Millán and Whyte, 2016). Cell membrane ALP was hypothesized to condition not only the active transport of Pi but also Ca^{++}, fat, protein, carbohydrate, and Na^{+}/K^{+} (Muller et al., 1991; Simko, 1991). As the four isoenzymes of ALP in humans became recognized (see later), sequence analyses suggested they coupled to other proteins including collagen (Wu et al., 1992). In the placenta, ALP bound the Fc receptor of IgG and perhaps transcytosed this immunoglobulin (Makiya et al., 1992). During embryogenesis, ALP seemed to act intracellularly (Narisawa et al., 1992), although we now know that ALP functions importantly when bound to cell surfaces (see later).

Additional proposals also emerged for TNSALP action specifically in skeletal mineralization (Table 66.1) (Whyte, 1989, 1994). Perhaps TNSALP was a plasma membrane transporter for Pi (Wuthier and Register, 1985), an extracellular Ca^{++}-binding protein that stimulates Ca^{++}-Pi precipitation and orients mineral deposition into osteoid (DeBarnard et al., 1986), a Ca^{++}/Mg^{++}-ATPase (Birge and Gilbert, 1974), or a phosphoprotein phosphatase that conditions skeletal matrix for ossification (Lau et al., 1985; Tsonis et al., 1988). Certain structural domains of ALP suggested it could bind to types I, II, and X collagen in cartilage and bone (Tsonis et al., 1988; Wu et al., 1992). Nevertheless, a theory that captured Robison's missing "factor" (Robison, 1932) emerged and gained preeminence in the 1960s; i.e., TNSALP hydrolyzes an inhibitor of calcification (Neuman and Neuman, 1957; Caswell et al., 1991; Moss, 1992; Whyte, 1994; Heinonen, 2001; Millán, 2006; Millán and Whyte, 2016), with the principal candidate being PPi. High concentrations of extracellular PPi bind to HA and thereby impair HA crystal growth. TNSALP was shown to hydrolyze PPi (Moss et al., 1967). In fact (see later), plasma and urine levels of PPi became recognized as increased in HPP (Russell, 1965; Russell et al., 1971) consistent with PPi being a natural substrate of TNSALP.

Ironically, however, approaching a century after its discovery, methods for assaying ALP activity still do not deal with Robison's quandary of the alkaline pH optimum (McComb et al., 1979; Harris, 1990; Moss, 1992; Whyte, 1994; Coburn et al., 1998). In both clinical and research laboratories, ALP continues to be measured using nonphysiological alkalinity (e.g., pH 9.2 to 10.5). Furthermore, the assays involve high concentrations (millimolar) of artificial substrates whose

hydrolysis products can be followed colorimetrically (e.g., p-nitrophenylphosphate) (McComb et al., 1979). Also, biological specimens for ALP assay are diluted into buffers without Pi, although Pi competitively inhibits TNSALP (Coburn et al., 1998). Such assays were devised especially for their clinical utility (Wolf, 1978), yet it had been known for decades that the pH optimum for ALP is considerably less alkaline for lower concentrations of physiological substrates, although hydrolytic rates are reduced (McComb et al., 1979; Moss, 1992). Until the discovery of the natural substrates for TNSALP in studies of HPP, the significance of this was unknown (McComb et al., 1979; Harris, 1990; Moss, 1992; Whyte, 1994).

To understand what HPP teaches us about ALP, it is helpful to review the genomic structure, protein chemistry, and enzymology of ALP.

Genomic structure, protein chemistry, and enzymology of alkaline phosphatase

ALP (orthophosphoric-monoester phosphohydrolase, alkaline optimum, EC 3.1.3.1) is found throughout nature in plants and animals (McComb et al., 1979). In humans, four ALP isoenzymes are encoded by four separate genes (Millán, 1988, 2006; Harris, 1990; Moss, 1992). Three of the isoenzymes have essentially tissue-specific expression and are designated intestinal, placental, and germ-cell (placental-like) ALP. The fourth ALP isoenzyme is expressed ubiquitously and therefore is designated TNSALP (Stigbrand and Fishman, 1984; Harris, 1990; Moss, 1992). Skeletal, hepatic, and renal tissue are especially rich in TNSALP. The distinctive physicochemical properties (heat stability, electrophoretic mobility, etc.) among ALPs purified from human bone, liver, and kidney are lost upon exposure to glycosidases (Moss and Whitaker, 1985), and TNSALP is therefore a family of "secondary" isoenzymes (I will call them "isoforms"). They are encoded by the same gene, have the identical polypeptide sequence, and differ only by posttranslational modifications involving carbohydrates (Harris, 1980).

The gene mapping symbol for TNSALP is *ALPL* ("ALP-liver"), although the function of the liver isoform of TNSALP is not known (see later). *ALPL* is located near the tip of the short arm of chromosome 1 (1p36.1−p34), whereas the genes for the intestinal, placental, and germ-cell ALPs are at the tip of the long arm of chromosome 2 (2q34−q37) (Harris, 1990; Millán, 2006). *ALPL* seems to represent the ancestral gene, whereas the tissue-specific ALPs were likely formed by gene duplication (Harris, 1990). *ALPL* is somewhat larger than 50 kb and contains 12 exons, 11 of which are translated to form the mature enzyme consisting of 507 amino acid residues (Weiss et al., 1988b). TATA and Sp1 sequences may be regulatory elements, but basal expression seems to reflect "housekeeping" promoter effects, whereas differential expression in various tissues may be mediated by a posttranscriptional mechanism (Kiledjian and Kadesch, 1990). *ALPL* has two promoters and two corresponding 5′-noncoding exons, 1a and 1b. Their expression results in two different mRNAs with differing 5′-untranslated regions (Nosjean et al., 1997). Transcription occurs preferentially from the upstream promoter (1a) in osteoblasts and from the downstream promoter (1b) in the liver and kidney (Millán, 2006).

The tissue-specific ALP genes are smaller than *ALPL*, primarily owing to shorter introns. Amino acid sequences deduced from their cDNAs suggest 87% positional identity between placental and intestinal ALP but only 50%−60% identity between the tissue-specific ALPs and TNSALP (Harris, 1990).

The amino acid residue sequence of TNSALP indicates five potential N-linked glycosylation sites (Weiss et al., 1988). N-glycosylation is necessary for catalytic activity. O-glycosylation characterizes the bone, but not the liver, isoform (Nosjean et al., 1997).

In 2000, the crystal structure for human placental ALP was delineated at 1.8-Å resolution (Le Due et al., 2000). The active site of TNSALP would derive from a nucleotide sequence conserved in ALPs throughout nature (Henthorn and Whyte, 1992), reflect six exons, and comprise 15 amino acid residues (Zurutuza et al., 1999).

ALPs are Zn^{++}-metalloenzymes (McComb et al., 1979). Catalytic activity requires a multimeric configuration of identical subunits with each monomer having one active site and two Zn^{++} atoms that stabilize the tertiary structure (Kim and Wycoff, 1991).

ALPs are generally considered homodimeric in the circulation (McComb et al., 1979). TNSALP, in its symmetrical dimeric form, has αβ topology for each subunit including a ten-stranded β-sheet at its center (Hoylaerts and Millán, 1991). However, in tissues, ALPs are tethered (see later) to cell surfaces, perhaps as homotetramers (Fedde et al., 1988).

In vitro, ALPs have broad substrate specificities and pH optima that depend on the type and concentration of phosphocompound undergoing catalysis (McComb et al., 1979). Catalytic activity requires Mg^{++} as a cofactor (McComb et al., 1979). PPi as well as phosphoesters can be hydrolyzed (Xu et al., 1991). The reaction involves phosphorylation−dephosphorylation of a serine residue. Dissociation of the covalently linked Pi seems to be the rate-limiting step. In fact, Pi is a potent competitive inhibitor of ALP (McComb et al., 1979; Kim and Wyckoff, 1991; Coburn et al., 1998). However, it may also be that Pi stabilizes the enzyme (Farley, 1991).

Uncertainties persist about the biosynthesis of ALP in higher organisms. The gene sequences of the human ALP isoenzymes indicate that the nascent polypeptides have a short signal sequence of 17−21 amino acid residues (Harris, 1990) and a hydrophobic domain at their carboxyl terminus (Weiss et al., 1988b). Intracellular degradation of ALPs can involve proteasomes (Cai et al., 1998). Nevertheless, these ALPs link to the external surface of plasma membranes tethered to the polar head group of a phosphatidylinositol−glycan moiety (Whyte et al., 1988; Whyte, 1994) and can be released by phosphatidylinositol-specific phospholipase (Fedde et al., 1988). However, their precise interaction with phosphatidylinositol may differ among ALP isoenzymes (Seetharam et al., 1987).

Lipid-free ALP is the moiety normally found in the circulation. Yet, the mechanisms for ALP release from cell surfaces are not known. The process could involve a phosphatidase of the C or D type, detergent action, proteolysis, membrane fractionation, or lipolysis (Alpers et al., 1990).

In healthy men and women, nearly all ALP activity in serum or plasma derives from approximately equal amounts of the bone and liver isoforms of TNSALP (Millán et al., 1980). Infants and children, particularly newborns and adolescents, have higher bloodstream levels of the bone isoform (McComb et al., 1979). Some individuals with B and O blood types who are "secretors" increase the small amount of intestinal ALP in their circulation after ingesting a fatty meal (Langman et al., 1966; McComb et al., 1979). Typically, however, intestinal ALP contributes just a few percent to serum total ALP activity (maximum 20%) (McComb et al., 1979; Mulivor et al., 1985). Placental ALP is usually expressed and circulates only during the last trimester of pregnancy (Birkett et al., 1966). Various cancers, however, release placental or germ-cell ("placental-like") ALP (Millán, 1988) into the bloodstream. Clearance of circulating ALP, as for many other glycoproteins, probably involves uptake and degradation by the liver (Young et al., 1984).

Hypophosphatasia

Subnormal extracellular levels of Ca^{++} and Pi, or Pi alone, cause nearly all types of rickets and osteomalacia (Whyte, 2002; Drezner and Whyte, 2018). In fact, some believe that hypophosphatemia is common to all such patients (Tiosano and Hochberg, 2009). HPP is, however, a distinctive and remarkably instructive exception. This heritable form of rickets and osteomalacia has hypophosphatasemia as its biochemical hallmark. In HPP, circulating levels of Ca^{++} and Pi are typically normal but often elevated, and the skeleton does not mineralize properly (Whyte, 1994, 2001). Thus, HPP has been "nature's window" for understanding the important physiological role of TNSALP in humans. With the discovery beginning in 1988 (Weiss et al., 1988a) of loss-of-function mutations in TNSALP in HPP, Robison's hypothesis that ALP acts in biomineralization became confirmed. TNSALP was necessary not only for skeletal mineralization but also for mineralization of the teeth (Whyte, 1994). However, undisturbed function of other organs/tissues in HPP, notably the liver and kidney, questioned the biological significance for TNSALP elsewhere (Whyte, 1994, 2001).

History

John C. Rathbun, MD (Fig. 66.2), a Canadian pediatrician, coined the term "hypophosphatasia" in 1948 when he reported an infant boy who died of seemingly acquired rickets and epilepsy whose ALP activity in serum, bone, and other tissues

FIGURE 66.2 John C. Rathbun, MD (1915−1972), who identified and characterized hypophosphatasia in 1948.

obtained at autopsy was paradoxically subnormal (Rathbun, 1948). Hundreds of case reports of HPP are now in the medical literature (Whyte, 1994, 2001), and we now know the disorder's etiology and its key clinical, radiographic, biochemical, and skeletal histopathological features, and in addition understand well (but not completely) its pathogenesis (Whyte, 2018). A PubMed (http://www.ncbi.nlm.nih.gov/sites/entrez/) search from 1948 onward shows 687 articles with "hypophosphatasia" in the title, and 1072 where it appears in the text. Reviewed following, our understanding of both the metabolic basis for HPP and the physiological function of TNSALP was advanced importantly by the discoveries of elevated endogenous levels of three phosphocompounds (i.e., TNSALP natural substrates) in affected individuals. In 1955, in the era of paper chromatography to diagnose inborn errors of metabolism, identification of increased amounts of phosphoethanolamine (PEA) in urine provided a second biochemical marker for HPP other than hypophosphatasemia (Fraser et al., 1955; McCance et al., 1955). In 1965 and 1971, the discovery of elevated levels of PPi in the urine (Russell, 1965) and plasma (Russell et al., 1971), respectively, of HPP patients would explain the disorder's defective skeletal mineralization, because PPi was now recognized as inhibiting this process (Heinonen, 2001). In 1985, the discovery of often markedly elevated plasma concentrations of pyridoxal 5′-phosphate (PLP), the major circulating form of vitamin B_6 in HPP, coupled with an understanding of vitamin B_6 metabolism, revealed that TNSALP functions as a cell-surface enzyme. This explained the extracellular accumulation of these three phosphocompounds in this "inborn-error-of-metabolism" (Whyte et al., 1985).

Clinical features

Hypophosphatasia (OMIM #146300, #241500, and #241510) seems to occur in all ethnicities (Whyte et al., 2006). However, it is especially prevalent in Mennonites in Manitoba, Canada, where about 1 in 25 individuals carries a "founder" *ALPL* missense mutation (Greenberg et al., 1993), and 1:2500 newborns manifests the severe autosomal recessive disease (Leung et al.). Canadian Hutterites too have a relatively high prevalence of HPP. In Toronto, Canada, the incidence for what would be the severest forms of HPP was estimated in 1957 to be 1 per 100,000 live births (Fraser, 1957). Inexplicably, HPP seems to be particularly rare in people of black ancestry (Whyte et al., 2006).

Despite the high expression of TNSALP in bone, cartilage, liver, kidney, and adrenal tissues (and at least some ubiquitous TNSALP) in healthy individuals (McComb et al., 1979), HPP seems to disrupt only the skeleton and dentition directly (Whyte, 2001). Discussed later, vitamin B_6–dependent seizures are a metabolic consequence of HPP when it is most severe (Baumgartner-Sigl et al., 2007). Muscle weakness is often an important finding, but its pathogenesis is not understood.

Nevertheless, a remarkable feature of HPP is its extraordinarily wide-ranging expressivity, spanning from death in utero with an essentially unmineralized skeleton to early shedding of deciduous "baby" teeth without skeletal disease (Fraser, 1957; Whyte, 2001). In fact, many individuals with relatively mild biochemical characteristics of HPP and harboring one defective *ALPL* allele seem, at least early in adult life, to have escaped the disorder's complications and can be considered "carriers" (Whyte et al., 1982a). I consider HPP to manifest the most broad-ranging severity of all skeletal diseases. This partly reflects the polymeric nature of the active enzyme, the many ($>$ 360) different deactivating predominantly missense mutations found throughout *ALPL*, and the two patterns of autosomal inheritance (Weiss et al., 1988; Henthorn et al., 1992; Mornet et al., 1998; Whyte, 2000; Mumm et al., 2002). Some *ALPL* mutations have dominant/negative effects and cause autosomal dominant disease. However, it is increasingly apparent that other unknown genetic or nongenetic factors can significantly condition HPP expressivity. This is obvious from the discordant HPP severity that sometimes occurs among siblings sharing identical *ALPL* defects (Henthorn et al., 1992; Whyte et al., 2006; Mumm et al., 2006) **(**Fig. 66.3**)**. Accordingly, the prevailing nosology for patients with HPP (Whyte, 2001) remains a clinical one based primarily on consideration of age-of-onset as suggested by Fraser beginning in 1957 (Fraser, 1957). Understandably, an alternative *ALPL* mutation-based nosology might add too little for prognostication (Whyte, 2001).

Six principal forms of HPP are now discussed. The age at which the disorder presents and is diagnosed distinguished early on the perinatal, infantile, childhood, and adult forms (Fraser, 1957; Whyte, 2001). Those affected individuals who do not have skeletal disease but instead manifest dental features only are said to have "odontohypophosphatasia" (odonto-HPP) (Whyte, 2001). With the approval in 2015 of asfotase alfa as a TNSALP-replacement therapy for HPP, it became important to recognize "mild" versus "severe" forms of childhood HPP (see later). Nevertheless, this nosology of six forms of HPP does not unambiguously classify all patients, and it is important to appreciate that the disorder features a continuum of expressivity. An extremely rare form of HPP called "pseudohypophosphatasia" recapitulates infantile HPP, except that serum ALP activity is not subnormal but instead within or above the age-appropriate reference range in the clinical laboratory, where the assay reflects highly nonphysiological conditions (see later) (Scriver and Cameron, 1969; Whyte, 2001). Importantly, a not uncommon "benign perinatal" form of HPP, characterized from fetal sonography, revealed that

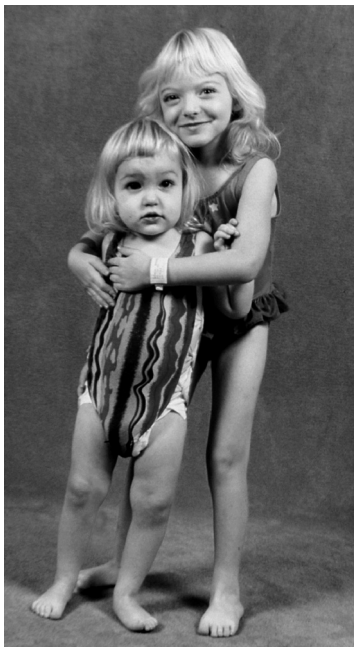

FIGURE 66.3 Variable clinical expressivity of hypophosphatasia is exemplified by these sisters who are compound heterozygotes sharing the same two *ALPL* missense mutations. The proposita (right) at age 5−3/12 years survived infantile HPP featuring poor weight gain, hypercalcemia with nephrocalcinosis, and severe rickets (Barcia et al., 1997) that was followed by short stature, premature loss of teeth, and craniosynostosis. Her younger sister (left) at age 2−2/12 years appears well and has mild rickets despite very similar hypophosphatasemia and endogenous elevations of the TNSALP substrates.

skeletal deformity in utero owing to HPP does not predict a lethal outcome (Moore et al., 1999; Pauli et al., 1999). This form of HPP manifests skeletal disease at birth but with spontaneous postnatal ex utero improvement, although with a broad-ranging clinical outcome (Wenkert et al., 2011).

The prognoses for the six major forms of HPP are determined by the severity of the skeletal disease. Typically, the earlier in life that skeletal signs and symptoms present, the worse the outcome (Fraser, 1957; Whyte, 2001). The benign prenatal form of HPP is, however, an important exception.

Perinatal hypophosphatasia

This most severe form of HPP (OMIM #241500), featuring profound generalized skeletal disease obvious in a neonate, reflects nearly a complete lack of mineralization of endochondral and membranous bone and typically causes death before or soon after birth. Remarkable skeletal softening can result in caput membranaceum and limbs that are short and deformed. Some affected newborns survive a few days or weeks but succumb to respiratory compromise owing to rachitic disease of the chest. In some, the lungs appear hypoplastic (Silver et al., 1988). There may be vitamin B_6−dependent seizures (Baumgartner-Sigl et al., 2007). Myelophthisic anemia can occur, perhaps from encroachment of excessive osteoid on the marrow space (Terheggen and Wischermann, 1984). Long-term survival is very rare (Whyte et al 2016a, 2019a).

Skeletal radiographs (Fig. 66.4) taken at birth readily distinguish perinatal HPP from even the most severe types of osteogenesis imperfecta or congenital dwarfism; the findings are diagnostic. Nevertheless, there is patient-to-patient variability (Shohat et al., 1991). In some stillborns, the bones appear nearly devoid of mineral (see Fig. 66.4A). In others, severe rachitic changes are apparent (see Fig. 66.4B). Occasionally, individual or sequential vertebrae appear completely or partly missing (Shohat et al., 1991). In the skull, the membranous bones may calcify only at their centers, giving the illusion that cranial sutures are widely separated ("open"), although they may be functionally closed (see Fig. 66.4C). Other unusual radiographic features (Whyte, 1988) include bony protrusions (Bowdler spurs) extending from the midshafts of the ulnas and fibulas (see Fig. 66.4D).

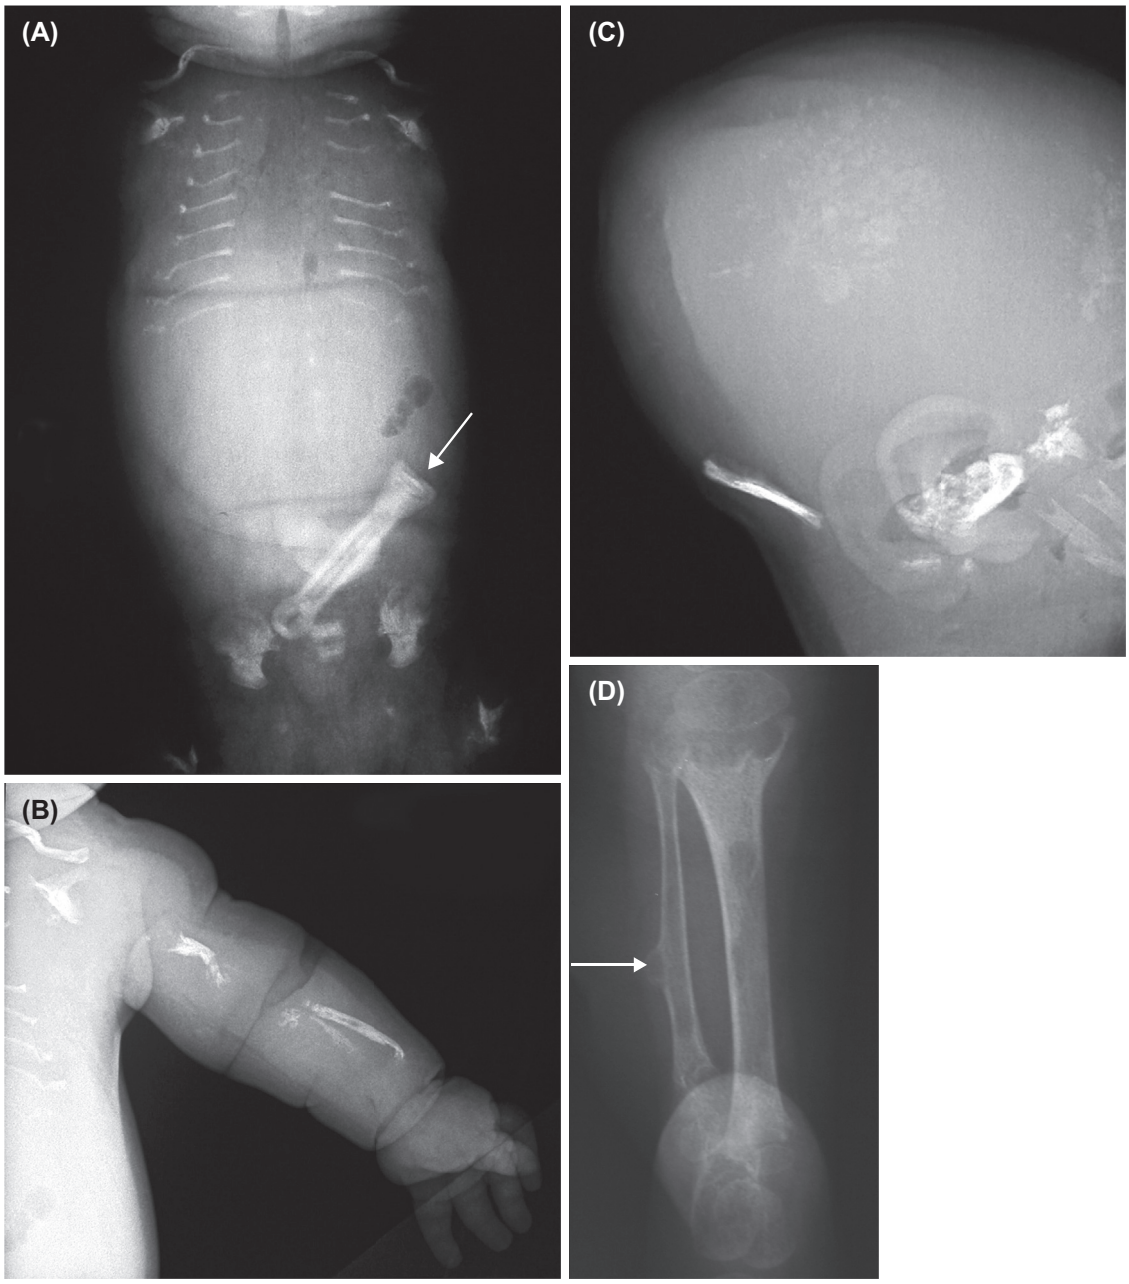

FIGURE 66.4 Perinatal hypophosphatasia. (A) Profound skeletal hypomineralization is obvious at birth (arrow points to umbilical cord clip). (B) The ends of the upper extremity long bones at 1 day of age show characteristic, extreme, rachitic changes. (C) Severe hypomineralization of the calvarium is present at 1 day of age. (D) A Bowdler spur (arrow) is found in some patients.

Infantile hypophosphatasia

This is the form of HPP (OMIM #241500) that was encountered by Rathbun (Rathbun, 1948). Signs and symptoms manifest after birth but before 6 months of age (Fraser, 1957; Whyte, 2001). Development may seem normal until there is hypotonia, poor feeding, and inadequate weight gain. At this time, the clinical and radiographic manifestations of rickets appear. Rarely, vitamin B_6–dependent epilepsy precedes the skeletal changes, and this complication predicts a lethal outcome (Baumgartner-Sigl et al., 2007). A flail chest from rib fractures, rachitic deformity, etc. often leads to pneumonia. Hypercalcemia and hypercalciuria are common and may explain episodes of recurrent vomiting as well as acquired nephrocalcinosis and renal compromise (Fraser, 1957; Whyte et al., 1982b, 2012).

Although the striking radiographic features of the skeletal disease of infantile HPP are diagnostic (see Fig. 66.5A), they are less severe than in perinatal HPP. Radiographs may suggest that the cranial sutures are wide open, but this can be an illusion from hypomineralization of the calvarium, and instead "functional" craniosynostosis can be present. Later, bony fusion of the sutures can occur if the patient survives infancy, causing the symptoms and complications of craniosynostosis (see Fig. 66.5B). In some babies, an abrupt transition from relatively normal-appearing diaphyses to poorly mineralized metaphyses (see Fig. 66.5C) suggests that metabolic deterioration occurred suddenly (Fraser, 1957). This observation is supported by the hypercalciuria and hypercalcemia that can develop in this form of HPP. Serial radiographs may reveal not only impaired skeletal mineralization (i.e., rickets) but also gradual, generalized demineralization of all osseous tissue (Whyte et al., 1982b) indicating a lethal outcome (Whyte et al., 2003; Cahill et al., 2007) (see Fig. 66.5D). However, spontaneous but unexplained improvement sometimes occurs (Ish-Shalom et al., 1986).

Childhood hypophosphatasia

This form of HPP (OMIM #241510) has especially wide-ranging expressivity (Fallon et al., 1984; Whyte, 2001). When asfotase alfa TNSALP-replacement therapy became available multinationally in 2015, characterization of mild versus

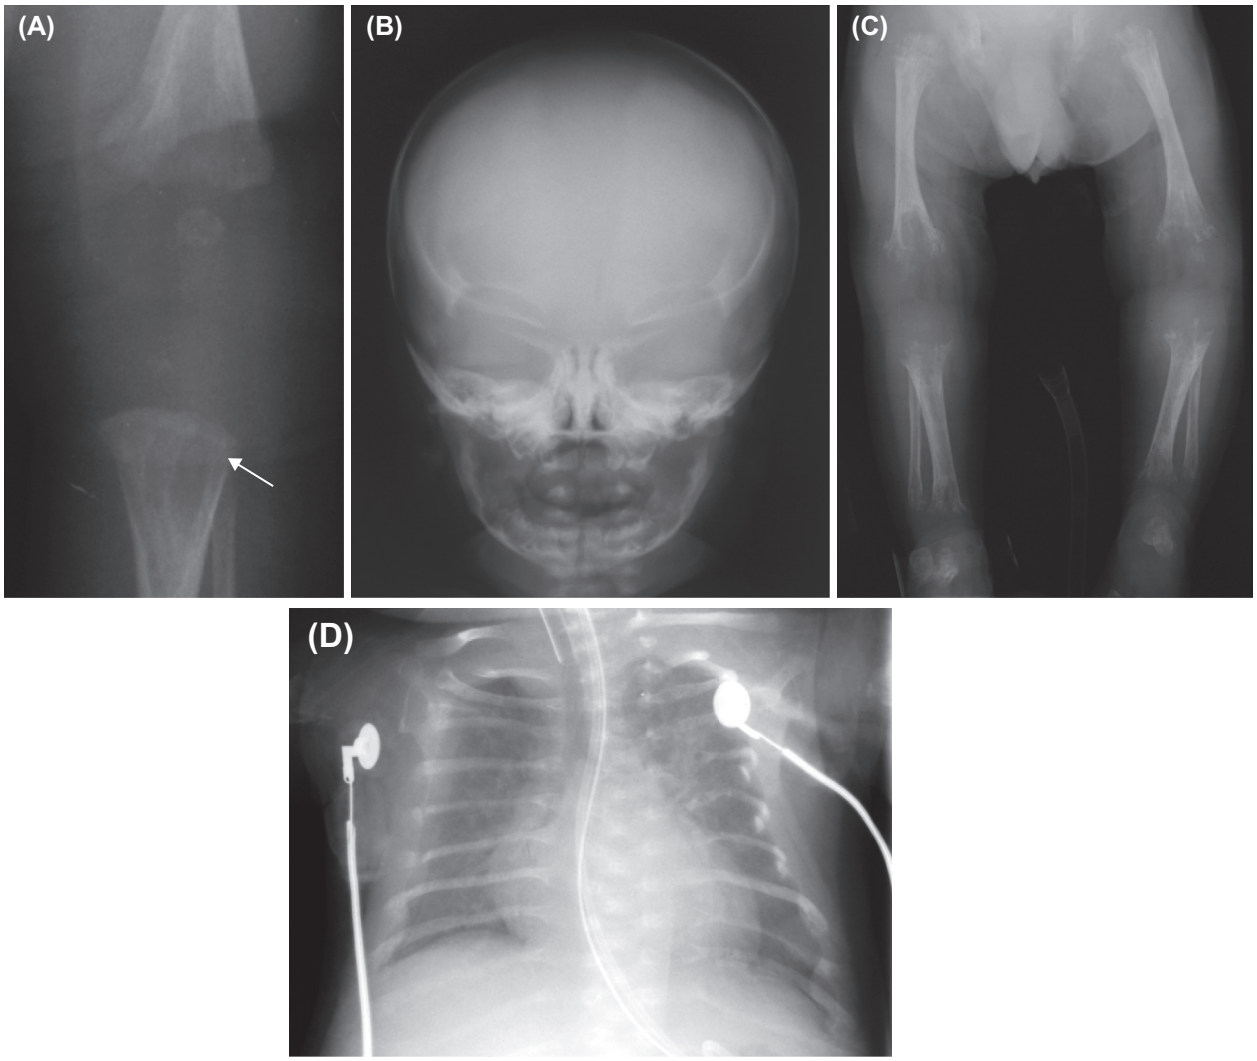

FIGURE 66.5 Infantile hypophosphatasia. (A) Characteristic tongues of radiolucency (arrow) extend from the growth plate into the metaphysis. (B) Cranial sutures appear widened in this hypomineralized skull at 1 month of age. (C) An abrupt transition seems to have occurred from well-mineralized diaphyses to poorly mineralized metaphyses by the age of 3 months. (D) The "bell-shaped" configuration of the chest from a soft thorax together with rib fractures will predispose to respiratory complications at 23 months of age.

severe childhood HPP helped in appreciating the clinical trial assessments of treatment (Whyte et al, 2015, 2016b). Childhood HPP is diagnosed when the presentation is after 6 months of age but before skeletal maturity. In 1953, premature loss of deciduous teeth was found to be a major clinical feature (Sobel et al., 1953). Early shedding of "baby" teeth (i.e., at less than 5 years of age) results from hypomineralization of aplastic or hypoplastic dental cementum (Van den Bos et al., 2005). Consequently, tooth roots are not bound sufficiently to the periodontal ligament (Lundgren et al., 1991), and teeth are shed painlessly, bloodlessly, and without trauma (see Fig. 66.6A). The mandibular incisors are typically lost first, and occasionally nearly all the primary dentition exfoliates prematurely. We have encountered premature loss of at least one deciduous tooth in 98% of our pediatric patients with HPP (Whyte et al., 2015). Delayed walking with a characteristic

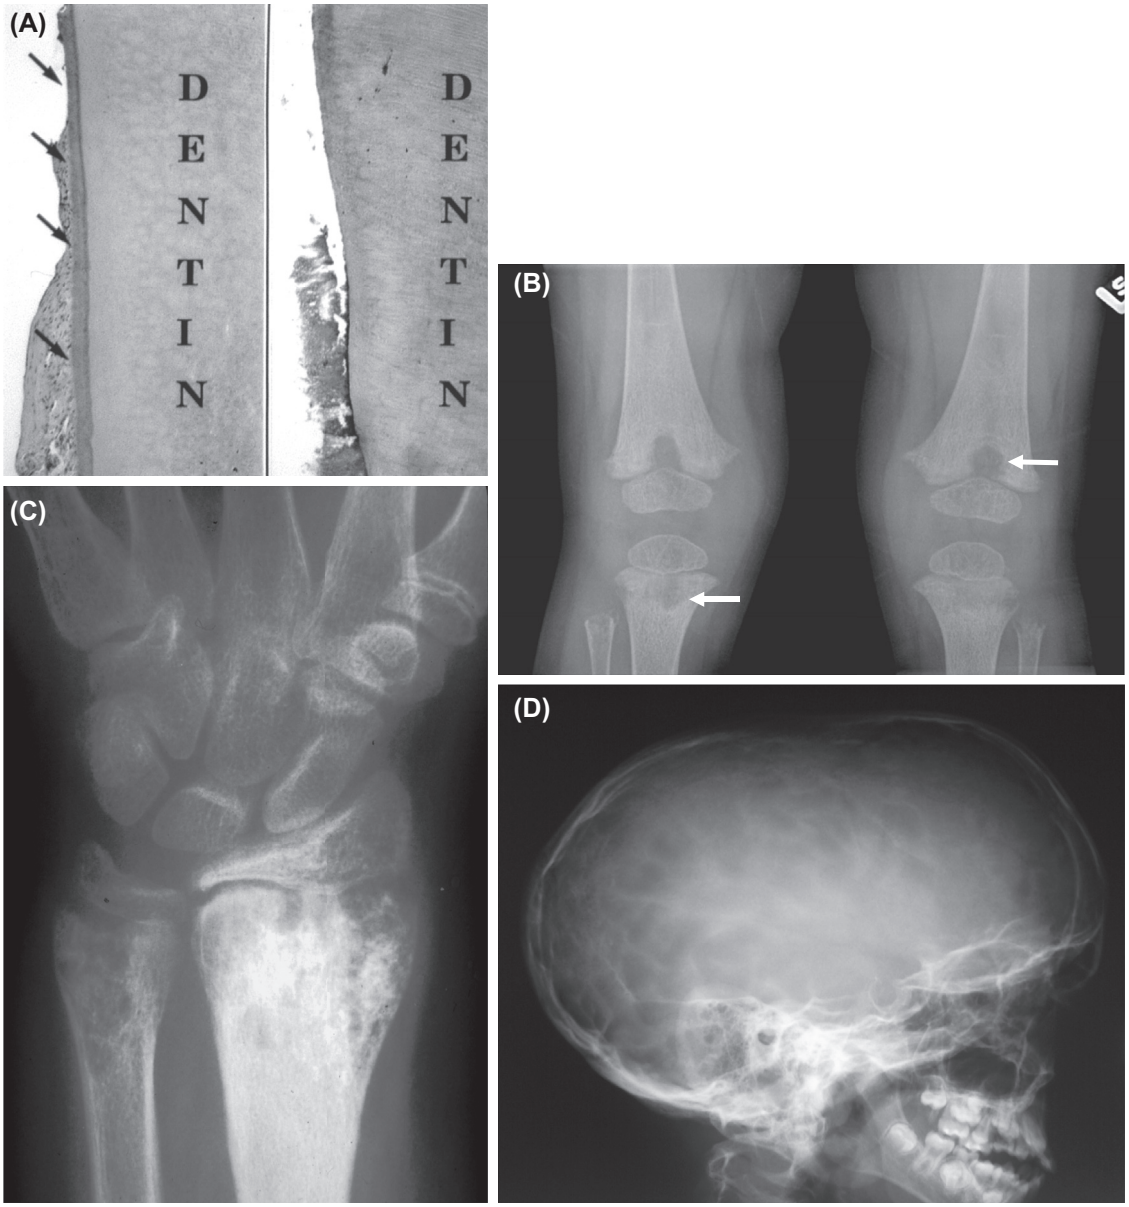

FIGURE 66.6 Childhood hypophosphatasia. (A) Dental findings. (Left) Decalcified section of part of the root of a maxillary incisor from a child with X-linked hypophosphatemia is essentially normal and shows primary cementum (delineated by arrows) at its surface (original magnification, ×150). (Right) In hypophosphatasia, cementum is absent (original magnification, ×150). (B) Characteristic tongues of radiolucency (arrows) project from growth plates into metaphyses at 16 months of age. (C) Idiopathic, patchy, metaphyseal osteosclerosis is a common finding. (D) A "beaten copper" appearance in the calvarium, here at 11 years of age, signifies premature closure of cranial sutures (craniosynostosis) that can lead to raised intracranial pressure. *(A) Reproduced with permission from Whyte, M.P., 2001. Hypophosphatasia. In: Scriver, C.R., Beaudet, A.L., Sly, W.S., Valle, D., (Eds.) The Metabolic and Molecular Bases of Inherited Disease, eighth ed., pp. 5313–5329. McGraw-Hill, New York.*

waddling gait is typical of severe childhood HPP. Patients may have appendicular muscle weakness (especially in the thighs) consistent with a nonprogressive myopathy (Seshia et al., 1990) and complain of stiffness and pain. There may also be delayed speech and language acquisition (unpublished observations).

Radiographs usually show characteristic focal "tongues" of radiolucency that project from rachitic growth plates into adjacent metaphyses (see Fig. 66.6B). Patchy metaphyseal osteosclerosis can occur (see Fig. 66.6C). True premature bony fusion of cranial sutures may raise intracranial pressure (see Fig. 66.6D). Dental radiographs sometimes show enlarged pulp chambers and root canals that characterize the "shell teeth" of various types of rickets.

Adult hypophosphatasia

This form of HPP (OMIM #146300) typically presents in middle age or later (Whyte, 2001; Whyte et al., 1982a). Not infrequently, however, such patients recall being told of early loss of their deciduous teeth followed by rickets or weakness in childhood. Subsequently, there is good health during young adult life (Weinstein and Whyte, 1981). Others among these patients may have been considered "carriers" of HPP until they manifested the characteristic complications of the disease (Sutton et al., 2012).

In adult HPP, osteomalacia often presents as recurrent metatarsal stress fractures (see Fig. 66.7A) (Whyte et al., 2007; Camacho et al., 2016). With more advanced disease, persistent aching or tenderness in the thighs or hips may be explained by femoral pseudofractures (see Fig. 66.7B) that will not heal spontaneously unless they progress to complete fractures (Coe et al., 1986; Khandwala et al., 2006; Whyte, 2009). Early loss or extraction of the secondary dentition is not uncommon, although the pathogenesis is not well understood (Whyte et al., 1982a). Calcium pyrophosphate dihydrate (CPPD) deposition disease troubles some patients, and occasionally overt attacks of pseudogout also reflect the increased endogenous levels of PPi (see later) (O'Duffy, 1970; Whyte et al., 1982a; McKiernan et al., 2014). Affected adults may suffer degeneration of articular cartilage from "pyrophosphate arthropathy" (Whyte et al., 1982a). Radiographs often reveal chondrocalcinosis and osteopenia (Lassere and Jones, 1990; Whyte et al., 1982a). In certain families manifesting hypophosphatasemia, Ca^{++}-Pi deposition manifests as "calcific periarthritis" (Guañabens et al., 2014) or ossification of ligaments (syndesmophytes) resembling spinal hyperostosis (Forestier's disease) (Lassere and Jones, 1990).

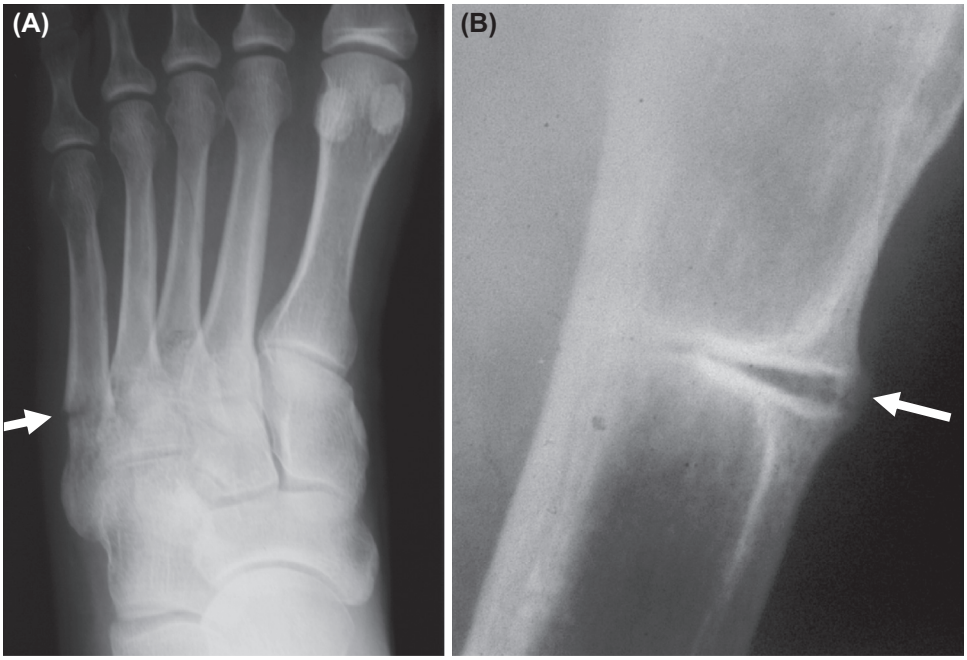

FIGURE 66.7 Adult hypophosphatasia. (A) Recurrent, poorly healing metatarsal stress fractures (arrow) may be the most common skeletal manifestation of the adult form of hypophosphatasia. (B) Femoral pseudofractures (arrow) are often painful and characteristically occur on the lateral aspect proximally in adult hypophosphatasia. They do not heal spontaneously unless a through-and-through break occurs.

Odontohypophosphatasia

This form of HPP is diagnosed when there are characteristic dental manifestations but no radiographic or histological evidence of rickets or osteomalacia.

Pseudohypophosphatasia

This extremely rare variant of HPP has been documented convincingly in two infants (Scriver and Cameron, 1969; Whyte, 2001). The clinical, radiographic, and biochemical findings are those of infantile HPP with one key exception—serum total ALP activity is not low but instead normal or increased (Whyte, 1994, 2001). The enzymatic explanation for pseudo-HPP involves defective TNSALP with diminished hydrolysis for PPi, PLP, and PEA endogenously, but normal or increased catalysis for artificial substrates in the nonphysiological conditions of the ALP assays used in clinical laboratories (see later) (Fedde et al., 1990).

Benign prenatal hypophosphatasia

Sonography may reveal a fetus with HPP showing bowing of major long bones that does not represent a lethal form of the disease. Spontaneous improvement of the skeletal deformities may occur later in the pregnancy as well as ex utero and then the severity range from infantile HPP to odonto-HPP (Moore et al., 1999; Pauli et al., 1999; Wenkert et al., 2005).

Laboratory diagnosis

Biochemical findings

HPP can be diagnosed with confidence from a consistent medical history and physical findings together with typical skeletal radiographic changes and serum ALP activity that is subnormal for the patient's age (Whyte, 2001, 2017b, Whyte et al., 2018). Even individuals with odonto-HPP are expected to have low serum ALP activity for their age, although their values can approach the lower end of carefully established reference ranges (see Fig. 66.8). Although HPP severity correlates inversely with age-appropriate serum ALP activity (Whyte et al., 2018), this correlation is not sufficiently strong to offer help with prognostication. In perinatal and infantile HPP, hypophosphatasemia is detectable at birth in umbilical cord blood (Whyte, 2001), while circulating ALP levels in carrier or affected mothers normalize or become elevated from placental ALP (Whyte et al., 1995).

Hypophosphatasemia can occur from other conditions (starvation, hypothyroidism, scurvy, severe anemia, Wilson's disease, celiac disease, multiple myeloma, hypomagnesemia, Zn^{++} deficiency, etc.), certain drugs (glucocorticoids, clofibrate, chemotherapy, vitamin D intoxication, milk-alkali syndrome, etc.), and exposure to radioactive heavy metals or a massive transfusion of blood or plasma (Macfarlane et al., 1992; McKiernan et al., 2014). These clinical situations should, however, be readily recognized and diagnosed. Especially rare cases of extremely severe osteogenesis imperfecta (Royce et al., 1988) and cleidocranial dysplasia in some infants (Unger et al., 2002; Wycoff et al., 2005) can also manifest hypophosphatasemia (apparently from the paucity of skeletal mass together with impaired cellular processing of bone ALP, or from osteoblast hypofunction, respectively). The skeletal changes of cleidocranial dysplasia might pose the greater confusion (Unger et al., 2002; Wycoff et al., 2005).

Transient increments in circulating bone ALP activity have been postulated for individuals with HPP after orthopedic surgery or significant fracturing (Whyte et al., 2013). In theory, circumstances that increase serum levels of any type of ALP (e.g., pregnancy, liver disease) could obscure the enzymatic and biochemical diagnosis of HPP. Thus, documenting hypophosphatasemia on more than one occasion during clinical stability, particularly from the earliest medical record, seems advisable for the exceptional, confusing patient. Quantitation of circulating ALP isoenzymes (Mulivor et al., 1985), isoforms of TNSALP (Whyte et al., 1996), or leukocyte ALP (Iqbal et al., 2000) in clinical laboratories may also be helpful.

Mineral homeostasis

Neither circulating Ca^{++} nor Pi levels are subnormal in HPP. Serum levels of 25(OH)D, $1,25(OH)_2D$, and parathyroid hormone (PTH) are typically normal (Whyte and Seino, 1982) unless altered physiologically by hypercalcemia or renal failure (Fallon et al., 1984). In fact, in infantile HPP there may be hypercalcemia, secondary hypoparathyroidism, and hyperphosphatemia together with hypercalciuria (Fraser, 1957; Shohat et al., 1991; Whyte et al., 1982b, 2012). The

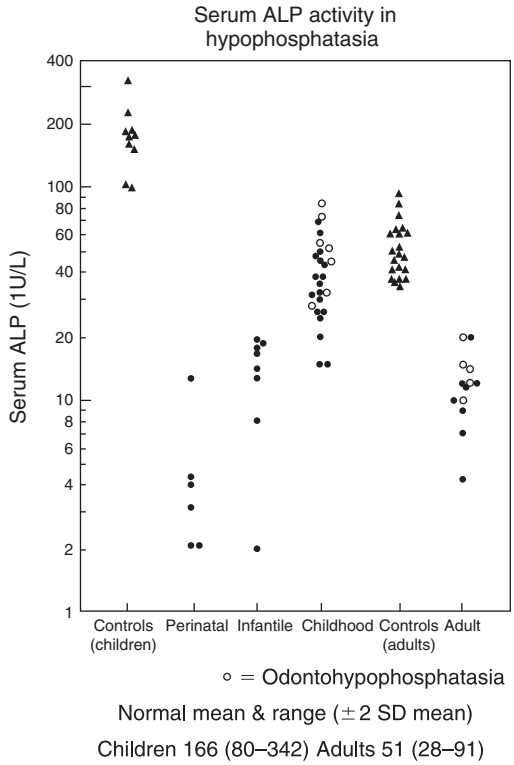

FIGURE 66.8 Serum alkaline phosphatase activity in hypophosphatasia. Serum total ALP activity in healthy children and adults and in 52 patients from 47 families with the various clinical forms of hypophosphatasia (note the logarithmic scale). All assays were performed at the Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children-St. Louis, St. Louis, MO, USA. *Reproduced with permission from Whyte, M.P., 2001. Hypophosphatasia. In: Scriver, C.R., Beaudet, A.L., Sly, W.S., Valle, D., (Eds.) The Metabolic and Molecular Bases of Inherited Disease, eighth ed., pp. 5313–5329. McGraw-Hill, New York.*

disturbed mineral homeostasis seems largely due to impaired Ca^{++} and Pi uptake by a poorly mineralizing and growing skeleton, sometimes with progressive skeletal demineralization perhaps reflecting patient immobility. Low circulating levels of PTH, reflecting increased ionized Ca^{++} levels, are common in severely affected pediatric patients. In childhood HPP, affected individuals may manifest hypercalciuria but usually not with hypercalcemia. In the past, several HPP patients were reported to have elevated serum PTH levels, but impaired kidney function may have been the explanation in some (Whyte, 1994). Rarely, affected adults with HPP do have primary hyperparathyroidism (Faas et al., 1974; Whyte, 2001).

Of interest, individuals with the childhood or adult forms of HPP have serum Pi levels above average values for age-matched controls (Whyte, 2001). Indeed, >50% of these patients are distinctly hyperphosphatemic. Enhanced renal reclamation of Pi (increased TmP/GFR) underlies this finding (Whyte and Rettinger, 1987). However, in only some instances is suppressed circulating PTH contributory. The pathogenesis seems complex, perhaps involving low levels of TNSALP activity in the kidney tubules, subnormal or inappropriately normal circulating levels of phosphatonins, and/or elevated levels of urinary PPi (Whyte et al., 2019). In contrast, hypophosphatasemia with hypophosphatemia from renal Pi wasting was reported in 1981 (Juan and Lambert, 1981).

Phosphoethanolamine

Elevated urine levels of PEA support a diagnosis of HPP (Rasmussen, 1968) but are not pathognomonic. Licata et al. (1978) demonstrated that phosphoethanolaminuria occurs in other conditions including several metabolic bone diseases. Reference ranges for urine PEA vary according to patient age and somewhat by diet and follow a circadian rhythm. PEA values can be unremarkable in mildly affected HPP patients. Age-adjusted normal ranges (expressed as micromoles of PEA per gram of creatinine) are for less than age 15 years, 83 to 222; for 15–30 years, 42 to 146; for 31–41 years, 38 to 155; and for more than 45 years, 48 to 93 (Licata et al., 1978).

Pyridoxal 5′-phosphate

Increased plasma PLP ("vitamin B_6") is a sensitive and reliable marker for HPP (Coburn and Whyte, 1988; Whyte et al., 2018) including pseudo-HPP (Cole et al., 1986). Even patients with odonto-HPP manifest this biochemical finding (Whyte et al., 1985, 2018). However, the earliest studies showed that PLP values overlap between the different clinical forms of HPP (see Fig. 66.9). Now testing is available from commercial laboratories. In order to avoid false-positive results, vitamin supplements containing pyridoxine should not be taken, if possible, for 1 week before blood is obtained for the assay. HPP disease severity correlates positively but not precisely with the elevation in plasma PLP concentration (Whyte, 2001; Whyte et al., 2018). Quantitation of plasma PLP after challenge with pyridoxine given orally once each day for 6 days seems to distinguish HPP patients especially well (Whyte, 1994). The procedure has been used to identify Canadian Mennonite carriers of severe HPP (Chodirker et al., 1990).

Inorganic pyrophosphate

Assay of PPi in plasma or urine is not commercially available. Urine PPi levels are increased in most HPP patients but can be unremarkable in mildly affected individuals (Caswell et al., 1991). Nevertheless, this test may help with carrier detection (Whyte, 2001). Assays of both circulating PPi and PLP were used as efficacy and safety parameters during the clinical trials of asfotase alfa treatment for HPP (Whyte et al., 2016b, 2019b; Kishnani et al., 2019).

Radiographic findings

Radiographic features are illustrated elsewhere for the principal clinical forms of HPP (see Figs. 66.4 to 66.7).

Histopathological findings

Histopathological disturbances in HPP that are a direct consequence of TNSALP deficiency seem to be hard tissue hypomineralization and perhaps the seemingly paradoxical ectopic mineralization of calcific periarthritis and enthesopathy.

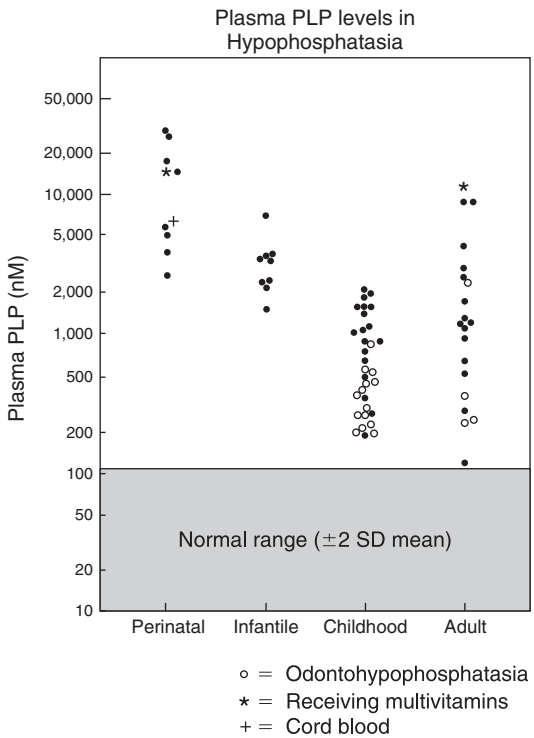

FIGURE 66.9 Plasma pyridoxal 5′-phosphate (PLP) levels in hypophosphatasia. PLP concentrations in plasma in various clinical forms of hypophosphatasia (hatched area is the normal range for children and adults). Note the logarithmic scale with some overlap between clinical forms (assays performed courtesy of Dr. Stephen P. Coburn, Fort Wayne State Developmental Center, Fort Wayne, IN). *Reproduced with permission from Whyte, M.P., 2001. Hypophosphatasia. In: Scriver, C.R., Beaudet, A.L., Sly, W.S., Valle, D., (Eds.) The Metabolic and Molecular Bases of Inherited Disease, eighth ed., pp. 5313–5329. McGraw-Hill, New York.*

Pulmonary hypoplasia (Silver et al., 1988) seems secondary to a small thorax. Myopathic changes are not observed despite muscle weakness.

Skeleton

In all but the mildest cases of HPP (i.e., odonto-HPP), nondecalcified sections of the skeleton reveal defective mineralization (Fallon et al., 1984; Ornoy et al., 1985). The degree of rickets or osteomalacia generally reflects the clinical severity overall (Fallon et al., 1984). Features of secondary hyperparathyroidism (present in rickets or osteomalacia associated with hypocalcemia) are typically absent (Fallon et al., 1984; Anderson et al., 1997). In severe cases, extramedullary hematopoiesis (Fallon et al., 1984; Ornoy et al., 1985) may reflect marrow space crowding owing to the osteomalacia.

In growth plates and osseous tissue, cellular sources of the bone isoform of TNSALP (chondrocytes and osteoblasts) are present (Anderson et al., 1997) but their TNSALP activity is deficient (Fallon et al., 1984; Ornoy et al., 1985). Other forms of rickets or osteomalacia cannot be excluded by their histopathological features unless ALP activity is assessed. In HPP, ALP activity in bone inversely reflects the degree of osteoid accumulation and therefore the severity of the skeletal disease (Fallon et al., 1984).

Electron microscopy of skeletal tissue obtained at autopsy from perinatal HPP has shown normal distribution of MVs, proteoglycan granules, and collagen fibers in the extracellular space of cartilage (Fallon et al., 1984; Ali, 1986), although the MVs lacked ALP activity. Early reports described only isolated or tiny groups of HA crystals (calcospherites) that frequently were not associated with vesicular structures (Ali, 1986; Shohat et al., 1991). Actually, HPP MVs do contain HA, but the crystals fail to enlarge due to the superabundance of extracellular PPi after these structures rupture (Anderson et al., 1997). Thus, "secondary," but not "primary," mineralization is compromised in HPP.

Dentition

Premature exfoliation of primary teeth occurs in a few diseases other than HPP, such as cyclical neutropenia and Papillon–Lefèvre syndrome (Van den Bos et al., 2005). In HPP, a paucity of mineralized cementum (despite the presence of cells that look like cementoblasts) seems to explain this complication (see Fig. 66.6A) (el-Labban et al., 1991; Lundgren et al., 1991). Desiccated teeth remain useful for histopathological examination. What cementum is present appears afibrillar (el-Labban et al., 1991). The severity of this defect varies from tooth to tooth but typically reflects the degree of skeletal disease (Whyte et al., 2015). Incisors are usually affected most and are the first to be shed.

In addition to defects in cementum, dentinogenesis seems to be impaired as shown by big pulp chambers. Dentin tubules may be enlarged although reduced in number. The excessive width of predentin, increased amounts of interglobular dentin, and impaired calcification of cementum are analogous to the osteoidosis found in bone. Reportedly, the enamel is not impacted directly (Lundgren et al., 1991). The histopathological changes of the permanent teeth are similar to those in deciduous teeth (el-Labban et al., 1991), but their prognosis early on is better (Lepe et al., 1997).

Biochemical and genetic defects

HPP is caused by mono- or biallelic loss-of-function mutation(s) in *ALPL*.

Tissue-nonspecific alkaline phosphatase deficiency

Early on, postmortem studies of perinatal and infantile HPP revealed selective deficiency of TNSALP isoenzyme activity and thereby identified HPP as an inborn error of metabolism while suggesting its genetic basis. Profound deficiency of ALP activity was discovered in bone, liver, and kidney tissue but not in intestine or placenta (fetal trophoblast) (Vanneuville and Leroy, 1981). This observation matched emerging amino acid sequence analyses from proteolytic peptide digests of ALPs purified from healthy human tissues (Stigbrand and Fishman, 1984) and indicated selective deficiency of the various isoforms within the TNSALP isoenzyme family. Leukocyte ALP activity can be subnormal in any form of HPP except perhaps pseudo-HPP, and therefore likely represents a type of TNSALP (Fallon et al., 1984).

Postmortem studies of children or adults with HPP have not been reported, but globally diminished TNSALP activity is indicated by deficiency in serum, bone, circulating granulocytes (Fallon et al., 1984), and skin fibroblasts (Vanneuville and Leroy, 1981; Whyte and Vrabel, 1985).

Hypophosphatasemia in HPP does not seem to involve accelerated clearance of TNSALP from the circulation (Gorodischer et al., 1976). Purified placental ALP (Whyte et al., 1992) as well as the bone isoform of TNSALP contained in the

plasma of patients with Paget bone disease (Whyte et al., 1982b) showed normal circulating half-lives of several days when infused intravenously into infants with life-threatening HPP during attempted ALP replacement therapy (see later).

Furthermore, coincubation experiments with mixtures of serum and coculture studies with fibroblasts provided evidence against the presence of an inhibitor or the absence of an activator of TNSALP in HPP (Fraser, 1957; O'Duffy, 1970; Whyte and Vrabel, 1985). Then, in 1985, skin fibroblast heterokaryon studies indicated a defect at a single gene locus causing severe HPP (Whyte and Vrabel, 1985).

ALP immunoreactivity has been studied in tissues obtained at autopsy as well as in skin fibroblasts from patients with severe HPP (Fallon et al., 1989; Fedde et al., 1996). In a preliminary report, a polyclonal antibody to the liver isoform of TNSALP indicated normal amounts of immunoreactive TNSALP in bone, liver, and kidney tissues from five patients (Fallon et al., 1989). Others, using isoelectric focusing and enzyme inhibition studies, suggested that the low ALP activity in one HPP patient reflected intestinal ALP (Mueller et al., 1983). In a fibroblast study, ALP had somewhat different physicochemical and immunological properties compared with ALP from healthy controls but seemed to be a type of TNSALP (Fedde et al., 1996). In studies of ALP in the circulation, monoclonal antibody-based immunoradiometric assays for polymeric TNSALP demonstrated low levels of the bone and liver isoforms in sera from patients with all clinical types of HPP except pseudo-HPP (Whyte et al., 1996). Upon release from cell surfaces into blood, TNSALP in HPP seemed altered in such a way that immunoreactivity was diminished and/or clearance was accelerated (Whyte et al., 1996). Fedde et al. (1996) concluded that the precise impact of the underlying *ALPL* mutation(s) (see later) must be understood to fully appreciate its effect(s). Now, these early findings are explained by the identification of >360 typically missense loss-of-function mutations of *ALPL* in HPP, including their effects on cellular processing of the enzyme as well as its structure (see later).

Inheritance

Mutational analysis of *ALPL* established both autosomal dominant and autosomal recessive patterns of inheritance for HPP. Perinatal and infantile HPP represent autosomal recessive disease (Weiss et al., 1988; Henthorn et al., 1992; Mumm et al., 2001; Whyte et al., 2003, 2006, 2012, 2015), whereas all milder forms of HPP can reflect either autosomal recessive (Henthorn et al., 1992) or autosomal dominant transmission of *ALPL* defects (Mumm et al., 2006; Whyte et al., 2007). Certain *ALPL* mutations have dominant-negative effects and account for multigenerational HPP (Mumm et al., 2006) (see later). Pseudo-HPP too involves *ALPL* defects (Madson et al., 2015). The utility of quantitating the biochemical parameters of HPP to identify carriers has been discussed (Sorensen et al., 1978; Chodiker et al., 1990; Whyte et al., 2017b).

ALPL gene defects

In 1988, proof that HPP can be caused by loss-of-function alteration of *ALPL* came with the discovery by Weiss and coworkers of a homozygous missense defect within *ALPL* in a consanguineous boy who died from perinatal HPP (Weiss et al., 1988). Transfection studies showed that his single-base transition in *ALPL* compromised the enzyme's activity, perhaps by impairing the binding of a metal ligand to an important arginine residue at the catalytic pocket (Weiss et al., 1988). In 1992, Henthorn et al. reported eight further missense mutations in four additional unrelated patients with perinatal or infantile HPP (Henthorn et al., 1992) and found two siblings with childhood HPP and one unrelated woman with adult HPP who were compound heterozygotes for the identical *ALPL* defects. In 1993, Greenberg and coworkers demonstrated that homozygosity for a "founder" tenth *ALPL* missense mutation accounts for the high prevalence of HPP in Mennonites living in Manitoba, Canada (Greenberg et al., 1993). Now, all clinical forms of HPP have been shown to involve loss-of-function mutation(s) in *ALPL* (Whyte, 2000, 2016, 2019), and all patients are expected, depending on sufficient rigor of the search, to carry one or two defective *ALPL* alleles (Whyte, 2017a; 2017b, 2018). There has not been genetic heterogeneity for HPP. A web site organized by Etienne Mornet, PhD, summarizes the *ALPL* mutations identified in HPP patients worldwide (http://www.sesep.uvsq.fr/Database.html). Currently, >360 different *TNSALP* mutations are recorded, of which the considerable majority are missense. Some seem to have increased regional or national prevalence (Mumm et al., 2006).

ALPL structural defects

Many *ALPL* mutations causing HPP (Taillander et al., 2001; Mumm et al., 2002) alter the amino acid residue in all mammals (Henthorn and Whyte, 1992; Mornet et al., 1998) and sometimes conserved in the ALPs of bacteria (Henthorn et al., 1992). Characterization of the three-dimensional structure of *Escherichia coli* ALP (Kim and Wyckoff, 1991) and human placental ALP (Le Due et al., 2000) by X-ray crystallography accelerated our understanding of the enzymatic basis for HPP (Henthorn et al., 1992; Kim and Wyckoff, 1991; Millán, 2006). Missense mutations in *ALPL* could now be

examined for their impact on the catalytically active dimeric TNSALP molecule (Chemscape Chime version 1.02 by MDL Information Systems, Inc., San Leandro, CA, at http://www.mdli.com and RasWin Molecular Graphics, Windows version 2.6 by Roger Sayle, Glaxo Wellcome Research and Development, Stevenage, Hertfordshire, UK, at http://www.umass.edu/microbio/rasmol/index.html). Some *ALPL* mutations would disturb the enzyme's catalytic pocket or structurally important metal ligand-binding sites; others possibly compromised the formation of TNSALP dimers (Mornet et al., 1998; Millán, 2006). Nevertheless, why all *ALPL* loss-of-function (Brunt-Heath et al., 2005) mutations associated with HPP are deleterious is not understood (Whyte, 2000; Millan and Whyte, 2016). For example, site-directed mutagenesis with the Ala161-Thr substitution first discovered to cause HPP (Weiss et al., 1988) did not compromise the catalytic activity of *E. coli* ALP (Chaidaroglou and Kantrowitz, 1993). In fact, some *ALPL* mutations alter the intracellular processing of TNSALP (Mornet et al., 1998; Shibata et al., 1998; Fukushi et al., 1998). Clinical, radiological, and perhaps histopathological studies of elderly individuals harboring the wide range of *ALPL* defects may prove especially helpful for understanding whether they ever cause HPP complications (Whyte, 2000, 2017a, b).

Prognosis

Untreated perinatal HPP is almost always rapidly fatal (Whyte et al., 2019). With intensive life support, these neonates may live for a short time, but long-term survival is rare. Now, however, asfotase alfa treatment can rescue these patients and lead to enjoyable health (Whyte et al., 2012; 2019b) (see later).

Infantile HPP, when first diagnosed, has a less certain outcome. Often there is clinical and radiographic deterioration, with historically ~50% of affected babies said to die from pneumonia and respiratory compromise owing to worsening skeletal disease particularly affecting the chest (Fraser, 1957; Whyte et al., 2003; Cahill et al., 2007). Sometimes instead, considerable spontaneous improvement occurs. The prognosis seems better if there is survival past infancy. In fact, a preliminary report in 1986 from Canada (Ish-Shalom et al., 1986) suggested that the adult stature of survivors of infantile HPP may be normal. Nevertheless, I am aware of less favorable outcomes (Whyte, 2001). Childhood HPP may also spontaneously improve, typically after growth plate fusion in young adult life. During childhood, however, the various pediatric forms of HPP usually do not alter their expressivity (Whyte et al., 2016c). Unfortunately, recurrence of skeletal symptoms and complications later in adulthood can occur (Fraser, 1957; Weinstein and Whyte, 1981; Khandwala et al., 2006; Whyte et al., 2007), but not predictably. Adult HPP often presents with recurrent metatarsal stress fractures and then further orthopedic difficulties become chronic (Whyte et al., 1982a). Worsening osteomalacia associated with osteopenia and fractures was not prevented in two affected women by estrogen replacement given at their menopause (personal observation).

Treatment

When the previous 2008 version of this chapter was published, clinical trials of HA-targeted asfotase alfa (Strensiq) for HPP had just begun. The results were transformative, especially for affected neonates, infants, and children, and this biologic was approved multinationally in 2015, typically for pediatric-onset HPP (Whyte, 2017b). The evolution of treatment trials for HPP is instructive concerning the physiological role of TNSALP.

Supportive

Symptoms from CPPD crystal deposition or periarticular HA precipitation (calcific periarthritis) may respond to nonsteroidal antiinflammatory agents.

Intramedullary rodding of femoral fractures or pseudofractures has been the mainstay of orthopedic management (Coe et al., 1986; Sutton et al., 2012). Recurrent metatarsal stress fractures have benefitted from wearing a boot.

Medical

Before asfotase alfa, there was no established medical treatment for HPP. Several informative approaches had been attempted (Fraser et al., 1955) including trials of nontargeted ALP replacement therapy (Whyte et al., 1982b, 1984, 1992), marrow cell transplantation (Whyte et al., 2003; Cahill et al., 2007), and teriparatide administration (Whyte et al., 2007). Cortisone given to a few pediatric patients with severe HPP reportedly coincided with periods of normalization of serum ALP activity and radiographic improvement (Fraser and Laidlaw, 1956) but was an inconsistent finding. Brief supplementation with Mg^{++} or Zn^{++} had been unsuccessful (Fraser, 1957). Because patients with HPP are often hyperphosphatemic (Whyte, 2001; Whyte et al., 2019), restriction and/or pharmacological binding of dietary Pi seemed

potentially useful for HPP (Wenkert et al., 2002). The superabundance of extracellular Pi might be competitively inhibiting TNSALP (McComb et al., 1979; Coburn et al., 1998) or suppressing *ALPL* gene expression (Goseki-Sone et al., 1999). Nevertheless, full clinical studies did not follow.

Hypercalcemia in infantile HPP can be treated by restriction of dietary Ca^{++} that hopefully does not exacerbate any progressive skeletal demineralization reflecting patient immobility (Whyte et al., 1982b, 1986). If necessary, glucocorticoids may be helpful for elevated blood Ca^{++} levels (Whyte et al., 1982b) but could pose an additional risk. Hypothetically, an antiresorptive treatment like subcutaneous injections of salmon calcitonin might address some of the hypercalcemia while blocking skeletal demineralization in HPP (Barcia et al., 1997), but experience has not been positive, likely because the skeletal disease involves osteoidosis covering bone surfaces. In fact, antiresorptive bisphosphonates have not had success and are derivatives of PPi that theoretically could exacerbate the rickets or osteomalacia (Whyte, 2001; Sutton et al., 2012). Some drugs that stimulate TNSALP biosynthesis in the skeleton, such as teriparatide, may benefit HPP, especially if there is only one defective *ALPL* allele (Whyte et al., 2007; Camacho et al., 2016).

Assessing therapy for infantile HPP can seem uncertain because some patients demonstrate spontaneous, and sometimes quite significant, improvement (Ish-Shalom et al., 1986; Whyte et al., 1986), whereas others show progressive skeletal demineralization leading to a fatal outcome (Whyte et al., 1982b). Now, we understand that the latter is more common (Lueng et al., 2013; Whyte et al., 2016a, 2019a).

Enzyme replacement therapy for HPP has been attempted by intravenous infusion of several types of ALP, but generally the results have been disappointing. In 1972, serum from a patient with Paget bone disease given to an affected infant was said to precede radiographic improvement (Macpherson et al., 1972). In 1982, weekly infusion of fresh plasma from healthy subjects was followed by clinical and radiographic advances in a child (Albeggiani and Cataldo, 1982). However, subsequent infusions of Paget plasma were without significant clinical or radiographic benefit for four patients with infantile HPP (Whyte et al., 1982b, 1984). One boy with infantile HPP showed remarkable but transient correction of hypophosphatasemia and substantial clinical, radiographic, and histological improvement after a brief trial of prednisone, bovine PTH 1−34, and then pooled plasma infusions from healthy individuals, but succumbed soon after to pneumonia (Whyte et al., 1986). He was later confirmed to have a homozygous *ALPL* missense mutation (Whyte et al., 2006). In follow-up to a brief report in 1989 that suggested infusions of ALP purified from liver improved the histological appearance of bone and decreased urinary PEA levels (Weninger et al., 1989), purified placental ALP was given to a severely affected infant, but despite repeated doses that led to transient hyperphosphatasemia there were only modest decrements of plasma PLP and urinary PEA concentrations, no change in urinary PPi levels, and no clinical or radiographic improvement (Whyte et al., 1992). Placental ALP was given because elevated concentrations of PLP in plasma and increased levels of PEA and PPi in urine diminished as endogenous natural production of this ALP isoenzyme corrected the hypophosphatasemia of pregnant women who were carriers of HPP (Whyte et al., 1995). Perhaps pregnancy with large amounts of placental ALP present physiologically in situ represents an "endogenous" form of enzyme replacement in HPP. However, the symptoms, radiology, skeletal histology, etc. of women who are carriers or affected by HPP have not been assessed across a pregnancy. Extreme skeletal disease in perinatal HPP despite placental ALP circulating in the mother shows that the in utero environment may not be protective for the fetus (Whyte, 2001).

These cumulative discouraging observations, showing that circulating ALP activity could be corrected in infantile HPP yet have no clinical benefit, suggested that ALP must be within the skeleton itself for physiological activity and therapeutic efficacy (Whyte et al., 1995). In fact, two subsequent reports of patient rescue and clinical and radiographic improvement in infantile HPP following mesenchymal cell transplantation suggested sufficient numbers of TNSALP-replete osteoblasts had formed (Whyte et al., 2003; Cahill et al., 2007). These improvements occurred without significant biochemical alterations of mineral metabolism, consistent with a beneficial effect limited to the skeleton.

In 2007, injections of teriparatide (recombinant PTH 1−34) were associated with clinical, biochemical, and radiographic improvement in a woman with adult HPP (Whyte et al., 2007), possibly from increased expression of her normal *ALPL* allele in her osteoblasts and/or PTH-induced phosphaturia documented by increased serum ALP and decreased Pi, respectively.

Later, I discuss the multinational availability of asfotase alfa to treat HPP.

Prenatal diagnosis

A number of reports have concluded that lethal perinatal HPP has been diagnosed in utero during the second trimester using ultrasonography with particular attention to the shape and mineralization of the skull and major long bones (van Dongen et al., 1990). However, relatively mild HPP, inherited either as an autosomal dominant or autosomal recessive trait, can bow major bones in utero and suggest the presence of this lethal form of HPP, yet the deformities correct postnatally,

reflecting instead the benign prenatal form of HPP (Moore et al., 1999; Pauli et al., 1999; Wenkert et al., 2005, 2011; Stevenson et al., 2008). The >360 specific defects possible in *ALPL* show that for mutation analysis it is necessary to examine *ALPL* exons 2−12 and their splice sites for new patients with HPP (Mumm et al., 2002). Microarray study for *ALPL* deletion/duplication is occasionally necessary. *ALPL* mutation analysis is possible to detect HPP prenatally (Henthorn and Whyte, 1995), but prognostication from the results and early fetal sonography can be problematic (Wenkert et al., 2011).

Physiological role of alkaline phosphatase explored in hypophosphatasia

As reviewed previously, several roles for TNSALP in skeletal formation have been proposed (Table 66.1). Hence, investigation of HPP has been a "window of opportunity" to explore a number of them directly in humans.

The discovery by Weiss and coworkers more than 3 decades ago that homozygosity for a loss-of-function missense mutation within *ALPL* caused severe HPP (Weiss et al., 1988) confirmed Robison's hypothesis; i.e., the enzyme that came to be called ALP functions crucially in skeletal mineralization (Robison, 1923). Subsequent characterization of the dental manifestations of HPP revealed that ALP is important also for the formation of teeth; i.e., "hard tissues." Now, it appears that all bona fide cases of HPP are explained by mono- or biallelic loss-of-function mutation(s) in *ALPL* (Whyte, 2016; 2017b, 2018, 2019).

Electron microscopy of bone and cartilage obtained at autopsy from patients representing the most severe forms of HPP demonstrated that deficient activity of TNSALP is associated with a fundamental disturbance in the process of "secondary" skeletal mineralization. Extravesicular mineralization is impeded in HPP (Anderson et al., 1997). HA crystal growth appears to fail after MVs rupture.

Mineralization defects in the cementum and dentin of HPP teeth have been considered as analogous to those in the skeleton (Lundgren et al., 1991). A prominent role for TNSALP during two critical phases of dental mineralization, initiation and completion, was proposed (Hotton et al., 1999). In 2005, Van den Bos and coworkers reported that both cellular and acellular cementum formation was impaired, but not mineralization of the dentin (Van den Bos et al., 2005).

Although healthy liver, kidneys, and adrenal glands are rich in TNSALP activity (McComb et al., 1979), they seem to function normally in HPP (see later) with the exception that reclamation of filtered Pi by the kidney is enhanced and hyperphosphatemia is common. This can be explained by suppression of circulating PTH levels in the often hypercalcemic perinatal and infantile forms of HPP (Whyte and Rettinger, 1987; Whyte et al., 2012), but otherwise seems to have a complex pathogenesis also involving a role for TNSALP in kidney tubules; phosphatonin deficiency or inappropriately normal levels despite hyperphosphatemia; and/or effects on TmP/GFR by the elevated levels of urinary PPi (Whyte et al., 2019).

It has been suggested that the TNSALP deficiency of severe HPP might impair the biosynthesis of phospholipids and thereby explain occurrences of pulmonary atelectasis (Silver et al., 1988). However, the respiratory problems of severely affected patients are attributable to rib cage fractures, thoracic deformity, and chest muscle weakness, perhaps also accounting for hypoplastic lungs.

In the 1980s, it became clear from investigation of HPP patients that TNSALP is important not only for hard tissue mineralization but also for dephosphorylation of extracellular PLP and therefore vitamin B_6 metabolism (Whyte, 1994). In severe pediatric HPP, insufficient hydrolysis of PLP to pyridoxal (PL) for entry into neurons impairs the biosynthesis of the neurotransmitter γ-aminobutyric acid (Baumgartner-Sigl et al., 2007). In fact, epilepsy is an important characteristic of the murine model of infantile HPP and is associated with low levels of γ-aminobutyric acid in the central nervous system (Waymire et al., 1995). Pyridoxine supplementation briefly extends the lives of these patients (Baumgartner-Sigl et al., 2007) and mice (Fedde et al., 1999) with HPP.

Tissue-nonspecific alkaline phosphatase substrates

The discoveries that PEA, PPi, and PLP accumulate endogenously in HPP were essential for elucidating the physiological role of TNSALP in humans. Each was thereby correctly inferred to be a natural substrate for TNSALP. However, a preliminary study using 31P-magnetic resonance spectroscopy of urine from patients with HPP suggested several additional phosphorylated TNSALP substrates (Whyte et al., 2000).

Phosphoethanolamine

The reports in 1955 by McCance and colleagues (1955) and Fraser and coworkers (1955) that PEA levels are elevated in the urine and plasma of HPP patients provided a second biochemical marker for the disorder and identified the first natural

substrate for TNSALP. In 1968, Rasmussen showed that this phosphocompound appears in the urine when plasma levels are scarcely detectable; i.e., there is essentially no renal threshold for PEA excretion (Rasmussen, 1968).

Although the metabolic origin of PEA is uncertain, the principal source of circulating PEA in HPP is considered to be the liver, which normally metabolizes PEA to ammonia, acetaldehyde, and Pi in a reaction catalyzed by O-phosphorylethanolamine phospholyase (Gron, 1978). In one family with adult HPP, urine levels of PEA correlated inversely with circulating activity of the liver but not the bone isoform of TNSALP (Millán et al., 1980). PEA is a component of the phosphatidylinositol-glycan linkage apparatus for cell surface proteins (Low and Zilversmit, 1980). Hence, PEA could be a degradation product of this link, but is not considered a degradation product of phosphatidylethanolamine; i.e., not from plasma membrane phospholipid breakdown.

Pyridoxal 5′-phosphate

The discovery in 1985 that circulating levels of PLP are elevated in HPP was key to understanding the physiological role of TNSALP (Whyte et al., 1985).

Reviewed later (Fig. 66.10), the forms of dietary vitamin B_6 (pyridoxine, pyridoxal, pyridoxamine, and their phosphorylated derivatives) are converted to PLP in the liver (Dolphin et al., 1986). Organ ablation studies of mammals identified hepatic tissue as the principal source of circulating PLP. PLP is released from hepatocytes into the bloodstream where more than 95% couples to albumin (Dolphin et al., 1986). Some PLP also binds in the circulation to various enzymes, but a small amount circulates freely.

Like many phosphorylated compounds, PLP cannot cross plasma membranes but must first be dephosphorylated to PL before it can enter tissues. Inside cells, PL is rephosphorylated to PLP or converted to pyridoxamine 5′-phosphate that then act as cofactors for many and varied enzymatic reactions. Ultimately, vitamin B_6 is degraded to 4-pyridoxic acid (4-PA), primarily in the liver, and then excreted into the urine (Dolphin et al., 1986; Coburn and Whyte, 1988).

In disorders that elevate circulating bone and liver TNSALP, plasma PLP concentrations are decreased (Anderson et al., 1980). Thus, discovery of elevated plasma PLP levels in HPP extended this reciprocal relationship. However, the wide-ranging elevated levels in circulating PLP are probably not of pathophysiological consequence in HPP because cell surface TNSALP controls extracellular but not intracellular dephosphorylation of PLP. Elevated plasma PLP levels in HPP do not reflect enhanced PLP synthesis but instead extracellular accumulation from diminished hydrolysis of PLP (Whyte

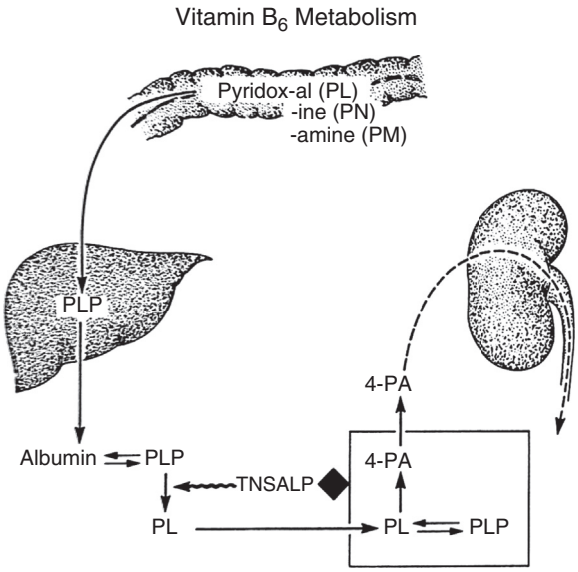

FIGURE 66.10 Role of tissue-nonspecific alkaline phosphatase (TNSALP) in vitamin B_6 metabolism. The various forms of vitamin B_6 are plentiful in the diet and absorbed into the hepatic portal circulation (phosphorylated forms are first dephosphorylated in the gut). In the liver, each is converted to PLP, which is then secreted bound to albumin into the plasma. In order to enter tissues, plasma PLP must be dephosphorylated to PL that can traverse membranes. 4-Pyridoxic acid (4-PA), the major degradation product of vitamin B_6, is excreted in the urine. High plasma levels of PLP in hypophosphatasia, yet normal plasma concentrations of PL, are consistent with a cell surface role for TNSALP in the extracellular dephosphorylation of PLP to PL. *Reproduced with permission from Whyte, M.P., 2001. Hypophosphatasia. In: Scriver, C.R., Beaudet, A.L., Sly, W.S., Valle, D., (Eds.) The Metabolic and Molecular Bases of Inherited Disease, eighth ed., pp. 5313–5329. McGraw-Hill, New York.*

et al., 1985). Clinical investigation of HPP led to this overview of vitamin B_6 metabolism because patients with HPP do not have symptoms of vitamin B_6 toxicity such as peripheral neuropathy (Dolphin et al., 1986) (see later). Similarly, in all types of HPP except the most severe perinatal and infantile forms where vitamin B_6–dependent epilepsy can occur, there are no signs or symptoms of chronic vitamin B_6 deficiency such as stomatitis, dermatitis, peripheral neuritis, anemia, or depression (Dolphin et al., 1986). Furthermore, a variety of biochemical findings indicated that intracellular levels of vitamin B_6 are unremarkable in HPP. First, urine levels of 4-pyridoxic acid are normal in patients with childhood HPP (Whyte et al., 1988). Second, these children respond normally to L-tryptophan loading—a test for vitamin B_6 deficiency (Whyte and Coburn, unpublished observation). Third, in homogenates of severely TNSALP-deficient HPP fibroblasts in culture, levels of PLP and the various other forms of vitamin B_6 are normal (Whyte et al., 1988). Finally, tissues obtained at autopsy from patients with perinatal HPP (plasma PLP concentrations elevated 50 to 900 times normal) contain essentially normal levels of PLP, PL, and total vitamin B_6 (Whyte et al., 1988). Accordingly, TNSALP seemed to function as a cell surface enzyme (Whyte et al., 1985; Fedde et al., 1988), and soon after how ALP and other proteins anchor to the plasma membrane was identified (Low and Saltiel, 1988).

Because TNSALP seemed responsible for the extracellular dephosphorylation of PLP to PL, plasma levels of PL could be low in HPP. However, only patients with the severest forms of HPP have low plasma PL concentrations, helping to explain the vitamin B_6–dependent seizures; the others show normal or sometimes elevated circulating PL levels (Whyte et al., 1985).

Vitamin B_6 deficiency is associated with renal stone disease and epilepsy. However, nephrocalcinosis in infants with HPP likely reflects hypercalciuria, although oxalate excess (a consequence of vitamin B_6 deficiency) has not been searched for in HPP (Dolphin et al., 1986). Epilepsy in severe HPP has the aforementioned metabolic explanation but also occurs in patients who may have cranial deformity, intracranial hemorrhage, periodic apnea, etc. Of interest, PEA reportedly caused seizures when given intravenously to an infant severely affected by HPP during a study of PEA metabolism (Takahashi et al., 1984). In two patients with perinatal HPP and epilepsy, both of whom had plasma PL levels below assay sensitivity, administration of vitamin B_6 as pyridoxine did not correct the seizure disorder (personal observation), perhaps because the pyridoxine was converted to more PLP rather than PL. Vitamin B_6–dependent seizures can be the first manifestation of infantile HPP. All reported cases of HPP with such seizures proved fatal (Baumgartner-Sigl et al., 2007). *Alpl* knockout mice manifest this type of epilepsy (see later), and require pyridoxine administration to extend their lives (Waymire et al., 1995; Fedde et al., 1999). Treatment of these mice, an excellent model for infantile HPP (Fedde et al., 1999), with asfotase alfa prevented their skeletal and dental disease and vitamin B_6-dependent epilepsy (Millán et al., 2008).

The clinical and biochemical observations concerning vitamin B_6 metabolism in HPP have indicated an extracellular role for TNSALP (Whyte et al., 1985). In 1988, Fedde and coworkers exposed cultivated human osteosarcoma cells (Fedde et al., 1988), and then dermal fibroblasts from patients with infantile HPP (Fedde et al., 1990), to PLP and PEA in the medium and confirmed that TNSALP is a plasma membrane-associated enzyme (see later). In 1980, characterization of porcine kidney ALP as membrane-bound by phosphatidylinositol (Low and Zilversmit, 1980) indicated this attachment apparatus for TNSALP (Low and Saltiel, 1988).

Inorganic pyrophosphate

Discovery in 1965 and 1971, respectively, that PPi levels are increased in HPP patient urine (Russell, 1965) and plasma (Russell et al., 1971) provided a plausible explanation for defective skeletal mineralization in HPP (Caswell et al., 1991) (Fig. 66.11). At that time, PPi was becoming recognized as a potent inhibitor of mineralization (Heinonen, 2001). Although low concentrations of PPi could enhance Ca^{++} and Pi precipitation from solution to form amorphous calcium phosphate, at higher concentrations PPi prevented the growth and dissolution of HA crystals (Caswell et al., 1991). Caswell and co-workers demonstrated that nucleoside triphosphate pyrophosphatase (NTP-PPi-ase, PC-1) activity is unremarkable in TNSALP-deficient fibroblasts from perinatal and infantile HPP patients. Extracellular generation of PPi from ATP by these cells was not hindered (Caswell et al., 1986). Therefore, NTP-PPi-ase seemed distinct from TNSALP. In 2000, this conclusion was supported by studies of osteoblasts from *Alpl* knockout mice (see later) (Johnson et al., 2000). From understanding PLP metabolism in HPP, it became clear how the clearance of 32PPi administered in the 1960s into the circulation of two adults with HPP was markedly delayed (R. G. G. Russell, personal communication). Endogenous accumulation of PPi in HPP reflects diminished extracellular hydrolysis (Caswell et al., 1991).

Consonant with the in vitro effects of PPi, several other abnormalities of mineralization in HPP may reflect the local concentration of PPi. Perhaps relatively minor excesses of extracellular PPi explain the precipitation of amorphous calcium phosphate and the calcific periarthritis observed in some adults with HPP (Lassere and Jones, 1990). Furthermore, ALP can dissolve CPPD crystals in vitro (Xu et al., 1991), and this PPi-ase activity seems additional to its capacity to hydrolyze

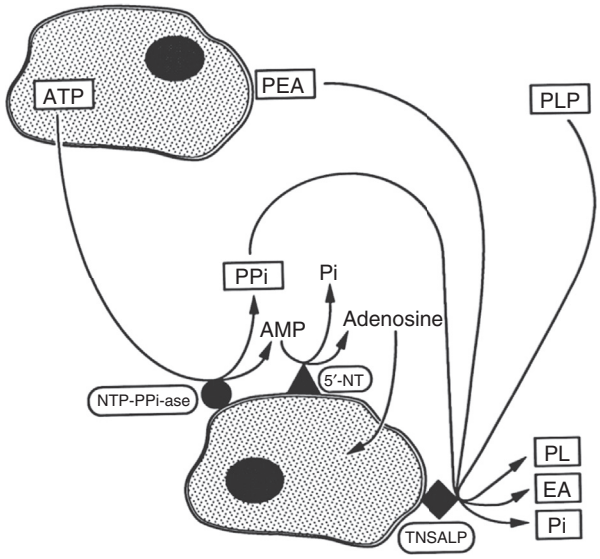

FIGURE 66.11 Metabolic basis for hypophosphatasia. Extracellular generation of PPi, presumably by the action of nucleoside triphosphate pyrophosphatase (NTP-PPi-ase), is normal. PPi is also pumped extracellularly from within cells via an ANK channel (not shown) (Millán, 2006). Extracellular degradation of PEA, PPi, and PLP is diminished because of deficient cell-surface TNSALP activity. Accumulation of PPi extracellularly accounts for CPPD precipitation and sometimes associated calcium phosphate crystal deposition. The inhibitory effect of PPi on extravesicular HA crystal growth accounts for the rickets/osteomalacia. *Reproduced with permission from Whyte, M.P., 2001. Hypophosphatasia. In: Scriver, C.R., Beaudet, A.L., Sly, W.S., Valle, D., (Eds.) The Metabolic and Molecular Bases of Inherited Disease, eighth ed., pp. 5313–5329. McGraw-Hill, New York.*

phosphoesters. Thus, CPPD crystal deposition leading to chondrocalcinosis, pseudogout, and pyrophosphate arthropathy could be explained by the failure of TNSALP to hydrolyze not only PPi but also CPPD crystals. The especially high extracellular concentrations of PPi in HPP would inhibit HA crystal formation and growth; hence, rickets or osteomalacia becomes readily explained. As discussed, electron microscopy of skeletal tissue from lethal HPP and in Tnsalp knockout mice (see later), showed that the precise pathogenesis involves secondary mineralization surrounding MVs (Anderson et al., 1997).

Circulating tissue-nonspecific alkaline phosphatase

Several observations suggest that circulating ALPs are physiologically inactive. Infants with severe HPP who received intravenous infusions of plasma from patients with Paget bone disease or purified placental ALP demonstrated no significant clinical or radiographic improvement despite transient correction in circulating ALP activity, sometimes to elevated levels. Such therapy failed to normalize urinary PEA or PPi levels or plasma PLP concentrations (Whyte et al., 1982b). The deficiency of TNSALP activity within the skeleton itself seemed to account for the rickets and osteomalacia of HPP. In fact, in studies reminiscent of Robison's work (Robison, 1932), Fraser and Yendt reported in 1955 that rachitic rat cartilage would calcify in serum obtained from an infant with HPP, yet slices of HPP costochondral junction would not mineralize in synthetic calcifying medium or in pooled serum from healthy children (Fraser and Yendt, 1955). Subsequently, transfection studies using ALP cDNA showed both catalysis against Pi esters and mineralization in a calcification system (Yoon et al., 1989; Farley et al., 1991). Nevertheless, there has been skepticism that such experiments reflect true biomineralization, because increased Pi in metastable solutions is expected to simply precipitate as calcium phosphate (Khouja et al., 1990). As discussed, it seemed necessary to augment ALP activity in the skeleton tissue itself to treat HPP. In fact, the aforementioned experience with marrow cell transplantation for infantile HPP suggested that even small increases in ALP activity within the skeleton can improve its mineralization in HPP (Whyte et al., 2003). Transient transfection studies of various *ALPL* mutations causing HPP also indicated that small differences in the magnitude of the deficiency of ALP activity within the skeleton can account for lethal versus nonlethal outcomes (Mornet et al., 1998).

Hypophosphatasia fibroblast studies

Healthy dermal fibroblasts in culture (Fedde et al., 1990; Whyte and Vrabel, 1985; Whyte et al., 1986) show some TNSALP-like activity that peaks at confluency (Whyte and Vrabel, 1987). Fibroblasts from severely affected HPP patients

are profoundly deficient in this ALP activity (less than 5% control) (Whyte et al., 1983), but the residual activity seems to be a type of TNSALP (Whyte et al., 1987). Using this model, preliminary studies indicated that the phospholipid composition and rates of 32Pi accumulation by these TNSALP-deficient cells were normal (Tsutsumi et al., 1986; Whyte and Vrabel, 1983). In 1990, Fedde et al. demonstrated that TNSALP is present primarily on the surface of these cells (Fedde et al., 1990) and hydrolyzed extracellular PEA and PLP under physiological conditions. Although some reports suggested that ALP conditions cell growth and differentiation by influencing the phosphorylation of nucleotide pools, HPP fibroblasts proliferated at normal rates in culture (Whyte et al., 1983), and TNSALP did not seem to be a phosphoprotein phosphatase acting at the plasma membrane (Fedde et al., 1993).

Alpl knockout animals

Since 1995, studies of *Alpl* knockout mice and then the creation of other murine models of ALP function have complimented and expanded the insights gained from investigation of HPP patients (Millan and Whyte, 2016). In 1995, Waymire and coworkers developed an *Alpl*-null mouse that manifested the deranged vitamin B_6 metabolism of HPP, including lethal seizures from deficient γ-aminobutyric acid in the brain (Waymire et al., 1995). With pyridoxine treatment, the epilepsy was controlled temporarily, and the animals survived long enough to develop dental disease. In 1997, Narisawa and colleagues created a different *Alpl*-null mouse with vitamin B_6–dependent epilepsy and dental defects that also manifested skeletal disease (Narisawa et al., 1997; Millán, 2006). In 1999, Fedde and coworkers demonstrated that both models recapitulated the infantile form of HPP remarkably well, including the acquired skeletal and dental disease and epilepsy together with endogenous accumulation of PPi, PLP, and PEA (Fedde et al., 1999). In 2000, the skeletal mineralization defect of HPP was reproduced in vitro using osteoblasts in culture from these mice (Wennberg et al., 2000). This disturbance did not seem to be related to the aberrations in vitamin B_6 metabolism (Narisawa et al., 2001). Defective secondary (extravesicular) skeletal mineralization was then confirmed by electron microscopy (Anderson et al., 2004). Subsequently, double-knockout mouse studies showed, as might be expected, that skeletal formation is essentially normal in mice that lack both Tnsalp and the PPi-generating enzyme PC-1 (NTP-PPi-ase) (Hessle et al., 2002). Furthermore, Tnsalp expressed under control of the APO-E promoter in the liver of *Alpl* knockout mice prevented the skeletal disease of HPP. It is uncertain, however, whether Tnsalp in the liver itself or in high amounts in the circulation of these mice explained the beneficial skeletal effects. In 2007, Hough and coworkers characterized a much milder, acquired, semi-dominant form of HPP in mice generated from N-ethyl-N-nitrosourea exposure. The adult mice manifested late-onset skeletal disease and arthropathy (Hough et al., 2007). Later, *Alpl*-null mice became the key preclinical model to test asfotase alfa therapy for HPP (Millán et al., 2008). Now, further mouse models of relatively mild HPP are undergoing investigation (Millán and Whyte, 2016; Foster et al., 2015). Recently, a large animal model (sheep) for HPP that includes dental findings has begun characterization (Williams et al., 2018). In 2019, infantile HPP was documented in a breed of dogs (Kyöstila et al., 2019).

Asfotase alfa treatment for hypophosphatasia

HPP was the last type of rickets or osteomalacia to have a medical treatment (Whyte, 2017a). In 2015, asfotase alfa was approved multinationally for HPP, typically if there was pediatric-onset disease. It is an expensive, HA-targeted, recombinant, human TNSALP-replacement therapy administered by subcutaneous injection with dosing based on the patient's weight (Whyte et al., 2012, 2016a; 2019b). The clinical trials encompassed patient ages ranging from newborn to adult life (Whyte et al., 2012, 2016a; Kishnani et al., 2019). Radiographic assessments using validated scales revealed relatively rapid and then sustained improvement in rickets—7 years for 1- to 3-year-old patients with perinatal or infantile HPP (Whyte et al., 2019b), and 5 years for 6- to 12-year-old survivors of infantile HPP or with severe childhood HPP (Whyte et al., 2016b). Osteomalacia seemed improved in both affected children and adults (Whyte et al., 2016b; Kishnani et al., 2019). Circulating ALP activity becomes markedly elevated with this treatment, but the clinical trials were reassuring against ectopic mineralization from excessive lowering of endogenous PPi levels. With treatment, circulating PPi and PLP levels were generally lower and often in the normal range. Rapid and marked improvements were demonstrated, especially by the most severely affected pediatric patients, but bony craniosynostosis was not prevented. Muscle weakness seemed to improve first. Thus, this experience has brought us "full circle," showing that today Rathbun's original patient (Rathbun, 1948) could overcome the pathogenesis of his TNSALP deficiency and enjoy good health. In the future, we must now aim to cure this highly informative inborn error of metabolism.

Summary and conclusions

HPP is the rare but remarkably instructive inborn error of metabolism that demonstrates a critical role for the tissue-nonspecific isoenzyme of ALP in hard tissue mineralization. Subnormal serum ALP activity (hypophosphatasemia), the biochemical hallmark of HPP, reflects a generalized deficiency of TNSALP activity. The three tissue-specific ALP isoenzymes (intestinal, placental, and germ-cell ALP) are not compromised in HPP, but the physiological function of these ALP isoenzymes is not certain.

HPP features impaired skeletal mineralization that manifests as rickets in newborns, infants, children, and adolescents and as osteomalacia in adults. Involvement of the dentition as well shows that all hard tissues are compromised. Clinical expressivity of HPP is, however, extremely broad-ranging and largely but not completely explained by autosomal dominant and autosomal recessive patterns of inheritance with a multitude of underlying loss-of-function mutations, primarily missense defects, in *ALPL*-encoding TNSALP. Perinatal HPP, apparent in utero, causes neonatal death from skeletal hypomineralization that is so severe that no calcification may be seen radiographically. Infantile HPP presents postnatally by the age of 6 months. Sometimes, there is nephrocalcinosis from hypercalcemia and hypercalciuria and functional craniosynostosis as well. Untreated, about 50% of these babies succumb to worsening rachitic disease that compromises pulmonary function. Vitamin B_6–dependent epilepsy indicates particularly severe TNSALP deficiency and a lethal outcome. Childhood HPP features premature loss of deciduous teeth, often preceding rickets and muscle weakness. Adult HPP causes recurrent metatarsal stress fractures, especially femoral pseudofractures, and often arthritis from CPPD crystal deposition, rarely calcific periarthritis from precipitation of amorphous calcium phosphate, and PPi arthropathy or pseudogout. Odonto-HPP refers to premature tooth loss from defective mineralization of dental cementum but no skeletal manifestations.

Perinatal and infantile HPP are transmitted as autosomal recessive traits involving >360 different loss-of-function, often missense, mutations scattered throughout *ALPL*. They compromise the catalytic site and/or structure of this cell surface homodimeric or homotetrameric phosphomonoester phosphohydrolase and sometimes its intracellular processing. All of the more mild forms of HPP can be inherited as an autosomal dominant trait owing to dominant-negative *ALPL* mutations. However, individuals with even the mildest forms of HPP can reflect autosomal recessive inheritance.

Prenatal diagnosis of HPP now involves *ALPL* mutation analysis. During the second trimester, fetal ultrasonography may identify skeletal disease; however, the considerable number and variety of *ALPL* mutations as well as the influence of other factors on the HPP phenotype preclude precise prognostication.

Discovery in HPP of increased endogenous levels of PEA, PPi, and then PLP demonstrated that TNSALP is a cell-surface phosphomonoester phosphohydrolase catalytically active toward a variety of natural substrates, acting also as a PPi-ase. However, additional substrates for TNSALP seem likely. Because these substrates are typically at nanomolar or micromolar concentrations, TNSALP acts physiologically at much lower pH and concentrations than those of the artificial substrates used in clinical and research assays of ALP activity. Clearly, "alkaline phosphatase" is a misnomer.

Clinical investigation of vitamin B_6 metabolism in HPP, supported by HPP fibroblast studies, confirmed that TNSALP acts as a cell-surface enzyme. Typically normal levels of PL in plasma, despite the superabundance of plasma membrane-impermeable PLP, explain the absence of signs or symptoms of vitamin B_6 deficiency (or toxicity) in all but the most severely affected HPP patients.

Attempts to treat HPP by intravenous infusions of ALPs purified from various human tissues was disappointing and suggested that circulating ALP is physiologically inactive. Marrow cell transplantation could be associated with clinical and radiographic improvement but without significant biochemical changes in blood or urine. Teriparatide stimulated bone ALP levels and appeared to heal fractures in several adults with HPP. Following successful treatment of *Alpl*-null mice with recombinant HA-targeted human TNSALP (asfotase alfa), clinical trials proved similarly beneficial, especially for the most severely affected pediatric patients.

Circulating PPi may be formed from extracellular ATP by cell surface NTP-PPi-ase and pumped there from cells by a channel protein called ANK. PLP appears to be from the liver. PEA seems to come from degradation of the phosphatidylinositol-glycan moiety that anchors many proteins to cells surfaces. Hyperphosphatemia owing to increased renal reclamation of Pi in HPP suggests that TNSALP plays a direct role in renal Pi excretion, although additional factors seem likely.

In HPP, PPi excess frequently results in chondrocalcinosis and sometimes in pseudogout or PPi arthropathy. Rickets and osteomalacia in HPP reflect the effect of high extracellular concentrations of PPi to inhibit HA crystal growth at sites of skeletal mineralization. Success using HA-targeted TNSALP-replacement therapy (asfotase alfa) for HPP was consistent with TNSALP acting physiologically within the skeleton but not in the circulation.

Acknowledgments

The staff at the Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children-St. Louis, St. Louis, Missouri, USA made this chapter possible. My colleague, Steven Mumm, PhD, continues to importantly advance our understanding of the molecular basis for hypophosphatasia, radiologist William H. McAlister, MD, continues to facilitate the diagnosis, assessment, and treatment of our HPP patients, and Jose Luis Millan, PhD, continues to advance our understanding of the alkaline phosphatases. Gary S. Gottesman, MD, and Deborah Wenkert, MD, are providing their expertise as pediatric medical geneticist and rheumatologist, respectively, to manage HPP. Karen Mack, LPN, has now cared for more than 220 children with hypophosphatasia during the past 35 years at our Research Center. Sharon McKenzie provided expert secretarial help.

This work was supported by Shriners Hospitals for Children as well as by The Clark and Mildred Cox Inherited Metabolic Bone Disease Research Fund and The Hypophosphatasia Research Fund at the Barnes-Jewish Hospital Foundation, St. Louis, Missouri, USA.

Chapter 67

Paget's disease of bone

Frederick R. Singer[1] and G. David Roodman[2]

[1]John Wayne Cancer Institute, Saint John's Health Center, Santa Monica, CA, United States; [2]Department of Medicine, Division of Hematology and Oncology, Indiana University School of Medicine, and Roudebush VA Medical Center, Indianapolis, IN, United States

Chapter outline

The patient

Paget's disease is a common disorder of the skeleton that is local in nature and extremely variable in its clinical manifestation (Singer and Krane, 1998). The majority of patients are without symptoms. When symptoms are present, skeletal deformity and pain are most common. Deformities are usually most apparent in the skull, face, and lower extremities. Pain is of several origins. Localized bone pain is surprisingly uncommon, but joint pain (hips and knees) is seen not infrequently, owing to degenerative arthritis. Pain of neural or spinal origin is unusual but the most severe.

A variety of complications may first bring the patient to medical attention. The complications depend on both the affected skeletal sites and the overall extent of the disease (six bones are commonly involved). Patients with Paget's disease in the skull often develop a hearing deficit if the temporal bone is affected. Massive enlargement of the cranium is associated with basilar impression and neurological impairment. Vertebral involvement may produce compression fractures, spinal stenosis, neurological impairment, and degenerative arthritis. Paget's disease in the pelvis and femurs commonly is associated with degenerative arthritis of the hips. Involvement of the femur and tibia may lead to pathological fractures of these long bones. Nonunion of a femoral fracture is relatively common. Degenerative arthritis in the knees is also a common feature when lower extremity long bones are extensively involved by Paget's disease. The most serious complication is the development of a sarcoma that, fortunately, occurs in less than 1% of patients. It always arises in a pagetic lesion and not in unaffected bone. Systemic complications of Paget's disease generally occur with more extensive disease.

Hypercalcemia, preceded by hypercalciuria, usually is noted with total bed rest and is related to the accelerated bone resorption induced by immobilization. Increased cardiac output, and less commonly, congestive heart failure, is a consequence of the great vascularity of bones affected by Paget's disease. Hyperuricemia has been observed in males with extensive disease and may reflect increased purine turnover.

Radiology and nuclear medicine

The diagnosis of Paget's disease is primarily accomplished by roentgenographic evaluation of the skeleton. Over the years it has become clear that the disease evolves through several stages, as observed by serial roentgenograms.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00067-1

The initial stage of the disease is represented by a localized area of reduced bone density often referred to as an osteolytic lesion. This is most readily detected in the skull, where it is found as a discrete round or oval lesion in the frontal or occipital bones. It is called osteoporosis circumscripta. Paget's disease in the long bones almost always begins in the subchondral region of either epiphysis (uncommonly, both may be affected simultaneously). The osteolytic process has then been seen to advance proximally or distally at about 1 cm/year in the untreated patient. The advancing front usually has a V-shaped or arrowhead appearance.

In the most advanced stage of Paget's disease, the areas of previous osteolytic dominance now are characterized by a chaotic sclerotic appearance, a phase that is called osteoblastic or osteosclerotic. In long bones the osteolytic phase is commonly seen preceding the osteosclerotic region when much of the bone has been affected by the disease. Another feature of this phase is considerable thickening of the sclerotic bone, which can reach monumental proportions in the skull. Osteolytic activity of a secondary nature often can be observed as clefts in the thickened bone. It is likely that the evolution of the disease into its most severe form occurs over much of the life span of the patient. Two other features of the disease have been noted through serial roentgenographic observations. Although the disease can slowly course through an entire bone, it does not cross a joint space to affect an adjacent bone. Also it is extremely rare for new lesions of Paget's disease to be detected at any site in the skeleton after the diagnosis and extent of the disease has been determined initially.

Bone scans are the most sensitive means of detecting pagetic lesions. Radiolabeled bisphosphonates accumulate in regions where blood flow and bone formation are increased and can outline early lesions that are not detectable on roentgenograms. Radioactive gallium can also define areas of Paget's disease activity because of the uptake of gallium by osteoclasts (OCLs).

Histopathology

Beginning with the observations of Schmorl in 1932, it has become appreciated that the OCL is the dominant cell in the pathogenesis of Paget's disease. OCLs are increased in number in the haversian canals of the cortex in the absence of other abnormalities and are present in great numbers at the leading edge of the osteolytic front. The OCLs in Paget's disease may be far greater in size than OCLs in normal bone and contain as many as 100 nuclei in a cross section, compared with two or three nuclei in a normal OCL. OCLs of Paget's disease have a characteristic ultrastructural abnormality (Gherardi et al., 1980; Howatson and Fornasier, 1982; Mills and Singer, 1976; Rebel et al., 1974). This consists of microfilaments, sometimes grouped in a paracrystalline array, located in the nucleus and sometimes in the cytoplasm of OCLs (Fig. 67.1). These microfilaments are not seen in nonpagetic bone or bone marrow cells. These inclusions closely resemble nucleocapsids of viruses of the Paramyxoviridae family, a group of RNA viruses responsible for some of the most common childhood diseases. Despite the finding of these inclusions in the vast majority of patients studied, the budding off of an infectious virus from the OCLs has rarely been observed (Abe et al., 1995).

Osteoblasts (OBs) are another prominent feature of the cellular pathology of Paget's disease. Large numbers of OBs are often found near areas of resorbed bone and may even be prominent in a lesion that appears purely osteolytic by X-ray. The OBs are usually prism-shaped or polyhedral and contain abundant rough endoplasmic reticulum, mitochondria, and a well-developed Golgi zone. These signs of cellular activity are consistent with the increased bone formation in active lesions established by the use of double labeling with tetracycline.

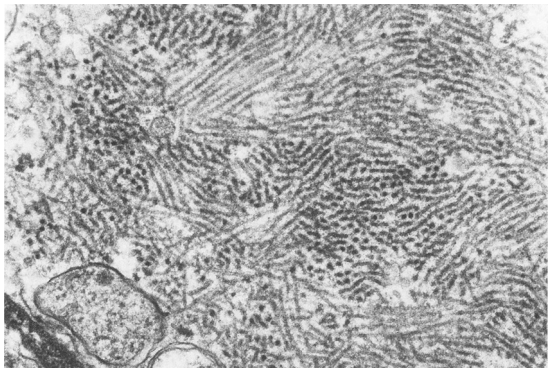

FIGURE 67.1 Electron micrograph of a nuclear inclusion in an osteoclast of a patient with Paget's disease. The microfilaments are seen both in longitudinal array and in paracrystalline array in cross section. *Provided by Dr. Barbara G. Mills.*

In addition to the increased numbers of OCLs and OBs, the marrow of pagetic lesions tends to be grossly abnormal. The normal hematopoietic elements are usually absent and replaced by mononuclear cells of indeterminate origin intermixed with highly vascular connective tissue.

The bone matrix in Paget's disease is highly abnormal in structure and arises as a consequence of disordered bone resorption and formation. The matrix consists of a "mosaic" of irregularly shaped pieces of lamellar bone with an erratic pattern of cement lines. The matrix is interspersed with numerous foci of woven bone, which, in adults, is ordinarily found associated with fracture healing. Analysis of bone biopsies indicates that there is a lower heterogeneous degree of bone mineralization and a younger tissue age than in control bone. This appears to result in less resistance to plastic deformation and a straighter crack path than in control bone (Singer, 2016).

Biochemistry

The biochemical findings in Paget's disease help to provide an integrated assessment of the cellular events occurring throughout the skeleton of affected patients.

Historically, the earliest index of bone matrix resorption was the measurement of urinary hydroxyproline excretion while ingesting a low-gelatin diet. This index is well correlated with the extent of the disease despite the fact that hydroxyproline is a prominent component of extraskeletal connective tissue as well as skeletal collagen. Measurement of collagen cross-link degradation products in serum and urine provides more specific measurements of skeletal matrix. Urinary N-telopeptide, C-telopeptide, pyridinoline, and deoxypyridinoline have all been reported to be more specific indices of skeletal matrix resorption and are not influenced by dietary gelatin (Alvarez et al., 1995; Reid et al., 2004; Shankar and Hosking, 2006). The telopeptide assays are most reliable.

Serum tartrate-resistant acid phosphatase, presumably released by OCLs, appears to be another index of bone resorption in Paget's disease but is not routinely available (Kraenzlin et al., 1990).

OB activity can be assessed by measurement of total alkaline phosphatase activity, bone-specific alkaline phosphatase activity, osteocalcin concentration, and procollagen type 1 N-terminal propeptide (P1NP) concentration in the serum. The most useful of these serum markers are the total alkaline phosphatase, bone-specific alkaline phosphatase, and P1NP (Alvarez et al., 1995; Reid et al., 2004; Shankar and Hosking, 2006). In the absence of liver disease, serum total alkaline phosphatase alone is least expensive and is adequate for following disease activity (Singer et al., 2014).

Treatment of Paget's disease

Salmon calcitonin by injection and etidronate disodium by the oral route were the first effective medications introduced in the 1980s. They generally suppress biochemical parameters of the disease by 50%. A variety of more potent bisphosphonates, including pamidronate, alendronate, risedronate, and ibandronate, have also proven to be effective in suppressing the activity of Paget's disease, but the most effective therapy has proven to be intravenous administration of zoledronic acid (Hosking et al., 2007). A 15-min infusion suppresses biochemical activity into the normal range for up to 6.5 years even in patients with markedly elevated parameters of bone resorption and formation (Reid et al., 2011). In patients with a mean age of 76 years a single infusion may produce a lasting remission for the remainder of their life (Cundy et al., 2017).

Surgery is sometimes necessary to treat patients with associated degenerative arthritis of the hip (total hip replacement) and of the knee (high tibial osteotomy). Orthopedic and/or neurosurgical procedures may occasionally be necessary after fractures and when skull or vertebral complications are present.

Evidence for the presence of paramyxoviruses in Paget's disease

Multiple environmental factors have been suggested as possible triggers for Paget's disease. These include dietary deficiencies (calcium, vitamin D), stress from repetitive use of affected bones, exposure to environmental toxins, a rural lifestyle or animal exposure, and chronic infection with a paramyxovirus such as measles virus (MV), canine distemper virus (CDV), and respiratory syncytial virus (RSV). A viral etiology of Paget's disease was first suggested by Rebel and coworkers (Rebel et al., 1974), who performed ultrastructural studies on OCLs from Paget's disease patients. These studies showed that nuclear and, less commonly, cytoplasmic inclusions resembling paramyxoviral nucleocapsids were present in pagetic OCLs, and immunologic and in situ hybridization studies suggested they were MV or a measles-like virus (Rebel et al., 1980a; Basle, 1986). Mills and colleagues (1984), using immunohistochemistry, found that RSV and MV nucleocapsid antigens were detectable in OCLs from Paget's disease patients, but not in OCLs from patients with other bone

diseases. More recently, however, other groups using a variety of techniques have been unable to detect MV or CDV in cells from Paget's disease patients (Ralston et al., 2007), making the role of a chronic paramyxoviral infection in Paget's disease controversial.

Additional evidence of paramyxovirus nucleocapsid transcripts in Paget's disease has come from the studies of Reddy and colleagues. They studied bone marrow mononuclear cells obtained from aspirations of the iliac crest of six patients with radiologically demonstrable Paget's disease and from the aspirations of 10 normal subjects (Reddy et al., 1995). Using reverse transcriptase−PCR techniques, they observed that five of the six patients had MV nucleocapsid transcripts, whereas none of the 10 normal subjects had detectable transcripts. Because granulocyte−macrophage colony-forming units (CFU-GM), the most likely OCL precursors, circulate in the peripheral blood, Reddy and colleagues (1996) examined peripheral blood samples for the presence of MV nucleocapsid transcripts by reverse transcriptase−PCR in Paget's disease and control subjects. In 9 of 13 patients, MV transcripts were detected. They were localized to peripheral blood monocytes (whose precursor is CFU-GM) by in situ hybridization. Results were negative in the 10 control subjects.

Three studies from the United Kingdom, one from the United States, and one from New Zealand have produced negative results with respect to detection of Paramyxoviridae mRNA in Paget's disease. In one study, RNA extracts of 10 bone specimens failed to exhibit MV, CDV, RSV, or parainfluenza 3 virus transcripts after reverse transcriptase−PCR evaluation (Ralston et al., 1991). In a second study, both bone cells cultured from pagetic explants and bone biopsies were studied similarly by reverse transcriptase−PCR techniques for the presence of MV and CDV transcripts (Birch et al., 1994). Completely negative results were obtained. A second UK study using the same primers also failed to find MV or CDV transcripts in long-term bone marrow cultures from lesions of Paget's disease (Ooi et al., 2000). In the US study, Nuovo and colleagues (1992) also could not detect MV-specific cDNA in pagetic specimens by using PCR and in situ hybridization in combination. The New Zealand study (Matthews et al., 2008) reported no evidence of MV ribonucleic acid in 13 OB and 13 bone marrow cell cultures. The explanation for the disparate results is unclear because these investigators demonstrated that they can detect very low levels of MV transcripts by PCR (Ralston et al., 2007).

Several studies have addressed the levels of circulating antibodies against various paramyxoviruses in patients with Paget's disease. Antibody titers have not been found to be greater in Paget's disease than in control subjects (Basle et al., 1983; Gordon et al., 1991; Pringle et al., 1985).

Cellular and molecular biology of Paget's disease

The development of in vitro techniques for the study of the ontogeny of human OCLs has made it possible to gain new insights into the pathogenesis of Paget's disease. Kukita and colleagues (1990) first established long-term cultures of marrow from involved bones of patients with Paget's disease and noted that the multinucleated cells that formed shared many of the characteristics of pagetic OCLs. Compared with OCL-like cells formed in normal marrow cultures, the pagetic OCL-like cells formed more rapidly and in much greater numbers (10- to 100-fold greater), had increased numbers of nuclei, and had higher levels of tartrate-resistant acid phosphatase. Examination of these cells by electron microscopy did reveal many features of OCLs found in pagetic bone biopsies, but the characteristic nuclear and cytoplasmic inclusions were not observed. As mentioned previously, the antigens of MV and RSV nucleocapsids were detectable in these cells (Mills et al., 1994); apparently the nucleocapsid structures do not form in this in vitro setting, perhaps because the formation of nucleocapsid structures requires more than the nucleocapsid gene alone.

Because the increased numbers of OCLs in pagetic lesions are of obvious importance in the pathogenesis of the disease, it seemed logical to examine OCL precursors in the marrow aspirates to determine whether they were abnormal or whether other cells in the marrow microenvironment were participants in the pathology. Demulder and colleagues (1993) examined CFU-GM in cultures of unfractionated marrow mononuclear cells and found that CFU-GM colony formation was significantly increased compared with that of normal cells. Using an antibody that recognizes the CD34 antigen present on most hematopoietic precursors, they also isolated enriched hematopoietic precursors and found similar numbers of OCL precursors in pagetic and normal marrow aspirations. Subsequent coculture experiments with highly purified hematopoietic precursors ($CD34^+$ cells) and nonhematopoietic marrow accessory cells ($CD34^-$ cells) demonstrated that the growth of pagetic precursors was significantly enhanced by both normal and pagetic $CD34^-$ cells. CFU-GM colony formation was also significantly increased when normal $CD34^+$ cells were cocultured with pagetic, but not with normal, $CD34^-$ cells. CFU-GM colony-derived cells from pagetic patients also formed OCL-like multinucleated cells with 1,25-dihydroxyvitamin D ($1,25(OH)_2D_3$) in concentrations 1/10 of that required for normal multinucleated cell formation. Thus, these experiments suggest that OCL precursors are abnormal in Paget's disease and that other cells in the pagetic marrow microenvironment may stimulate the growth and differentiation of these abnormal precursors. Menaa and coworkers (2000a) have extended the original studies of Demulder et al. (1993) to further understand the enhanced

sensitivity of OCL precursors from patients with Paget's disease to the marrow microenvironment and the enhanced osteoclastogenic potential of the marrow microenvironment from Paget's patients. Menaa and coworkers (2000a) showed that pagetic OCL precursors are hyperresponsive to receptor activator of NF-κB ligand (RANKL), a member of the tumor necrosis factor (TNF) gene family, which is absolutely required for OCL formation. The increased sensitivity to RANKL was caused by the additive effects of interleukin-6 (IL-6) produced by the pagetic marrow and RANKL on OCL formation. Furthermore, Menaa and coworkers (2000a) showed that marrow stromal cells from patients with Paget's disease expressed higher levels of RANKL than normal marrow stromal cells, although Naot and colleagues (2007) did not find increased RANKL expression by OBs from pagetic lesions by using gene expression profiling. Thus, in pagetic lesions the OCL precursors are hyperresponsive to RANKL, and increased amounts of RANKL may be expressed in the marrow microenvironment, further enhancing the osteoclastogenic potential of the pagetic lesion. In areas of bone not affected by Paget's disease, enhanced expression of RANKL was not detected.

As noted earlier, a strong candidate for a significant autocrine/paracrine factor involved in the increased OCL formation in Paget's disease is IL-6. Roodman and colleagues (1992) found that conditioned media from long-term pagetic marrow cultures increased multinucleated cell formation in normal marrow cultures, and antibodies to IL-6 blocked the stimulatory activity. Antibodies to IL-1, granulocyte−macrophage colony-stimulating factor, and TNFα had no effect on the stimulatory activity. In situ hybridization studies demonstrated that the multinucleated cells in the pagetic marrow cultures were actively transcribing IL-6 mRNA. In addition, bone marrow plasma samples obtained from sites of Paget's disease had increased levels of IL-6 in 9 of 10 patients compared with samples from normal subjects. Peripheral plasma also had elevated IL-6 levels in 17 of 27 patients. In another study, basal plasma IL-6 activity was increased in 19 of 22 patients (Schweitzer et al., 1995). The concept that IL-6 may be an important autocrine/paracrine factor in Paget's disease is also supported by the studies of Hoyland and colleagues (1994a), who used in situ hybridization to localize the expression of IL-6, IL-6 receptor, and IL-6 transcription factor in the bone of patients with Paget's disease in comparison with those with osteoarthritis. The OBs in both disorders expressed all three mRNAs, but in Paget's disease IL-6 and its receptor mRNA showed higher levels of expression. In the OCLs of both disorders, the receptor and transcription factor were expressed, but only in Paget's disease was IL-6 mRNA expressed in OCLs. Hoyland and Sharpe (1994b) also examined the expression of c-fos protooncogene in the bone of six patients with Paget's disease by in situ hybridization. c-fos has been found to be important in the regulation of OCLs and was markedly upregulated in pagetic OCLs and, to a lesser extent, in the OBs. It is possible that this is a consequence of IL-6 action (Korholz et al., 1992).

Ralston and colleagues (1994) also studied cytokine and growth factor expression in bone explants of Paget's disease and in control subjects (postmenopausal women with and without osteoporosis and young bone graft patients) and could not find differences between pagetic and nonpagetic bone. IL-6 mRNA was not detected in 40% of the pagetic specimens from severely affected individuals. There is no obvious explanation for their nonconfirmatory data.

Another abnormality of pagetic OCL precursors is that they are hyperresponsive to $1,25(OH)_2D_3$. OCL precursors form OCLs in vitro with concentrations of $1,25(OH)_2D_3$ that are 1−2 logs less than that required to induce OCL formation by normal OCL precursors (Kukita et al., 1990). Menaa and coworkers (2000b) have shown that this increased sensitivity to $1,25(OH)_2D_3$ is not caused by increased numbers of vitamin D receptors in pagetic OCL precursors or by mutations in the vitamin D receptor. Kurihara and colleagues (2000a) have used a GST−vitamin D receptor fusion protein to further examine the increased sensitivity of pagetic OCL precursors to $1,25(OH)_2D_3$. These workers found that TAFII-20, a component of the transcription factor IID transcription complex, was increased in OCL precursors from patients with Paget's disease compared with normal patients. This increase in expression of TAFII-20 did not require treatment of the cells with $1,25(OH)_2D_3$. These data suggest that pagetic OCL precursors express higher levels of TAFII-20 or have increased levels of a coactivator that can bind to TAFII-20 and the vitamin D receptor in the presence of lower concentrations of $1,25(OH)_2D_3$ to initiate transcription of vitamin D receptor-responsive genes.

Kurihara et al. (2000b) provided initial evidence for a pathophysiological role of MV in the abnormal OCL activity in Paget's disease. They found that OCL precursors from normal subjects transduced with retroviral vectors expressing the MV nucleocapsid protein (MVNP) gene formed OCLs that displayed many of the abnormal characteristics of pagetic OCL. Similarly, MV infection of bone marrow cells from mice that expressed the CD46 MV receptor formed OCLs that expressed the characteristics of pagetic OCL (Reddy, 2001). Further, transgenic mice with MVNP targeted to the OCL lineage formed OCL and bone lesions characteristic of Paget's disease (Fig. 67.2). These results demonstrated that MVNP expression in OCL was sufficient to induce OCL and bone lesions characteristic of Paget's disease.

Teramachi et al. (2014) then examined how MVNP expression in OCLs results in formation of OCLs that express a pagetic phenotype. They found that MVNP expression in OCLs induced them to secrete high levels of IL-6, and loss of IL-6 expression in MVNP mice abrogates the formation of pagetic OCLs and bone lesions in vivo. However, overexpression

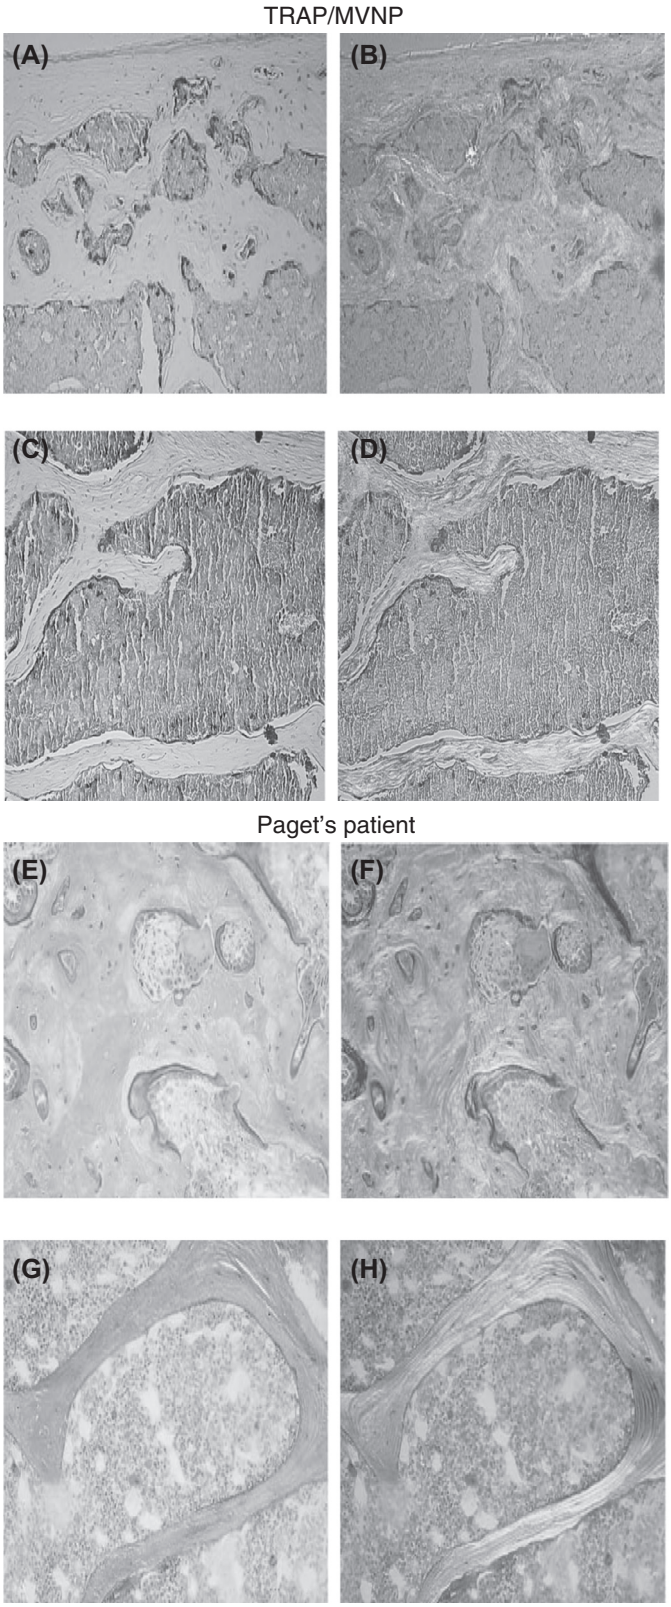

FIGURE 67.2 Histological features of a 12-month-old tartrate-resistant acid phosphatase/Edmonston strain measles virus nucleocapsid protein (*TRAP/MVNP*) transgenic mouse compared with wild-type (WT) control, a Paget's patient, and a normal subject. (A–D) Histological features in a TRAP/MVNP mouse (A and B) are compared with a WT control (C and D) at 12 months of age. Note thickened, irregular trabeculae, increased osteoclast number (A), tunneling resorption, and increased amounts of woven bone in the TRAP/MVNP mouse (B) compared with the WT control (C and D). (E–H) Provided for comparison are sections from a 58-year-old woman with Paget's disease (E and F) and a 58-year-old normal subject (G and H). (A and C) Viewed under polarized light. (E and G) Sections viewed under polarized light. Original magnification, ×3100. *From Kurihara, N., Zhou, H., Reddy, S.V., Garcia-Palacios, V., Subler, M.A., Dempster, D.W., Windle, J.J., and Roodman, G.D., 2006. Expression of the measles virus nucleocapsid protein in osteoclasts in vivo induces Paget's disease-like bone lesions in mice. J. Bone Miner. Res. 21, 446–455. (See plate section).*

of IL-6 in OCL precursors was not sufficient to induce pagetic OCL formation or pagetic bone lesions in mice (Teramachi et al., 2014).

Sun and coworkers (2014) reported that MVNP also regulates expression of TANK-binding kinase 1 (TBK1) and optineurin (OPTN) in OCL precursors, which also contribute to the generation of pagetic OCL. Prior to these studies, the roles of TBK1 and OPTN (members of the IκB kinase family) in bone metabolism were previously unknown. These authors found that MVNP interacts with TBK1−OPTN complexes in OCL precursors to increase the TBK1 kinase activity and protein stability, while decreasing OPTN levels. Overexpression of TBK1 alone in normal mouse OCL precursors increased endogenous IL-6 expression but did not induce formation of pagetic OCLs. However, overexpression of TBK1 in OCL precursors expressing MVNP synergized with MVNP to increase pagetic OCL formation. Similarly, TBK1 knockdown in OCL precursors expressing MVNP impaired the development of pagetic-like OCLs. These results demonstrate that TBK1 is an important contributor to MVNP's capacity to increase expression of IL-6 in OCL precursors and induce development of OCLs that express a pagetic phenotype.

Although much is known about the abnormal OCL activity in Paget's disease, very little is known about the mechanisms responsible for the abnormal OB activity in Paget's disease. Bone resorption and formation are tightly linked, with bone formation normally occurring only at sites of previous bone resorption. This "coupling" of bone remodeling is largely dependent on communication between OCLs and OBs with Eph receptors expressed on OBs, and ephrins on OCLs and OBs have been implicated as major regulators of coupling (Zhao et al., 2006). Ephs and ephrins are cell surface molecules that have bidirectional signaling and play major roles in tumor progression, angiogenesis, cell migration, and morphogenesis (Matsuo, 2012). Zhao and coworkers showed that OCLs express the nuclear factor of activated T cells 1 (NFATc1) target gene ephrinB2, while OBs express its receptor EphB4. Increased EphB4 signaling in OBs can increase bone mass in mice, while reverse signaling through ephrinB2 on OCLs suppresses OCL differentiation by inhibiting the c-fos/NFATc1 cascade. These data suggest that ephrinB2/EphB4 signaling can play a major role in coupling between bone resorption and new bone formation. Since Paget's disease represents the most exaggerated form of coupled bone formation, Teramachi et al. (2016) examined the expression of ephrins and their receptors in OCLs and OBs from MVNP, $p62^{P394L}$/MVNP, $p62^{P394L}$-knock-in, and wild-type mice. The presence of MVNP but not $p62^{P394L}$ in OCLs increased the expression of ephrinB2 in OCLs and EphB4 in OBs. Further, coculture of OCLs expressing MVNP with OBs from MVNP mice enhanced OB differentiation. These data suggested that increased ephrinB2/EphB4 expression induced by MVNP may drive the enhanced bone formation in MVNP mice. A preliminary gene expression profiling study of highly purified OCLs from MVNP, $p62^{P394L}$, and wild-type mice showed that OCLs from MVNP mice expressed elevated levels of insulin-like growth factor 1 (IGF-1) mRNA compared with wild-type mice, while OCLs from $p62^{P394L}$-knock-in mice did not (Teramachi et al., 2016). They further found that IL-6 regulated the increased IGF-1 protein expression in OCLs from MVNP mice, and IL-6 and IGF-1 in turn increased ephrinB2 expression by OCLs. IL-6 also increased EphB4 on OBs, while IGF-1 enhanced OB differentiation (Fig. 67.3). Importantly, OCLs from Paget's disease patients that express MVNP also express increased levels of IGF-1 and ephrinB2 compared with OCLs from normal donors. These results suggest that IL-6 and IGF-1 expression by pagetic OCLs contributes to the increased bone formation in Paget's disease.

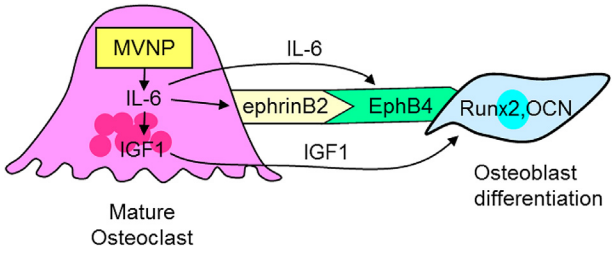

FIGURE 67.3 Model of osteoclast (OCL)/osteoblast (OB) coupling in Paget's disease. Measles virus nucleocapsid protein (*MVNP*) expression induces high levels of interleukin-6 (*IL-6*) in OCLs, which increases insulin-like growth factor 1 (*IGF1*) and ephrinB2 in OCLs and increases EphB4 in OBs to increase coupling. IGF1 further enhances ephrinB2 expression on OCLs and increases Runx2, a transcription factor required for osteoblast differentiation, and osteocalcin (*OCN*) levels in OBs to increase bone formation. *From Teramachi, J., Nagata, Y., Mohammad, K., Inagaki, Y., Ohata, Y., Guise, T., Michou, L., Brown, J.P., Windle, J.J., Kurihara, N., Roodman, G.D., 2016. Measles virus nucleocapsid protein increases osteoblast differentiation in Paget's disease. J. Clin. Investig.126, 1012−1022.*

Genetic mutations linked to Paget's disease

As noted earlier, genetic factors are an important contributor to the etiology of Paget's disease, with 15%–40% of affected patients having a first-degree relative with Paget's disease, and multiple families with Paget's disease have been reported with vertical transmission of Paget's disease in an autosomal dominant mode of inheritance (Morales-Piga et al., 1995). Not surprisingly, most of the mutations or single-nucleotide polymorphisms (SNPs) linked to or that predispose patients to Paget's disease affect OCL activity. Mutations in the coding regions of sequestosome 1 (SQSTM1) and valosin-containing protein (VCP/p97 or CDC48) have been linked to Paget's disease (Laurin et al., 2002, Mehta et al., 2013). SQSTM1 encodes the p62 protein, a multidomain scaffold protein that serves as a platform for the formation of cytokine signaling complexes, including RANKL and TNF, and acts as a cargo adaptor for polyubiquitinated proteins for proteasomal degradation and autophagy (Roodman, 2010). All 28 mutations in p62 identified in Paget's patients cause loss of function of the C-terminal ubiquitin association domain and result in increased cytokine activation of NF-κB. These p62 mutations increase RANKL responsivity of OCL precursors to enhance OCL formation. The most common p62 mutation linked to Paget's disease results in a proline (P) to leucine (L) substitution at codon 392 ($p62^{P392L}$). This mutation occurs in 10% of sporadic and 30% of familial Paget's patients (Hocking et al., 2000,Laurin et al., 2002,Morisette et al., 2006). Paget's disease patients with p62 mutations have an earlier onset and increased severity of disease compared with other Paget's disease patients, although the severity and age of onset of disease among affected members with the same p62 mutation vary (Bolland et al., 2007; Leach et al., 2006; Gennari et al., 2010). Further, mutations in p62 linked to Paget's disease demonstrate incomplete penetrance, because 15%–20% of patients with p62 mutations fail to develop Paget's disease (Bolland, 2013). In addition, Kurihara et al. (2011) found that mice with targeted expression of $p62^{P392L}$ in OCLs or mice with knock-in of the murine equivalent of human $p62^{P392L}$ ($p62^{P394L}$) develop increased numbers of OCLs, and do not develop bone lesions or OCLs characteristic of Paget's disease (Fig. 67.4). Importantly, Kurihara and colleagues (2011) showed that antisense knockdown of MVNP expression in MVNP-positive OCL precursors from Paget's patients harboring the $p62^{P392L}$ mutation resulted in loss of their ability to form OCLs that expressed a pagetic phenotype, although the OCL precursors still had increased responsivity to RANKL. These results indicated that $p62^{P392L}$ by itself was insufficient to induce a pagetic phenotype in OCLs from $p62^{P392L}$ patients, and that MVNP is a required cofactor for pagetic OCL formation in this subset of Paget's disease patients. However, when $p62^{P394L}$-knock-in mice were crossed

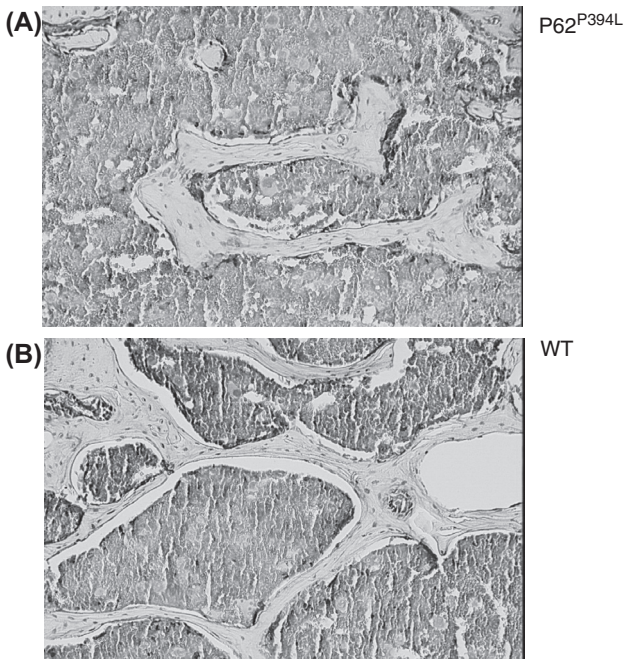

FIGURE 67.4 Histological studies of bone from TRAP-$p62^{P392L}$ mice. Vertebral cancellous bone from (A) TRAP-p62P392L mice or (B) wild-type (*WT*) littermates is shown. Note increased osteoclast perimeter, reduced cancellous bone volume, fewer and thinner trabeculae, and loss of trabecular connectivity in TRAP-p62P392L bone. *From Kurihara, N., Hiruma, Y., Zhou, H., Subler, M.A., Dempster, D.W., Singer, F.R., Reddy, S.V., Gruber, H.E., Windle, J.J., Roodman, G.D., 2007. Mutation of the sequestasome-1 (p62) gene increases osteoclastogenesis but does not induce Paget's disease. J. Clin. Investig. 117, 133–142. (See plate section).*

with mice expressing MVNP in cells of the OCL lineage, the $p62^{P394L}$/MVNP mice developed greater numbers of pagetic-like OCLs and more dramatic bone lesions that were strikingly similar to those seen in Paget's disease (Kurihara et al., 2011). These results suggest that p62 mutations linked to Paget's disease predispose patients to develop Paget's disease through their capacity to enhance RANKL responsivity of OCL precursors. However, since MVNP-negative Paget's patients carrying $p62^{P392L}$ also have pagetic lesions in vivo, these results suggest that a second genetic mutation or another environmental factor may have contributed to the development of their Paget's disease. In contrast, Daroszewska and coworkers (2011) generated similar $p62^{P394L}$-knock-in mice and reported that these mice developed small pagetic lesions in their long bones. It is unclear why the phenotypes of the two knock-in mouse lines differ, although differences in the genetic background and the phenotypic analyses performed may have contributed.

Like mutations in p62, mutations in VCP and a common variant of OPTN linked to Paget's disease also affect ubiquitin-dependent autophagy. Mutations in VCP are associated with a syndrome characterized by inclusion body myopathy, frontotemporal dementia, and early-onset Paget's disease. VCP mutations have also been linked to hereditary and spontaneous amyotrophic lateral sclerosis (ALS) (Mehta et al., 2013). OPTN is a negative regulator of NF-κB signaling and OCL formation that has been linked to glaucoma and ALS as well as Paget's disease (Obaid et al., 2015). Further, genome-wide association studies have identified at least seven loci with genetic polymorphisms (SNPs) linked to increased susceptibility to develop Paget's disease and that together account for 13% of the familial risk of Paget's disease (Albagha et al., 2010). Many but not all of these predisposition SNPs occur in genes that can affect OCL function, such as CSF1, OPTN, RANK, DC-STAMP, Ras, and RAB interactor 3. In contrast to mutations in p62 or VCP, these SNPs do not have an impact on the severity of Paget's disease (Bolland, 2013).

However, genetic causes alone cannot be responsible for the development of Paget's disease, since several epidemiologic studies showed that the prevalence and severity of Paget's disease has significantly decreased over the past 20–30 years (Doyle et al., 2002; van Staa et al., 2002; Cundy et al., 2004; Poor et al., 2006). These data suggest that additional factors are required for patients to develop Paget's disease, since this marked change in the epidemiology of Paget's disease is too rapid to be explained on a genetic basis. More likely, changes in environmental factors that contribute to Paget's disease have occurred.

Further, studies with families with Paget's disease linked to mutations in p62 also suggest that these mutations cannot completely account for the pathogenesis of Paget's disease, because the severity of the disease in family members carrying these mutations varies widely, and up to 83% of patients harboring the p62 mutation do not have Paget's disease (Laurin et al., 2002b; Bolland et al., 2007). These data suggest that additional factors may affect the pathogenesis of Paget's disease.

The etiology of Paget's disease

As reviewed earlier, Paget's disease is characterized by focal regions of highly exaggerated bone remodeling, with abnormalities in all phases of the bone remodeling process. In most affected individuals, it progresses slowly over many years without extending to new sites of involvement. The underlying pathophysiology appears to reflect a localized increase in the number of OCLs followed by a secondary increase in OB activity. These OCLs have striking characteristics by both light and electron microscopy. In Paget's disease, the OCLs may be far greater in size than OCLs in normal individuals and in patients with diseases in which OCLs are activated, such as primary hyperparathyroidism. Genetic and nongenetic factors have been implicated in the pathogenesis of Paget's disease, and genetic factors are clearly an important component of its etiology. However, microenvironmental factors appear to also play an important role. As indicated previously, the prevalence of Paget's disease has decreased over the past several decades, but not in all countries (Corral-Gudino et al., 2013). One possible explanation is that measles vaccination, beginning in 1963, was variably introduced over time into populations of different countries (Singer, 2015). Further, expression of the most common mutation linked to Paget's disease, the $p62^{P392L}$, when expressed in normal OCL precursors or targeted to the OCL lineage in transgenic mice, does not induce pagetic lesions or pagetic-like OCLs. In contrast, expression of the MVNP gene in vitro or in vivo results in formation of OCLs that express all the phenotypic characteristics of OCLs from patients with Paget's disease and form bone lesions that are very similar to those found in Paget's disease. The requirement for a nongenetic factor participating in the etiology of Paget's disease would explain why some individuals who have Paget's-associated mutations do not develop Paget's disease. One possibility is that such mutations predispose patients to Paget's disease by enhancing basal osteoclastogenesis, thereby creating a permissive environment for the development of Paget's disease. A second environmental factor, such as the expression of certain viral proteins, may further alter signaling pathways or the expression of specific transcription factors, which results in development of pagetic OCLs. These include changes in vitamin D receptor transcription as well as changes in the NF-κB signaling pathways and other signaling pathways

involved in OCL formation. Further, the increased numbers of OCLs would then secrete high levels of IL-6, which would then further expand OCL formation. Because OCL and OB activities remain coupled in Paget's disease, the increased OCL activity would result in increased OB numbers and rapid formation of new bone. In addition, Hiruma and colleagues (2008) found that marrow stromal cells expressing the $p62^{P392L}$ mutation express higher levels of RANKL than normal stromal cells when treated with low concentrations of $1,25(OH)_2D_3$. These results suggest that genetic mutations linked to Paget's disease may increase OCL formation both by enhancing OCL activity per se and by creating a more osteoclastogenic environment in the pagetic lesions. However, these mutations by themselves are not sufficient to induce Paget's disease in animal models or pagetic-like OCLs in human marrow cultures.

Thus, there has been a tremendous output of new information on the etiology and pathophysiology of Paget's disease. Identification of genes involved in osteoclastogenesis that are mutated in Paget's disease and the characterization of nongenetic factors such as MV that may be involved have provided important insights in the control of bone remodeling in Paget's disease as well as normal bone. Studies of abnormal bone remodeling in Paget's disease could result in identification of coupling factors produced by OCLs, which enhance new bone formation. Understanding the pathophysiology of Paget's disease should provide important insights into the mechanisms that control normal OCL differentiation and bone formation and may lead to both new therapies for patients with Paget's disease and the identification of new anabolic factors for treating patients with severe bone loss.

Chapter outline

Introduction

Osteoporosis is a disease characterized by low bone mineral density (BMD), deteriorated bone microstructure, and increased risk of fracture that affects over 12 million individuals in the United States (Black and Rosen, 2016) https://paperpile.com/c/K3pMVk/i02VE). Family history is the strongest risk factor for development of osteoporosis, indicating a strong genetic basis (Christian et al., 1989; Ralston and de Crombrugghe, 2006; Ralston and Uitterlinden, 2010). Indeed, fracture-related traits, such as BMD, are among the most highly heritable disease-associated quantitative traits ($h^2 > 0.50$) (Christian et al., 1989; Ralston and de Crombrugghe, 2006; Ralston and Uitterlinden, 2010). As a result, developing a comprehensive biological understanding of bone requires a detailed understanding of the identity and function of the genes contributing to variation in bone traits.

Genome-wide association studies

Genome-wide association study (GWAS) using high-throughput microarrays to genotype hundreds of thousands and even millions of the most common genetic variants and relating them to phenotypic variation has transformed the field of genetics over the past decade. Table 68.1 lists resources of GWAS findings, disease-risk genetic variants, and their functional impact and druggable targets.

Conceptually, performing a GWAS is straightforward and consists of two main steps: (1) "data generation"—acquisition of genotypes and phenotypes and (2) "analysis"—associating genotype with phenotype (Bush and

Moore, 2012). The first step of GWAS requires the generation of genome-wide single-nucleotide polymorphism (SNP) genotypes in a cohort of individuals who have been phenotyped for a trait of interest. In the osteoporosis field, the trait of interest most often has been DXA-derived BMD (Estrada et al., 2012; Rivadeneira et al., 2009), though other bone traits have been interrogated, such as bone size (Deng et al., 2013; Lei et al., 2012; Liu et al., 2008; Ran et al., 2013), trabecular density (Nielson et al., 2016), and estimated BMD of the heel measured by ultrasound (Kemp et al., 2016). Genotypes are generated using massively parallel genotyping arrays that simultaneously generate genotypes for 500,000 to 55,000,000 SNPs per individual. The most popular genotyping arrays are those produced by Illumina and Affymetrix (Chee et al., 1996; Gunderson et al., 2004). Array SNPs are spaced throughout the genome and typically designed to "capture" as much common genetic variation as possible in the human genome.

A key concept in the GWAS, and for that matter any genetic analysis, is linkage disequilibrium (LD). LD is often confusing to nongeneticists but provides the basis upon which GWAS is possible. LD is a phenomenon in which the alleles at two positions on a chromosome (SNPs or other variants) are not randomly distributed in a population. LD arises from the fact that alleles are inherited together on the same chromosome. Recombination during meiosis acts to separate alleles, but this takes many generations and is extremely rare for genetic variants in close proximity. If LD did not exist, all alleles would segregate independently. In this context, all variants would have to be tested in a GWAS to capture the majority of genetic variation potentially contributing to a disease. However, LD causes considerable redundancy among variants. For the vast majority of common genetic variants (those where the rarest allele is present in at least 5% of individuals), a number of other variants in the human genome will be in high LD. In practical terms this means that if the genotype is known for one variant, the genotype of any other variant in high LD is also known. Because of LD, it is possible to conduct a GWAS without genotyping all variants and still capture most variation from common variants across the genome. While this is a significant advantage of LD, it does have negative consequences when it comes to identifying variants that are truly causal for GWAS associations.

This approach interrogates the whole genome to search for associations without any prior assumptions about the underlying cause of a disease or the genetic architecture of a trait. GWASs have provided valuable information about the contribution of genetic variants to phenotypes including the following observations: (1) Most variants having a statistically significant association with phenotypes have small effect sizes and only explain a small percent of variance in a trait

(Manolio, 2009); (2) Many more variants with effect sizes that do not reach statistical significance account for some of the so-called "missing heritability" of complex diseases that have been studied (Yang et al., 2010); (3) Many rare variants with larger effect sizes also contribute to phenotypic variance (Marouli et al., 2017); (4) Most significant genetic associations from GWAS are located in noncoding regions of the genome such that their associations with phenotypic variation are mediated through regulatory effects (Maurano et al., 2012); (5) Current models of genetic associations with disease postulate that genetic variants collectively contribute multiple weak effects on key genes and regulatory pathways that confer the risk of various diseases.

The polygenic nature of complex disease has been well studied in the field of musculoskeletal genetics in a similar evolution as has been observed for other diseases. Thus, collaborative efforts across the world have enabled the scientific community interested in complex diseases of the skeleton to pool data to achieve the large sample sizes needed to characterize the genetic architecture of common diseases of the skeleton such as osteoporosis (Karasik et al., 2002, 2007, 2017a, 2017b), which has a high heritability regardless of how one measures the skeletal features and fracture (Michaelsson et al., 2005). Over time these collaborations have produced sample sizes that have now achieved upwards of half-a-million individuals.

Several large-scale GWAS meta-analyses of osteoporosis-related traits have been published (Estrada et al., 2012; Rivadeneira et al., 2009; Nielson et al., 2016; Hsu et al., 2010; Kung et al., 2010; Liu et al., 2012; Oei et al., 2012; Zheng et al., 2015). A summary of those loci can be found in a review article (Hsu and Kiel, 2012) as well as more recent publications (Nielson et al., 2016; Zheng et al., 2015; Hsu et al., 2016a). To date, the two largest GWAS meta-analyses for BMD have involved ~36,000 Caucasian men and women with 2.5 million HapMap-imputed common SNPs as well as one involving up to 31,016 fracture cases and 102,444 controls without fracture as part of the Genetic Factors for Osteoporosis consortium (Estrada et al., 2012). To date, ~70 genome-wide significant loci have been found to be associated with DXA-measured BMD of the lumbar spine (LS) and/or femoral neck (FN). Eighteen of these 70 BMD-associated loci were also associated with fracture risk in a case–control study (Estrada et al., 2012; Hsu and Kiel, 2012; Oei et al., 2011). As is true for many GWAS efforts, the identified common SNPs with the most significant *P*-values may not be the causal variants and are more likely to be in LD with underlying untyped causal variants or variants with less significant *P*-values. To illustrate the growing number of significant genetic associations observed with increasing sample sizes, one only has to consider that the first GWAS for DXA-derived BMD and hip geometry traits, the Framingham Study using a genotyping platform with only 100,000 SNPs in a sample of only 1,141 men and women, yielded no significant genome-wide findings. The most recent GWAS based on quantitative calcaneal ultrasound (estimated BMD—eBMD) in 445,326 individuals from the UK Biobank cohort identified 1,103 conditionally independent signals mapping to 515 loci and explained 18% of the variance in eBMD (Morris et al., 2019). At these 515 loci, 301 of which were novel when compared with the next largest GWAS in the same cohort when genotyping 140,623 individuals of European descent, 307 conditionally independent SNPs attained genome-wide significance at 203 loci (of which 153 were novel), altogether explaining 11.8% of the variance. These included the majority of SNPs previously associated with DXA-derived BMD as well as 308 novel loci, including many containing genes that had not been previously implicated in bone physiology. The growing number of loci for bone density highlights the value of expanding the sample size of GWASs and the great potential for identifying new biology as a next step toward driving these discoveries in the direction of clinical applications (e.g., drug targets). In fact, when all the GWAS signals are considered in pathway analyses, gene clusters are characterized by factors from major pathways critical to bone biology such as the RANK–RANKL–OPG pathway, mesenchymal–stem cell differentiation, endochondral ossification, and Wnt signaling. New targets may also be identified from GWAS. In a recent study, a low-frequency noncoding variant near a novel locus, engrailed homeobox-1 (*EN1*), with an effect size fourfold larger than the mean of previously reported common variants for BMD of the LS (rs11692564 (T), minor allele frequency (MAF) = 1.6%, replication effect size = +0.20 standard deviations, *P*-value for the meta-analysis = 2×10^{-14}), was confirmed. This variant's positive effect on BMD was accompanied by a decreased risk of fracture when comparing 598,742 fracture cases with 409,511 controls (odds ratio = 0.85; $P = 2 \times 10^{-11}$).

As more GWASs are performed, phenotypes other than BMD are being targeted. A GWAS of quantitative computed tomography of the spine identified a novel genetic variant associated with increased vertebral volumetric BMD (vBMD) not previously found to be significant for traditional spine DXA-derived BMD (Nielson et al., 2016). Also in this study, rs2468531 (5p13, near SLC1A3), the allele associated with higher vBMD, was found to be associated with a lower odds ratio of radiographic vertebral fracture after correction for multiple testing (odds ratio = 0.75 per minor allele; false discovery rate (FDR) $P = .01$). Finally, this GWAS identified SNP rs12742784 in the 1p36.12 locus as being associated with increased expression of *EPHB2*, which lies about 355 kb downstream ($\beta = 0.12$, FDR $P = 1.72 \times 10^{-3}$), but was only marginally associated ($P = .08$) with *ZBTB40*, the nearest gene in this GWAS locus (about 96 kb downstream).

With the advent of high-resolution peripheral quantitative computed tomography (HR-pQCT) scanning, further refinement of skeletal phenotypes may be realized. Bone microarchitecture assessed by HR-pQCT has been reported to be heritable even after adjusting for DXA-based areal BMD (aBMD) (Karasik et al., 2017, 2017a) and has been associated with fracture risks. Genetic studies of these phenotypes may reveal unique, novel genes that contribute to skeletal integrity not identifiable in previous GWASs of aBMD. Recently, results were reported from a study using data from 5,692 adult Caucasians obtained from seven cohort studies (Framingham Study, Mayo Clinic, Geneva Retirees Cohort, Os des Femmes de Lyon, Structure of the Aging Men's Bones, Osteoporotic Fractures in Men Sweden, and Gothenburg Osteoporosis and Obesity Determinants study) (Hsu et al., 2016b) with replication in 2,100 independent samples (Canadian Multicentre Osteoporosis Study and QUAlité Osseuse LYon Orléans, or QUALYOR, study). Multiple HR-pQCT phenotypes were assessed, all of the studies were genotyped by SNP chips, and whole-genome imputation to ~40 million SNPs was performed based on the Haplotype Reference Consortium. Meta-analysis was performed to combine association results.

Of the 17 genome-significant loci (386 SNPs with $p < 5 \times 10^{-8}$), 12 were not reported by previous aBMD GWAS meta-analyses: *SIX2, PNPT1, chr4q35.2, KCNIP1, chr5q11.2, chr7q31.31, CSMD1, NRG1, PTHLH-CCFC91, FAM155A, C3*, and *FMN2* loci. The majority of these loci were specifically associated with the phenotype of failure load calculated using finite element analysis (FEA-FL), total area, cortical thickness, trabecular spacing (TbSp), trabecular number, or cortical BMD. The most significantly associated SNP, rs10254825, was associated using FEA-FL ($P = 2.6 \times 10^{-22}$) and associated with a risk for fracture. The remaining 5 loci (*ZBTB40, SPTBN1, MEF2C-AS1, WNT16-FAM3C,* and *AKAP11-TNFSF11*) were previously reported by aBMD GWAS and are associated with multiple HR-pQCT phenotypes at both the radius and the tibia (e.g., Trabecular BMD, Total BMD, TbSp). These findings suggest that the genetic control of bone microarchitecture may provide additional insights into the pathogenesis of skeletal integrity not available from aBMD.

In the largest GWAS meta-analysis to date evaluating the influence of genetic variation on fracture risk, comprising 37,857 cases and 227,116 controls with replication in up to 147,200 fracture cases and 150,085 controls, the signals mapped to genes clustering in pathways known to be critical to bone biology (e.g., *SOST*, *WNT16*, and *ESR1*) and others identifying novel pathways (*FAM210A, GRB10*, and *ETS2*). Using the genetic variants as instrumental variables in a "Mendelian randomization" analyses demonstrated a causal effect of BMD on fracture risk, where each standard deviation decrease in genetically determined FN BMD was associated with a 55% increase in fracture risk (odds ratio = 1.55; 95% CI: 1.48−1.63; $P = 1 \times 10^{-68}$) (Trajanoska et al., 2018).

Focusing on the hallmark fracture of osteoporosis, the vertebral fracture, a recent GWAS was conducted in 1,553 postmenopausal women with clinical vertebral fractures and 4340 controls, with a two-stage replication involving 1,028 cases and 3,762 controls (Alonso et al., 2018). Potentially causal variants were identified using expression quantitative trait locus (eQTL) data from transiliac bone biopsies and bioinformatic studies. In contrast to much larger case−control studies, this modestly sized study identified a locus tagged by rs10190845 on chromosome 2q13 that was significantly associated with clinical vertebral fracture (odds ratio = 1.74; 95% CI: 1.06−2.6; $P = 1.04 \times 10^{-9}$). Bioinformatic analysis of this locus identified several potentially functional SNPs that are associated with expression of the positional candidate genes *TTL* and *SLC20A1*. Three other suggestive loci were identified on chromosomes 1p31, 11q12, and 15q11. The fact that this study identified loci that were novel and had not previously been associated with BMD or clinical fractures highlights the importance of studying various skeletal phenotypes. Available resources that may be used in conducting GWASs in human populations are shown in Table 68.1.

Follow-up of genome-wide association studies

Functional annotations

Given that the majority of significant GWAS associations are located in noncoding regions of the genome, one of the challenges of GWAS approaches is to be able to identify the most likely causal variant in a GWAS locus. Due to the LD structure, it is most likely that a cluster of SNPs all show strong associations with a phenotypes in each GWAS locus. Based on statistical association information alone, it is almost impossible to identify which variant(s) are potential causal variants and which gene(s) these causal variants map to. A growing number of tools have been developed to identify the likely causal noncoding variant such as fitness consequence scores (fitCons) (Gulko et al., 2015); prediction tools with machine learning algorithms such as DeepSEA (Zhou and Troyanskaya, 2015), deltaSVM (Lee et al., 2015), and Basset (Kelley et al., 2016); and epigenetic resources from ENCODE (Dunham et al., 2012), and the NIH Epigenetics RoadMap

Project (Roadmap Epigenomics et al., 2015). In addition, colocalization of eQTL (Heyn, 2016) and allelic specific expression in bone tissue (Jemtland et al., 2011), osteoclast cells (Mullin et al., 2018), multiple tissues of the Genotype-Tissue Expression (NIH GTEx) project (GTE, 2012), and miRBase databases for miRNA-coded regions and targets (Griffiths-Jones et al., 2006) can be used to narrow down the variants that may affect gene expression levels (see Fig. 68.1).

Expression quantitative trait loci in human bone tissue and cells

The limitation of currently available bone eQTL studies is their relatively small sample size, which makes it challenging to find associations with less common and rare variants. Two human eQTL studies have been reported. One is for osteoblasts and the other is for PBMC-derived osteoclast-like cells. Primary osteoblasts were derived from trabecular bone of proximal femora obtained from 95 Caucasians undergoing total hip replacement (Grundberg et al., 2009). A gene expression profile with 18,144 known genes via Illumina Human Ref8v2 BeadChips was measured. Genome-wide genotyping of 561,303 SNPs was done using Illumina 550k Duo chips. No imputation was done for this study. All gene expression levels were adjusted for sex and year of birth. Using a P-value $< 3.5 \times 10^{-8}$ (Bonferroni adjusted $P = .05/1{,}404{,}011$ tests), a total of 590 cis-eQTLs were identified. The osteoblast cis-eQTL findings are available through an interactive web-based browser (http://www.regulatorygenomics.org). Cultures of osteoclast-like cells from peripheral blood mononuclear cells were obtained from 158 female patients aged 30−70 years (Mullin et al., 2018). Genotyping was done by the Illumina Infinium

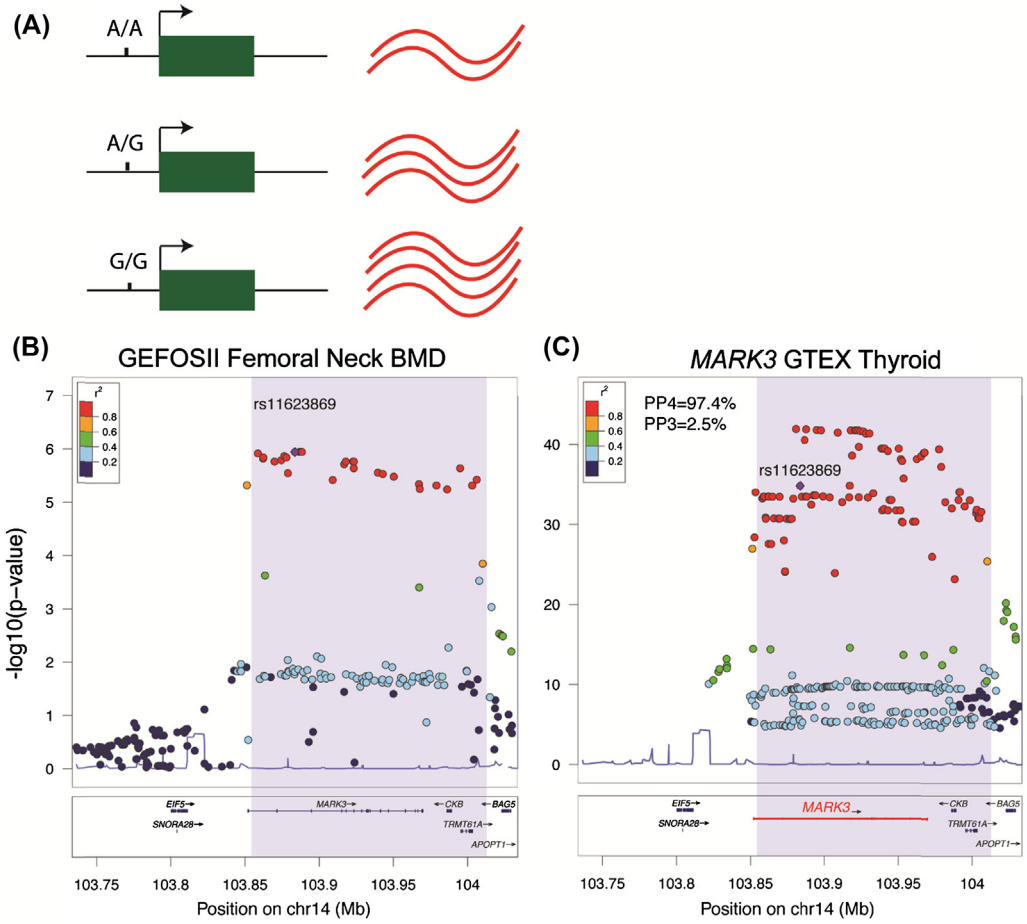

FIGURE 68.1 Using expression quantitative trait locus (eQTL) analysis to inform GWAS. (A) An eQTL is a genetic variant—single-nucleotide polymorphism (SNP), insertion/deletion, etc.—that alters the transcript levels of a gene. In this example, the "G" allele of an SNP increases transcription. eQTL can influence transcription, promoter usage, and posttranscriptional processes such as mRNA stability and splicing. (B and C) A locus influencing BMD and a colocalizing eQTL for *MARK3* in thyroid tissue. A colocalization approach was used to determine that the probability that a single shared variant is responsible for the two associations is 97.4% (PP4). Based on these data, one can hypothesize that variants in this region of chromosome 14 influence *MARK3* expression, which in turn influences BMD. *Data from GTEx.*

OmniExpress-24 BeadChip array and imputed by the Sanger Imputation Service using the Haplotype Reference Consortium release 1.1 reference panel. RNA samples extracted from the osteoclast-like cells and RNA-seq was done by 50 bp single-end reads on an Illumina (San Diego, CA, USA) HiSeq 2500 NGS machine. Several of the eQTL associations identified are relevant to genes that present strongly as having a role in bone, particularly IQGAP1, CYP19A1, CTNNB1, and COL6A3. In addition to specific bone cells, eQTLs on human whole bone have been performed. Iliac bone biopsies from 84 postmenopausal women from Oslo, Norway, were collected, and whole-bone gene expression was done by Affymetrix microarrays (Hsu et al., 2010; Grundberg et al., 2008). Genome-wide genotyping was performed using Affymetrix Genome-Wide Human SNP Array 6.0/Affymetrix Axiom Biobank array (1,000,000 and 700,000 SNPs assessed, respectively) (Reppe et al., 2017). Cis-eQTL analysis within a 2 Mb flanking region (1 Mb upstream and 1 Mb downstream) was performed to evaluate whether they influence transcript levels of genes in human whole bone (Hsu et al., 2010; Grundberg et al., 2008). A hypergeometric test was used to analyze clustered human bone eQTL and GWAS findings from 15 phenotypes from the NHGRI GWAS catalog. The top six phenotypes with their GWAS findings significantly enriched in the whole-bone cis-eQTLs include height, rheumatoid arthritis (RA), serum HbA1c level, ulcerative colitis, schizophrenia, and LS BMD. The enrichment analysis reflected the complexity and mixture of different cell types (including osteocytes, osteoblasts, osteoclasts, and bone marrow composed of hematopoietic and stromal stem cells and their lineages such as endothelial and fibroblast cells) in the whole-bone biopsies (Reppe et al., 2017). Given the mixture of cell types, there was still significant enrichment for the LS BMD GWAS. It is notable that the GWAS of human height, which was the most significantly enriched in human bone eQTLs, has been reported in several studies to be highly correlated with BMD (El-Bikai et al., 2015). The GWAS of RA also demonstrated a high correlation with human bone cis-eQTLs. In previous studies (Lodder et al., 2004), patients with low to moderately active RA have been found to have lower BMD at the hip and high radiological RA damage, which suggests a correlation between the severity of RA and the risk of bone loss. Hence, this correlation could corroborate the significant association between RA and human bone cis-eQTLs. To increase sample size, as part of the EU-supported Osteogene Consortium (PI: Drs. Kaare M. Gautvik (Jemtland et al., 2011; Reppe et al., 2006; Reppe et al., 2010), Sjur Reppe (Reppe et al., 2006, 2010, 2013), and Harish Datta (Reppe et al., 2013; Kalogeropoulos et al., 2010)), 120 low-trauma osteoporotic fracture patients (80 adult Caucasian women and 40 men, aged >50 years) undergoing hip replacement and 60 nonfracture controls were recruited from Diakonhjemmet Hospital, the Lovisenberg Hospital in Oslo, and the Oslo University Hospital. Bone biopsies are done for each patient during hip replacement surgery. Three bone samples are collected at the (1) FN, (2) FN near the fracture zone, and (3) intertrochanteric region. Whole-genome sequencing (WGS) and RNA-seq are planned.

Cell/tissue types targeted by genome-wide association study loci for bone mineral density and osteoporotic fractures

Previous work has shown that noncoding variants are enriched in tissue and cell type-specific enhancer regions, therefore suggesting disease-relevant cell types (Maurano et al., 2012; Ernst et al., 2011; Lo et al., 2014; Parker et al., 2013; Trynka and Raychaudhuri, 2013). Studying a diverse set of 66 GWAS traits in 127 human reference epigenomic maps from the NIH Roadmap Epigenomics Project has demonstrated that GWAS loci are enriched in gene regulatory elements in known disease-relevant tissue/cell types (for example, pancreatic islets for T2D and liver and intestine for cholesterol levels). In addition, in some instances new discoveries were found in those tissues/cell types that were not suspected as being relevant (for example, immune cell types for Alzheimer's disease), suggesting that GWAS loci may alter the differentiation of precursor cells of expected tissues of involvement (Roadmap Epigenomics et al., 2015; Farh et al., 2015). Several enrichment analytical approaches have been developed (Roadmap Epigenomics et al., 2015) to identify tissue/cell types whose regulatory elements (such as enhancer, promoter, bivalent, and repressed regulatory regions estimated by histone marks using the HMM algorithm; Ernst and Kellis, 2012) are significantly enriched in GWAS loci, which increases the chance of identifying potential underlying causal variants and their affected tissue and cell types. While osteoblasts and osteoclasts are clear candidate target cell types for BMD and osteoporotic fracture-associated GWAS loci, other cell/tissue types may also affected. For example, an unbiased search using cell type enrichment tests for the comprehensive set of all 127 cell/tissue types available in the NIH RoadMap Project that might be related to the previously identified 56 BMD GWAS loci (Estrada et al., 2012) identified a total of 6 cell types, including primary osteoblast, skeletal muscle, skeletal muscle myoblasts, muscle satellite cultured cells, and mesenchymal stem cells derived from chondrocyte cells and derived from adipocytes whose enhancers significantly overlap the BMD loci. Among the 56 loci, associated SNPs in 24 loci were enriched in candidate regulatory modules specific to human primary osteoblasts. The remaining loci were not enriched in regulatory modules in osteoblasts but in other cell/tissue types, suggesting potential additional pathophysiological pathways of osteoporosis that are not relevant to bone cells. The

identified tissue/cell types will also inform the design of in vitro experiments that will select relevant cells for functional validation of associated BMD variants.

Informing genome-wide association studies using biological knowledge and networks

GWAS is not expected to implicate genes that are random with respect to function. In fact, genes located within BMD GWAS associations are enriched for gene ontology terms such as "skeletal system development" and "Wnt signaling," among many others related to bone development (Estrada et al., 2012). These data suggest that truly causal genes participate in specific bone-relevant processes, such as osteoblast-mediated bone formation and osteoclast-mediated bone resorption. Although this observation is not unexpected, it has important implications. The most important is that by examining all genes within a locus it is possible to predict causality based on a gene's "connection" to or membership in a bone-relevant process or pathway.

There are a number of ways to group genes into functional groups. A common approach is to group genes based on prior knowledge or known function. Two examples of approaches developed to do this specifically in the context of GWAS are Gene Relationships Among Implicated Loci ("GRAIL") (Raychaudhuri et al., 2009) and Meta-Analysis Gene-set Enrichment of variaNT Associations ("MAGENTA") (Segre et al., 2010). GRAIL queries a set of genomic regions identified by GWAS and assesses relationships between genes across regions through a comprehensive cocitation analysis of PubMed. GRAIL was used in the largest GWAS meta-analysis for DXA-derived BMD and highlighted the RANK−RANKL−OPG, mesenchymal stem cell differentiation, and Wnt signaling pathways as functional groups whose members contribute to the genetic architecture of BMD (Estrada et al., 2012). MAGENTA identified very similar sets of pathways when applied to a recent GWAS for heel ultrasound-derived BMD (Kemp et al., 2016).

A second approach is to group genes based on empirical data. Data-driven Expression Prioritized Integration for Complex Traits (DEPICT) predicts gene function using coexpression relationships mined from a large compendium of ~78k expression profiles (Pers et al., 2015). It then uses predictions for all genes in the genome to identify functional groups containing more genes than would be expected by chance from a list of genes across a set of GWAS loci. Using this information, DEPICT prioritizes genes within a locus based on the likelihood they are causal. DEPICT also predicts the tissues and cell types responsible for a significant portion of the "genetic load" for a particular disease. When applied to the heel eBMD GWAS, 273 genes were identified as likely driving eBMD association signals (Kemp et al., 2016). For 189 of these genes, the mouse homologue had been characterized in a knockout line, and 62 (33%) were found to have skeletal abnormalities.

Another strategy for informing GWAS is the use of networks (Farber, 2013; Leiserson et al., 2013). The idea is very similar to DEPICT; however, genes are prioritized based on their network topology with known disease genes. Furthermore, such approaches can address more fundamental questions, such as "Are hub genes in protein−protein interactions more or less likely to be genetically associated with complex traits?" In the context of bone, a coexpression network generated from mouse cortical bone expression profiles was recently used to predict potential causal genes for 56 BMD GWAS loci (Estrada et al., 2012; Calabrese et al., 2017). A list of mouse homologues located within the loci were mapped onto the bone coexpression network. Two network modules were found to be enriched for genes implicated by GWAS. These modules were themselves enriched for genes important for osteoblast activity. The authors used this information to predict 33 potentially causal genes at 30 loci. Two loci were studied in depth, and experimental evidence supported *SPTBN1* and *MARK3* as causal for the two associations.

Knockout animal models for functional analysis

A more direct approach to provide functional evidence is the validation of GWAS genes and variants via animal models. However, due to challenges such as time and resource requirements as well as the difficulty of pinning down the variants and affected genes in each GWAS locus, such experiments are not always easy to conduct. Databases such as the International Mouse Phenotyping Consortium (IMPC, http://www.mousephenotype.org/) offer the opportunity to identify GWAS candidate genes in silico using reported bone phenotypes from characterized knockout mice. The IMPC has created knockout mice on 20,000 protein-coding genes. Another example is the Origins of Bone and Cartilage Disease (OBCD, http://www.boneandcartilage.com) project, which is an international collaboration identifying genetic causes of bone and cartilage disease through the systematic characterization of knockout strains. As part of this project, 733 knockout mice strains have gone through a comprehensive bone phenotyping protocol, including digital X-ray microradiography to measure femur length and bone mineral content; micro-CT to measure trabecular bone (BV/TV, Tb. N, Tb. Th) and cortical bone (Ct.Th, BMD); and biomechanical testing with three-point bending tests of the femur (yield, maximum and fracture

loads, stiffness, toughness) and vertebral compression testing (yield and maximum loads, stiffness) in adult and embryonic mice via the OBCD. Such resources can be used to prioritize GWAS candidate genes based on bone phenotyping from knockout mice as well as to obtain knockout mice strains for functional validation of GWAS findings. Previously, an SNP, rs11692564, was found to be associated with LS BMD (*P*-value for the meta-analysis $= 2 \times 10^{-14}$) (Zheng et al., 2015). The SNP is located 53 kb downstream from the *EN1* gene on chromosome 2. A cluster of SNPs in LD with rs11692654 and located in 5′ promoter and 3′ regulatory regions of the *EN1* gene was also found to be significantly associated with higher BMD and lower risk of osteoporotic fractures in Caucasians. The *En1* gene was conditioned knockout in mice. *En1* expression was detected during osteoblastogenesis in developing and mature cultured murine calvarial osteoblasts but not in marrow-derived osteoclasts. Conditional loss of *En1* resulted in low bone mass. Measured by μCT, mutants had lower trabecular bone volume fraction, number, and thickness in both lumbar L5 vertebrae. By histomorphometry, mutants had a statistically higher proportion of osteogenic and osteoclastic cells compared with littermate controls, suggesting low bone mass likely as a consequence of high bone turnover.

Genome-wide association studies for bone traits in mice

As discussed above, GWAS in humans has significantly informed our understanding of the genetics of BMD. It has provided the approximate location of hundreds of sites in the human genome that harbor genetic variants influencing BMD. This serves as the foundation to identify key genes responsible for the heritable component of BMD and begin to comprehensively unravel the complex genetic architecture of bone mass (Timpson et al., 2018). These findings have important implications for our understanding of bone biology, precision medicine, drug development, and ultimately the prevention and treatment of osteoporosis (Richards et al., 2012). However, a primary limitation of GWAS for osteoporosis is that large-scale (N ~ hundreds of thousands) studies have only been performed for BMD. In the context of fracture, this is problematic because BMD explains only part of the risk of fracture (Cummings et al., 2002; Dufresne et al., 2003; Lochmuller et al., 1998). Other aspects of bone, such as geometry and trabecular and cortical microarchitecture, have not been interrogated by large-scale GWAS, and such studies will likely take years to perform. Other characteristics such as bone cell activities, biomechanical bone strength, and bone quality will likely be impossible to study using human GWAS. Given the clinical importance of these independent predictors of fracture, how do we dissect their genetic architecture? One promising approach is to gain insight through GWAS in mice.

Mice have played a key and central role in our understanding of bone biology. In particular, mouse models have been used to generate the majority of our understanding of basic bone biology. Besides the obvious fact that mice possess a skeleton, there are a number of other reasons why mouse genetic mapping is a promising complementary approach to human GWAS. First, mouse genomes are highly similar to those of humans. Sequencing of the mouse reference genome revealed that ~40% of the mouse genome can be aligned at the sequence level (Mouse Genome Sequencing et al., 2002) to the human genome. This level of similarity rises to ~80% for coding genes (ranging from ~60% to 99%), and less than 1% of mouse genes do not have a clear human orthologue (Mouse Genome Sequencing et al., 2002). Second, it has been demonstrated that while only 5% of regulatory sites across a number of mouse tissues have been conserved in humans at the sequence level, 95% of the networks between transcription factors and the genes they regulate are the same between mice and humans (Stergachis et al., 2014). Third, while important differences exist, a large body of literature indicates a high level of similarity in gene function in the context of bone and overall bone physiology between rodents and humans. Fourth, there is evidence of correspondence between genes identified by mouse genetic means also playing a role in the genetic regulation of skeletal traits in humans (Ackert-Bicknell et al., 2008; Ghazalpour et al., 2012; Mesner et al., 2014; Tang et al., 2009).

Resources and the application of genome-wide association studies for skeletal traits in mice

In recent years there have been significant efforts placed toward developing state-of-the-art genetic mapping tools in mice (Flint and Eskin, 2012).

Similar to human approaches, early mouse genetic mapping strategies relied on linkage analysis in "families." The most popular approach was the generation of F2 populations of mice derived through the interbreeding of two classical inbred strains (Abiola et al., 2003; Darvasi, 1998). Such studies were extremely successful at localizing genomic regions harboring trait-associated variants (termed quantitative trait loci, or QTLs) (Shmookler Reis, 2003). In fact, hundreds of QTLs for BMD, trabecular and cortical architecture, bone geometry, bone strength, and other skeletal traits have been mapped using this approach (Ackert-Bicknell et al., 2010). The problem with F2 crosses, however, is that QTL confidence intervals are quite large (many centimorgans or megabase pairs [Mbp]), making it very difficult to identify the responsible causative genes. In fact, they are only a small number of cases in which this approach was successful for the purpose of

gene identification for bone traits (Mesner et al., 2014; Edderkaoui et al., 2007; Klein et al., 2004). As the mouse genome was sequenced (Mouse Genome Sequencing et al., 2002) (Mouse Genome Sequencing Consortium et al., 2002) and genotyping capabilities expanded, the ability to transition from linkage to GWAS emerged.

While this section is focused on the mouse, we should note that several other model organisms have made and will continue to make important contributions to our understanding of complex skeletal traits. For example, GWAS in outbred rats has been used to map a number of loci influencing BMD, bone architecture, and biomechanical bone strength (Alam et al., 2014; Levy et al., 2015; Rat Genome et al., 2013).

Inbred strains

The first application of GWAS in mice used panels of inbred strains (Cervino et al., 2007; Grupe et al., 2001; Pletcher et al., 2004). The strategy consists of performing an association analysis with existing genome-wide genotype profiles and phenotypes collected in a set of strains by treating the strain set like a group of unrelated individuals. In many cases, GWASs were performed "in silico" with archival sets of phenotypes that may have been collected years or decades prior (Grupe et al., 2001; Bogue et al., 2018). While this approach was superior in terms of the resolution of association (confidence intervals for associations were typically <1 Mbp), it had limitations (Payseur and Place, 2007). Because inbred strains share a common and complex breeding history, strains are not entirely unrelated. In fact, some sets of strains are highly related (the sets of B6 and 129 related strains are examples). Uneven relatedness (called population structure or population stratification) can lead to false positive associations if the phenotype under investigation also differs dependent on the complex patterns of relatedness (which is often the case). The other limitation was statistical power due to the small number of strains readily available for phenotyping—this resulted in the identification of only the largest genetic effects on complex traits. The limitations of using inbred strain panels were partly resolved through the development of analytical approaches that adjusted for population structure (EMMA, etc.; Kang et al., 2008) and leveraging QTL information from linkage study to mitigate false positive associations (Su et al., 2010).

Hybrid mouse diversity panel

The Hybrid Mouse Diversity Panel (HMDP) is a high-resolution resource for GWAS that was developed in part to solve the problem of low statistical power for GWAS in inbred strain panels (Ghazalpour et al., 2012; Bennett et al., 2010; Lusis et al., 2016). Instead of relying strictly on classical inbred strains, the HMDP combined these strains with recombinant inbred (RI) strains. RIs are F2 mice that have been inbred, and RI panels themselves have been used to map genes for complex bone phenotypes. By combining classical lab and RI strains, initial versions of the HMDP comprised approximately 100 strains. By boosting the number of strains surveyed, the HMDP had 80% probability of detecting an association explaining 5% of the variance in a complex trait (Bennett et al., 2010). Also, because of the inclusion of the classical lab strains, the resolution of associations in the HMDP was <1 Mbp. One of the first studies to use the HMDP identified *Asxl2* as a regulator of BMD (Farber et al., 2011). *Asxl2* was later shown to be a master regulator of skeletal, lipid, and glucose homeostasis (Izawa et al., 2015).
