Nearly 15 years ago the mouse genetics community set out to develop an "ideal" population for genetic mapping (Churchill et al., 2012). This population, termed the "Collaborative Cross" (CC) is a multiparental population created by "combining" eight genetically diverse inbred founders: A/J, C57BL/6J, 129S1/SvImJ, NZO/H1LtJ, NOD/LtJ, WSB/EiJ, PWK/PhJ, and CAST/EiJ (Collaborative Cross, 2012; Aylor et al., 2011; Churchill et al., 2004). The CC was created using funnel mating designs, each of which resulted in a unique recombinant inbred strain whose genome is a mosaic of the eight founders. Importantly, the genomes of the founders have been sequenced, leading to the discovery of at least 31.5 million SNPs and 6.1 million insertion/deletions (Srivastava et al., 2017). Importantly, the number of variants in the CC is roughly three times higher than existing mouse reference populations, increasing the likelihood that genes involved in the regulation of skeletal phenotypes are functionally polymorphic and can be identified through mapping.

Early in the generation of the CC, mice from 144 of the CC mating funnels were used to create the Diversity Outbred (DO) population (Churchill et al., 2012; Srivastava et al., 2017). The DO has all the characteristics of the CC except that mice are outbred and genetically unique. This offers the advantage of being highly heterozygous with the ability to characterize large populations for well-powered GWAS scans. It also means that the recombination number and the mapping resolution increase with each generation of the DO (Logan et al., 2013; Svenson et al., 2012). The disadvantage of the DO is that each mouse is unique, which excludes the ability to generate multiple phenotypes over time and in different

environments that the reproducible genetic background of the CC affords. Both the CC and DO have been shown to be powerful resources for the dissection of complex traits (Svenson et al., 2012; Chick et al., 2016; Recla et al., 2014; Shorter et al., 2018; Yuan et al., 2018) including bone (Levy et al., 2015). Large-scale efforts are underway to use CC/DO for high-resolution GWAS scans for a comprehensive suite of complex bone traits.

Advantages of genome-wide association studies in mice

We have already discussed one of the most important advantages of GWAS in mice, which is to study clinically relevant bone traits other than BMD. But there are a number of other advantages of GWAS in mice. Some advantages include the ability to investigate gene × environment interactions, genetic effects over time, and pleiotropy across large numbers of disparate disease-related traits. These advantages are particularly evident when using inbred strain collections (i.e., HMDP or CC). Since these strains are inbred and reproducible, one can sample the same genotype across environments or interventions that require multiple animals. These resources also represent a resource in which data can accumulate over time.

Identifying less common and rare variants associated with bone-relevant phenotypes via next generation sequencing

Although common-variant SNP chip–based GWASs have made strides in identifying loci that point to underlying disease pathophysiology, such approaches have inherent limitations. The narrow-sense heritability (h_g^2) of BMD has been estimated to be ∼85% of its variation, yet GWAS-identified common variants associated with DXA-BMD explained only ∼6% of the genetic variance of this trait. Thus, GWAS detects a small fraction of variance in BMD. Although genome-wide deep imputation using large reference panels is adequate to detect significant associations between common variants and quantitative traits like BMD (Walter et al., 2015), imputation for less common, rare, private mutations or even structural variations that might reveal unique pathways influencing bone metabolism is likely unavailable or will be associated with low imputation quality (McCarthy et al., 2016). Undiscovered, less common, rare, and private coding and noncoding variants as well as structural variations that have larger effect sizes are likely important for identifying novel genes and pathways influencing BMD and fractures. Recent studies (Zheng et al., 2015; Fuchsberger et al., 2016; Danjou et al., 2015; Morrison et al., 2013; Styrkarsdottir et al., 2003) have established the potential for next generation sequencing (NGS) to provide comprehensive enumeration of the sequence variation necessary for the detection of functional alleles that provide important clues to disease pathophysiology. The identification of causal variants underlying osteoporosis via NGS to provide complete coverage of genome variation now represents a compelling research opportunity.

To fine-map previous GWAS loci to identify potential causal variants responsible for GWAS signals, Hsu and colleagues performed targeted sequencing of four loci (chr1p31.3: *WLS,* 5q14.3: *MEF2C,* 11p11.2: *LRP4,* and 20p12.2: *JAG1*) using NGS in 1291 Caucasians from the Framingham Heart Study (n = 925) and Cardiovascular Health Study (n = 366) (Hsu et al., 2016a). Among them, 206 women and men had extremely low FN BMD. A total of 4,964 sequence variants (SNVs) were observed. Of them, 77% were novel variants and not imputed (or not well-imputed) using the 1000G Phase III reference panel. In addition, 80% are rare, with MAF <1%. The associations between previously identified SNPs in these loci and BMD, while nominally significant in sequenced participants, were no longer significant after multiple testing corrections. Conditional analyses did not find protein-coding variants that may be responsible for GWAS signals. On the other hand, in the sequenced subjects, novel associations were found in *WLS*, *ARHGAP1*, and *5′ of MEF2C* (*P*-values $< 8 \times 10^{-5}$; FDR q-value < 0.01) that were much more strongly associated with BMD than were GWAS SNPs. These associated SNVs were less common; independent from previous GWAS signals in the same loci; and located in gene regulatory elements. Our findings suggest that protein-coding variants in selected GWAS loci did not contribute to GWAS signals. By performing fine-mapping using the NGS approach in GWAS loci, less common and rare noncoding SNVs were found to be associated with BMD independently from GWAS common SNPs, suggesting both common and less common variants may associate with disease risks and phenotypes in the same loci, and that sequencing is required to discover these variants.

Whole-exome sequencing (WES) and WGS among Icelandic people with low versus high BMD revealed *LGR4* (Styrkarsdottir et al., 2013), *COL1A2* (Styrkarsdottir et al., 2016a), and *PTCH1* (Styrkarsdottir et al., 2016b) mutations that result in functional disruption of the protein. LGR4 plays a role in Wnt signaling, and embryonic mice lacking functional LGR4 were shown to have delayed osteoblast differentiation and mineralization (Styrkarsdottir et al., 2013). WES has identified functional coding variants for complex phenotypes, but only 5% of trait-associated SNPs from GWASs lie in coding regions (Maurano et al., 2012). If this proportion is representative of the distribution of truly causal

TABLE 68.2 Resources for genome-wide association studies in mice.

Population	Description	Advantages	Disadvantages
Hybrid Mouse Diversity Panel	~100 mouse strains treated as a population of unrelated individuals	• commercially available inbred strains • reproducible inbred strains • high mapping resolution	• low statistical power • population stratification • limited genetic variation
Collaborative Cross	~50 recombinant inbred strains derived from eight highly diverse inbred strains	• reproducible • genetically diverse • highly accurate genome reconstruction	• low statistical power • limited mapping resolution
Diversity Outbred	Outbred population derived from eight highly diverse inbred strains—at 30th generation of outbreeding as of August 2018	• high mapping resolution • genetically diverse • unlimited sample size; increasing power to detect subtle genetic effects • highly accurate genome reconstruction	• nonreproducible • each individual is unique and must be genotyped

variants, WGS will be required to discover variants underlying the majority of GWAS associations located in intronic, intergenic, and promoter regions. Indeed, Zheng and colleagues recently demonstrated that less common variants in noncoding regions of the *EN1* gene (Zheng et al., 2015) have an effect size two to four times larger than those of the common variants previously described in prominent genes (e.g., *LRP5*). In other fields, numerous examples now demonstrate the biological importance of rare variants in human disorders as well as the usefulness of this information in developing novel therapeutics.

The Trans-Omics for Precision Medicine (TOPMed), sponsored by the National Institutes of Health's National Heart, Lung, and Blood Institute, is the largest population-based WGS project for common/complex disorders/phenotypes. This resource may be utilized to identify less common and rare variants associated with bone density and fracture phenotypes. The TOPMed project is part of a broader Precision Medicine Initiative. In addition to WGS, the project is also measuring other omics, including metabolic profiles, protein and RNA expression pattern data with other phenomics, and environmental and clinical data. This resource will offer the opportunity to integrate different "omics" to understand pathophysiology of diseases as well as develop better therapeutic approaches. The current TOPMed project studies have a variety of study designs including population-based, family-based, case−control, pharmacogenomic, founder populations, and clinical studies. As of November 2018, over 120,000 deeply sequenced whole genomes have been done.

Future directions

Based on the richness of the growing number of GWASs and whole-genome association studies focusing on skeletal phenotypes and the increasing sample sizes available, understanding the genetic architecture underlying skeletal biology offers the promise of novel discovery of potential drug targets. In fact, there is a higher likelihood of successful drug development when a target is identified using genetic studies (Nelson et al., 2015) (Table 68.2).

As described in the commentary by the GTEx team, "Identifying any particular genetic variant's cascade of effects, from molecule to individual, requires assaying multiple layers of molecular complexity" (e GTEx Project, 2017), suggesting a complexity of gene function and gene expression regulations and the need to construct gene regulatory landscapes in multiple human primary cells and tissue types (see Fig. 68.2).

Future directions include the study of ethnic groups other than those of European ancestry and the follow-up of the novel genetic loci identified in these studies using cellular and animal models to identify the causal variants and their targeted genes.

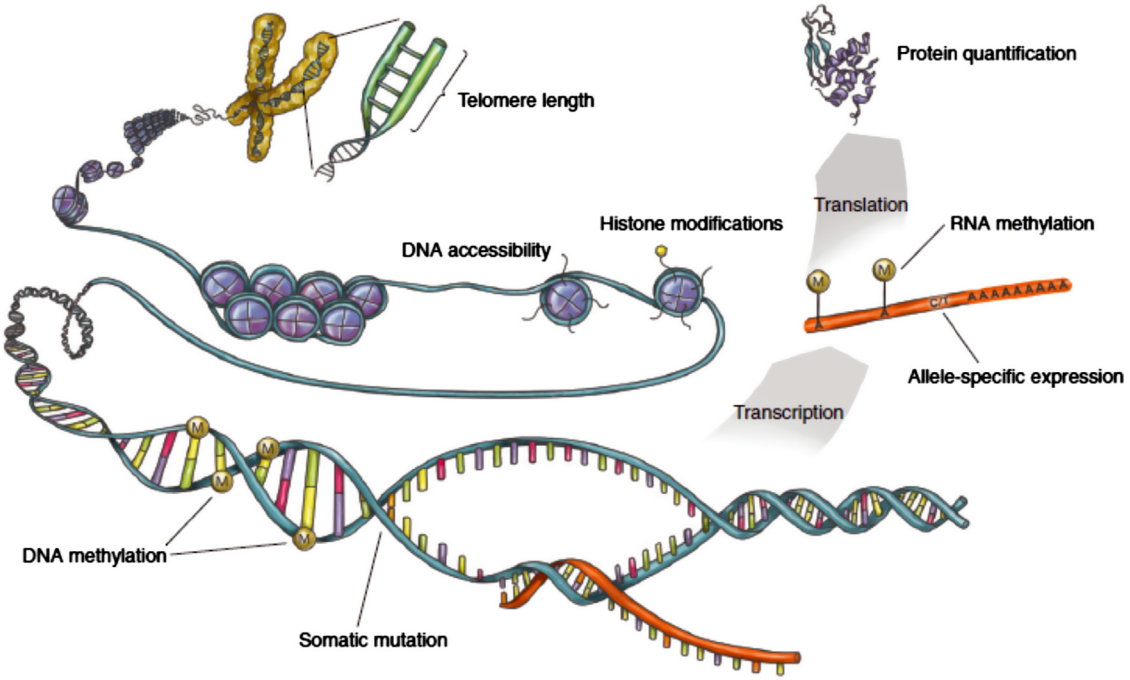

FIGURE 68.2 Quantifying layers of molecular and cellular phenotypes. The eGTEx project plans to study telomere length, DNA accessibility, histone modifications, DNA and RNA methylation, somatic mutation, allele-specific expression, and protein quantification across individuals and tissues.

Chapter outline

Introduction

Physiology of parathyroid hormone

Parathyroid hormone (PTH) is a full-length polypeptide hormone made up of 84 amino acids. The precursor hormone harbors a presequence of 25 amino acids and a prosequence of 6 amino acids, both of which are cleaved before the full-length mature PTH is released from the parathyroid glands. The classical biological properties of full-length PTH are resident in the first N-terminal 34-amino-acid sequence (Potts et al., 1971). The actions of PTH are physiologic and homeostatic. They are integral to maintaining normal calcium homeostasis. PTH tightly regulates and maintains the ambient extracellular ionized calcium concentration within a narrow range through its direct effects on the kidneys and bone and indirect effects on the gastrointestinal tract. In direct response to a reduction in the ionized calcium level, PTH secretion increases; in direct response to an increase in the ionized calcium level, PTH secretion falls. This physiological behavior is described by the well-known inverse sigmoid curve−shaped relationship between calcium and PTH (Brown, 1983). The proximal mediator of this relationship is the calcium-sensing receptor on the surface of parathyroid cells to which Ca^{2+} has affinity. The Ca^{2+}−calcium-sensing receptor interaction dictates to what extent PTH will be upregulated or downregulated. The renal actions of PTH include the stimulation of renal tubular reabsorption of calcium (at the thick ascending limb of the loop of Henle and distal convoluted tubule); thus, the renal actions of PTH are to conserve calcium. The skeletal actions of PTH include stimulation of osteoclast-mediated bone resorption to mobilize calcium stores. The third classical target organ of PTH is the gastrointestinal tract, but it is an indirect one. Through PTH's actions to stimulate the renal 1α-hydroxylase, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$) is formed to increase gastrointestinal absorption of calcium in the duodenum and jejunum. In response to a hypocalcemic stimulus, these three servomechanisms, to varying extents and with different time courses, help to restore calcium levels. In response to a hypercalcemic signal, a reversal of these actions, also to varying extents and with different time courses, helps to restore calcium levels. In the case of high

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00069-5

extracellular calcium, under normal physiological conditions, PTH levels fall, leading to decreased renal tubular reabsorption, osteoclastic bone resorption, and intestinal absorption of calcium.

The secretion of PTH is best characterized by three components. A tonic component describes the continual secretion of PTH throughout the day at a constant rate. Superimposed upon this background constant secretory component, there is a circadian rhythm with an early morning peak and late morning trough and a smaller peak in the afternoon (el-Hajj Fuleihan et al., 1997). A third component, the pulsatile secretion of PTH exists that overlaps with the background secretroy rate and circadian rhythm that appears to be stochastic, occurring 10 or more times a day. These random bursts of PTH secretory activity account for about 30% of the total secretion (Chiavistelli et al., 2015). Circulating levels of PTH are determined mainly by the production rate of the hormone because PTH is rapidly metabolized by renal and hepatic tissue endopeptidases and its metabolites are excreted into the urine by glomerular filtration (Bringhurst et al., 1988). The biological half-life of endogenous PTH is thus very short. This very short half-life is illustrated well by patients undergoing parathyroidectomy for primary hyperparathyroidism (PHPT), who demonstrate a rapid decrease in circulating PTH levels very soon after removal of the parathyroid adenoma (Maier et al., 1998; Allgrove and O'Riordan, 1985; Leiker et al., 2013). Within 10 min after removal of the parathyroid adenoma, circulating levels of PTH are well below 50% of the preoperative values. From these studies, the biological half-life has been estimated to be about 3 min.

Apart from these physiologic homeostatic functions, PTH has been associated with anabolic or catabolic actions on the skeleton. This dual catabolic−anabolic aspect of PTH can be understood in pharmacokinetic, molecular, and cellular terms.

Pharmacokinetic mechanism: effects of ligand exposure

The duration of interaction between PTH and its receptor, PTH/PTH−related protein (PTHrP) type 1 receptor (PTH1R), is short. Depending on the duration of ligand exposure to its receptor, PTH can be predominantly anabolic or catabolic. Excessive and continuous PTH exposure favors bone resorption over bone formation, while intermittent PTH exposure favors bone formation over bone resorption. Intermittent PTH dosing more closely mimics a pulse of endogenous PTH secretion. This underlying principle has been exploited pharmacologically by utilizing once-daily injections of PTH to stimulate bone formation. The experimental basis for these functional distinctions was supported by Tam et al., who observed that continuous infusion of bovine PTH in rats leads to an increase in both formation and resorption surfaces and reduced trabecular bone, while intermittent daily injections of the hormone lead to an increase in formation surfaces without an increase in resorption surfaces along with an increase in trabecular volume (Tam et al., 1982). These findings were further clarified by Dobnig et al., who compared in rats the skeletal effects of daily subcutaneous injection, infusion (1, 2, or 6 h/day) and continuous 24-h exposure (Dobnig and Turner, 1997). Daily intermittent subcutaneous injections or 1 h/day infusion was associated with rapid anabolic effects in cancellous bone. Double-label perimeter, mineral apposition rate, and bone formation rate were higher in the setting of daily intermittent subcutaneous injections or 1 h/day infusions versus longer infusion times. In marked contrast, continuous infusion of PTH was associated with catabolic skeletal changes resembling PHPT. This body of knowledge led to the impression that low-dose intermittent use of PTH was likely to be anabolic, while chronic, continuous exposure of PTH was likely to be catabolic for bone.

Clinically, the best illustration of the catabolic actions of PTH is PHPT, a disorder in which tissues are exposed to continuous, excessive secretion of PTH. In PHPT, the excessive, continuous secretion of PTH leads to hypercalcemia. Basal secretion of PTH is higher and the amplitude of the pulses is higher, accounting for 50% of the total PTH secretion, virtually all emanating from the hyperactive parathyroid gland(s) (Harms et al., 1989). Renal tubular reabsorption of calcium is enhanced but the filtered load of calcium often exceeds the ability of the kidney to conserve the filtered load of calcium. If hypercalciuria follows, stone risk is higher, particularly if accompanied by other stone risk factors. The archives of yesteryear describe best the devastating potential of PTH to destroy the skeleton. The PHPT of Captain Charles Martell (Bauer and Federman, 1962) led to many fractures and dramatic height loss. He shrank in height until he was a shadow of his former athletic self. The eventual parathyroidectomy led to a severe hypocalcemic state and death, not long after removal of an ectopic mediastinal parathyroid adenoma, his seventh operation. Fortunately, such devastating manifestations of symptomatic PHPT are no longer common. What is more commonly seen in the current era is a form of PHPT that is discovered incidentally by the widespread use of the autoanalyzer that contains a serum calcium analysis channel. Even though this form of PHPT is much milder than the form seen more commonly 75 years ago, it nevertheless is associated with increased fracture risk and microarchitectural abnormalities seen best with high-resolution peripheral quantitative computed tomography. These abnormalities are seen in both the cortical and the trabecular compartments, though by bone mineral densitometry, there seems to be a predilection to affect cortical bone. Nevertheless, even by the trabecular bone score, involvement of trabecular bone is readily demonstrated. Both anabolic and catabolic markers of bone metabolism are typically elevated as a consequence of continuous exposure of PTH in PHPT (Costa and Bilezikian, 2013). The extent to

which these biochemical markers will be elevated is a function of the severity of the disease, but even in mild, asymptomatic PHPT, bone formation and resorption markers can be elevated or at the upper limits of normal (Guo et al., 1996; Silverberg et al., 1995). High bone turnover has been associated with increased fracture risk in many conditions, such as in PHPT and in postmenopausal osteoporosis (Vasikaran et al., 2011). Bone histomorphometric studies from the iliac crest bone biopsy in patients with PHPT confirm the detrimental effects of continuous exposure of PTH on cortical bone. Cortical porosity and cortical thinning are evident. Trabecular bone mass and structure were conserved, as assessed by structural indices such as trabecular bone volume, trabecular number, connectivity, and separation (Silverberg et al., 1989; Parisien et al., 1990, 1992; Dempster et al., 1999, 2007; Uchiyama et al., 1999; van Doorn et al., 1993). Dynamic parameters also demonstrate an increase in new bone formation as evidenced by an increased adjusted mineral apposition rate and active formation period in PHPT compared with normal postmenopausal women (Dempster et al., 1999; Parisien et al., 1995). These observations, along with relatively well-preserved lumbar spine bone density, helped to demonstrate, even under predominantly catabolic conditions, namely PHPT, that PTH has a potential to be anabolic.

Molecular mechanisms: ligand selectivity for receptor conformational state

The anabolic action of PTH depends upon its interaction with the PTH/PTHrP receptor. The PTH/PTHrP receptor type 1 (PTH1R) is a member of the B subfamily of G-protein-coupled receptors. In the skeleton, these receptors are found in osteoblasts and osteocytes (Fermor and Skerry, 1995). Binding to this receptor by the amino-terminal portion of PTH is an activation step. The receptor is coupled to both the adenylate cyclase-activating G protein (Gs) and the phospholipase C-activating G protein (Gq). Initiation of the Gs-mediated signaling cascade leads to an increase in cyclic AMP (cAMP) production, which results in protein kinase A (PKA) activation. Initiation of the Gq-mediated signaling cascade leads to activation of protein kinase C (PKC). The cAMP/PKA signaling is the dominant pathway that mediates PTH's anabolic response, since PTH ligands that lack the ability to initiate the Gq-mediated signaling cascade are still able to effect an anabolic response. For example, the truncated ligand [Gly^1,Arg^{19}] PTH (1−28), with substitution of glycine for alanine at position 1 and glutamic acid for arginine at position 19, lacks the ability to activate PKC, but it can stimulate cAMP production. This truncated ligand−receptor interaction led to an increase in bone formation, thus demonstrating that the PKC signaling cascade is not necessary for the anabolic effect of PTH (Yang et al., 2007). It was also shown that the Gq signaling cascade may inhibit the osteoanabolic effect of PTH. Daily PTH treatment in mice with loss of function of the Gq signal resulted in a higher increase in bone mass than in wild-type counterparts receiving the same therapy (Ogata et al., 2011). This implies that the Gq signaling cascade could mediate an inhibitory signal for the osteoanabolic response of PTH, since the loss of an inhibitory signal resulted in a greater osteoanabolic effect. Thus, cAMP signaling and downstream effects are considered to be the primary anabolic signaling system for PTH.

The PTH/PTHrP receptor (PTH1R) assumes at least two distinct conformation states. The two conformational states are R^G, when the receptor is coupled to heterotrimeric G proteins, and R^0, when it is free. Ligands that bind selectively to the R^G state induce a shorter signaling response, whereas ligands that bind selectively to the R^0 state induce a more prolonged signaling response (Dean et al., 2008; Okazaki et al., 2008). Also pertinent is the ratio of affinities of either of these two conformational states of the PTH/PTHrP receptor (PTH1R) for the ligand. Therefore, the state of the receptor and its affinity for a PTH ligand can determine biological activity (Dean et al., 2008). Since most PTHs have some affinity for either state of the PTH/PTHrP receptor (PTH1R), the behavior of a given PTH vis-à-vis duration of effect is determined by the ratio of binding affinities to each of these receptor states (Fig. 69.1).

Cellular mechanisms: Indirect effect on osteoclasts, and direct effects on osteoblast and osteocytes

The ultimate effect of PTH on the skeleton depends on the balance of the osteoblastic or osteoclastic activities stimulated by the ligand (Silva et al., 2015). Under physiological conditions, PTH stimulates bone remodeling, with a resultant increase in both bone formation and bone resorption through its direct effect on the osteoblasts and osteocytes and through its indirect effects on the osteoclasts. PTH increases bone formation by increasing osteoblast proliferation, decreasing osteoblast apoptosis, and converting quiescent lining cells into osteoblasts. PTH also increases osteoclast activity by enhancing receptor activator of nuclear factor-κB ligand (RANKL) production from osteoblasts and osteocytes (Bonewald, 2011). The stimulation of RANKL, a highly potent cytokine, is due, in part, to a decrease in osteoprotegerin, a decoy receptor to which RANKL binds (Huang et al., 2004). Therefore, PTH is anabolic by virtue of its ability to stimulate bone formation through remodeling-based formation (Ma et al., 2006), in which the bone formation phase of bone turnover is stimulated to

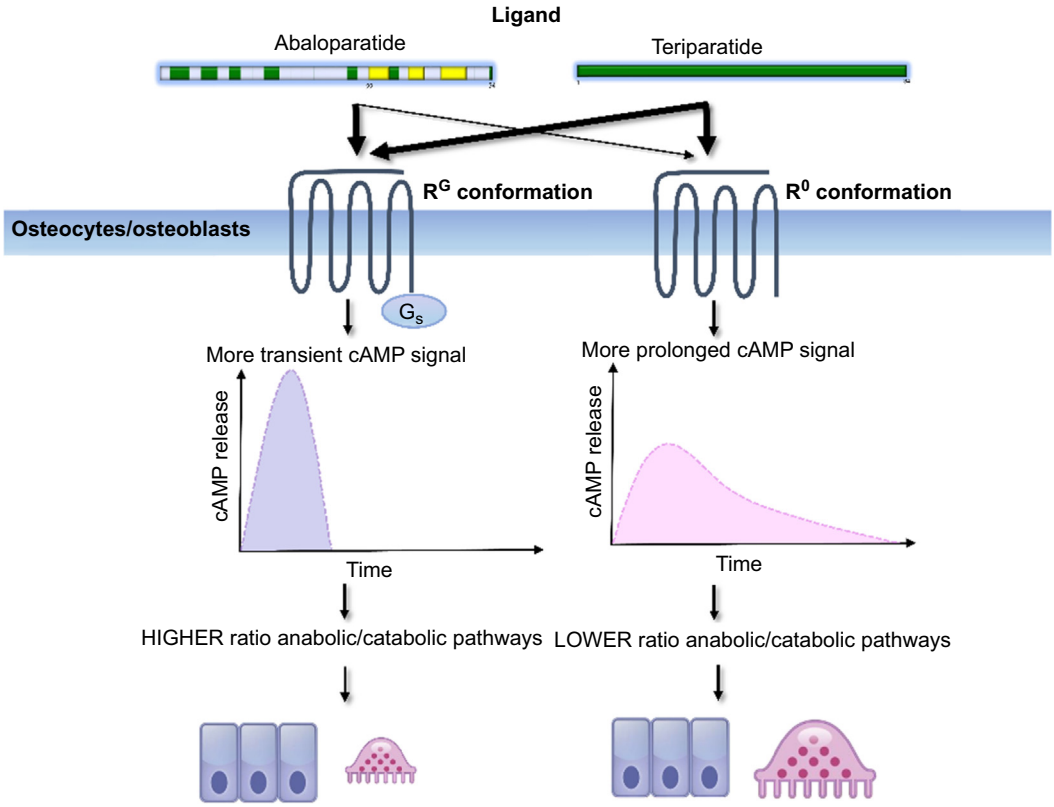

FIGURE 69.1 Different ligands have different binding selectivities for the different conformational states of the PTH/PTHrP receptor. Abaloparatide binds preferentially to the R^G state and elicit a more transient cyclic AMP signaling response favoring a less pronounced catabolic effect and a lower degree of hypercalcemia. Teriparatide has a preferential binding for the R^0 state and elicit a more prolonged cyclic AMP signaling response and a more pronounced catabolic effect and a relatively higher risk for hypercalcemia than abaloparatide.

a greater extent than the bone resorption phase. Remodeling-based accrual of bone is the primary mechanism by which PTH increases bone mass. The anabolic actions of PTH can also be affected by directly stimulating bone formation. This is known as modeling-based bone formation and is not preceded by bone resorption. Modeling-based bone formation occurs on quiescent surfaces of bone. It is typically evident during skeletal growth and development, but modeling, under very special circumstances, is now appreciated to occur throughout life, even in adults. With intermittent teriparatide administration, much of bone formation is remodeling based, but as much as 30% of bone accrual can be attributed to bone modeling. Bone modeling could not be demonstrated in control subjects not treated with teriparatide in that study (Lindsay et al., 2006). Modeling-based bone formation can be differentiated from remodeling-based bone formation on histomorphometry by the absence of scalloping beneath the surface of the newly formed bone. It can be inferred that smooth surfaces represent bone formation on quiescent surfaces (modeling), whereas scalloped surfaces indicate a site of bone resorption (remodeling). A third mechanism of bone accrual induced by PTH has been called "overflow remodeling" (Tabacco and Bilezikian, 2018). This occurs when osteoblasts refill the resorption cavity of the bone remodeling unit and "overflow" onto adjacent unresorbed quiescent surfaces (Lindsay et al., 2006).

The catabolic actions of PTH are thought to be based upon continuous exposure. Catabolic effects have been shown to depend on the presence or absence of SAA_3, serum amyloid A, an apolipoprotein. Released from preosteoclasts, SAA_3 inhibits osteoblastic differentiation during continuous PTH administration. This mechanism would account for the catabolic actions of PTH to be enhanced. In SAA_3-knockout mice (SAA_3 absent), Choudhary et al. showed that continuous PTH had anabolic effects on trabecular bone. PTH can directly or indirectly (via RANKL) stimulate the COX2 enzyme and in turn prostaglandin E_2 production, which subsequently results in secretion of SAA_3 from preosteoclasts. In that study, continuous PTH also increased osteoblast differentiation in osteoprogenitor cells when COX2 or RANKL activity was inhibited (Choudhary et al., 2018).

Not only does PTH directly influence osteoblastic activities, PTH can also indirectly influence osteoblastic activities via insulin-like growth factors, IGFs (McCarthy et al., 1989; Watson et al., 1995). Intermittent administration of PTH stimulates IGF-1 expression, which in turn leads to increased osteoblast differentiation (Xian et al., 2012). Both PTH and IGF-1 work in concert to regulate bone remodeling and thus couple bone resorption to bone formation (Elis et al., 2010). IGF-1 is deposited in the bone matrix bound by IGF-binding proteins. During PTH-induced bone remodeling, osteoclastic resorption leads to cleavage of the binding proteins and release of IGF-1 (Crane and Cao, 2014). Paracrine IGF-1 in turn stimulates the differentiation of mesenchymal stem cells to osteoblasts, therefore synergistically mediating the anabolic effects of PTH.

Complementary mechanisms can also enable PTH to exert its anabolic effects. One pathway is related directly to the osteocyte. Intermittent PTH reduces sclerostin, an osteocyte product (Keller and Kneissel, 2005). Sclerostin normally binds to low-density lipoprotein receptor−related protein (LRP) 5/6 and inhibits the canonical WNT signaling pathway, which leads to an inhibition of osteoblast-mediated bone formation. Activation of this WNT signaling pathway occurs when WNT binds to a receptor complex made up of LRP5 or LRP6 and the Frizzled receptor. This leads to an increase of intracellular β-catenin due to a reduction in its degradation. The degradation is prevented because activation of WNT signaling leads to the dissociation of the degradation complex formed by Dishevelled, Axin, adenomatous polyposis coli protein, protein phosphatase 2A, glycogen synthase kinase-3β (GSK-3β), and β-catenin. This occurs because activation of WNT leads to activation of Dishevelled, which in turn inhibits GSK-3β, which normally phosphorylates β-catenin, marking it for ubiquitination and proteolysis. β-Catenin, protected from cytoplasmic degradation in this manner, translocates to the nucleus where it modifies gene expression ultimately in an anabolic manner (Johnson and Kamel, 2007). Subsequent effects are associated with cellular changes that increase bone formation, such as differentiation of mesenchymal stem cells toward osteoblastogenesis, osteoblast proliferation, and inhibition of osteoblast apoptosis (Krishnan et al., 2006). This is an important complementary system that could account in a number of settings for the anabolic actions of PTH.

Both osteoblasts and marrow adipocytes originate from their skeletal precursors, mesenchymal stem cells. When these skeletal precursors are exposed to intermittent PTH, they are directed toward osteoblastogenesis and away from adipogenesis. Marrow adipocytes are a source of RANKL and are able to stimulate osteoclastogenesis. Fan et al. showed that deletion of the PTH/PTHrP receptor in mice resulted in increased marrow adiposity and that the marrow adipose tissue was capable of secreting RANKL, resulting in increased bone resorption and a resultant low bone mass phenotype (Fan et al., 2017). On the other hand, PTH (1−34) therapy in seven osteoporotic men showed a decrease in marrow adiposity in paired bone biopsies at baseline and 18 months (Dempster et al., 2001). These findings support the hypothesis that PTH is able to determine marrow mesenchymal cell fate. PTH may also in part regulate the provision of energy needed to fuel osteoblastic functions. Intermittent PTH can increase glycolysis via IGF signaling with increased anabolic effect (Esen et al., 2015). Intermittent PTH has also been shown to induce lipolysis in marrow adipocytes and release fatty acids to the osteoblasts to use as fuel for bone formation (Larsson et al., 2016).

Use of osteoanabolic agents in osteoporosis

Teriparatide

PTH is available pharmaceutically as teriparatide, human recombinant PTH (1−34). With teriparatide, we can appreciate how the pharmacokinetic properties of PTH can be manipulated to enhance its pharmacologic effect. The basic points are that the amino-terminal fragments demonstrate a much shorter half-life (of minutes), when injected subcutaneously, than the carboxy-terminal fragments and that the first 34 amino-terminal residues of PTH can produce a biological response as potent as that of the full-length peptide. Thus, PTH (1−34) administered as daily subcutaneous injections would allow it to function as an osteoanabolic agent since it is this form of administration that re-creates the desired brief intermittent ligand exposure to the PTH/PTHrP receptor (PTH1R). Intravenously administered PTH (1−34) has a very short half-life, measured in minutes (Fraher et al., 1995). When administered subcutaneously, the half-life approximates 1 h. The difference is accounted for by absorption kinetics from the subcutaneous reservoir, which delays uptake, rather than the metabolism of teriparatide (Satterwhite et al., 2010). In the pivotal trial that led to the approval of teriparatide [PTH (1−34)] by the US Food and Drug Administration (FDA), Neer et al. tested 20- and 40-μg doses against placebo in a double-blinded, randomized study. Once-daily injections of 20 μg PTH (1−34) reduced vertebral and non-vertebral fracture incidence by 65% and 53%, respectively. Bone mineral density (BMD) at the lumbar spine and femoral neck regions was increased by 9% and 3%, respectively, but not at the radius. There were, however, small declines at the radial site with the higher 40-μg dose (Neer et al., 2001). The 20-μg dose was developed further as the therapeutic dosage

because it was associated with fewer adverse events (less hypercalcemia and no reduction in radial BMD), while providing the same fracture protection as the 40-μg dose.

Abaloparatide

PTHrP is homologous to PTH in that the first eight amino-terminus residues are identical. It maintains three-dimensional functional homology through residue 34 (Martin, 2016). PTHrP is a longer peptide than PTH, with a linear sequence that is 141 amino acids long in humans. Nonetheless, PTHrP binds to the same receptor as PTH, and hence the designation of the receptor as PTH/PTHrP type 1 (PTH1R). Naturally occurring PTHrP has important physiological roles that include but are not limited to mammary gland development, lactation, tooth eruption, regulation of keratinocyte differentiation, vascular and uterine smooth muscle regulation, and placental calcium transport to the fetus. The pleiotropic effects of PTHrP expand concepts of PTH and PTHrP to evolutionary biology and nonskeletal actions of these peptides. In the skeleton, both PTHrP and PTH exert their distinct effects through binding and activation of a common PTH/PTHrP type 1 receptor (PTH1R) in osteoblasts. While both peptides share similar abilities to stimulate bone formation, PTH principally functions as a circulating endocrine response system, while PTHrP is believed to be primarily a paracrine regulator.

Abaloparatide was approved in April, 2017 by the US FDA for therapy of postmenopausal women with osteoporosis at high risk for fracture (Peterson and Riggs, 2010). Abaloparatide is identical to PTHrP through the first 22 residues, but thereafter, several substituent amino acids render this molecule very different in terms of its interactions at the receptor level. By virtue of these different primary sequences, empirically deduced, abaloparatide's interaction with the PTH/PTHrP type 1 receptor (PTH1R) appears to be more transient than that of PTHrP or teriparatide. Abaloparatide binds with lower affinity to the R^0 conformation state of the PTH/PTHrP type 1 receptor (PTH1R) but demonstrates an affinity to the R^G conformation state that is similar to that of teriparatide or PTHrP. Preferential binding of abaloparatide to the R^G state (ratio of binding affinities for the two receptor conformations favors R^G) elicits a transient cAMP signaling response, stimulating the mechanisms associated with greater anabolic potential (Hattersley et al., 2016).

The pharmacokinetic profiles of abaloparatide and teriparatide are similar. A single dose of subcutaneously administered abaloparatide (80 μg) has a half-life of 2.3 h, peaks at about 45 min, and remains in the circulation for about 7 h (Obaidi et al., 2010). In addition to greater selectivity, another distinguishing property that has clinical relevance is that abaloparatide does not require refrigeration.

In the dose-finding phase II trial, daily subcutaneous injections with 20, 40, or 80 μg of abaloparatide were compared with 20 μg of teriparatide for up to 24 weeks (Leder et al., 2015). There was a linear dose response to gains in BMD at the lumbar spine with increasing dose of abaloparatide. Both the 40- and the 80-μg doses were effective at increasing lumbar spine BMD compared with placebo (5.2% and 6.7% vs. 1.6%), with only the 80-μg dose showing similar efficacy compared with 20 μg of teriparatide. At the hip, only the 80-μg dose was effective at increasing the femoral neck or total hip BMD compared with placebo. At this dose, the change in femoral neck BMD was not different between abaloparatide and teriparatide, but the increase in total hip BMD was higher with abaloparatide compared with teriparatide. Of note, teriparatide did not significantly increase hip BMD at 24 weeks in this short study. The effects on bone-turnover markers were also different between the two anabolic agents. There was a linear dose response with bone formation markers with abaloparatide. The increase in formation markers was similar between 40- and 80-μg doses and 20 μg teriparatide. In contrast, and as expected, abaloparatide's effect on bone resorption markers was smaller than that of teriparatide.

The 80-μg abaloparatide dose was thus chosen for the definitive phase III double-blinded, randomized controlled clinical trial (ACTIVE) (Miller et al., 2016). Eighty micrograms of abaloparatide was compared with placebo and in an open-label comparison with teriparatide over 18 months. The primary end point was new vertebral fractures. The study was underpowered to appreciate the differences in the primary end point between abaloparatide and teriparatide, although both appeared similarly effective in reducing new vertebral fractures by 86% and 84%, respectively, compared with placebo. Abaloparatide reduced nonvertebral fractures by 43% compared with the 28% reduction in the teriparatide group, the latter of which did not reach statistical significance. If one takes into account the non-vertebral fracture efficacy from the original teriparatide phase III study, the reduction in non-vertebral fracture with teriparatide was appreciable only after 9–12 months of use (Neer et al., 2001; Miller et al., 2016). In contrast, fracture efficacy with abaloparatide was evident earlier compared with the time course from the report of Neer et al. for teriparatide.

Abaloparatide increased femoral neck BMD by 3.6%, total hip BMD by 4.2%, and lumbar spine BMD by 11.2% by 18 months. Abaloparatide demonstrated significantly greater BMD gains at the hip compared with teriparatide, but the gains at the lumbar spine were similar. The effects on bone-turnover markers were different between the two ligands. Increases in bone formation markers with abaloparatide were smaller from 3 months to the end of the study, and a transient and smaller increase in bone resorption markers from 3 to 12 months was observed compared with teriparatide.

Abaloparatide demonstrated less hypercalcemia than teriparatide (3.42% vs. 6.1%, respectively). The less prominent change in bone-turnover markers was mirrored by findings of lower eroded surface in the substudy evaluating the effect of abaloparatide on bone histomorphometry (Moreira et al., 2017). This is consistent with a smaller effect on parameters of bone resorption.

Use of parathyroid hormone in hypoparathyroidism

Recombinant human PTH (1−84)

Hypoparathyroidism is characterized by hypocalcemia with absent or deficient PTH associated with abnormal bone remodeling. The lack of PTH results in an inability to regulate calcium and phosphate homeostasis resulting in the characteristic biochemical profile of hypocalcemia and hyperphosphatemia. Typical symptoms of neuromuscular irritability, cognitive dysfunction, and renal and cardiac manifestations are prevalent in this disorder. They are not fully relieved with conventional therapy, namely calcium and active vitamin D (calcitriol) supplementation. Renal complications such as nephrolithiasis, nephrocalcinosis, and renal impairment, as well as systemic calcification, are typically seen as long-term complications of hypoparathyroidism. It is thought that both the natural history of the disease and the conventional therapy with large doses of supplemental calcium and calcitriol contribute to renal and other soft tissue calcifications in hypoparathyroidism. In the United States and many European countries, human recombinant (rh) PTH(1−84) is approved for the management of hypoparathyroidism not well controlled by conventional approaches (Clarke et al., 2014). PTH replacement therapy has been shown to reduce the burden of large supplemental doses of calcium and calcitriol while maintaining biochemical indices stably within the therapeutic range. By the psychometric SF-36 scale, it has also been shown to improve quality of life (Vokes et al., 2018; Cusano et al., 2014).

The ultimate therapeutic goal in hypoparathyroidism is total replacement of all three phases of normal PTH secretory dynamics. As a first step, a PTH ligand with a more prolonged state of binding to the PTH/PTHrP receptor (PTH1R) would be expected to approximate the homeostatic function PTH. This goal is opposite that of using PTH ligands in osteoporosis, in which the intention is to selectively stimulate the anabolic pathway of PTH action. Thus, teriparatide and abaloparatide function well in this regard but would not be as helpful in hypoparathyroidism. In hypoparathyroidism, it is the longer-lived configuration of the PTH−PTH1R interaction, not the shorter one, that is attractive therapeutically.

The difference in pharmacokinetics between intact PTH(1−84) and PTH (1−34) is further illustrated by the clinical experience with both molecules in the treatment of hypoparathyroidism. As anticipated by the foregoing discussion, PTH (1−34) requires at least twice-daily injections and sometimes three injections per day to achieve adequate control, whereas PTH (1−84) can be used successfully with a once-daily dosing regimen (Winer et al., 1998). Therapy with PTH replacement reduces the need for calcium and calcitriol. Mannstadt et al. showed that 53% of patients who received PTH (1−84) replacement were able to reduce their oral calcium and active vitamin D intake by 50% while maintaining stable and normal calcium levels at 24 weeks of therapy (Mannstadt et al., 2013). An even more physiological delivery of PTH may reduce urinary calcium excretion to a greater extent. Winer at al., for example, showed that continuous delivery of PTH (1−34) via continuous pump administration was able to reduce urinary calcium by 59% compared with twice-daily injections of PTH (1−34) which seems to suggest that a more physiological approach is beneficial (Winer et al., 2012).

Fox et al. compared four routes and sites of administration of PTH (1−84) (Fox and Garceau, 2011). Intravenously administered PTH(1−84) was cleared rapidly and provided the shortest calcium response, clearly not an attractive course for a disease like hypoparathyroidism. Subcutaneous routes were compared between the thigh and the abdomen. The thigh sites provide for slower absorption than the abdomen and therefore a more prolonged calcemic response. Subcutaneous thigh injection results in a biphasic profile with an initial peak 15 min post-injection, representing rather direct delivery of the drug into the circulation, and a second peak after 2 h (Sikjaer et al., 2013), indicating a slower uptake mechanism via the lymphatic system. PTH levels return to baseline after 12 h and calcium levels return to baseline after 24 h. For this reason, thigh injections are recommended for the treatment of hypoparathyroidism with PTH (1−84) (Clarke et al., 2014).

PTH replacement in hypoparathyroidism reverses the low bone turnover state characteristic of this disease. Intermittent replacement with PTH (1−34) increases bone-turnover markers above the normal range. Winer et al. showed that bone-turnover markers remained persistently elevated, with a twice a day regimen, for up to 3 years (Winer et al., 2003). A smaller increase in bone-turnover markers was observed in the twice a day regimen compared with the once a day regimen with PTH (1−34), although both bone formation and resorption markers were above the normal range (Winer et al., 1998). However, continuous administration of PTH (1−34) via pump delivery was able to keep both bone formation and resorption markers within normal range compared with the twice-daily regimen (Winer et al., 2012). In studies of PTH (1−84), once-daily injections of PTH (1−84) for up to 6 years also resulted in an increase in bone-turnover markers. Bone-

turnover markers peaked at 1 year of therapy and then fell, but remained elevated above baseline values by 6 years of therapy (Rubin et al., 2016). It remains to be studied, but we expect that more frequent regimens of PTH (1−84), either twice-daily injections or continuous administration via pump, will reverse the low bone turnover state, possibly keeping bone-turnover markers within the normal range without inducing bone remodeling excessively. Longitudinal observational studies with PTH (1−84) show an increase in BMD by dual-energy X-ray absorptiometry, which reflects the known site-specific effects of PTH seen from the use of these anabolic agents in osteoporotic patients, namely increases in lumbar spine and declines in distal one-third radius site. Although BMD at the lumbar spine and total hip was higher than that of age- and sex-matched reference standards prior to PTH replacement, lumbar spine BMD increased in the early years and seem to plateau after 4 years, while the increase in total hip BMD was seen in the later years of PTH therapy. Femoral neck BMD remained unchanged throughout the study. These changes seem to reflect the differential effects of PTH on cortical bone (distal one-third radius) and trabecular bone (lumbar spine). Histomorphometric analysis of bone biopsies from 13 subjects with hypoparathyroidism who were treated with rhPTH (1−84) for 8 years showed the presence of intratrabecular tunneling and increases in cancellous bone volume and trabecular number. PTH is known to increase cortical porosity and endosteal resorption (Rubin et al., 2011). Increased cortical porosity with PTH use is limited to the inner aspect of the cortex and is unlikely to contribute to a loss in bone strength. It must also be noted that PTH use is associated with an increase in bone size, and since the strength of a tube is related to the fourth power of its radius, this biomechanical advantage from the increase in bone size may offset the endosteal resorption and cortical porosity seen with PTH use in this disorder. Nonetheless, fracture data are ultimately needed to determine the clinical consequences of these observed structural changes. Long-term treatment of hypoparathyroidism with rhPTH (1−84) presents a unique opportunity to observe skeletal changes with long-term PTH exposure.

Chapter outline

Introduction

Calcium is the fifth most abundant element in the biosphere, after iron, silicon, oxygen, and aluminum. Unlike silicon and aluminum, whose compounds are quite insoluble, calcium salts exhibit an intermediate solubility that permits them both to be present in solution in the waters in which life evolved and to support development of various hard, solid organs for use by evolving life forms.

The radius of the Ca^{2+} ion is just right to fit naturally into the folds of many proteins, coordinating with up to eight oxygen atoms in the peptide chain and its side groups. Calcium thus stabilizes critical tertiary structures of both catalytic and structural proteins (Carafoli and Penniston, 1985). Calcium has an intermediate binding capacity, making it the perfect on−off switch. Zinc binds so tightly to proteins, it can stabilize them but cannot come off after a physiological action is complete. Magnesium, calcium's closest relative in the cell and, like calcium, a divalent alkaline earth element, has a smaller ionic radius and does not bind as strongly as does calcium. Calcium's functionality is so broad, in fact, that essentially all cells have found it necessary to restrict calcium concentration in the cell sap to something like 4−5 orders of magnitude below that in the extracellular fluid (ECF) surrounding the cell, about 1.25 mM. These low cytosolic concentrations are the context that permits cells to use calcium as a nearly universal second messenger. They do so by admitting controlled quantities into critical cellular compartments when specific functions are to be activated, and promptly pumping it out, either into the extracellular space or into intracellular vesicles, when the cell action is to be shut off. Intracellular storage of calcium is the rule, rather than the exception. Examples include the sarcoplasmic reticulum of muscle and calcium phosphate crystals in mitochondria. Calcium is so critical to intracellular function that most cells have developed a means to maintain their own supply. In general, their dependence on extracellular calcium is limited to initiating the cascade by opening calcium channels in the cell membrane. Movement of ECF calcium into the cytosol through these channels then activates a much larger release of calcium from intracellular stores, as in muscle contraction, neuronal synaptic transmission, and blood clotting.

Bone as the body's calcium sink and reserve

Bone is the reservoir of calcium stored following a meal and tapped during fasting. Calcium is stored in bone mainly in the process of mineralizing newly deposited bone matrix, that is, by adding new volumes of bone tissue; and it is withdrawn from bone mainly by resorption of old bone tissue. Thus, the reservoir functions of bone are mediated by modulating, on a moment-to-moment basis, the balance between new bone formation and old bone resorption.

A good example of this modulation is afforded by what happens during calcium absorption from milk in infant mammals. The quantity of calcium ingested in a short period of time, coupled with the efficiency of absorption in infants and the small volume of the extracellular water into which that calcium is dumped, is such that near-fatal hypercalcemia would ensue if there were not some way to damp the absorptive rise in ECF [Ca^{2+}]. This is accomplished by calcitonin-mediated suppression of osteoclastic bone resorption. Because bone formation is continuing, the mineralization of recently deposited bone matrix effectively soaks up the absorbed calcium. Then, as absorptive input decreases, bony resorption resumes. The result is a nearly steady input of calcium into the ECF, with the relative contributions of bone and gut varying inversely.

Once suitable crystal nuclei are formed, mineralization is mainly passive. Most of the skeletal control of extracellular calcium levels throughout life is exerted on the resorptive side of the remodeling apparatus, for the simple reason that osteoclastic activity is susceptible to very rapid response to humoral mediators, whereas mineralization is not.

An example of the reservoir function of bone is seen during pregnancy, a period of more positive calcium balance than can be accounted for by fetal mineralization, and then, with substantial loss of bone, during the hypoestrin state of lactation (Heaney, 1996). For example, the nursing rat, across lactation of a full litter of pups, loses on the order of one-third of the skeletal mass she had at delivery (Brommage and DeLuca, 1985).

Bidirectional remodeling imbalances (decreasing and then augmenting local bone mass) are capable of both removing and replacing calcium from bone by tiny minute-to-minute alterations of bone mass. Except for the accumulation of remodeling errors, this in-and-out process would not be expected to exert a deleterious effect on bone; in fact, it probably has a net beneficial effect on bone quality, inasmuch as evoked remodeling seems to focus preferentially on old, fatigue-damaged tissue, replacing it with fresh, new bone. However, when withdrawals are protracted or payback is incomplete or absent, structural elements may be lost (Fig. 70.1). When this occurs, the loss becomes irreversible, inasmuch as the scaffolding for osteoblastic replacement vanishes. Nutrient repletion can be expected only to fatten up existing structures, not replace lost ones. In this sense, calcium differs from a nutrient such as iron for which full repletion of functional iron mass is possible even after loss of a major fraction of total body iron stores.

There is an important asymmetry about this bidirectional flux of calcium in and out of bone through the remodeling cycle. Although bone can be resorbed essentially without limit, there is a practical ceiling that governs how much calcium can be stored. Given an environmental abundance of calcium, bone mass is normally regulated not by nutrient availability but by a mechanical feedback loop that works to maintain bony strain under load at a constant level in all skeletal parts and

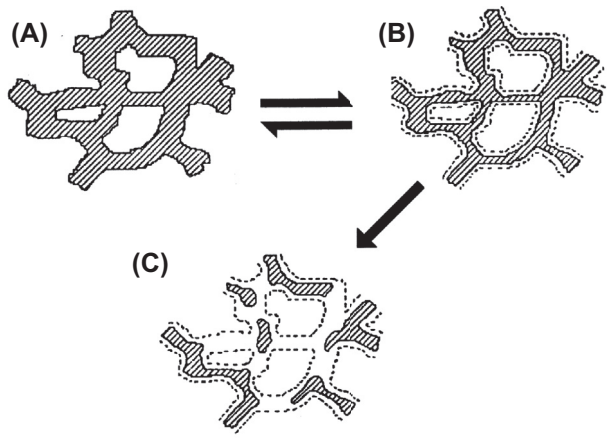

FIGURE 70.1 Schematic representation of the bidirectional flux of calcium in and out of the skeleton in a small volume of cancellous bone (A and B). Calcium is mobilized by resorbing bone tissue. So long as the basic structure is preserved (B), lost bone can be fully replaced. But when whole structures are resorbed (i.e., trabecular plates penetrated and trabecular beams severed; C), replacement of lost bone becomes difficult or impossible. *Reproduced from Heaney, R.P. 1994. The bone remodeling transient: implications for the interpretation of clinical studies of bone mass change. J. Bone Miner. Res. 9, 1515–1523, with permission. Copyright Robert P. Heaney 1995.*

regions. The bone set point (or "mechanostat") is poorly understood (as is true for most biological set points), but appears to involve the low-density lipoprotein receptor–related protein 5 (LRP5) that, in turn, controls osteoblast formation through the canonical Wnt signaling pathway (Robinson et al., 2006). Animals with functional mutation of the LRP5 gene produce more bone in response to mechanical loading than do animals with the wild-type gene (Robinson et al., 2006).

The regulation of this set point is complex and poorly understood, but in addition to mechanical loading, it is influenced, at least in part, by estrogen (which explains why bone tissue is added to the skeleton at puberty [Gilsanz et al., 1988] and during pregnancy [Heaney and Skillman, 1971], when estrogen levels rise, and withdrawn from it at menopause and during lactation [Brommage and DeLuca, 1985], when estrogen levels fall). But under a hormonal steady state, bone balance will become zero when the optimal level of strain is reached. Additional dietary calcium cannot be stored. The upshot is that, although the organism can withdraw calcium virtually without limit, storage is limited by the extent to which the skeleton continues to be subject to normal loading stresses, contingent upon preservation of structural elements and consistent with the set point of the bone mechanostat.

Calcium in bone

The adult human body contains, on average, slightly more than 1 kg of calcium, better than 99% of which is in the form of bone and teeth. Calcium is the principal cation of bone, comprising slightly less than 40% of the mass of the bone mineral and slightly less than 20% of the dry weight of bone. Calcium exists in bone in a mineral form that is usually characterized as hydroxyapatite, i.e., $Ca_{10}(PO_4)_6(OH)_2$. This is only approximately correct, and it is more accurate to say, after Posner (1987), that bone mineral is a "structurally imperfect analogue of hydroxyapatite." Bone mineral contains, for example, carbonate, citrate, potassium, magnesium, and fluoride among other ionic species. Carbonate content is especially high. It varies fairly substantially from species to species, in humans comprising in the neighborhood of 6%–9% of the mass of the mineral. Because the carbonate ion does not fit well into the hydroxyapatite crystal lattice, it is generally presumed to be located in superficial positions on the mineral crystals. The lability of bone carbonate, as reflected in changes in carbonate content with metabolic acidosis, suggests also that its location may be mostly on anatomic surfaces.

The crystals of bone exist in intimate association with the collagen fibers of the bone matrix. They are long and needle shaped, are ~70 Å in diameter and from 200 to 3000 Å long, and are constrained in size and orientation by the dense, orderly packing of the matrix collagen fibrils, which are laid down before mineralization begins. Matrix, as deposited, consists of about half protein and half water. As mineralization proceeds, mineral crystals displace the water, aligning themselves with the collagen fibrils. Ultimately, at full mineralization, the extracellular bony material contains virtually no free water. One consequence is the fact that mineral ions deep to anatomical surfaces are frozen in place, neither exchanging with nor supporting the level of the corresponding ionic species in solution in the ECF.

The calcification of matrix presents an interesting illustration of the importance of specificity of crystal habitus and takes advantage of the marginal solubility characteristics of calcium phosphate. Both calcium and phosphate, the latter in the form of H_2PO_4 and HPO_4^{2-}, circulate in the body fluids in solution and do not precipitate, neither in the bloodstream nor in healthy body tissues. However, the same minerals, in exactly the same concentrations, support mineralization when the blood flows past a bone-forming site. The reason, very simply, is that the concentrations of calcium and phosphate in ECF are such that body fluids are approximately half-saturated with respect to $CaHPO_4$ (the most likely crystal form at physiological pH and pCO_2). However, bone mineralization is not simple precipitation. Rather, it involves the creation of a template for formation of a crystal more like hydroxyapatite or tricalcium phosphate ($Ca_9(PO_4)_6$). Such minerals would not form spontaneously below pH 8; they are much less soluble, and body fluid concentrations of calcium and phosphate are approximately twice their K_{sp}. Local creation of such crystal nuclei is the means by which vertebrates have been able to control deposition of mineral, placing it only in loci specifically prepared to receive it, e.g., where it is needed to provide the necessary rigidity for the structural role of bone.

Noncollagenous matrix proteins are believed to play the critical role in configuring Ca^{2+} and PO_4^{3-} ions in space so as to create the hydroxyapatite template. Alkaline phosphatase, produced by the osteoblast late in the matrix deposition process, is believed to function by hydrolyzing pyrophosphate and organic phosphate esters present in the medium, which both makes extra phosphate available and removes components that otherwise function as crystal poisons, inhibiting crystal growth (Whyte, 2010). The chemistry of formation of the apatite mineral can be summarized as:

$$10Ca^{2+} + 3.5H_2PO_4^- + 2.5HPO_4^{2-} + 2H_2O$$

$$\rightleftarrows Ca_{10}(PO_4)_6(OH)_2 + 13.5H^+$$

The proportion of $H_2PO_4^-$ and HPO_4^{2-} in ECF at body pH is such that this reaction produces 13 protons for each unit cell[1] of hydroxyapatite formed. These must, of course, be removed from the mineralizing environment, or the reaction would cease or tend to run in reverse. By the same token, ~13 protons must be produced by osteoclasts to solubilize one unit cell of hydroxyapatite during bone resorption.

The calcium requirement

What the requirement ensures

The strength of bone, as with all material structures, resides in four features: the intrinsic strength of the mineral−matrix composite, the massiveness of the structure, the geometric arrangement of the bony elements in space, and the loading history of a structural element, expressed in accumulated fatigue damage. A major mechanism by which calcium is recognized to influence bone strength is through its effect on bone mass. Because bone functions as the calcium nutrient reserve, it follows inexorably that any depletion of that reserve (or failure to produce the genetically programmed skeletal mass during growth) will carry with it a corresponding decrease in bone strength.

In addition, at prevailing calcium intakes, bone remodeling occurs at a rate considerably in excess of the need to repair fatigue damage (Heaney, 2003; Parfitt, 2004), and this excess remodeling is a more important fracture risk factor than had been previously recognized. It is likely that contemporary calcium intakes, which are low by Paleolithic standards, are a part of the cause. In any event, supplementation reduces bone remodeling and reduces fracture risk as well (Heaney and Weaver, 2005).

As already noted, the calcium needed for critical cell metabolic functions is, in most cells, derived from intracellular stores of the mineral. Bone constitutes such a large reserve of calcium that cellular functions could virtually never deplete it, no matter how low the oral intake of the nutrient. The same is true for the maintenance of ECF Ca^{2+} concentration. A mere 5 g of bone contains as much calcium as the entire ECF space of an adult human. The requirement for calcium relates, thus, not to the metabolic role of the nutrient, but to building and maintaining the size of the calcium reserve, i.e., to its secondary function, bone strength.

The physiological adaptations to a low calcium intake

When the agricultural revolution positioned five cereal grains, i.e., wheat, corn, barley, oats, and rye, as the major source of energy largely replacing the roots, tubers, and other plants in the diet of early humans, intake of calcium as well as potassium and magnesium decreased markedly (Eaton and Nelson, 1991). Milk became the major source of calcium in the diet, and it is not usually consumed in sufficient quantities to meet the needs of hominids, who evolved in an environment of an abundance of calcium. Mammals typically have low intestinal calcium absorption efficacy, unregulated cutaneous losses, and poor renal conversion. Thus, humans are more often in a state of calcium deficiency, with homeostatic regulatory mechanisms trying, but largely failing, to adequately compensate.

When serum calcium levels fall, calcium-sensing receptors detect reduced Ca^{2+} concentrations in the ECF, and inhibition of parathyroid hormone (PTH) release from the parathyroids is removed and calcitonin release is suppressed. PTH activates conversion of vitamin D to its active form, $1,25(OH)_2D_3$, by cytochrome P450, subfamily 27A, polypeptide 1 (CYP27A1) in the liver and CYP27B1 in the kidney to activate three tissues, the gut, the kidney, and bone, to sustain blood calcium levels within the normal range (Fig. 70.2). Active calcium absorption is enhanced through upregulation of calcium transporters in the gut. PTH and $1,25(OH)_2D_3$ increase renal tubular calcium reabsorption to reduce urinary losses. Bone resorption ensues to mobilize calcium from this large reservoir. Sustained mobilization of bone to meet ECF Ca^{2+} concentrations comes at great cost to the skeleton over time.

Defining the calcium requirement

The calcium requirement can be defined as the intake needed to support genetically programmed acquisition of bone during growth and to sustain acquired bone during maturity and the declining years of life. Because of differing absorption and retention efficiencies, individuals will inevitably have differing requirements for a skeletal end point. Table 70.1 gives the adequate intake (AI), estimated average requirement (EAR), and recommended dietary allowance (RDA) for calcium, most recently revised in 2011 (IOM, 2011). The EAR is the value at which half the population is meeting their needs and the

1. A unit cell, in this case containing 10 calcium ions, is the smallest symmetrical repeating unit of the crystal lattice.

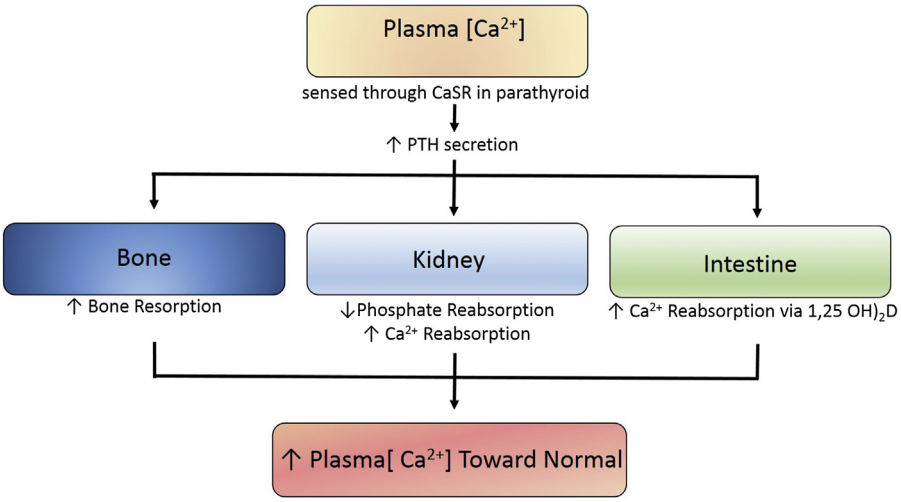

FIGURE 70.2 Homeostatic regulation of Ca^{2+} when plasma calcium falls to less than 2.5 mM. *CaSR*, calcium-sensing receptor; *PTH*, parathyroid hormone.

TABLE 70.1 Recommendations for calcium intake.

		Males (mg/day)		Females (mg/day)		
Life stage	**Age**	**EAR**	**RDA**	**EAR**	**RDA**	**UL**
Infants	0–6 months		200 (AI)		200 (AI)	1000
Infants	0–12 months		260 (AI)		260 (AI)	1500
Children	1–3 years	500	700	500	700	2500
Children	4–8 years	800	1000	800	1000	2500
Children	9–13 years	1100	1300	1100	1300	3000
Adolescents	14–18 years	1100	1300	1100	1300	3000
Adults	19–50 years	800	1000	800	1000	2500
Adults	51–70 years	800	1000	1000	1200	2000
Adults	71 years and older	1000	1200	1000	1200	2000
Pregnancy	14–18 years		–	1000	1300	3000
Pregnancy	19–50 years		–	800	1000	2500
Breastfeeding	14–18 years		–	1100	1300	3000
Breastfeeding	19–50 years		–	800	1000	2500

AI, adequate intake; *EAR*, estimated average requirement; *RDA*, recommended dietary allowance; *UL*, tolerable upper level.
From the Institute of Medicine, Dietary Reference Intakes for calcium and vitamin D. Washington, DC, 2011.

RDA provides a safety margin of 2 SDs so that 97% of the population are expected to meet their needs. AIs are used for infants to reflect intake from mother's milk for breastfed infants.

Calcium is a threshold nutrient. This means that, at subthreshold intakes, calcium retention is less than optimal. Bone gain during growth is then a direct function of intake (i.e., it is less than is genetically programmed), whereas in the mature organism, subthreshold intakes lead to actual bone loss. On the other hand, the threshold character of the relationship means that intakes above the threshold produce no additional bone effect. These relationships are depicted schematically in Fig. 70.4. Recommendations for calcium intake do not increase for pregnancy and lactation. Adaptations in calcium homeostasis during these life stages result in increased calcium absorption efficiency starting as early as 12 weeks in pregnancy to meet the needs of the fetus (Ritchie et al., 1998) and upon weaning of the infant following

cessation of lactation to recover bone loss experienced during lactation (Kalkwarf et al., 1997). In the elderly, optimizing calcium intake may not prevent a negative bone balance. In a randomized controlled trial (RCT) (McKane et al., 1996) in elderly women supplemented with calcium for 3 years, unsupplemented individuals, with intakes averaging close to 20 mmol (800 mg)/day, exhibited the high 24-h mean PTH levels, the enhanced PTH secretory reserve, and the elevated bone resorption that have all been taken to characterize the calcium and skeletal economies of the aged (Epstein et al., 1986). By contrast, women supplemented to 60 mmol (2400 mg)/day decreased both their bone remodeling and their parathyroid functional indices, restoring them to young adult normal values. The inference is that the increases in parathyroid cell mass and function represent not so much characteristics of old age as adaptive responses to long-standing calcium deprivation.

Contributing causes for this increased parathyroid activity in the elderly, aggravating the effect of low calcium intake, include a decline in vitamin D status with age (reflecting both decreased solar exposure and decreased efficiency of skin conversion of 7-dehydrocholesterol to previtamin D) and declining absorption and conservation efficiency for dietary calcium. Holding calcium intake constant at about 20 mmol (800 mg)/day, gross absorption efficiency declines from a mean at age 40 of 0.24, at a rate of 0.002/year through at least age 65, with a one-time additional drop of 0.02 at menopause (Heaney et al., 1989). Over that period, the decline thus amounts to 0.07, or a fall of 30% in absorptive efficiency. Nordin and others have shown also that renal conservation of calcium deteriorates across menopause (e.g., Nordin et al., 1991). The net result is that extraction of ingested calcium from food falls with age and conservation of that which is absorbed falls as well.

It must be noted that the absorption values cited earlier are *gross* absorption, such as would be measured by calcium tracer flux from the intestinal lumen into the bloodstream. They do not account for the contrary movement of calcium into the lumen in the digestive secretions and sloughed off mucosa (which turns over at a rate of 20%/day). In adult women, this calcium from endogenous sources entering the intestinal stream amounts to 3.5−3.75 mmol (140−150 mg)/day (Heaney and Recker, 1994). Most of this calcium is subject to the same absorptive probability as is ingested calcium, but given the low efficiency of calcium absorption in general, inevitably most endogenous calcium will be lost into the feces. Thus net absorption from intakes in the range of 20 mmol (800 mg)/day is on the order of only 10%−15% of ingested calcium. Not all of even this small amount of net calcium gain from the intestine can be retained, because the tiny elevation of blood calcium produced when calcium is absorbed elevates the filtered load at the kidney and leads to an increase in urinary calcium loss. The net result of the low net absorption and poor renal conservation is that, even during times of calcium need, only a small fraction of an ingested load is retained. Further, at the higher intakes achieved by calcium supplements, fractional retention is smaller still, because absorption fraction declines with the logarithm of the intake load size (Heaney et al., 1990, 2000).

Achieving the calcium requirement: dietary sources

Calcium must be consumed in sufficient quantities to replace obligatory losses through excretion and dermal sloughing and to supply needs for skeletal growth, or calcium balance will be more negative than optimal to build and maintain bone. The main sources of calcium are dairy products, fortified foods and beverages, and dietary supplements containing calcium.

Calcium is a shortfall nutrient around the globe, but even more so in Asian and African countries, where dairy product consumption is especially low. In US adults, surveyed in the 2009−12 National Health and Nutrition Examination Survey, 35.9 ± 1.0% of whites, 56.3 ± 1.4% of blacks, 36.4 ± 2.1% of Hispanics, and 61.4 ± 2.5% of Asians failed to meet the EAR from diet alone, which decreased to 24.2 ± 0.7% of whites, 48.2 ± 1.4% of blacks, 30.1 ± 2.0% of Hispanics, and 47.0 ± 2.6% of Asians when considering both diet and multivitamin and mineral supplement consumption (Blumberg et al., 2017). Calcium absorption from most of these sources, i.e., dairy, fortified foods and beverages, and supplements, is similar (Weaver and Heaney, 2006). However, other factors should be considered when planning how to achieve calcium recommendations.

Dairy foods not only provide calcium in high concentration, but also provide the whole package of nutrients needed for bone, including protein, phosphorus, magnesium, potassium, and B vitamins. Other natural sources of calcium in the diet typically have much less calcium in a serving than milk. Thus, even foods with very high calcium absorption efficiency due to absence of inhibitors such as oxalate and phytate cannot practically substitute for dairy recommendations. The number of servings to replace the absorbable calcium in one glass of milk is 3.5 for kale and 4.5 for broccoli. Fortified foods and beverages may contain good-quality protein and highly bioavailable calcium (Zhao et al., 2005). None of the other plant-based beverages becoming popular have been tested for calcium bioavailability. They have variable quantities of protein, potassium, and other nutrients important to bone and they all cost more than cow's milk. Supplements typically provide only calcium and maybe vitamin D; but not usually protein, potassium, magnesium, and other nutrient important to bone.

Nutritional factors influencing the calcium requirement

It is a truism of nutritional science that nutrients interact with one another and thereby alter their mutual requirements. Thus, requirements of certain of the B vitamins and of ascorbic acid vary with total energy intake (and expenditure). The lack of evolutionary development of efficient conservation of calcium has rendered this nutrient unusually sensitive to such nutrient−nutrient interactions. Most of this interaction is expressed in urinary calcium excretion, which, for example, is strongly influenced by the ingested load of sodium and by the acid/alkaline residue of the diet (Wigertz et al., 2005; Heaney, 1993b; Sebastian et al., 1994). The sodium effect is attributable to the fact that sodium and calcium share a common transport mechanism in the proximal tubule, and thus an increased filtered load of either ion will lead to increased excretion of the other. The magnitude of the sodium effect on the calcium economy is an increase of 0.5−1.5 mM urine calcium for every 100 mM sodium ingested (Devine et al., 1995; Nordin et al., 1993; Itoh and Suyama, 1996)).

These effects are linear across the full range of prevailing intakes from low to high, and are not thus consequences only of excessive intake. With diets characteristic of typical North American and European women, nutrients such as sodium account for 100 mg/day of obligatory calcium loss through the kidneys. Given the extremely poor net absorption efficiency for calcium, these nutrients can thus easily account for up to 1000 mg/day of the calcium requirement. It has been noted, for example, that individuals with low, but nutritionally adequate, intakes of sodium may have calcium requirements as low as 500 mg/day, whereas those with intakes more typical of contemporary patterns may have intake requirements closer to 2000 mg/day. This quite extraordinary sensitivity of calcium to the intake of other nutrients is but one more reflection of the lack of evolutionary acquisition of efficient mechanisms for calcium absorption and conservation.

The well-documented effect of the acid/alkaline residue of the diet (Berkelhammer et al., 1988; Sebastian et al., 1994) is probably a function of the "hard" anions (sulfate, chloride), either ingested with food or produced in metabolism. In any event, substitution of acetate or bicarbonate for chloride produces substantial reductions in urinary calcium loss and therefore in the ability to maintain calcium equilibrium on low calcium intakes.

It is important to stress this last point, that these nutrient interactions negatively affect calcium balance mainly at low calcium intakes. This is because they limit an individual's ability to adapt to a low intake. At the higher intakes near the RDA, adaptation is easily possible. High protein intakes do not have a negative effect on the skeleton, as once thought based on increased urinary calcium excretion (Ince et al., 2004). This increased loss through the kidney can be offset by increased calcium absorption (Kerstetter et al., 2005). A systematic review and meta-analysis of RCTs and observational studies showed no overall detrimental effect of dietary protein on bone (Shams-White et al., 2017). Protein supplementation in institutionalized elderly with recent hip fractures reduced bone loss (Schürch et al., 1998). There is evidence of an interaction of protein and calcium intakes on bone (Dawson-Hughes and Harris, 2002; Sahni et al., 2010). In the Framingham Study, those in the highest tertile of animal protein consumption taking <800 mg Ca/day had 2.8 times the risk of hip fracture of those in the lowest tertile of protein intake ($P = .02$), whereas protein decreased fracture incidence when calcium intakes were >800 mg/day (Sahni et al., 2010).

Another example of a dietary constituent influencing calcium metabolism is caffeine. Similar to the effect of protein, caffeine was considered detrimental to bone because of its impact on increasing urinary calcium excretion. However, at practical intakes, caffeine has little effect on calcium homeostasis or bone outcomes, including risk of fractures and falls, bone mineral density (BMD), and osteoporosis. In a systematic review of 14 studies, evidence of the effects of caffeine intake below 400 mg/day on these outcomes was of low magnitude and observed only under conditions of low calcium intake (Wikoff et al., 2017). A typical cup of coffee contains 50 mg, suggesting little effect up to eight cups of coffee or caffeine equivalent. The greater risk is displacement of milk consumption by caffeinated beverages.

Toxicity

It is possible to consume too much of any nutrient, and calcium is no exception. However, in healthy individuals, available evidence indicates that the toxic threshold is quite high. Many young adult males in the United States regularly consume more than 75 mmol (3000 mg)/day (Blumberg et al., 2017), and in pastoralist societies, such as the Maasai of East Africa, calcium intakes regularly average more than 150 mmol (6000 mg)/day. In both instances, there are no known ill effects associated with such intakes.

However, there are special circumstances in which high calcium intake can definitely be harmful. Even at the low-absorption fractions typical of high intakes, substantial quantities of calcium will enter the body and will need to be excreted in the urine (unless active bone building is occurring). Under conditions of dehydration or hypovolemia, perfusion of both bone and kidney can be sufficiently compromised so that absorbed calcium produces significant hypercalcemia. Likewise, under conditions of systemic alkalosis, large calcium intake can produce renal calcinosis and severe impairment

of kidney function. Furthermore, under these somewhat unusual and extreme circumstances, elements of positive feedback can cause the situation to deteriorate rapidly. Hypercalcemia impairs the ability of the kidney to retain water and thus aggravates a preexisting dehydration, with consequently worsening hypercalcemia. A fatal downward spiral can easily ensue. Published reports of such toxicity have generally involved intakes of more than 150 mmol (6000 mg)/day in individuals with preexisting impairments of water and electrolyte metabolism. Whatever the underlying cause, such problems can be easily handled by rehydration and by correction of the underlying abnormality, so long as these situations are recognized in time.

Kidney stones are the complication of most concern in setting tolerable upper levels (ULs) (see Table 70.1). Kidney stones are most often composed of calcium, oxalate, or calcium phosphate. Those with hypercalciuria are more at risk for kidney stones, which led to earlier recommendations to reduce calcium intake if risk of kidney stones was high (Curhan et al., 1993, 1997; Taylor et al., 2004; Taylor and Curhan, 2013). In these large prospective studies of men and women, there was an inverse correlation between calcium intake from either dairy or nondairy sources and stone formation; those with the highest calcium intakes had the lowest risk of kidney stones, although in elderly men, who experience lower incidence of stones, there was no relationship. This seeming paradox is explained by the fact that oxalate excretion in the urine is a more significant risk factor for calculi than is urine calcium. High calcium intake binds oxalate, both of dietary origin (when coingested) and produced by bacterial fermentation in the gut before it can be absorbed; dietary calcium thereby lowers the renal oxalate burden. In fact, very large calcium supplements have long been standard therapy for the kidney stones occurring with intestinal hyperoxalosis, sometimes found in patients with short-bowel syndrome. A protective effect of high calcium intake on both oxalate loads and stone recurrence was seen in an RCT in which those on a reduced calcium intake had twice the rate of stone occurrence as those on a high intake (Borghi et al., 2002).

In summary, the levels of calcium intake discussed in the foregoing sections of this chapter, as well as those needed to support osteoporosis pharmacotherapy (see next section on "Calcium and osteoporosis treatment"), are well within the safety limits for the ingestion of this nutrient. Mild adverse gastrointestinal events, including constipation, cramping, and bloating, have been associated with calcium supplementation (Lewis et al., 2012).

Calcium and osteoporosis treatment

Osteoporosis is a skeletal disorder characterized by increased risk of fracture and reduced BMD and bone strength. Effective osteoporosis treatments involve a combination of pharmacotherapy designed to reverse the negative remodeling balance prevailing in the skeleton and diet and physical therapy designed both to increase function and to increase mechanical loading on the skeleton. Currently recommended calcium intakes are presumably adequate to sustain bone mass, but they may not be sufficient to support bone gain in most individuals (i.e., net absorption from such intakes is just sufficient to offset obligatory losses). Furthermore, there is essentially no evidence that calcium alone, in any quantity, will lead to substantial gain in bone in individuals who already have osteoporosis. The small increase in BMD with supplementation in the classic study by Chapuy et al. (1992) illustrated in Fig. 70.3 probably reflects a remodeling transient (Heaney, 1994) and not a new steady-state rate of change. However, elevating calcium intake from 13 mmol (520 mg)/day to 42.5 mmol (1700 mg)/day in 1800 French women, average age 84, reduced fracture rates at the hip by an impressive 20% and at other sites by 40% within 18 months of supplementation (Chapuy et al., 1992). This occurred not due to the small increase in BMD in the supplemented group, but due to the prevention of erosion of bone mass observed in the control group. Participants in the intervention group were also given 800 IU vitamin D, which also would have resulted in fracture risk reduction.

Effective pharmacotherapy, including fluoride (Pak et al., 1995; Riggs et al., 1990), bisphosphonates (Liberman et al., 1995; Black et al., 1996; Cummings et al., 1998; Harris et al., 1999), selective estrogen receptor modulators (SERMs) (Ettinger et al., 1999), and PTH (Kurland et al., 2000; Neer et al., 2001), does increase bone mass, and for some of these agents at a rate of up to 8% per year. To realize this potential gain, and particularly to optimize it, calcium intake probably needs to be above the maintenance level. Most medications for osteoporosis treatment are prescribed with calcium and vitamin D supplementation as adjuvant therapy based on trials showing efficacy in that context (Harvey et al., 2017). Also, it is worth noting that the antiresorptive agents (principally bisphosphonates and SERMs, as well the receptor activator of NF-κB ligand and cathepsin K inhibitors), by blocking osteoclastic resorption, force higher levels of PTH secretion and hence better utilization of ingested calcium. Hence, the calcium intake requirement for optimal BMD response to these agents is unclear.

There is, however, some evidence. With respect to fluoride, Dure-Smith et al. (1996) showed, during effective fluoride therapy, an extraordinary degree of bone hunger, suggesting the need for calcium intake during fluoride therapy of perhaps

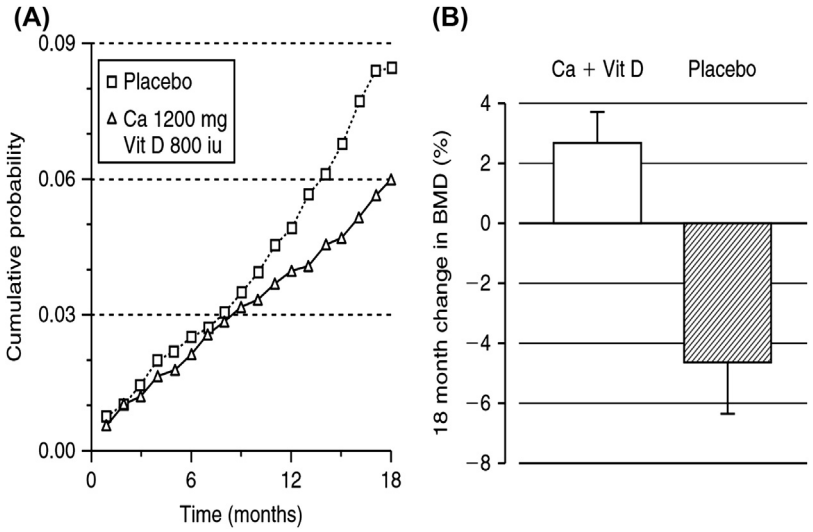

FIGURE 70.3 Effects of supplementation with calcium phosphate and vitamin D on hip fracture rate and hip bone mineral density (*BMD*). (A) The cumulative probability of fracture for the supplemented and unsupplemented groups is shown, as is (B) the change from baseline in hip BMD for the two groups. *Redrawn from the data of Chapuy, M.C., Arlot, M.E., Duboeuf, F., et al. 1992. Vitamin D3 and calcium to prevent hip fractures in elderly women. N. Engl. J. Med. 327, 1637–1642.*

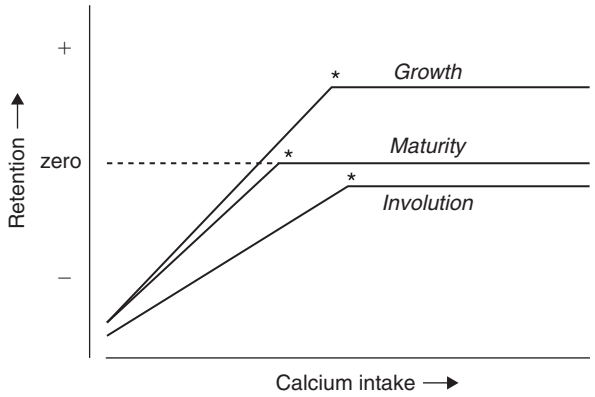

FIGURE 70.4 Schematic depiction of the relationship between calcium intake and skeletal retention at three life stages. Given sufficient intake, retention is positive during growth, zero at maturity, and variably negative during involution. Intakes above the threshold do not affect retention, but subthreshold intakes limit bone acquisition or lead to bone loss. The location of the minimum requirement is indicated by the *asterisk* above each line. *From Heaney, R.P. 1997. Nutrient effects: discrepancy between data from controlled trials and observational studies. Bone 21, 469–471, with permission. Copyright Robert P. Heaney 1998.*

as much as 62.5 mmol (2500 mg)/day. Other clear examples of the importance of ensuring adequate calcium intake when using other bone active agents are provided by a series of papers. First is a meta-analysis of 31 controlled trials of estrogen replacement therapy (Nieves et al., 1998), which showed that estrogen in trials using supplemental calcium (at an average intake of 1187 mg/day) produced bone responses more than twice as great as those that did not (at an average intake of 583 mg/day). In addition, Recker et al. (1999) showed that a reduced dose of estrogen (0.3 mg of conjugated equine estrogens) produced a 5% increase in bone mass in women given supplemental calcium and vitamin D. By contrast, in at least three earlier trials without supplemental calcium, this estrogen dose was essentially ineffective.

Calcium supplementation and bone health

The importance of a high calcium intake for bone health has often been questioned (e.g., Kanis and Passmore, 1989) and, even more often, has been termed "controversial." This is because some studies showed strong effects of calcium intake on bone status, but others showed no benefit at all. "Confusing" is the more accurate term. There are several reasons for this confusion.

First, osteoporotic fracture is a distinctly multifactorial disorder. Nutrition, and specifically calcium nutrition, is only one of many contributing factors. Although calcium intake is of critical importance in many individuals, it plays little or no role in others, just as iron intake is limiting in only certain forms of anemia. One example of this distinction is seen in menopausal bone loss, which is dominantly caused by estrogen deficiency and cannot be substantially influenced by calcium intake (although estrogen-related loss may be exaggerated if calcium intakes are very low) (Heaney, 1990). This is seen, for example, in the fact that even intakes of more than 75 mmol (3000 mg)/day, in the study by Elders et al. (1991), were able only to slow menopausal loss, not to prevent it. However, menopausal loss is self-limited and is mostly confined to the 5-year period surrounding cessation of ovarian function.

Observational studies do not always show a benefit of calcium supplementation or milk intake to bone, or they may show a benefit to one sex, but not the other, though which sex is not consistent (Bischoff-Ferrari et al., 2011; Michaelsson et al., 2014). There are many reasons for these discrepancies, including one sex being older with more comorbidities compared with the other sex (Sahni et al., 2017). Perhaps the more common and important reason for inconsistent results is the weak ability to estimate calcium intake from food records, or food frequency questionnaires, no matter how carefully these methods are applied, resulting in substantial classification bias (Heaney, 1991, 1997).

Results from RCTs are also inconsistent. Frequently, calcium and vitamin D supplementation are given together, making it difficult to distinguish the effects of calcium alone. Some systematic reviews or meta-analyses of RCTs fail to show a benefit of dietary calcium or supplements to lowering fracture risk (Zhao et al., 2017) and others show rather small benefits to BMD (<2%) (Tai et al., 2015).

Frequently, confounding issues also plague RCTs. Failure to consider baseline status is important, as calcium is a threshold nutrient and benefits will be realized only if status can be improved. Lack of compliance within either the intervention or the control group must be considered, as there is a tendency for convergence of intakes between the two arms (Atkinson et al., 2008). The largest of the RCTs is the Women's Health Initiative (WHI). A meta-analysis of eight RCTs with 30,970 subjects showed the powerful effect of supplementation on lowering hip fracture risk by 30% (Weaver et al., 2016). In this analysis, participants in the WHI study not consuming their own calcium and vitamin D supplements and who were not compliant were excluded. This contrasts with no significant association when this trial is not adjusted for compliance and baseline status. Additional confounding occurs when life stages are combined, such as perimenopausal women with women postmenopausal for greater than 5 years.

A final consideration relates to the uncritical use of transnational comparisons (e.g., Hegsted, 1986). Differences in fracture rate between ethnic and national populations have many bases, only some of them nutritional. An example is the lower hip fracture rates of contemporary Chinese and blacks, despite lower BMD values for Chinese (Walker et al., 2006) and despite mean calcium intakes for both groups that are lower than those of North American or European Caucasians. Behind this difference there is, first, the large effect of the other nutrients in the diet, previously described. Thus, the predominantly vegetable-based and low protein intakes of many Third World populations would be expected to lower their calcium requirements. Similarly, there are major racial differences in ability to conserve calcium. American blacks, for example, both absorb at higher efficiency for any given ingested intake and conserve better at the kidney than do Caucasians (Bryant et al., 2003; Abrams et al., 1995; Bell et al., 1985; Aloia et al., 1998; Cosman et al., 1997). Chinese American adolescents have a higher calcium absorption efficiency than other races (Wu et al., 2010). Thus they have lower calcium requirements. Finally, there are important racial differences in bone geometry that have their own effect on fracture rate. Hip axis length, for example, explains most or all of the difference between the hip fracture rates of Caucasians, on one hand, and Chinese and Japanese, on the other, after adjusting for bone mass (Faulkner et al., 1993; Nakamura et al., 1994).

Instead of making cross-cultural comparisons, the correct approach is to assess the effect of nutrient intakes within a cultural and ethnic group. When this has been done, bone mass and hip fracture rate are found to be inversely correlated with calcium intake (Anderson et al., 1995; Hu et al., 1993; Lau et al., 1988).

Calcium supplementation and cardiovascular risk

Calcium supplementation became associated with a risk of cardiovascular disease when a retrospective analysis of an RCT to determine the effect of calcium supplementation on BMD revealed an increased risk of myocardial infarction (Bolland et al., 2008). This finding spawned many additional retrospective analyses, prospective studies, and meta-analyses with mixed results with a variety of cardiovascular outcomes (Li et al., 2012; Xiao et al., 2013; Avenell et al., 2012; Samelson et al., 2012; Lewis et al., 2012, 2015; Khan et al., 2015). In an evaluation of the state of evidence base using Bradford Hill criteria, the association between calcium supplementation and cardiovascular risk was judged to fail because of a weak strength of relationship (relative risk <2.0), lack of consistent results, no dose−response relationship, and no biological

plausibility or proven mechanism (Heaney et al., 2012). A systematic review and meta-analysis examined four RCTs and 27 prospective cohort and nested case−control studies for the effects of calcium intake on cardiovascular disease among healthy adults (Chung et al., 2016). No statistically significant differences in risk for cardiovascular disease events or mortality between supplementation and placebo groups in the RCTs were observed. Nor were any consistent dose−response relationships between calcium intake from any source and cardiovascular mortality, risk for stroke, or stroke mortality observed in cohort studies.

In all of these studies, cardiovascular outcomes were secondary end points. Lacking are trials with cardiovascular end points as a primary outcome. The updated analysis by Chung et al. (2016) informed a joint position statement from the National Osteoporosis Foundation and American Society for Preventive Cardiology that concluded there is a B level, or moderate level, of evidence that calcium with or without vitamin D intake from food or supplements has no beneficial or harmful relationship to risk of cardiovascular or cerebrovascular disease, mortality, or all-cause mortality (Kopecky et al., 2016). Calcium intake up to the UL was considered safe from a cardiovascular standpoint.

Summary

Calcium is the principal cation of bone, making up 20% of its dry weight. Bone constitutes a very large nutrient reserve for calcium in terrestrial vertebrates, a reserve that has acquired a major mechanical function. The requirement for calcium is related to the protection of this mechanical function, not to the metabolic actions of calcium, which could be adequately protected by a reserve several orders of magnitude smaller. Calcium was abundant in the environment in which hominids evolved and in the foods they ate. Probably as a consequence, efficient calcium conservation mechanisms did not develop. Contemporary diets are low in calcium by comparison, and our Paleolithic physiologies are poorly adapted to them. Yet other features of the modern diet (e.g., high salt and low potassium) increase obligatory calcium loss and thereby reduce the ability to adapt to lowered intakes. The evidence is compelling that inadequate calcium intake weakens bone and contributes to the growing osteoporosis problem.

Chapter outline

Introduction

The extracellular calcium sensing receptor (CaSR) is a G-protein-coupled receptor that monitors and maintains the level of ionized calcium (Ca^{2+}) in the blood and extracellular fluids (Brown, 2013). It is expressed at its highest levels in the parathyroid glands and the kidney, where it regulates, respectively, the secretion of parathyroid hormone (PTH) and the tubular reabsorption of Ca^{2+}. The essential molecule regulating systemic Ca^{2+} homeostasis, it has been rightly called the body's "calciostat." Because of this pivotal role, it was suggested, in the first edition of *Principles of Bone Biology*, that the CaSR might be a viable drug target to treat a number of bone and mineral-related disorders such as hyperparathyroidism (HPT) and osteoporosis (EF et al., 1996). Some of those predictions have proven to be correct, others have not.

A number of significant advances have been made since the last edition of this chapter, including understanding the genetic basis of some disorders associated with hyper- or hypocalcemia, the development of two new calcimimetic drugs, and insights into the molecular mechanisms of action of calcimimetic and calcilytic compounds (Nemeth et al., 2018). In addition, it has become clear that calcilytics are not suitable treatments for osteoporosis, as they fail to stimulate new bone formation (Nemeth and Goodman, 2016). There are, however, other indications that calcilytics might be therapeutically useful, but more work will be needed if this potential is to be realized.

Primary hyperparathyroidism

Primary HPT (PHPT) is a common endocrine disorder characterized by hyperfunction of one or more of the four parathyroid glands. The diagnosis is made readily by an elevated serum calcium in association with elevated or inappropriately normal PTH levels. Surgical removal of the hyperfunctioning gland(s) is the only definitive cure for this disease. It is indicated in symptomatic patients or in those who meet established guidelines (Bilezikian et al., 2014). In those who do not meet any of the surgical guidelines, parathyroidectomy is also an option if there are no medical contraindications. Those

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00071-3

who do not have parathyroid surgery typically do not meet any surgical criteria, have had previous unsuccessful surgery, or refuse surgery. If the patient's serum calcium is in the range where one would ordinarily recommend surgery but surgery is not going to occur, then pharmacological approaches to reducing the serum calcium may be indicated (Bilezikian et al., 2014). Cinacalcet is approved to reduce the serum calcium in these patients.

The indications in the United States are to control hypercalcemia in patients with either PHPT or parathyroid carcinoma for whom parathyroidectomy is not an option. In Europe, cinacalcet is registered for the reduction of hypercalcemia in patients with PHPT for whom parathyroidectomy is contraindicated.

In a randomized, double-blind, placebo-controlled, short-term, multicenter study Shoback et al. assessed the efficacy and safety of cinacalcet in PHPT. The drug was administered twice daily orally at different dosages, and the authors demonstrated that cinacalcet significantly reduced serum calcium, with maintenance of reduced levels during the 12-h interval between doses (Shoback et al., 2003). Decreased serum calcium levels were observed during the entire 15-day study period, with return of calcium levels to baseline values a week after discontinuation (Shoback et al., 2003). Cinacalcet also reduced PTH levels by 47%−51% 4 h after administration (Shoback et al., 2003). Although PTH levels increased after reaching their nadir, they remained below baseline levels in the 12-h interval between the two daily doses (Shoback et al., 2003). No safety signals emerged from this study, but paresthesias were noted commonly (Shoback et al., 2003).

A longer, randomized, double-blind, placebo-controlled study followed that clarified the long-term efficacy and safety of cinacalcet in PHPT (Peacock et al., 2005). Women and men (mean age, 62 years) with mild to moderate PHPT were randomized to receive cinacalcet (30 mg twice daily) or placebo and followed for up to 52 weeks (Peacock et al., 2005). Seventy-three percent of patients receiving cinacalcet experienced a $\geq$0.5 mg/dL decrease in serum calcium levels from baseline, reaching levels $\leq$10.3 mg/dL, a figure that was significantly lower than the placebo group. At week 52, mean serum calcium levels were normal in the cinacalcet group. A more modest 7.6% decrease in PTH remained significantly below the baseline up to week 12, with a return to baseline values thereafter (Peacock et al., 2005). Serum phosphorus, bone-specific alkaline phosphatase (BSAP), and N-telopeptide levels, although within the normal range, were significantly higher in the cinacalcet group at week 52 compared with placebo (Peacock et al., 2005). No significant differences between groups were observed in bone mineral density (BMD) or in safety parameters. Nausea and headache were reported as the most common adverse events.

Data from this clinical trial confirming the effectiveness and tolerability of cinacalcet as a nonsurgical approach to PHPT were further supported by results from an even longer 5-year study (Peacock et al., 2009). This experience was an open-label extension of the 52-week study of Peacock et al. The placebo group was crossed over to receive cinacalcet. The mean follow-up time was 4.5 years. Throughout the study period, those who received cinacalcet from the outset maintained reduced, normal serum calcium levels. The crossover group, receiving cinacalcet after 1 year of placebo, demonstrated a rapid reduction in serum calcium, similar to the observations in the 1-year study among those who originally received cinacalcet. Again, serum PTH levels fell by up to 21% but did not normalize during the extension period. Serum phosphorus and alkaline phosphatase rose in the first 12 weeks but remained within normal limits during the entire study with no further increases. No changes in BMD were observed. The only noteworthy adverse event was nausea, occurring more commonly compared with the placebo group in year 1 of the parent study.

The initial studies demonstrating the safety and efficacy of cinacalcet in PHPT were followed by several further clinical trials in which cinacalcet was tested in the context of patients with more severe PHPT and with parathyroid cancer. For example, Marcocci et al. reported the results from an open-label, single-arm, dose-titration study assessing the efficacy of cinacalcet in reducing serum calcium in patients with PHPT whose serum calcium was much higher (>12.5 mg/dL) (Marcocci et al., 2009). These individuals either had had unsuccessful parathyroid surgery or had contraindications to surgery. Notwithstanding the small number of patients, the study provided interesting data on the biochemical efficacy of cinacalcet in this setting. Eighty-eight percent of patients experienced a reduction in serum calcium concentration of at least 1 mg/dL; a majority showed normal serum calcium levels at the end of the titration phase. Quality of life measures were improved.

A pooled analysis of data from this study and those of Peacock et al. (2005, 2009) assessed the comparative efficacy of cinacalcet among patients with varying severity of PHPT (Peacock et al., 2011). Eighty-one patients were categorized into three groups: failed parathyroidectomy, indication for parathyroidectomy but not performed, and mild asymptomatic disease. More than 70% of patients from the entire cohort demonstrated normal serum calcium levels by 6 months with maintenance of control for up to 4 years. The serum PTH decreased within the first year of treatment. The serum phosphorus increased. There were no relevant changes in BMD, bone-turnover markers, or calcium excretion in any group. All groups responded similarly. This composite analysis demonstrated that cinacalcet effectively reduces the serum calcium

and maintains normal levels across a wide range of disease severity, with good tolerability. No group showed changes in BMD at any sites.

The further development of cinacalcet addressed patients with "nonoperable" PHPT (Khan et al., 2015). This phase III double-blind, placebo-controlled trial enrolled 67 patients who were randomized to cinacalcet at the initial dose of 30 mg twice daily that was titrated in the 12-week titration phase or to placebo. Serum calcium fell by at least 1 mg/dL in 84.8% and became normal (≤10.3 mg/dL) in 75.8% of study subjects, results that were significantly different from those of the placebo group. PTH levels fell, on average, by 23.8%. Although serum phosphorus rose, it remained within the normal range. No significant changes in the health-related quality of life as assessed by the parathyroid assessment of symptoms, medical outcomes scores - cognitive functioning scale, and short form-36 questionnaire were noted. Nausea and muscle spasm were the most common adverse events, but were not significantly different from the placebo group.

The benign, solitary parathyroid adenoma is the most common cause of PHPT (85%–90% of cases), while the involvement of more than 1 or all four glands as adenomatous or hyperplastic glands is observed in 10%–15% of cases (Silverberg et al., 2019). Most cases of parathyroid hyperplasia are in the setting of familial disease, whereby PHPT may occur as the only disorder or in association with other endocrinopathies (multiple endocrine neoplasia, MEN). In these cases, the surgical approach is the removal of all but one-half of a gland or total parathyroidectomy and autotransplantation. These procedures are associated with complications such as hypoparathyroidism and recurrence or persistence of disease. In these situations, nonsurgical approaches are worthy of consideration. A 2016 multicenter, phase IV, prospective, open-label, noncomparative trial evaluated the efficacy of cinacalcet in 33 patients with PHPT associated with MEN1 (Giusti et al., 2016). These patients either refused surgery or had contraindications that precluded further surgery. The initial dose of 30 mg once daily was maintained in 55% but was increased to 60 mg twice daily in the others during the 12-month follow-up period. The vast majority of patients showed normal serum calcium values by 6 (78.5%) or 12 (89.3%) months. No significant changes in serum PTH, bone-turnover markers, or BMD were observed (Giusti et al., 2016).

Parathyroid carcinoma is a rare form of PHPT occurring in less than 1% of hyperparathyroid patients. It is associated with a poor ultimate prognosis and high rate of local recurrence and metastatic disease (Silverberg et al., 2007, 2019). Typically, the serum calcium concentration is much higher than the degree of hypercalcemia in the benign form of the disease. In patients with recurrent and inoperable disease, therefore, management of hypercalcemia is a major challenge. Several clinical studies have clearly demonstrated that cinacalcet is an effective and safe treatment option in these patients. Silverberg et al. (2007) reported results from a multicenter, open-label, single-arm, dose-titration study of 29 patients with recurrent parathyroid carcinoma. The design of the trial permitted dose escalation from 30 mg twice daily during the 2–16 week "run-in" phase. The mean treatment duration was about 300 days. Under these circumstances, cinacalcet reduced and maintained serum calcium levels (Silverberg et al., 2007). In 62% of study subjects, the serum calcium fell by at least 1 mg/dL after the initial dosing and in 94% of them by the end of the titration period. The average reduction was 3.8 mg/dL. Given the wide range of initial serum calcium concentrations in these subjects, it was possible to relate the effect of the drug to starting calcium values. The strongest effect was observed in patients with the highest baseline serum calcium concentration. Serum PTH levels slightly declined in the first 4 h after dosing, with no significant changes during the entire observation period. The increase in serum phosphorus was significant but it remained within normal limits. No changes in the health-related quality of life scores were observed. The most common adverse events were nausea, vomiting, dehydration, and headache. It is interesting to note that these adverse events are also classic features of symptomatic hypercalcemia. It is possible that this calcimimetic is mimicking this calcemic symptomatology even though the serum calcium is actually lowered by the drug.

Since approval and registration of cinacalcet for management of the hypercalcemia of PHPT, additional studies have become available. The PRIMARA study in Europe described the clinical profile and main outcomes of patients with PHPT treated with cinacalcet (Schwarz et al., 2014). This prospective multicenter observational study was conducted in 303 patients with PHPT of various etiologies (adenoma, hyperplasia, carcinoma) and varying disease severity. The mean daily dose during the 1-year study period was 49.6 mg. At the end of the observation period, more than 70% of patients achieved the study target levels of serum calcium (≤10.3 mg/dL), with approximately 60% demonstrating a reduction of at least 1 mg/dL. An 8%–13% decrease in serum PTH and a 20% increase in serum phosphorus were observed. As was seen in most of the clinical trials, nausea and vomiting were the most common adverse events, in 13.5% and 3.7% of patients, respectively.

Other hypercalcemic disorders

The use of cinacalcet has been proposed in familial forms of PHPT associated with specific gene mutations (Arnold and Thakker, 2019). Among them, familial hypocalciuric hypercalcemia (FHH) has been an attractive model because the

disease is characterized by abnormalities in the calcium-sensing receptor (CaSR) gene. This autosomal dominant syndrome can be subtyped by three different mutations (Lee and Shoback, 2018). The most prevalent (about 65% of FHH cases) is FHH1, caused by a loss-of-function mutation of CaSR. The FHH2 and FHH3 subtypes are associated with inactivating mutations of the GNA11 gene encoding the G-protein subunit α11 and of the AP2S1 gene encoding the adaptor protein-2 σ subunit. These genes are intimately involved in the CaR signal and transduction systems, respectively (Lee and Shoback, 2018; Nesbit et al., 2013).

Based upon the pathogenesis of FHH, the rationale for expecting cinacalcet to be effective is clear. The calcimimetic could enhance the Ca−CaSR interaction and thus could amplify the weakened or dysfunctional signals arising from the mutations described in FHH. Further, the calcimimetic could amplify normal CaSR encoded by the normal gene (Brown, 2010). The case reports on the use of cinacalcet in all three subtypes of FHH describe high rates of success in terms of reducing serum calcium and improving hypercalcemia-related symptoms (Mayr et al., 2016; Gorvin et al., 2018). In 2016, Mayr et al. reviewed 16 cases of FHH1 and FHH3 treated with cinacalcet and reported a reduction in serum calcium and improvement of symptoms in 14 (Mayr et al., 2016). Adverse effects, reported in only three subjects, consisted of eye palpitations, hypotension, nausea, and paresthesia (Mayr et al., 2016). Notwithstanding substantial variability in the individual case reports, such as age, reason for starting cinacalcet treatment, and duration of therapy (from 8 days to 3 years) among these cases, the authors concluded that calcimimetics should be considered as a first-line option in patients with FHH who are symptomatic of hypercalcemia. Starting with a low dose of cinacalcet and titrating upward according to serum calcium levels was recommended. In 2018, a case report of FHH2 treated with cinacalcet was published (Gorvin et al., 2018). In this 33-year-old man who was symptomatic of hypercalcemia, cinacalcet at a daily dose of 60 mg was successful in reducing ionized calcium and PTH to normal levels (Gorvin et al., 2018). In vitro studies demonstrated that cinacalcet modulates and rectifies the loss-of-function mutation of the Gα11 (Gorvin et al., 2018).

The overall data need confirmation by randomized controlled trials, but an interesting perspective on the use of cinacalcet in these familial forms, particularly on the long-term effects of the drug, has become a topic of discussion. In this context, a prolonged cumulative effect on serum calcium in FHH has led to the suggestion of a drug holiday as an option (Mayr et al., 2016; Marx, 2017).

Neonatal severe PHPT (NSHPT) is a very rare disorder caused by inactivating homozygous or double heterozygous mutations of CaSR. It is characterized by severe, life-threatening hypercalcemia and very high PTH levels with consequent severe skeletal disease (Brown, 2010). A traditional primary therapeutic approach is urgent and life-saving parathyroidectomy and medical therapy with fluids and bisphosphonates. These approaches, however, have noteworthy drawbacks with only short-term or little beneficial outcomes (Brown, 2010). Cinacalcet has been proposed in children with NSHPT, with the idea that it would "rescue" CaSR function and stabilize calcium levels, with surgery an option thereafter (Arnold and Thakker, 2019; Brown, 2010). Cinacalcet use has been reported in nine infants with NSHPT, with successful results in five cases (Sun et al., 2018). Sun et al. hypothesized that different outcomes could be a function of mutation type (homozygous vs. double heterozygous), location of the mutation in the Ca^{2+}-binding domain, or residual function of CaSR (Sun et al., 2018).

Secondary hyperparathyroidism

Cinacalcet

The several disorders of mineral metabolism associated with chronic kidney disease (CKD) are included under the term "chronic kidney disease−mineral and bone disorder" (CKD−MB) (KDIGO, 2017). Among them is secondary HPT (SHPT), in which the multifactorial pathogenesis includes reduced $1,25(OH)_2D$ levels, hypocalcemia, hyperphosphatemia, and high fibroblast growth factor 23 (FGF23) levels (KDIGO, 2017). This is the only manifestation of CKD−MB that will be covered in this chapter. The severity of the SHPT is directly related to the level of renal dysfunction and is associated with negative cardiovascular and skeletal outcomes (Ganesh et al., 2001; Investigators et al., 2012). In addition, such patients, particularly those on hemodialysis, have increased morbidity and mortality (KDIGO, 2017). The therapeutic goal for this form of CKD−MB is to control PTH levels by several therapeutic modalities. In this regard, active vitamin D and related analogs are widely used. According to Kidney Disease Improving Global Outcomes guidelines, formulations of active vitamin D as well as precursor moieties such as parent vitamin D and calcifediol are recommended in patients with stage G3a−G5 and not on dialysis. In patients with stage G5 on dialysis (G5D), calcimimetic therapy is recommended (KDIGO, 2017). Calcimimetics may be used alone or in combination with calcitriol or vitamin D analogs in these patients (KDIGO, 2017). At this writing, cinacalcet is recommended as first-line therapy in stage G5D to lower PTH levels

(KDIGO, 2017). In the aggregate, these clinical trials, which have involved, in some cases, more than 1000 patients, have had as their end point reductions <250 pg/mL or 30% of baseline levels (Eidman and Wetmore, 2018).

Calciotropic end points

The clinical trials of cinacalcet in hemodialysis patients were first published in the early 2000s, showing collectively that cinacalcet had the potential to lower PTH with a good safety profile (Goodman et al., 2002; Quarles et al., 2003; Lindberg et al., 2003). Goodman et al. reported results from a single-dose and a multiple-dose randomized clinical trial (RCT) in which PTH levels declined by 40%−60% after 2 h of administration of cinacalcet at doses of 25−100 mg and by 30%−40% within a few days when administered for 8 days at doses of 25−50 mg (Goodman et al., 2002). Data from a subsequent double-blind, placebo-controlled, multicenter RCT showed, with doses up to 50 mg/day, a significant 26% decrease in mean PTH levels after a 12-week titration phase and a 6-week maintenance phase, compared with placebo (Lindberg et al., 2003). In addition, the calcium × phosphorus product fell by 11.9%, significantly different from placebo. Adverse events consisted mostly of nausea, dyspnea, and transient hypocalcemia (Lindberg et al., 2003). Similar results were reported by Quarles et al. in a placebo-controlled, double-blind RCT (Quarles et al., 2003). These investigators observed a progressive decline in PTH during the initial 12-week dose-titration phase (during which the 25-, 50-, 75-, and 100-mg doses were sequentially administered, as needed) and a 33% reduction in the 6-week maintenance phase (Quarles et al., 2003). The calcium × phosphorus product fell by 7.9% in the cinacalcet group.

Block et al. published, in 2004, results from two randomized, double-blind, placebo-controlled clinical trials conducted in North America, Europe, and Australia (Block et al., 2004).The two studies involving 741 study subjects were identical in design, consisting of a 12-week dose-titration phase and a 14-week efficacy-assessment phase (Block et al., 2004). The titration protocol started at 30 mg/day and could be increased sequentially every 3 weeks up to 180 mg/day if PTH levels remained >200 pg/mL (Block et al., 2004). Vitamin D and/or phosphate binders could be used as needed (Block et al., 2004). The primary end point, a mean reduction of PTH levels to ≤250 pg/mL, was met by 43% of patients in the cinacalcet group versus only 5% in the placebo group (Block et al., 2004).The magnitude of the reduction was independent of the vitamin D dose. The secondary end point, ≥30% decline in serum PTH, was met by 64% of the cinacalcet group versus 11% of the placebo group (Block et al., 2004). Other noteworthy findings were a 35% decrease (significantly lower than the placebo group) in bone alkaline phosphatase activity and reduction in serum calcium and phosphorus by 6.8% and 8.4%, respectively (Block et al., 2004). Mild to moderate upper gastrointestinal (GI) adverse events, mainly nausea and vomiting, along with hypocalcemia, were noted in the cinacalcet arm of the study (Block et al., 2004). The hypocalcemia was seen in 5% of patients on cinacalcet but was asymptomatic and not influenced by vitamin D (Block et al., 2004). Similar results have been observed in patients on peritoneal dialysis (Lindberg et al., 2005). Three multicenter trials involving over 1136 patients from 182 centers in North America, Europe, and Australia have confirmed these impressive results (Moe et al., 2005a).

Pharmacokinetics studies demonstrate a linear increase in plasma concentration of the drug for doses ranging from 25 to 200 mg, while no further increases in exposure are seen for doses >200 mg (Harris et al., 2004). The increase in plasma concentration of cinacalcet is inversely associated with changes in PTH levels (Harris et al., 2004). The greatest decline in PTH levels occurs 1 and 6 h after administration of drug, with return to baseline levels at 24 h and an increase at 48 h (Arenas et al., 2013). Long-term data from an open-label extension study in hemodialysis patients showed that the chronic administration of cinacalcet, up to 180 mg/day, is associated with reduced PTH levels for up to 3 years (Moe et al., 2005b).

Other clinical settings in which cinacalcet has been studied include tertiary HPT in patients after renal transplantation and SHPT in patients who are not dialysis dependent (Serra et al., 2005, 2007; Charytan et al., 2005). Small open-label studies in patients following renal transplantation collectively have shown good efficacy, tolerability, and safety when cinacalcet is administered for up to 6 months (Serra et al., 2005, 2007; Kruse et al., 2005). In patients who are not dialysis dependent, a multicenter, randomized, double-blind, placebo-controlled study conducted in 404 patients with CKD stage 3 or 4 reported a 43% decrease in PTH levels (Chonchol et al., 2009). Hypocalcemia, <8.4 mg/dL, was observed at least twice in 62% of patients along with a 21% increase in serum phosphorus levels (Chonchol et al., 2009).

Different combined regimens of cinacalcet and vitamin D in hemodialysis patients have been investigated (Block et al., 2008; Fishbane et al., 2008; Zawierucha et al., 2019; Chertow et al., 2006). In particular, combination therapy with cinacalcet and low-dose paricalcitol or doxercalciferol was compared with therapy with vitamin D sterols and cinacalcet alone in two multicenter, open-label studies (Block et al., 2008; Fishbane et al., 2008). Target levels of PTH, calcium × phosphorus product, or both were reached with the combination of cinacalcet + paricalcitol, but the cinacalcet arm performed as well (Block et al., 2008). In contrast, Fishbane et al. reported a greater reduction of PTH levels when combined therapy with cinacalcet + paricalcitol or doxercalciferol was compared with vitamin D alone (paricalcitol or

doxercalciferol), but there was no difference in the proportion of patients reaching target PTH and calcium × phosphorus product end points (Fishbane et al., 2008). In 2018, the combination of cinacalcet, calcitriol, and cholecalciferol was shown to reduce PTH levels even further (Zheng et al., 2018).

Some studies have tracked changes in FGF23 levels in the context of combination therapy with cinacalcet and vitamin D analogs. To this end, Wetmore et al. conducted a phase IV, open-label, placebo-controlled, multicenter RCT. FGF23 levels significantly declined with combination therapy of cinacalcet + paricalcitol or doxercalciferol compared with vitamin D (paricalcitol or doxercalciferol) (Wetmore et al., 2010).

Skeletal end points

Skeletal effects related to cinacalcet therapy in SHPT have been inconsistent when BMD has been measured. Tsuruta et al. observed a 7.3% increase in femoral BMD in a small group of hemodialysis patients treated with cinacalcet for 1 year. The increase in BMD was associated with a reduction in bone-turnover markers (Tsuruta et al., 2013). Changes in femur BMD were also evaluated as a secondary end point in an RCT. No differences between the cinacalcet and the placebo groups of renal transplantation recipients were noted (Evenepoel et al., 2014).

Histomorphometry data in hemodialysis patients showed that treatment with cinacalcet for 6−12 months is associated with a decline in measures of bone formation and resorption concomitant with the reduction in PTH levels (Behets et al., 2015).

The EVOLVE trial found no effect of cinacalcet on rate of fractures (Moe et al., 2015a). However, only clinical fractures were evaluated as a secondary end point of the study and no radiological assessment was routinely performed (Moe et al., 2015a).

Cardiovascular end points

Several studies have not been able to demonstrate beneficial effects of cinacalcet on cardiovascular outcomes such as cardiovascular disease, all-cause mortality, and vascular calcification (Investigators et al., 2012; Raggi et al., 2011; Floege et al., 2015; Moe et al., 2015b). EVOLVE, a multicenter, prospective, randomized, placebo-controlled trial (Investigators et al., 2012), enrolled 3883 dialysis patients with moderate-to-severe SHPT. Cinacalcet was used initially at 30 mg/day followed by a monthly dose titration protocol for 20 weeks and then an every-8-weeks follow-up period (Investigators et al., 2012). The primary end point, namely time to death or the first cardiovascular event, was not different between the cinacalcet and the placebo groups (Investigators et al., 2012). The incidence of parathyroidectomy was lower in the cinacalcet group (Investigators et al., 2012). Subsequent analyses showed that arterial calcifications were reduced by 69% −75% with cinacalcet treatment (Floege et al., 2015). Hypocalcemia was seen in as many as 58% of patients who received cinacalcet (Floege et al., 2018). Severe hypocalcemia was observed in 18% of patients, particularly in younger patients, those with prior parathyroidectomy and kidney transplantation, and those on phosphate binders (Floege et al., 2018). Finally, Moe et al. described the results of a secondary analysis of the EVOLVE trial showing that the reductions in FGF23 levels with cinacalcet were associated with declines in cardiovascular mortality and major cardiovascular events (Moe et al., 2015b).

The information we have at this writing argues for a key role of cinacalcet in the management of the SHPT associated with renal failure, particularly in those who are undergoing hemodialysis. The use of cinacalcet appears to ameliorate the secondary hyperparathyroid state, which in and of itself is a desirable goal. More work is needed to understand more completely the extent to which this calcimimetic might have beneficial effects on target organs such as the skeleton and the cardiovascular system.

Evocalcet

Evocalcet (Fig. 71.1) is a structural analog of cinacalcet that acts as a positive allosteric modulator of the CaSR. It increases $[Ca^{2+}]_i$ in HEK-293 cells expressing the human CaSR and shifts the concentration-response curve for extracellular Ca^{2+} to the left; it is without effect in the absence of extracellular Ca^{2+} (Kawata et al., 2018). The in vitro potencies of evocalcet and cinacalcet for increasing intracellular Ca^{2+} $[Ca^{2+}]_i$ in CaSR-expressing HEK-293 cells are similar (93 and 51 nM, respectively). The oral administration of evocalcet rapidly lowers circulating levels of PTH and Ca^{2+} in normal rats and in those with SHPT induced by a 5/6 nephrectomy. Again, these effects are very similar to those of cinacalcet but the oral bioavailability of evocalcet in the rat is much greater than that of cinacalcet (80% vs. 2%), so comparable efficacy in vivo occurs at much lower doses of evocalcet. Unlike cinacalcet, evocalcet does not affect the activity of a number of

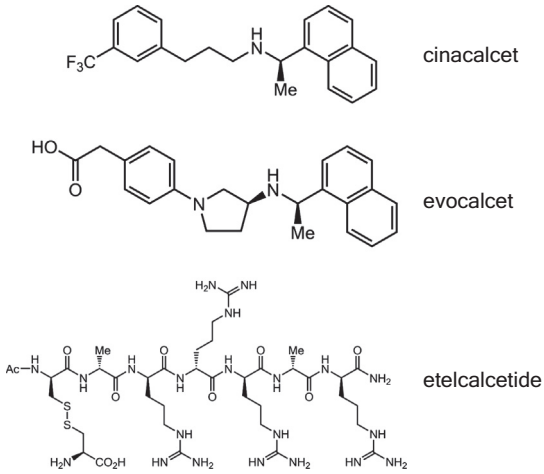

FIGURE 71.1 The structure of calcimimetics.

cytochrome P450 enzymes in vitro, including CYP2D6 (Miyazaki et al., 2018), nor does it affect the pharmacokinetic profiles of various drugs that are metabolized through P450 enzymes (Narushima et al., 2019). These findings indicate that evocalcet could be expected to be associated with fewer drug−drug interactions than cinacalcet.

The major adverse effects of cinacalcet are GI symptoms such as nausea and vomiting, which seriously limit compliance. A head-to-head comparator study of evocalcet and cinacalcet was performed to assess emetic responses in normal marmosets and gastric emptying time in the rat 5/6 nephrectomy model of SHPT. In marmosets, the incidence of emesis was lower for evocalcet compared with cinacalcet. In the rat, evocalcet did not affect gastric emptying time (compared with vehicle) at doses that maximally lowered plasma levels of PTH, whereas cinacalcet inhibited gastric emptying time by 46%. Evocalcet also had lower binding affinity to receptors associated with emesis (dopamine, cannabinoid, opioid, and serotonin) than did cinacalcet (Kawata et al., 2018).

A phase III head-to-head comparator trial of evocalcet and cinacalcet in Japanese patients with SHPT has been reported (Fukagawa et al., 2018). Both compounds were orally administered once a day for 30 weeks to patients on hemodialysis, and the primary end point was a plasma PTH level between 60 and 240 pg/mL. The proportions of patients achieving the primary end point were 72.7% in the evocalcet group and 76.7% in the cinacalcet group, a nonsignificant difference showing that evocalcet was noninferior to cinacalcet as regards efficacy. Secondary end points of efficacy (percentage of patients achieving $\geq$30% decrease in PTH from baseline and mean percentage change in PTH levels) were also similar for evocalcet- and cinacalcet-treated patients. Serum levels of calcium, phosphorus, and FGF23 were decreased by evocalcet and cinacalcet to similar extents. Evocalcet was superior to cinacalcet as regards safety. Specifically, the incidence of upper GI symptoms (nausea, vomiting, abdominal discomfort, abdominal distension, or decreased appetite) were significantly less in subjects treated with evocalcet (18.6% of patients) compared with those receiving cinacalcet (32.8%). Evocalcet was approved for the treatment of SHPT in patients on dialysis by the Ministry of Health, Labor, and Welfare in Japan in 2018.

The initial preclinical and clinical results obtained in comparator studies suggest that evocalcet might produce a lower incidence of upper GI symptoms than cinacalcet. However, the doses of cinacalcet used in preclinical gastric emptying time studies were 60- to 200-fold higher than the effective dose 50 for lowering plasma levels of PTH in the rat. Moreover, the incidence of upper GI symptoms in the clinical comparator trial was unusually high in patients treated with cinacalcet (it is typically 20%−25%). More real-world clinical experience with evocalcet will be required to determine if it has an improved GI side effect profile compared with cinacalcet.

Etelcalcetide

Etelcalcetide (Fig. 71.1) is a structurally novel calcimimetic for the treatment of SHPT in adult patients on dialysis (Hamano et al., 2017). Etelcalcetide is an octapeptide consisting of a linear chain of seven D-amino acids. Surprisingly, given the finding that polybasic peptides like protamine and poly-L-arginine are agonists at the CaSR (Nemeth et al., 2018), etelcalcetide behaves as an allosteric modulator with a unique mechanism of action. Etelcalcetide forms a covalent disulfide bond with Cys482 in the extracellular domain of the CaSR (Alexander et al., 2015). This binding to the extracellular domain of the CaSR is a reversible covalent linkage that undergoes thiol substitution with other sulfhydryl-donating

proteins and small endogenous molecules. The CaSR also undergoes continual recycling, and new receptors are constantly being added to the cell surface, so this covalent modification temporarily, but not permanently, activates the CaSR.

The D-amino acid backbone of etelcalcetide creates a molecule that is essentially metabolically inert and does not undergo proteolytic cleavage. Unlike cinacalcet, etelcalcetide does not affect the activity of cytochrome P450 enzymes (Subramanian et al., 2016, 2017). Nonclinical toxicology studies revealed no adverse effects other than those expected by the pharmacodynamic response of hypocalcemia (tremors, convulsions, and a prolongation of the QT interval; Fielden et al., 2016).

Etelcalcetide is not orally bioavailable and is administered by intravenous (iv) injection. Once injected, it is rapidly cleared from the circulation primarily by glomerular filtration; its pharmacokinetic profile is thus largely dependent on renal function. In healthy volunteers with normal kidney function, the terminal half-life for etelcalcetide is around 18 h, whereas in patients with CKD and on dialysis, the half-life can exceed 7 days (Shen et al., 2014). Etelcalcetide is mostly removed during a dialysis session and is therefore administered through the iv line at the end of a dialysis session.

In rat models of SHPT, the subcutaneous administration of etelcalcetide thrice weekly for 6 weeks lowered plasma levels of PTH and decreased vascular calcification. It also diminished parathyroid gland hyperplasia and increased expression of the CaSR, the vitamin D receptor, and the receptor for FGF23 (FGFR1) in parathyroid glands (Walter et al., 2013). Nephrocalcinosis and increased aortic calcium content in another rat model of SHPT were also reduced by etelcalcetide (Yu et al., 2017). These studies demonstrate the effectiveness of etelcalcetide in slowing the progression of SHPT. Etelcalcetide is also effective in a rodent model of established SHPT, in which it reduces plasma levels of PTH and FGF23 and halts parathyroid gland hyperplasia (Walter et al., 2014). The results obtained with etelcalcetide in rodent models of SHPT are similar to those obtained with other calcimimetics.

All the phase III registration trials for etelcalcetide involved adult hemodialysis patients with moderate to severe SHPT. Etelcalcetide was administered iv thrice weekly at the end of each dialysis session, and blood samples for determining PTH and other blood analytes were drawn just prior to a dialysis session. All the trial designs used a dose-titration period and in each study, patients assigned to etelcalcetide or placebo groups continued to receive standard of care (vitamin D sterols and phosphate binders) but had to be free of cinacalcet use for at least 4 weeks prior to screening for eligibility.

The primary end point of the study in Japanese hemodialysis patients was the proportion of patients achieving a serum PTH level between 60 and 240 pg/mL (Fukagawa et al., 2017). At the end of 12 weeks, 59.0% of patients treated with etelcalcetide achieved this target end point compared with only 1.3% of patients receiving placebo. Significant reductions from baseline in serum Ca and phosphorus persisted throughout the study, whereas there was no reduction in serum levels of either mineral in placebo-treated patients. There were no remarkable differences in serum levels of BSAP and tartrate-resistant acid phosphatase 5b (TRACP-5b) in patients treated with etelcalcetide compared with those treated with placebo. Serum FGF23 levels trended downward throughout the study in etelcalcetide-treated patients and by 12 weeks were 72.0% lower than baseline values, whereas FGF23 levels did not change in patients treated with placebo. The administration of etelcalcetide was generally safe and well tolerated. Adverse effects occurring in the etelcalcetide group but not in the placebo group were blood calcium decrease (6.4%), vomiting (3.8%), nausea (1.3%), and symptomatic hypocalcemia (1.3%). There were no clinically relevant cardiovascular complications in either treatment group (Fukagawa et al., 2017).

This phase III trial in Japan was followed by an open-label study with the ability to adjust the dose of etelcalcetide and concomitant medications to optimize serum levels of PTH and Ca (Shigematsu et al., 2018). Etelcalcetide was administered iv thrice weekly at the end of a dialysis session for 52 weeks. The percentage of patients achieving the primary end point (serum PTH levels between 60 and 240 pg/mL) increased from 6.3% on day 1 to 87.5% after 52 weeks of treatment with etelcalcetide. Although serum calcium levels were lower than baseline during the first 2 months of the study, they recovered toward baseline after adjustments to concomitant medications. The types and prevalence of adverse effects in the etelcalcetide-treated patients were similar to those in the earlier study.

The primary end point in two other phase III trials run in parallel was the percentage of patients achieving a $>30\%$ reduction in serum levels of PTH (Block et al., 2017a). The results for the two trials were similar and the averages of both are presented here. The primary end point was met in 74.6% of patients treated with etelcalcetide, but in only 8.9% of those treated with placebo. Decreases in serum PTH levels to ≤ 300 pg/mL (a secondary end point) were achieved by 51.4% of patients receiving etelcalcetide but by only 4.8% of patients in the placebo group. Treatment with etelcalcetide caused progressive decreases in serum calcium and phosphorus levels that reached a nadir between 10 and 12 weeks, whereas serum mineral levels in the placebo group remained at baseline values throughout the study. The percentage of patients taking calcium supplements, calcium-containing phosphate binders, and/or vitamin D sterols increased in the etelcalcetide group, as did the concentration of calcium in the dialysate compared with patients in the placebo group. Decreases in serum levels of FGF23, BSAP, and type I cross-linked C-telopeptide occurred in patients treated with etelcalcetide compared with those in patients receiving placebo.

Etelcalcetide was generally safe and well tolerated and the most frequent adverse event was blood calcium decrease (Ca <8.3 mg/dL), which occurred in 63.8% and 10.1% of patients treated with etelcalcetide and placebo, respectively. Overt symptomatic hypocalcemia occurred in 7% of patients in the etelcalcetide group and in 0.2% of patients in the placebo group. Hypocalcemic symptoms included muscle spasms (11.5% in the etelcalcetide group vs. 6.6% in the placebo group) and paresthesia (4.6% vs. 0.6%). Symptomatic hypocalcemia could also explain QT prolongation, which was 2.5-fold higher in etelcalcetide-treated patients compared with those receiving placebo. The incidences of nausea, vomiting, and diarrhea were also greater in the etelcalcetide group compared with the placebo group (see later). There were no major cardiovascular complications in either treatment group (Block et al., 2017a).

The fourth phase III trial was a head-to-head comparison of etelcalcetide and cinacalcet in patients randomized to receive iv etelcalcetide and oral placebo or oral cinacalcet and iv placebo (Block et al., 2017b). Etelcalcetide was administered three times a week and cinacalcet daily for 26 weeks. The primary end point was noninferiority of etelcalcetide to cinacalcet, specifically a >30% reduction from baseline in serum levels of PTH as measured during weeks 20−27. At the end of the study, 57.7% of patients treated with cinacalcet met the primary end point compared with 68.2% of patients treated with etelcalcetide ($P < 0.001$ for noninferiority; $P < 0.004$ for superiority). Significantly more patients treated with etelcalcetide achieved a >50% reduction from baseline in serum levels of PTH (52.4%) compared with those treated with cinacalcet (40.2%). Both calcimimetics decreased serum levels of calcium and phosphorus but the levels caused by etelcalcetide were greater in magnitude. Similarly, both calcimimetics decreased serum levels of FGF23, BSAP, and collagen type I cross-linked C but the magnitude was greater with etelcalcetide compared with cinacalcet. Taken together, the results of this study suggest that etelcalcetide is superior to cinacalcet as regards efficacy.

However, it is problematic to claim superiority or inferiority based on this trial because different routes of administration and different dosing regimens were used (Hai et al., 2017). And any superior efficacy came at the cost of safety. The most common adverse event in the head-to-head comparator trial was (as anticipated) decreased blood calcium, which occurred in 68.9% and 59.8% of patients treated with etelcalcetide and cinacalcet, respectively. Symptomatic hypocalcemia occurred twice as often in etelcalcetide-treated patients compared with those treated with cinacalcet, and heart failure events were fivefold higher in etelcalcetide-treated patients. High doses of cinacalcet would have efficacy comparable to that of etelcalcetide, but this would have caused greater decreases in serum calcium levels and compromised safety. Based on their mechanisms of action and the clinical results, there is no reason to suppose that the efficacy of these two calcimimetics differs.

What is perhaps most significant is the *similarity* of these two calcimimetics, especially in the incidence of upper GI symptoms like nausea and vomiting. Upper GI symptoms are the leading cause of stopping cinacalcet treatment in patients (note the EVOLVE study). It was anticipated that the iv route of administration, because it would eliminate exposure to a calcimimetic in the gut lumen, would diminish the incidence of GI symptoms. Because they were similar, GI symptoms might be an inherent pharmacodynamic property of calcimimetics resulting from actions on CaRs expressed throughout the GI tract.

Some features of etelcalcetide might prove superior to those of cinacalcet but at this writing it does not appear to be either efficacy or safety. One is the iv route of administration, which should improve adherence and will certainly reduce the pill burden in this patient population. Because etelcalcetide causes a sustained decrease in serum PTH levels, rather than the fluctuating one characteristic of cinacalcet, it will be easier to monitor these levels. Whether sustained decreases in serum PTH levels will translate into improved clinical outcomes is uncertain but this will obviously be the end point of future trials with etelcalcetide. Another is fewer concerns about drug−drug interactions because etelcalcetide does not affect the activity of P450 enzymes.

Calcilytics

Osteoporosis

The development of calcilytics as potential treatments for osteoporosis is based on their ability to stimulate secretion of PTH. Exogenously administered PTH or teriparatide stimulates new bone formation and the former peptide is an approved anabolic therapy for osteoporosis (Silva and Bilezikian, 2015). Despite encouraging preclinical results in rodent models of osteoporosis, three different calcilytic compounds lacked efficacy in clinical trials. It has been proposed that inhibitory effects of calcilytics on CaSR in bone block the stimulatory effects of PTH and explain, in whole or in part, the lack of efficacy (Nemeth et al., 2018; Nemeth and Goodman, 2016). Calcilytic compounds were, however, generally safe and well tolerated in clinical studies and because of this are being evaluated as therapies for alternative indications.

Repurposing calcilytics for new indications

Hypoparathyroidism

In all the clinical trials with calcilytics the magnitude and duration of increased circulating levels of PTH were sufficient to increase blood Ca^{2+} levels. Because of this, calcilytics are potentially useful for treating certain hypocalcemic disorders like hypoparathyroidism. While most cases of hypoparathyroidism arise from surgical removal of the thyroid gland, there are a number of rare genetic cases, of which the most prevalent is autosomal dominant hypoparathyroidism (ADH) (Abate and Clarke, 2016).

The conventional treatment for most hypoparathyroid disorders is supplementation with dietary calcium and active forms of vitamin D. Recombinant human PTH is also approved as an adjunct to calcium and vitamin D to control hypocalcemia in hypoparathyroidism. Calcilytics might be useful in postsurgical forms of hypoparathyroidism when there is some residual parathyroid tissue. They might also be useful even when no functional parathyroid tissue remains. Studies in rats show that the calcilytic NPS2143 (Fig. 71.2) can normalize serum Ca^{2+} levels in hypocalcemic rats whose parathyroid glands have been surgically removed (Loupy et al., 2012).

ADH is a rare genetic disorder resulting from germ-line activating mutations in either the CaSR gene (ADH type 1) or the gene encoding the G-protein subunit $G\alpha_{11}$ (ADH type 2; Hannan et al., 2016). These activating mutations increase the sensitivity of parathyroid cells to activation by extracellular Ca^{2+} and patients with ADH are therefore hypocalcemic with inappropriately low levels of PTH. Renal CaSRs are also affected and about a third of all patients are frankly hypercalciuric, while the remaining patients have unexpectedly normal urinary Ca^{2+} excretion given the prevailing hypocalcemia.

ADH is essentially a disorder of the set point of systemic Ca^{2+} homeostasis, and when the absolute level of blood Ca^{2+} is normalized (by calcium and vitamin D supplements), it will be sensed by the parathyroid glands and kidney as hypercalcemia, thereby further suppressing PTH secretion and increasing Ca^{2+} excretion. The resulting relative hypercalciuria often progresses to frank hypercalciuria leading to nephrocalcinosis, nephrolithiasis, and renal failure (Hannan et al., 2016; Hannan and Thakker, 2013). Therapy of ADH patients should strive to reset the set point by decreasing the sensitivity of parathyroid and renal CaSRs to extracellular Ca^{2+}. As negative allosteric modulators, this is precisely how calcilytics act, and they might provide an ideal therapy for ADH.

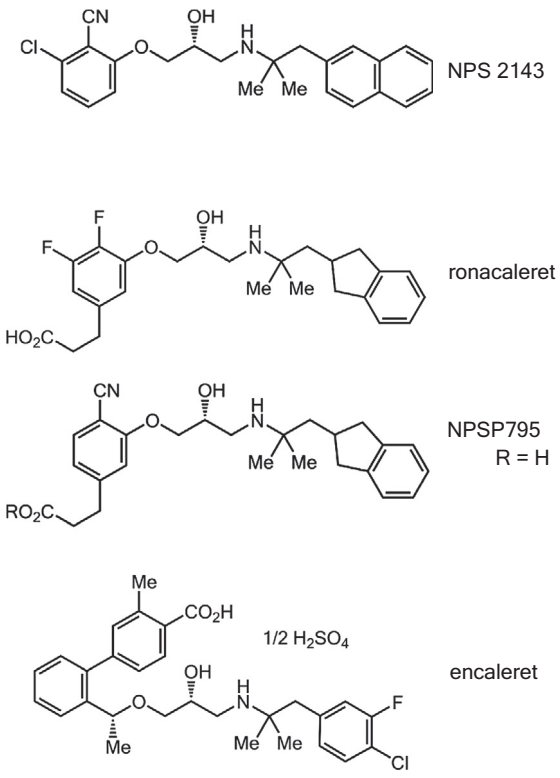

FIGURE 71.2 The structure of calcilytics.

In mouse models of ADH1, two different calcilytics (NPS2143 and JTT-305) have been shown to normalize serum Ca^{2+} (Dong et al., 2015; Hannan et al., 2015). Somewhat unexpectedly, NPS2143 also normalized serum Ca^{2+} levels in animal models of ADH2 (Gorvin et al., 2017). A small clinical trial in patients with ADH1 showed that NPSP795 caused small increases in plasma levels of PTH and tended to decrease renal Ca^{2+} excretion but, at the doses tested, did not increase blood Ca^{2+} levels (Ramnitz et al., 2015).

Pulmonary indications

There are other indications that are not associated with hypocalcemia and for which calcilytics might have some therapeutic benefit. The first is inflammatory lung disorders. In asthma, the expression of the CaSR is increased in airway smooth muscle cells. Airflow resistance in sensitized mice was depressed and airway hyperresponsiveness was reduced in a mouse model of allergic asthma (Yarova et al., 2015). In these in vivo studies, calcilytics were delivered directly into the lung and there were no changes in blood levels of Ca^{2+}.

Another indication is idiopathic pulmonary arterial hypertension (IPAH), a rare disease characterized by sustained pulmonary vasoconstriction that results in elevated vascular resistance and arterial pressure; it is progressive and fatal (Firth et al., 2010). As in certain inflammatory lung disorders, CaSR expression is increased in pulmonary arterial smooth muscle from humans with IPAH and in two different rodent models of this disease. Systemic administration of NPS2143 prevented the development of pulmonary hypertension and right-ventricular hypertrophy in both rodent models (Yamamura, 2014). Both IPAH and inflammatory lung disorders are attractive indications because the calcilytic can be delivered into the lung, thereby minimizing systemic exposure and avoiding changes in blood levels of PTH and Ca^{2+}.

Conclusion

- All allosteric modulators are really allosteric agonists, but as therapeutics they all behave as allosteric modulators.
- Newer calcimimetics might offer advantages over cinacalcet
  - evocalcet: fewer GI complications
    - caveat: only Japanese, only one study, not real world
  - etelcalcetide: better compliance
    - efficacy at cost of safety
    - GI side effects: inherent property of calcimimetics?
- Calcimimetics are generally applicable to a variety of hypercalcemic disorders, including FHH1−3
- Calcimimetics might be useful in treating some hypophosphatemic disorders.
- Calcilytics are not treatments for osteoporosis.
- Calcilytics might be useful in treating hypocalcemic disorders like ADH1 and 2 and certain forms of hypoparathyroidism.
- Calcilytics might be useful in treating certain pulmonary disorders.
- The ability of calcimimetics and calcilytics to normalize CaR signaling in FHH2 and 3 and ADH2 is surprising.

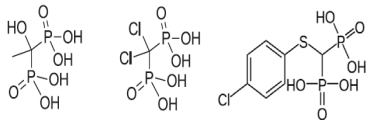
Chapter outline

Introduction

The year 2019 marks 50 years since the first publications on the biological effects of bisphosphonates (BPs) (Fleisch et al., 1969a, 1969b; Francis et al., 1969).These agents have served for the past several decades as the pharmacological cornerstone for the treatment of skeletal disorders such as Paget's disease of bone, osteoporosis and cancers metastatic to bone. The early discovery and clinical development of BPs has been reviewed elsewhere (Fleisch, 2000; Russell, 2011). Abundant preclinical, translational and clinical research with BPs has led to a wealth of data that now enable us to rationally prescribe these drugs to the right patients using tailored dosing regimens to provide an optimal balance between efficacy and side effects. Better insight into the precise effects of BPs on various bone cell populations has resulted in continued efforts to develop new BPs for the treatment of metabolic bone diseases, while non-skeletal-related indications for these drugs have been more recently explored. In addition, BPs are currently under investigation as agents for the targeting of other drugs, such as antibiotics, to bone tissue. This chapter provides an overview of our current knowledge on the (pre-) clinical and translational pharmacology of BPs, and illustrates how this knowledge has been used both for the development of new compounds and for the treatment of patients.

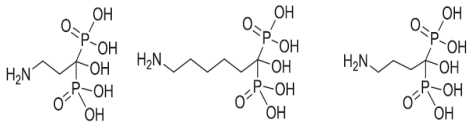
Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00072-5

- **Early BPs: non-nitrogen containing**



Etidronate Clodronate Tiludronate

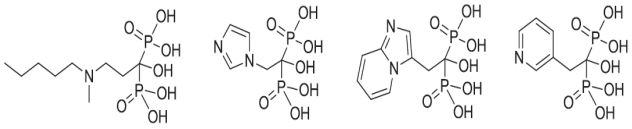
- **"Second" generation: nitrogen-containing with short alkyl chains**



Pamidronate Neridronate Alendronate

- **"Third" generation: (from medicinal chemistry optimisation):**

N-containing with branched or ring structure, more potent



Ibandronate Zoledronate Minodronate Risedronate

Ten BPs which have been approved for clinical use in various countries.

Mechanisms of action

Therapeutic

BPs have several mechanisms of action which underlie their therapeutic use. Initially, they were studied for their ability to block calcification as reported by Francis et al. (Francis et al., 1969). Their antiresorptive mechanism is based on their mineral binding and biochemical effects on cells. Their ability to inhibit the dissolution of bone mineral was the action that was first described by Fleisch, Francis and Russell (Fleisch et al., 1969a, 1969b; Francis et al., 1969). Subsequently, it became clear that BPs also inhibit osteoclast-mediated bone resorption through effects on the osteoclast itself. It took until the late 1990s to determine the mechanism by which BPs inhibit osteoclast-mediated resorption. Following endocytic uptake into osteoclasts (Luckman et al., 1998; van Beek et al., 1999a, 1999b; Rogers, 2003), nitrogen (N)-containing BPs inhibit the intracellular enzyme farnesyl pyrophosphate pyrophosphate (FPP) synthase, a key-enzyme of the mevalonate pathway (Fig. 72.1). Inhibition of FPP synthase leads to decreases in FPP levels, as well as to levels of geranylgeraniol pyrophosphate (GGPP). Collectively, this results in the decreased prenylation of signal transduction proteins such as Ras, Rac and Rho, ultimately resulting in a loss of function of the osteoclasts. The subsequent elegant studies using X-ray crystallography have fully characterized the binding of N-containing BPs with the FPP synthase enzyme (Kavanagh et al., 2006), and have led to the rational design of even more potent and selective BPs such as OX14 (Lawson et al., 2017).

In contrast to the N-containing BPs, non-N-containing BPs undergo intracellular metabolism to non-hydrolyzable analogues of ATP, as catalyzed by aminoacyl-tRNA synthetase enzymes (Frith et al., 2001) (Fig. 72.1). Consequently, ATP analogue accumulation within the cytosol triggers osteoclast apoptosis via inhibition of the mitochondrial ADP/ATP translocase (Lehenkari et al., 2002). Interestingly, N-containing BPs have also been shown to have additional effects on osteoclasts by inducing formation of the intracellular apoptotic ATP analogue 1-adenosin-5′-yl ester 3-(-3-methylbut-3-enyl) ester triphosphoric acid (ApppI), a consequence of their inhibition of FPP synthase in the mevalonate pathway and the subsequent accumulation of intracellular isopentenyl pyrophosphate (IPP) (Raikkonen et al., 2009). In contrast to the intracellular ATP analogue metabolites of non-N-containing BPs, ApppI does not contain a BP in its structure (Raikkonen et al., 2009).

Bisphosphonates, both N-containing and non-N-containing, also appear to have effects on osteoblasts and osteocytes. The lifespan of both cell types is prolonged by the anti-apoptotic effects of BPs, an effect which is established through Connexin 43 (Cx43) and the downstream activation of extracellular signal-regulated kinases (ERKs) (Bellido and Plotkin,

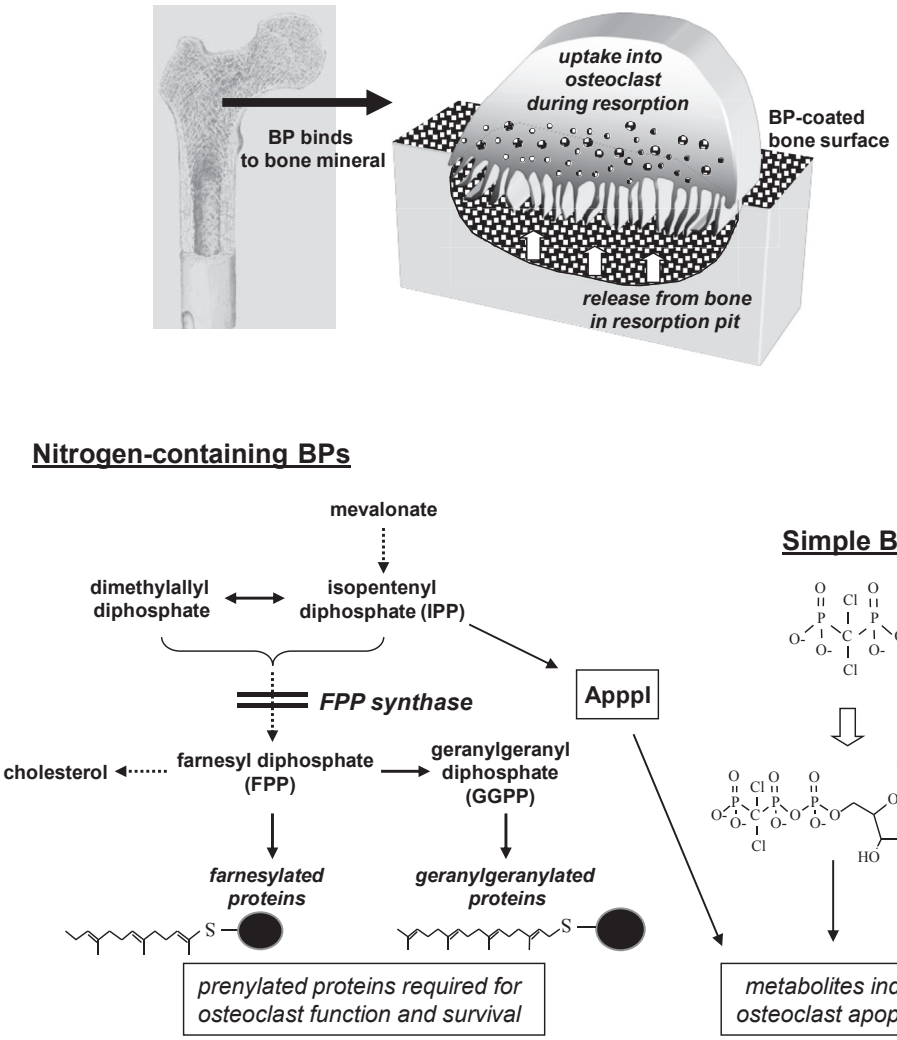


FIGURE 72.1 Mechanisms of action of bisphosphonates on osteoclasts. After binding to bone mineral, the drugs are internalized into bone-resorbing osteoclasts by endocytosis. Simple BPs (e.g., clodronate, etidronate) are metabolized in the osteoclast cytosol to ATP analogues that induce osteoclast apoptosis. Nitrogen-containing BPs inhibit FPP synthase, thereby preventing the prenylation of small GTPase proteins essential for the function and survival of osteoclasts. Inhibition of FPP synthase also causes the accumulation of IPP, which is incorporated into ApppI (an analogue of ATP capable of inducing osteoclast apoptosis).

2011). Interestingly these anti-apoptotic effects of BPs take place at very low concentrations, while the antiresorptive effects are evident at much higher concentrations of these drugs. These intriguing observations have led to the study of BPs such as IG9402 (Lidadronate) and NE11809 which show anti-apoptotic effects on osteoblasts and osteocytes, but without possessing the antiresorptive effect on osteoclasts (Bellido and Plotkin, 2011). Given these potentially positive effects of BPs on osteoblasts and especially osteocytes, the differential penetration of BPs into the canalicular network of bone, as discussed below in the PK section, might explain some of the clinically observed differences in effects of the various BPs, such as the differences between alendronate and risedronate (Roelofs et al., 2012; Russell et al., 2008; Ebetino et al., 2011). The different mechanisms of action of BPs on bone cells are illustrated in Fig. 72.2.

The effects of BPs on metastatic bone disease are thought to come mainly from their ability to decrease osteoclast-mediated bone resorption and to thereby effectively interrupt the vicious cycle that develops between metastatic tumor cells and bone cells (Croucher et al., 2016). However, direct anti-tumor cell activity has also been described for some BPs such as zoledronate which has been shown to inhibit cell viability, migration, invasion and metastasis (Mathew and Brufsky, 2015; Boissier et al., 2000; Jagdev et al., 2001). The anti-tumor effects of zoledronate might be exerted through the miRNA/PTEN/Akt signaling and activin signaling pathways (Fragni et al., 2016; Wilson et al., 2015). This pre-clinical data is consistent with the results of several clinical studies which have demonstrated a beneficial effect of the adjuvant use

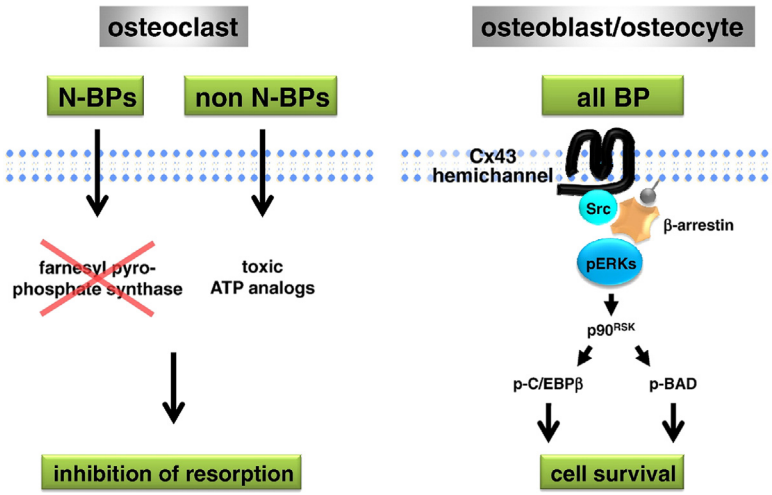

FIGURE 72.2 Bisphosphonates inhibit osteoclast activity and prevent osteoblast and osteocyte apoptosis via different mechanisms. For simplicity, only one of the six molecules of Cx43 that form the hemichannel is shown. See text for details (Bellido and Plotkin, 2011).

of zoledronate in elderly postmenopausal women with cancer, in addition to a role in preventing bone metastases (Mathew and Brufsky, 2015; Coleman et al., 2014; Chukir et al., 2018; Dionisio et al., 2019).

BPs are also currently under investigation as potential agents for the prevention and treatment of several neurodegenerative diseases including Alzheimer's Disease (AD), Parkinson's Disease and Huntington's Disease (Zameer et al., 2018). Some clinical studies suggest positive effects of BPs such as alendronate and etidronate on limiting brain calcifications, which may translate into alleviation of some of the symptoms that characterize these neurodegenerative diseases (Oliveira and Oliveira, 2016; Loeb et al., 2006). Several pre-clinical studies also suggest that the mechanism of action of BPs in neurodegenerative diseases is via inhibition of calcium crystal growth. However, the extent to which BPs might cross the blood brain barrier remains unclear. In contrast, other pre-clinical studies point toward the ability of BPs to inhibit FPP synthase and subsequently to decrease both protein prenylation and also cholesterol synthesis as a possible mechanism for their effects in neurodegenerative disease.

BPs have also been shown to prolong lifespan in pre-clinical models of progeria, an effect which may reflect their ability to inhibit FPP synthase (Varela et al., 2008; Gordon et al., 2014). Several human progerias, including Hutchinson–Gilford progeria syndrome (HGPS), are caused by the accumulation at the nuclear envelope of farnesylated forms of truncated prelamin A, a protein that is also altered during normal chronologic aging (Varela et al., 2008). Treatment with a combination of statins and zoledronate was shown to efficiently inhibit both farnesylation and geranylgeranylation of the proteins progerin and prelamin A and to markedly improve aging-like phenotypes of mice deficient in the metalloproteinase Zmpste24, including growth retardation, loss of weight, lipodystrophy, hair loss and bone defects (Varela et al., 2008). Likewise, the longevity of these mice was substantially extended. N-containing BPs might therefore be an interesting therapeutic approach for human progeroid syndromes associated with nuclear-envelope abnormalities (Varela et al., 2008). This pre-clinical data has been evaluated by clinical studies which suggest that farnesylation inhibition either by the farnsyltransferase inhibitor lonafarnib alone (Clinicaltrials.gov: NCT00425607) or by the combination of lonafarnib, pravastatin and zoledronate (NCT00879034 and NCT00916747), may improve the survival of patients with Hutchinson–Gilford progeria syndrome (Gordon et al., 2014).

Another potential application for N-containing BPs is to prevent the accumulation of DNA damage from radiation (Misra et al., 2016). Interestingly, this effect, which was demonstrated in vitro in mesenchymal stem cells, has been explained by the ability of BPs to inhibit FPP synthase and therefore to decrease the prenylation of signal transduction proteins such as Ras and Rheb, which in turns reduces activation of mTOR, a molecule implicated in lifespan extension (Misra et al., 2016). In addition, downstream effectors of mTOR, such as Forkhead Box O3 (FOXO3A), have been recognized as important effectors for the recruitment of DNA damage response proteins, such as the protein kinase ataxia telangiectasia mutated (ATM) (Misra et al., 2016).

Some BPs may also be useful in the treatment of certain ectopic calcification disorders. Etidronate has been used for more than 40 years to reduce flares in fibrodysplasia ossificans progressiva (FOP) and was registered for clinical use against heterotopic ossification (Wentworth et al., 2018). Interestingly, FOP results from activating mutations in the ACVR1 gene, which encodes the activin A Type 1 receptor. Aberrant signaling through this receptor leads to abnormal

activation of the pSMAD 1/5/8 pathway and triggers the formation of bone outside the skeleton. In FOP, BPs may have an effect on the abnormal extra-skeletal calcification as well as the locally increased bone (re)modeling, although definitive clinical data for BP use in this setting are sparse (Wentworth et al., 2018). Another rare ectopic calcification disorder for which BPs, especially etidronate, might be useful is pseudoxanthoma elasticum (PXE), in which an ABCC6 mutation has been shown to lead to reduced levels of circulating pyrophosphate, resulting in soft tissue mineralization (Li et al., 2018). Etidronate has been shown to prevent, but not to reverse, ectopic mineralization in a mouse model of PXE, which would be consistent with the proposed mechanism of action of BPs such as etidronate, which inhibits mineralization at clinically used doses (Li et al., 2018). It is currently unknown, however, if BP treatment might be beneficial to patients with PXE.

For some indications for which the potential effect of BPs is thought to depend on inhibition of osteoclast-mediated bone resorption, data is a more ambiguous and requires further investigation. Thus, for example, whereas preclinical data have suggested a beneficial effect of BPs on fracture healing, studies in humans have shown little to no effect, a potential benefit such that BPs can be started shortly after osteoporotic fracture (Kates and Ackert-Bicknell, 2016; Molvik and Khan, 2015). However, other approaches, such as treatment with intermittent parathyroid hormone (PTH) derivatives, might be more useful to improve fracture healing (Hegde et al., 2016). Another indication for which inhibition of bone resorption is thought to be effective is for the treatment of avascular necrosis of the femoral head (AVN) which can result from multiple causes such as Perthes Disease (an idiopathic childhood osteonecrosis of the femur head), sickle cell disease, or the use of high dose glucocorticoids (Guerado and Caso, 2016; Jamil et al., 2017). By inhibiting osteoclast-mediated bone resorption, BPs might be able to preserve femoral head strength and reduce the risk for femoral head collapse. Evidence that research for this indication is currently active both pre-clinically and clinically comes from a proposed multicenter, prospective, randomized controlled trial to evaluate the efficacy of zoledronate in Perthes Disease (Jamil et al., 2017). Changes in subchondral bone and crosstalk between subchondral bone and cartilage have been demonstrated to play an important role in the development of osteoarthritis (OA) (Bultink and Lems, 2013; Lems, 2018). In the early phase of OA, increased osteoclast activity, elevated bone remodeling and hypomineralization can be found (Bultink and Lems, 2013; Roman-Blas et al., 2014) It is therefore likely that BPs, via their effects as osteoclast resorption inhibitors, might be effective for the treatment of OA, especially in the early phase of the disease (Lems, 2018). Clinical trials (e.g., with risedronate) have shown equivocal results (Spector et al., 2005; Bingham et al., 2006). More recently, two large separate case-control studies suggest that BPs are effective for reducing the incidence of knee replacement in patients with OA (Lems, 2018; Fu et al., 2017; Neogi et al., 2018). While it is likely wise to treat patients with both osteoporosis and OA with antiresorptive drugs such as BPs, there is currently insufficient data to start antiresorptive therapy in patients with OA but without osteoporosis (Lems, 2018). Zoledronate has been shown to be able to reduce pain associated with bone marrow lesions in patients with osteoarthritis (Shabestari et al., 2016, 2017; Eriksen, 2015).

Another research direction for BPs is for the improvement of dental implants via local surface coating and/or direct application of BPs to the surgical site (Mendes et al., 2018). In animal models, local delivery of the BPs improves peri-implant bone formation (Ramalho-Ferreira et al., 2015; Meraw and Reeve, 1999; Back et al., 2012; Guimaraes et al., 2015) and in humans local BP delivery has been shown to improve the fixation of osteointegrated implants (Abtahi et al., 2012). While it has been suggested that systemic BP use may worsen dental implant outcomes, the available scientific evidence demonstrates that patients with a history of BP use do not have a higher risk of dental implant failure or marginal bone loss when compared to patients who have not used BPs (Mendes et al., 2018). In contrast, the existing literature does suggest that patients who undergo surgical trauma during dental implant installation may be more susceptible to BP-related osteonecrosis of the jaw (BRONJ, or ONJ, osteonecrosis of the jaw) (Mendes et al., 2018). Intriguingly, this potential side effect of BPs may be prevented by the use of pharmacologically non-active BPs, i.e., BPs with little to no effect on bone cells. The mechanism of this new approach appears to be via competitive equilibrium-based displacement of the pharmacologically active BPs (Hokugo et al, 2016, 2017, 2019; Sun et al., 2018; Ebetino et al., 2018).

Another side effect of N-containing BPs is an acute phase reaction (APR). This flu-like reaction is typically observed in a subset of patients, is more likely to occur with initial rather than subsequent intravenous (IV) administration (Anastasilakis et al., 2012), and is mediated by gamma-delta-T-cells (Kunzmann et al., 2000). The mechanism underlying this T-cell stimulation is N-containing BP inhibition of FPP synthase resulting in an increase in phospho-antigens for these cells such as isopentenyl pyrophosphate (IPP) and ApppI. This ability to stimulate gamma-delta T-cells has now been used for the development of cancer immunotherapies given that gamma-delta-T-cells have the ability to target cancer cells. The main challenge to this approach is the need to enhance uptake of the N-containing BPs into the cancer cells, an area for which nano-technology-based carriers such as ligand-targeted liposomes are actively being developed and investigated (Hodgins et al., 2017). Notably, this approach exemplifies how a side effect of the BPs is slowly but steadily being turned into a new indication.

Finally, N-containing BPs might also be applied to treat certain parasitic protozoan infections such as infections with Trypanosoma cruzi, the cause of Chagas' disease or American trypanosomiasis, infections with Schistosoma mansoni, also known as bilharzia, as well as Plasmodium falciparum, one of the causes of malaria (Montalvetti et al., 2001; Ziniel et al., 2013). In each of these species, a mevalonate pathway leads to the formation of sterols and polyisoprenoid compounds essential to survival, but which is susceptible to N-containing BPs which have shown to inhibit the growth of these parasites (Martin et al., 2001; Ghosh et al., 2004). Interestingly, the protozoan FPP synthase differs slightly from human FPP synthase; therefore, BP potency differs between species, as has been demonstrated for *Trypanosoma cruzi* (Montalvetti et al., 2001). These findings have been supported by both genetic and crystallographic studies and have led to the identification of more specific N-containing-BPs that may be useful for these infections (Rodriguez et al., 2016). Both current clinically used BPs as well as several more recently designed BPs are currently in various phases of pre-clinical development for these indications.

Side effects

Oral BPs are in some patients associated with gastrointestinal toxicity, where they can damage epithelial layers during absorption as demonstrated in vitro, in vivo and in humans (Cremers et al., 2019; Twiss et al., 1999, 2001, 2006). Some of the toxic effects on the GI tract have been linked to direct damaging effects of the BPs as acidic molecules, but the N-containing BPs' cellular mechanism of action including FPP synthase inhibition, as well as their effects on mitochondrial superoxide production and lipid peroxidation, may also play a role in the pathogenesis of GI toxicity (Cremers et al., 2019; Suri et al., 2001; Nagano et al., 2012). GI toxicity has been reduced by coating of the tablets, instructions to take the tablets with sufficient water and to not lie down immediately after intake, as well as the reduction of intake frequency from daily to weekly or monthly.

Renal toxicity is another potential side effect from BPs (Perazella and Markowitz, 2008) that has primarily been observed when high dose IV BP is provided as an injection or short infusion. It has also mainly been observed in patients already predisposed to renal impairment, such as those with multiple myeloma. The formation of precipitating aggregate complexes with bivalent cations such as calcium is one potential mechanism for nephrotoxicity, especially in subjects receiving high IV BP doses. However, FPP synthase inhibition has also been suggested to play a role in the nephrotoxicity of N-containing BPs (Luhe et al., 2008). Potential other mechanisms include dysregulation of fatty acid metabolism (Cheng et al., 2018), genotoxic effects, and/or cytotoxic effects (Singireesu et al., 2018). It is currently not clear how each mechanism may contribute to differences in the types of nephrotoxicity known to occur with the various BPs such as predominant glomerulotoxicity with pamidronate as compared to predominant tubular necrosis with zoledronate (Perazella and Markowitz, 2008). Here there is also controversy with respect to differences in nephrotoxicity between the clinically available BPs. As example, some investigators have reported differences, especially between IV ibandronate and zoledronate. Such differences might reflect differences in solubility between the two BPs, but alternative mechanisms have also been explored (Perazella and Markowitz, 2008). In comparison, others have reported no differences (Luedders et al., 2015).

An N-containing BP-specific side effect is the acute phase reaction that occurs in some patients after IV administration (Skjodt et al., 2018; Tsurukami, 2017). As discussed above, these flu-like symptoms of pyrexia and musculoskeletal pain are explained by an induction of gamma delta T cells through the formation of phospho-antigens formed as a result of FPP synthase inhibition. This side effect is manageable with acetaminophen, is most commonly seen after the first administration of the drug, and typically becomes less severe with subsequent administrations (Skjodt et al., 2018; Tsurukami, 2017).

One of the side effects first noted with use of BPs was the inhibition of mineralization seen with high doses of etidronate. This was attributed to direct physicochemical effects on inhibiting mineral deposition, which is not seen with other BPs used clinically where the window between inhibition of mineralization and bone resorption is much greater.

The mechanism of another severe side effect, BRONJ, remains unclear, despite much speculation about the role of suppressed bone turnover. FPP synthase inhibition in gingival fibroblasts leading to impaired wound healing might also play a role (Skjodt et al., 2018; Marolt et al., 2012; Cozin et al., 2011; Landesberg et al., 2011). ONJ occurs predominately in cancer patients, often associated with osteomyelitis after tooth extractions.

Finally, long-term BP use has been associated with the development of atypical femoral fractures. The precise mechanisms underlying this rare but serious side effect is not known, but again may reflect local reduction of bone resorption, perhaps combined with a pre-existing anatomic anomaly in the sub-trochanteric femur (Skjodt et al., 2018).

Other side effects of BPs may include cardiovascular harms or benefits, but these effects are controversial and potential mechanisms underlying these potential side effects are not fully understood (Skjodt et al., 2018).

Mathematical pharmacodynamic (PD) models of BPs

The effects of BPs on bone have been evaluated using a variety of preclinical in vitro and in vivo models in many animal species over the many decades since the first descriptions of their biological effects. In addition, the effects of BPs have been evaluated in healthy volunteers as well as patients. From this data, various quantitative parameters have been calculated that together describe BP potency in different models. A typical parameter is the LED_{50}, the lowest dose at which an antiresorptive effect is observed. A typical relationship between BP concentration and an antiresorptive effect might be described mathematically by a so-called inhibitory E_{max} − model: $E = E_0*(1 - E_{max} * C^{\gamma}/(EC_{50}^{\gamma} + C^{\gamma}))$. Parameters include the effect observed in the absence of BP (E_0), the maximum effect E_{max}, the BP concentration (C) at which 50% of the effect is seen (EC_{50}) and the Hill coefficient. These parameters differ from BP to BP for antiresorptive activity and also differ between experimental models. Other mathematical models include a so-called indirect inhibitory effect model, which is often used to describe the effect of BPs on bone resorption markers in patients. These models include a production rate and an elimination rate of bone resorption markers and have an effect of the BP concentration on the production rate, most often through an inhibitory E_{max} model. Other mathematical models have included the effect of BPs on bone multicellular units and subsequently on BMD (Hernandez et al., 2002), while others have developed more extensive and very complicated systems pharmacology approaches using differential equations (Riggs and Cremers, 2019). To our knowledge, there are few, if any, mathematical PD models for the many non-bone-related effects of BPs.

Pharmacokinetics (PK)

The general bio-distribution of BPs is illustrated in Fig. 72.3. Oral BPs are taken up in the stomach, duodenum and ileum via paracellular and active transport. All BPs have a low and variable bioavailability (Twiss et al., 2001; Lin, 1996), with the bioavailability of most BPs estimated at approximately 1% (Cremers et al., 2019). This declines to near zero if the drug is ingested with calcium- or magnesium-containing foods, drinks or drugs (Gertz et al., 1995). Various attempts to increase the bioavailability of BPs have included the use of pro-drugs as well as absorption enhancers such as caproic acid (Cremers et al., 2019). The influence of food can be decreased by slow release formulations that include chelators (McClung et al., 2012). The low bioavailability of oral BPs also increases when ingested with gastric pH raising drugs such as ranitidine and omeprazole (Gertz et al., 1995). The effects of most of these attempts to improve the oral bioavailability of BPs, however, are marginal.

BPs are bound to plasma and serum proteins, but the role of this protein binding for the PK and PD of BPs is not clear. Protein binding differs between BPs and depends on multiple factors including the BP concentration, local pH, presence of divalent cations such as calcium, as well as endogenous displacers (Lin, 1996). Protein binding also differs between species and has been reported to range between 5% and 90% (Cremers et al., 2019).

Once reaching the systemic circulation, BPs do distribute to various soft tissue organs including the liver but are not typically metabolized, with the exception of the metabolism of some non-N-containing BPs to ATP analogues within

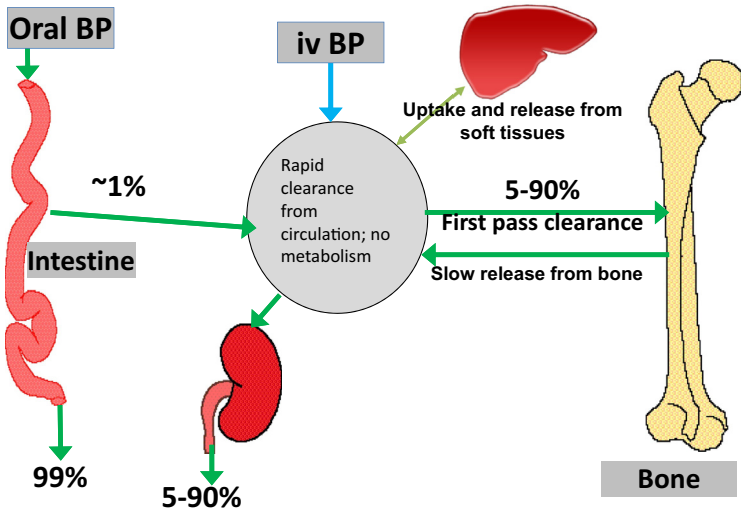

FIGURE 72.3 Schematic representation of the bio-distribution of BPs.

macrophages and osteoclasts as noted previously. Instead systemic BPs are either distributed to bone, or they are eliminated via the kidneys through glomerular filtration. Renal clearance of BPs correlates closely with creatinine clearance as has been demonstrated in various patient populations (Berenson et al., 1997; Bergner et al., 2007; Skerjanec et al., 2003). The United States FDA has used this correlation between renal function and the renal clearance of zoledronate to determine dose recommendations for zoledronate in patients with renal impairment (Booth et al., 2003). BPs remain contraindicated in patients with a creatinine clearance of less than 35 mL/min, although retrospective analyses of clinical trials suggest antifracture efficacy even in patients with low GFRs (Miller et al., 2005; Jamal et al., 2007). BPs are cleared from the systemic circulation by renal replacement therapy (Bergner et al., 2002; Buttazzoni et al., 2006; Beigel et al., 1995; Miller, 2007). However, most data on renal replacement therapy is relatively old and may not be applicable to the currently used dialyzers and membranes for patients on hemodialysis. Optimal BP dosing regimens for patients on dialysis are challenging to assess as there are effects of dialysis both on drug clearance and on the clearance of most biochemical markers of bone turnover, especially the resorption markers C-terminal and N-terminal peptides (CTX and NTX, respectively) (Miller, 2007). General recommendations for patients on hemodialysis are to decrease the BP dose by 50%, increase the infusion time, and to limit the overall number of doses provided (Miller, 2007). If the BP dose is given prior to a dialysis session, it is likely to result in elimination of at least part of the drug (Miller, 2007).

BPs are optimal drugs in terms of targeting the sites at which they are needed. They specifically bind to hydroxyapatite crystals and other calcium salts in bone, and thus are particularly available for binding at sites of active and increased bone turnover such as Pagetic lesions and bone metastases (Fleisch et al., 1969a; Fogelman et al., 1978). In bone, BPs bind strongly to sites of new mineral deposition at the 'calcification front' in osteoid as well as to resorption sites, most likely because of the exposure of calcium phosphate crystals during resorption. BPs bind specifically but not solely to high turnover sites. Binding to quiescent bone is less extensive, although numerically binding to quiescent bone can be substantial as for nearly all persons there is much more quiescent bone than bone that is actively turning over at any given time (Masarachia et al., 1996; Azuma et al., 1995). In the skeleton, comparatively more BP is taken up by trabecular as compared to cortical bone, which likely reflects the higher rate of bone turnover and the greater surface area available in the trabecular bone (Weiss et al., 2008). The distribution of BPs within the skeleton is therefore not homogeneous. BP deposition is even higher when bone turnover is increased locally, which is one reason why 99 mTc-labeled BPs are so successful for the diagnosis of diseases such as Paget's disease of bone and metastatic bone disease (Fogelman et al., 1978).

BPs differ from each other in terms of their binding affinity for hydroxyapatite (Dunford et al., 2008). This binding affinity might determine to some extent a BP's relative biodistribution between quiescent and actively remodeling bone, a function which differs between BPs (Masarachia et al., 1996; Azuma et al., 1995). It is, however, also likely that a BP's hydroxyapatite binding affinity determines not only the percentage of which a single IV dose will bind to the skeleton (Nancollas et al., 2006), but also how well a BP will penetrate the canalicular network within bone. As example, when compared to alendronate, risedronate has a weaker binding affinity for hydroxyapatite and lower skeletal retention, but exhibits higher penetration into the canalicular network and thus more pronounced access to osteocytes embedded within the bone matrix (Roelofs et al., 2012).

Most of an intravenously administered BP dose is either rapidly bound to bone or excreted into the urine, with only relatively small amounts accumulating in other tissues (Fig. 72.3). The amount of BP deposited in the skeleton can therefore be estimated from the IV dose and the amount of BP excreted into urine within a certain amount of time, e.g., 24 h, a technique developed and validated using 99 mTc-labeled BPs but also used to determine whole body retention (WBR) for multiple pharmacologically active BPs (Skerjanec et al., 2003; Fogelman et al., 1978; Khan et al., 1997; Cremers et al, 2003, 2005a; Pillai et al., 2004). These WBR_{24h} data correlate well with the hydroxyapatite affinity constants, illustrating that the amount of BP retained by the skeleton is determined by the binding properties of the BP (Nancollas et al., 2006). Skeletal retention, however, is also determined by additional patient related factors such as renal function, as well as the pretreatment rate of bone turnover, determined in cancer patients by the number of skeletal metastases and in patients with Paget's disease of bone by bone turnover levels (Cremers et al, 2003, 2005a; Chen et al., 2002). Interestingly, retention rates do not seem to change over time despite decreasing rates of bone turnover, which may illustrate that the biodistribution of BPs into bone may be more complex than suggested by currently available modeling efforts (Cremers et al, 2005a, 2019).

Once bound to bone, BPs may be either released by dissolution, or may become covered by new bone formed at resorption sites, with later release into the circulation during osteoclast-mediated bone resorption (Masarachia et al., 1996; Azuma et al., 1995). BPs are endocytosed into osteoclasts during resorption of bone (Coxon et al., 2008) (Fig. 72.4). While some BP is released into the circulation during this resorptive process, some BP may be released in association with osteoclast apoptosis and death. To our knowledge, however, there is no data on the actual contributions of either process to

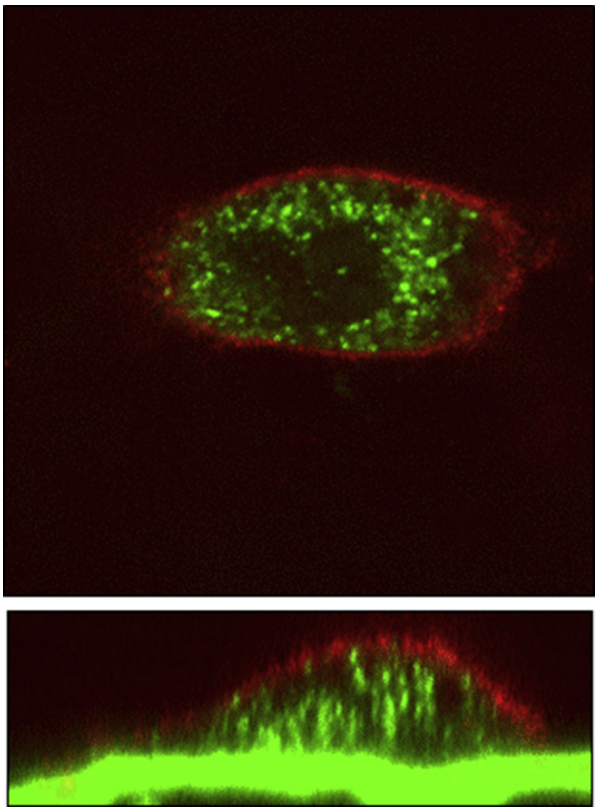

FIGURE 72.4 BP uptake into osteoclast. Rabbit osteoclasts were seeded onto dentine discs that had been pre-coated with 100 mM fluorescently labeled alendronate (green) and incubated for 18 h. Cells were then fixed, and actin stained with TRITC-phalloidin (red). Cells were examined by Light Scatter Confocal Microscopy (LSCM) (Luckman et al., 1998; Coxon et al., 2005, 2008).

long-term BP elimination in the urine. BPs released from bone may undergo re-uptake onto bone surfaces, a process that may depend on their relative affinity for hydroxyapatite. Importantly, BPs are detectable in urine for years after stopping treatment (Khan et al., 1997; Papapoulos and Cremers, 2007). Short-term and long-term urinary BP data are therefore highly informative about the overall amount of BP residing in bone, the latter especially when serum concentrations are too low to determine (Cremers et al., 2005b). Long-term (years) PK of BPs are characterized by half-lives determined by slow release from bone and subsequent excretion into urine. The few clinical studies which have collected blood and urine samples of sufficient duration to permit estimates of long-term half-lives suggest that the long-term half-lives of BPs in humans range between 1 and 10 years (Khan et al., 1997; Papapoulos and Cremers, 2007). Most studies, however, have been shorter such as one which directly compared alendronate and risedronate and followed urinary excretion of both BPs for a period of 4 weeks (Phipps et al., 2004). This study, which was originally planned as a 1 year study but for which only the 4 weeks results have been published, suggests that both short-term skeleton retention, as well as after 4 weeks, might be lower for risedronate than for alendronate. A fairly recent study comparing long-term excretion between BPs in $n = 43$ women previously treated for more than 4 years with either alendronate or risedronate showed that alendronate could be detected in the urine of some of the patients for more than a year after stopping treatment, whereas risedronate could not be detected even after 5 months after discontinuation of therapy (Peris et al., 2011). In more detail however, with a median time of discontinuation of 14 months for both groups alendronate was detected in $n = 15$ patients out of the $n = 36$ patients the alendronate group consisted of. Risedronate could not be detected in any of the $n = 7$ patients that the risedronate group consisted of (Peris et al., 2011). This data suggests differences in the elimination of alendronate and risedronate. However, it might also be the result of significantly differences in patient numbers between alendronate and risedronate users, a higher dose of alendronate versus risedronate for a period of more than 4 years prior to stop of treatment, as well as a more sensitive assay used in this study to quantify alendronate. The study might therefore also illustrate the potential influence of study design and methodologies on pharmacokinetic data reported in the literature (Cremers et al., 2005b).

Mathematical pharmacokinetic (PK) and pharmacokinetic-pharmacodynamic (PK-PD) models of BPs

PK of BPs can be described using compartmental mathematical models, the complexity of which is determined both by the drug modeled but also by available data (Riggs and Cremers, 2019; Cremers et al., 2005b). More extensive PK results for some BPs enable both short- and long-term PK models to be developed (Skerjanec et al., 2003; Chen et al., 2002; Cremers et al., 2002; Sedghizadeh et al., 2013). For other BPs, where such data were not available, simpler (e.g., kinetic) models have been developed and validated, although these latter models only describe the amount of BP delivered to the skeleton (Pillai et al., 2004). The common denominator in most of these models is typically the ability to describe the amount or concentration of BPs in the skeleton, which places these models in a good position to link them to mathematical pharmacodynamic (PD) models in a manner that is mechanism-based and results in so-called PK-PD and K-PD models.

A full integration of the PK and the PD of BPs comes from efforts to synthesize all available in vitro and in vivo experimental data, as well as all clinical studies. Various BP dosing regimens and their effects have been explored in several species as well as in humans across different disease states. Most of the effects observed in patients can be at least partially explained by accounting for a number of factors including the underlying disease, extent of the disease, disease progression, co-medication(s), mode of BP administration, dosing regimen, BP binding affinity and potency, pretreatment rate of bone turnover, bone turnover markers (BTMs), bone mineral density (BMD), fracture risk and renal function (Cremers et al., 2019). Many of these observations have been captured using mechanism-based mathematical models that simultaneously describe PK and PD of the BPs, with PD either restricted to bone resorption markers or expanded to include BTMs, BMD and fracture risk. Some models have also included the effects of co-medications such as calcium and vitamin D supplementation on BTMs, BMD and fracture risk, while other models have incorporated renal function (affecting both PK and PD) and disease progression (Pillai et al., 2004; Cremers et al., 2005b; Post et al., 2010; Berkhout et al., 2016; Schmidt et al., 2011; Peterson and Riggs, 2010, 2012; Riggs et al., 2012; Eudy-Byrne et al., 2017). To our knowledge, there exist no PK or PK-PD models focused on indications extrinsic to the skeleton.

Applications of the clinical and translational pharmacology of BPs

A major application of the clinical and translational pharmacology of BPs has been, and continues to be, the identification of optimal dosing regimens. Pharmacologic approaches have been used to identify optimal dosing regimens for first in human (FIH) studies, for phase 2 and 3 studies, and for modifications to dosing regimens after regulatory approval. To date, the PD markers of choice which have been used to address these challenges have been BTMs and BMD, which can provide helpful information during virtually all phases of drug development, and which subsequently often also are incorporated into the aforementioned mathematical PK/PD models used to simulate what happens to these markers across various dosing regimens (Cremers and Garnero, 2006; Leeming et al., 2006). For example, mathematical PK/PD models have been used to determine the oral monthly dosing regimen for ibandronate via simulations which found that changing from a dosing regimen of 2.5 mg daily to 150 mg monthly would result in a similar suppression of bone resorption (Fig. 72.5) (Zaidi et al., 2006). Likewise, a mathematical PK/PD model was earlier used to estimate the potential effects of

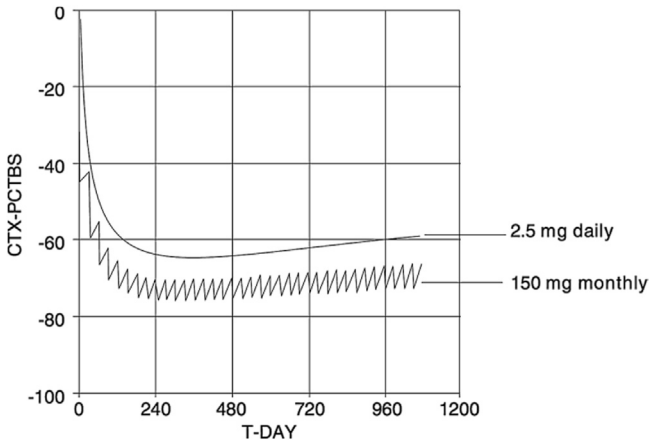

FIGURE 72.5 Kinetic-Pharmacodynamic (K-PD) model-based simulations of the median change in CTX from baseline with oral ibandronate 2.5 mg daily versus 150 mg monthly (Zaidi et al., 2006).

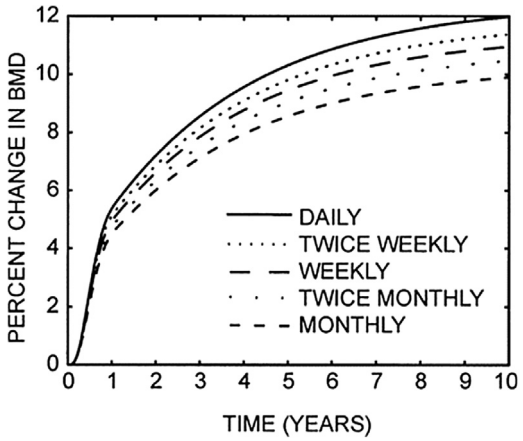

FIGURE 72.6 Model-based predicted changes in BMD in response to alendronate. Each line represents a different frequency of alendronate administration (Zaidi et al., 2006).

weekly alendronate 70 mg versus daily alendronate 10 mg on BMD changes, and contributed to the assumption that weekly administration would result in similar BMD effects as compared to daily treatment (Fig. 72.6) (Hernandez et al., 2002). Finally, a general knowledge of BP pharmacology combined with PK/PD studies and carefully derived mathematical models led to an initial dosing regimen of zoledronate 4 mg once monthly for the treatment of patients with metastatic bone disease, the subsequent exploration of a less intense dosing regimen of 4 mg every 3 months in these same patients, and an annual dose of zoledronate 5 mg in patients with osteoporosis (Berenson et al, 2001a, 2001b; Berenson, 2001; Reid et al., 2002).

Both mathematical PK/PD models and a deep understanding of the translational and clinical pharmacology of BPs have been instrumental in introducing so-called BP 'holidays' for patients provided with several years of continuous treatment with these drugs. Temporarily BP stoppage is mainly considered due to concerns for an increased risk of serious side effects such as atypical femur fractures and osteonecrosis of the jaw which might reflect over-suppression of bone turnover due to skeletal accumulation in the setting of prolonged BP treatment. A combination of bone resorption markers and BMD, two of the clinical PD markers for BPs, are typically used to monitor for the continued effects of BPs during these holidays. Collectively, these surrogate markers signal when the skeletal BP effects are waning and treatment may be reinstated. Interestingly, our knowledge of BP pharmacology explains why the effects of BPs are so protracted (especially when compared with other antiresorptive agents such as denosumab or cathepsin K inhibitors), and it may in part also explain differences in loss of the antiresorptive effect after treatment discontinuation for alendronate, risedronate, and ibandronate. In a head-to-head study which compared the effect of stopping alendronate, risedronate or ibandronate, BTM levels increased for all three BPs after treatment withdrawal, but remained below the pre-treatment baseline values with less BTM suppression in the risedronate group as compared to the alendronate and ibandronate groups up to 48 weeks after treatment cessation (Naylor et al., 2018). The only head-to-head study comparing the PK of BPs in humans used accelerator mass spectrometry to demonstrate that after IV administration, WBR of risedronate was less than that of alendronate [51.0% versus 55.5%, respectively after 24 h; 33.8% versus 44.9%, respectively after 4 weeks] (Phipps et al., 2004). This difference in retention might explain the difference in loss of the antiresorptive effect between alendronate and risedronate, despite the relatively small differences in both WBR and BTM levels. Interestingly, BMD changes evaluated 96 weeks after alendronate, risedronate or ibandronate discontinuation were the same (Naylor et al., 2018), which may reflect some of the other effects of BPs on bone such as their effects on osteocytes. Collectively, differences between BPs related to their effects on osteocytes, penetration into the canalicular network, FPP synthase inhibition potency, inhibition of osteoclast-mediated bone resorption, and skeletal retention, might also all contribute to the intriguing observation that risedronate 5 mg daily (or 35 mg weekly) and alendronate 10 mg daily (or 70 mg weekly) exhibit similar anti-fracture activity despite alendronate reducing biochemical BTMs to a greater extent than risedronate (Rosen et al., 2005).

The combination of BTMs and BMD has also been informative for so-called bridging trials, phase 2 studies designed to gain regulatory approval for comparable indications, i.e., seeking approval for glucocorticoid-induced osteoporosis based on BTM and BMD data if the BP has received previous approval for the treatment of postmenopausal osteoporosis. Drugs may be approved when similar effects on these PD parameters are observed in such studies (Kehoe et al., 2018). To our knowledge, there have been no full PK/PD studies of BPs conducted to support such bridging trial-based approvals. It is

therefore assumed that PK of the BPs, and PK/PD relationships are similar across these comparable but different patient populations.

BTMs, combined with BMD have also been very informative in studies which have examined treatment with BPs in combination with PTH derivatives. Thus, studies have examined BPs provided either continuously, prior to, or subsequent to intermittent PTH, either with or without intervening drug holidays (Cosman et al., 2017). While PK and PK/PD models exist for both BPs and for intermittent PTH (Tay et al., 2018), to our knowledge these models have not been used to predict the effects when these two classes of drugs are combined.

More recently, a renewed interest has emerged for the use of BPs to target other drugs, such as antibiotics and chemotherapeutics, to the skeleton via conjugation to BPs (Farrell et al., 2018; Sedghizadeh et al., 2017; Wang et al., 2018). The development of new chemical linkers now ensures that the active drugs are only released from the conjugates after reaching the bone. A challenge for the most efficacious use of these compounds lies in identifying optimal dosing regimens in both preclinical models and in patients. Knowledge of the PK and PD of BPs and the other compounds will be essential for approaches to resolve these issues.

Finally, in terms of the aforementioned new potential indications for BPs, PD models have been used to study BP effects in vitro. As noted previously, however, because traditional mathematical PK models for BPs have focused on assessing skeletal concentrations of BPs, they may be less useful for many of these new indications, the pathogeneses of which frequently lie outside the skeleton. Efforts to develop BPs for most of these new indications are currently preclinical, but will ultimately require the ability to quantify and simulate BP concentrations in brain, the GI tract, tumors, and other tissues, as well as their effects. We therefore anticipate that the translational and clinical pharmacology of BPs will need to look beyond the skeleton in the very near future.

Conclusions

Studies in the 1960s on the role of inorganic pyrophosphate (PPi) in controlling biological mineralization led to the search for stable PPi analogues. Studies with BPs showed that they also had effects on biological mineralization but had the added advantages that they were more stable and could be administered to animals orally without degradation. One of the early and somewhat unexpected observations was that BPs could also inhibit mineral dissolution and block bone resorption both in vitro and in living animals. This led rapidly to their clinical use. This began with the use of BPs as bone scanning agents and mineralization inhibitors, and then as resorption inhibitors in a variety of clinical disorders. Over the ensuing 50 years, the BPs have become established as leading drugs for the treatment of skeletal disorders characterized by increased bone resorption. BPs were first used in Paget's disease of bone and hypercalcemia of malignancy, and later to control skeletal-related-events associated with bone metastases and myeloma. When bone densitometry was developed and trials of sufficient size were conducted to demonstrate their remarkable efficacy in reducing fractures in patients with osteoporosis, several BPs were approved for osteoporosis on a world-wide basis.

There has been a vast amount of work done on BPs, with nearly 28,000 publications in PubMed alone. Much is now known about their biochemical actions within cells. A key intriguing discovery was that N-containing BPs appear to be specific inhibitors of enzymes in the mevalonate pathway of cholesterol biosynthesis, inhibition of which leads to interference with protein prenylation and intracellular signaling. Innovation continues to occur with new compounds and new applications. The safety and efficacy of this class of drugs ensure their continued use in clinical medicine, and potential extension to other applications for skeletal and non-skeletal conditions.

Chapter outline

History of osteoprotegerin/receptor activator of nuclear factor–kappa B ligand-based drug development

Before the mid-1990s, the molecular mechanisms underlying osteoclastogenesis were not well understood, and in vitro culturing of osteoclasts was technically challenging. As genetic mapping approaches progressed, parallel efforts from several commercial and academic groups began to unravel components of a key pathway that drives osteoclast formation, function, and survival. At Amgen, phenotypic screening of transgenic mice engineered to overexpress previously unknown secreted factors via the liver resulted in the discovery of osteoprotegerin (OPG) (Simonet et al., 1997). OPG, a secreted member of the TNF receptor superfamily, was identified based on increased radiographic density in OPG-overexpressing transgenic mice (Simonet et al., 1997). Histology demonstrated that OPG transgenic mice had few osteoclasts and

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00073-7

exhibited features reminiscent of human osteopetrosis. Subsequent experiments demonstrated that recombinant OPG inhibited osteoclast formation in vitro (Simonet et al., 1997), while genetic ablation of OPG resulted in severe osteopenia including fragility fractures (Bucay et al., 1998). Soon thereafter, independent investigators at the Snow Brand Milk Products Company reported an identical secreted protein with similar pharmacologic properties that they called osteoclast inhibitory factor (Yasuda et al., 1998).

The Amgen investigators then used OPG to find its binding partner, which OPG was presumably blocking to inhibit osteoclastogenesis. A longer-circulating recombinant form of OPG called OPG-Fc, which comprises the cysteine-rich TNF receptor-like domains of native OPG fused to the Fc portion of human IgG1, was found to bind to a molecule expressed on the surface of a myelomonocytic cell line (Lacey et al., 1998). The Amgen investigators named this molecule OPG ligand (OPGL), which they showed to be a potent promoter of osteoclast differentiation and activation (Lacey et al., 1998). Independent research by the investigators at Snow Brand Milk showed that an identical molecule, which they named osteoclast differentiation factor (ODF), stimulated osteoclastogenesis in vitro and caused hypercalcemia in vivo (Yasuda et al., 1998). Meanwhile, investigators at Immunex Corporation had identified the same "OPGL/ODF" molecule by direct sequencing of a myeloid dendritic cell cDNA library (Dougall et al., 1999; Hsu et al., 1999). They had initially identified a new member of the TNF receptor family they called "receptor activator of nuclear factor kappa B" (RANK) based on the key role of the transcription factor NF−κB in mediating its biological effects. Using an extracellular fragment of this receptor fused to Fc (RANK-Fc), they identified its binding partner via expression cloning and named this molecule RANK ligand (RANKL) (Anderson et al., 1997). The sequence of RANKL was identical to OPGL, and a nomenclature committee comprising representatives from the American Society for Bone and Mineral Research, along with esteemed advisors from the immunology field, proposed to adopt RANKL as the formal name with RANK as its receptor and OPG as the decoy receptor that binds RANKL and prevents it from activating RANK (American Society for Bone and Mineral Research President's Committee on Nomenclature, 2000; Fig. 73.1). Shortly after the Immunex group characterized roles for RANK and RANKL in T cells and dendritic cells (Anderson et al., 1997), investigators from Amgen, the Amgen Institute, and the University of Toronto demonstrated that RANKL was a critical mediator of osteoclastogenesis and that the genetic ablation of RANKL caused osteopetrosis in mice (Kong et al., 1999b). RANKL has since been demonstrated to exist in both membrane-bound and soluble forms (Ikeda et al., 2001), and soluble RANKL levels in peripheral blood and bone marrow appear to be regulatable (Abrahamsen et al., 2005; Li et al., 2009), which may allow RANKL to act in an endocrine, juxtacrine, or paracrine manner (Lacey et al., 2012).

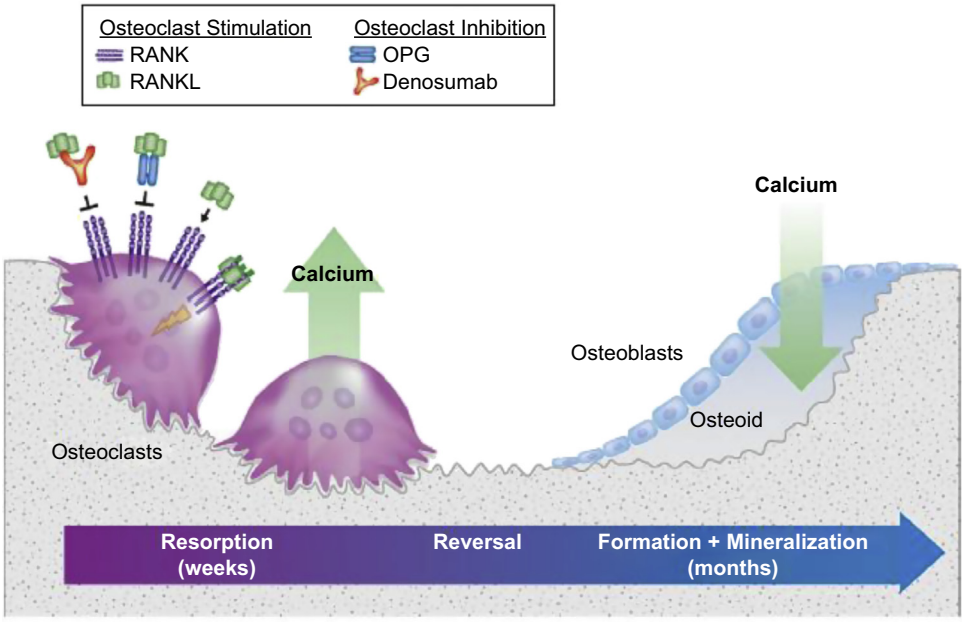

FIGURE 73.1 Role of the RANKL pathway and its inhibition on bone remodeling. Bone remodeling occurs as a coupled process of initiation of osteoclastic bone resorption followed by osteoblastic bone formation in the basic multicellular unit as shown here. Osteoclast formation, function, and survival are dependent on the binding of receptor activator of nuclear factor−kappa B ligand (RANKL) to its surface receptor (RANK). Prevention of this binding by the naturally occurring protein osteoprotegerin (OPG) and/or the engineered RANKL antibody denosumab results in the disruption of osteoclasts and their formation. This inhibition greatly reduces the rate of bone remodeling, resulting in increased bone mass. *Reproduced with Elsevier permission from Dempster et al., 2012. Clin. Ther. 34, 521−536.*

Recognizing the key and essential role of RANKL for bone resorption and bone loss, efforts were initiated to develop inhibitors of the RANK–RANKL pathway using a variety of therapeutic strategies. Investigators at Immunex developed RANK-Fc, which was an effective inhibitor of bone resorption, but preclinical studies indicated that immune responses arising against RANK-Fc had the potential to cause hypercalcemia via the activation of endogenous RANK, leading to the discontinuation of its development (Lacey et al., 2012). At Amgen, Fc-OPG was tested in Phase 1 clinical trials in postmenopausal women. Fc-OPG proved to be an effective inhibitor of bone resorption, with reductions in biochemical markers of bone resorption lasting for several weeks depending on dose (Bekker et al., 2001). In the pursuit of longer-acting versions that could be dosed less frequently for patient convenience, Amgen pivoted toward the development of OPG-Fc (AMGN-0007). OPG-Fc had a longer circulating half-life than that of Fc-OPG and also achieved more sustained reductions in bone resorption markers in subjects with breast cancer or multiple myeloma, with inhibitory effects lasting beyond the trial's 2-month endpoint (Body et al., 2003). However, concerns regarding potential anti-OPG-Fc immune responses that could also adversely affect the bioavailability of endogenous OPG led to the discontinuation of OPG-Fc development in favor of other approaches (Lacey et al., 2012). OPG-Fc remains a commonly used RANKL inhibitor in animal studies due to its ability to recognize and inhibit RANKL from various species including mice (Bonnet et al., 2016), rats (Ominsky et al., 2008), rabbits (Rodeo et al., 2007), cynomolgus monkeys (cynos) (Ominsky et al., 2007), and pigs (Sipos et al., 2011). Pharmacologic strategies were then initiated at Amgen to develop antibodies to inhibit RANKL (Lacey et al., 2012). The XenoMouse (Green, 1999) allowed the rapid generation of high-affinity, fully human monoclonal anti-RANKL antibodies including denosumab (Lacey et al., 2012). As outlined below, this RANKL-Ab strategy became the preferred therapeutic approach due to improved pharmacokinetics requiring less frequent administration compared with Fc-OPG or OPG-Fc, and the lack of potential for adverse immune-mediated perturbations of endogenous OPG or RANK activity. To date, there have been few if any cases of patients developing neutralizing immune responses against the fully human denosumab molecule, and the hypothetical impact of such a response might only involve loss of denosumab efficacy. In addition, unlike OPG, which can bind to TNF family member TRAIL, denosumab does not bind TRAIL or other TNF family members (Kostenuik et al., 2009). Beyond RANK, OPG, and antibody-based approaches to antagonize RANKL, there have been efforts to develop small-molecule (Idris et al., 2010) and peptide-based (Ta et al., 2010) approaches to inhibit RANKL. Although these modalities inhibit bone resorption in vitro and in animals, they have yet to demonstrate clinical efficacy. The section below summarizes some of the preclinical and clinical data generated during the development of the RANKL antibody denosumab.

Physiologic mechanisms and effects of receptor activator of nuclear factor–kappa B ligand inhibitors in bone

Numerous studies have examined the pharmacologic effects of RANKL inhibitors in healthy animals and in animal models of bone disease. The first such publications demonstrated that Fc-OPG and OPG-Fc inhibited RANKL-induced osteoclast formation in vitro and in vivo (Simonet et al., 1997; Lacey et al., 1998). Subsequent studies in bone disease models including rodent and nonhuman primate models of postmenopausal osteoporosis further demonstrated the impact of RANKL inhibitors on bone turnover, bone mass, bone microarchitecture, bone strength, and bone quality. Rodent studies have generally relied on recombinant RANK-Fc or OPG-based RANKL inhibitors because denosumab does not recognize mouse or rat RANKL (Kostenuik et al., 2009), though a number of pharmacology studies with denosumab were performed in nonhuman primates (Ominsky et al., 2011; Kostenuik et al., 2011, 2015) and in mice genetically engineered to express human or partially humanized RANKL (huRANKL) mice (Kostenuik et al., 2009; Rinotas et al., 2014).

The osteoclast-inhibiting effects of RANKL inhibitors are reflected in rapid decreases in biochemical markers of bone resorption followed by a delayed reduction in bone formation markers that reflects the coupled process of bone remodeling. In postmenopausal women with low bone mass, denosumab decreased bone resorption markers compared with placebo within 24 h after a single dose, and bone formation markers showed significant decreases several weeks later (Bekker et al., 2004). In growing male rats, a single injection of recombinant human OPG-Fc resulted in a significant decrease in the resorption marker serum TRACP within 48 h and a decline in the formation marker serum osteocalcin by day 10 (Capparelli et al., 2003). These inhibitory effects on bone turnover were associated with decreases in histological indices of osteoclasts and osteoblasts, effects that reversed over time as OPG-Fc concentrations diminished. Similar rapid declines in bone resorption markers were observed with OPG-Fc in OVX rats (Ominsky et al., 2008) and with denosumab in huRANKL mice (Li et al., 2009). Histomorphometry demonstrated that these changes corresponded to >95% reductions in the extent of trabecular osteoclast surfaces. Similar robust reductions in bone resorption and formation markers were reported in cynos treated with OPG-Fc (Ominsky et al., 2007) and denosumab (Ominsky et al., 2011) in association with marked

reductions in histomorphometric indices of resorption and formation at trabecular and cortical sites (Kostenuik et al., 2011).

Bone resorption and formation in adult animals occur predominantly in a coupled process known as remodeling, with resorption preceding formation as bone matrix is continually removed and replaced. Thus, the delayed reduction in bone formation indices after denosumab-mediated inhibition of bone resorption was expected, reflecting more remodeling spaces having completed their refilling with new bone matrix. In contrast, bone *modeling* represents temporally and spatially distinct mechanisms by which bone is formed or removed via uncoupled processes. Although bone modeling occurs predominantly during growth, there is evidence for continued bone modeling in adulthood. As denosumab was not thought to affect osteoblasts directly, its effects on bone modeling were investigated in OVX cynos (Ominsky et al., 2015). These results indicated that in the near absence of bone resorption and remodeling-based bone formation, modeling-based bone formation was present in the femur neck and ribs of denosumab-treated monkeys to a similar extent as that found in vehicle-treated controls. The extent of this modeling-based bone formation was small and location-dependent, but its presence and persistence over the 16-month treatment duration supported the hypothesis that bone modeling contributes to the uniquely progressive hip and femoral neck bone mineral density (BMD) gains observed in postmenopausal women receiving denosumab over a 10-year treatment period (Bone et al., 2017; Ominsky et al., 2015). In contrast, bisphosphonates do not induce incremental BMD gains at the hip or femoral neck beyond the first 3−4.5 years of therapy (Reid, 2015).

The reductions in bone turnover observed with RANKL inhibitors result in significant gains in bone mass and bone strength in various animal models. In OVX rats, 6 weeks of OPG-Fc resulted in increased in vivo DXA BMD and ex vivo bone volume by micro-CT at the lumbar vertebra and femur neck relative to OVX controls (Ominsky et al., 2008). Trabecular microarchitecture was also improved as reflected in increases in trabecular number and thickness. These improvements resulted in significant elevations in strength endpoint peak load in lumbar vertebrae and the femoral neck. Similar observations were made after 16 months of denosumab administration to OVX cynos, with denosumab-mediated gains in trabecular and cortical bone mass resulting in significantly greater peak load at the femoral neck (up to 34%), L3−L4 vertebral bodies (up to 55%), and L5−L6 cancellous cores (up to 82%) compared with OVX-Veh (Ominsky et al., 2011). In this study, microarchitectural improvements included increased cortical thickness and reduced cortical porosity as well as increased trabecular number.

Bone remodeling has long been considered by many to be essential for maintaining bone health via the removal and replacement of older bone matrix; as such, the longer-term effect of antiresorptives on bone quality has been a long-standing concern. Therefore, the demonstration that the near absence of bone turnover with up to 16 months of high-dose denosumab therapy led to gains in whole bone strength was reassuring. Linear regressions were performed to assess relationships between bone mass and bone strength variables, as such analyses were previously shown capable of identifying drug-related impairments in bone quality (Lafage et al., 1995). Regression analyses demonstrated that bone quality was maintained at the lumbar vertebra, femur neck, and femur diaphysis after 16 months of denosumab (Ominsky et al., 2011). In addition, calculated material properties from these tests, and destructive testing results for size-matched cortical samples machined from the humeral cortex, confirmed the maintenance of bone quality. A subsequent OVX cyno study verified these findings after 12 months of denosumab while also showing a lack of impaired bone quality measures with the bisphosphonate alendronate (Kostenuik et al., 2015). In addition, finite element strength estimates generated from vertebral CT images from the 16-month study strongly predicted measured bone strength, further supporting the interpretation that bone quality is maintained with denosumab (Lee et al., 2016).

Reduced bone remodeling, including that which results from RANKL inhibition, is expected to alter matrix mineralization properties primarily by affording remodeling sites more time to achieve a fuller degree of matrix mineralization. This effect often leads to a reduction in the heterogeneity of matrix mineralization distribution within the bone that some observational studies have associated with bone fragility (Lloyd et al., 2017). Aged OVX rats treated with OPG exhibited a higher average degree of matrix mineralization in femoral cancellous bone along with reduced heterogeneity of mineralization (Valenta et al., 2005), and the same femurs used for those analyses showed improved bone biomechanical properties with OPG treatment (Kostenuik et al., 2001). Vertebrae and femurs from huRANKL mice treated with denosumab or alendronate for 6 months also showed reduced heterogeneity of matrix mineralization, which was associated with improved biomechanical properties compared with vehicle-treated controls (Misof et al., 2011; Ominsky et al., 2008b). The degree of matrix mineralization in the vertebrae of OPG-treated OVX rats bore no relationship with vertebral bone strength, which was significantly increased in close association with increments in bone volume (Ominsky et al., 2008a). Increased matrix mineralization and reduced heterogeneity of mineralization is also observed in postmenopausal women treated with denosumab for up to 10 years (Dempster et al., 2018) in association with persistently reduced fracture rates (Bone et al., 2017). Together, these preclinical and clinical findings lend little support for the theory that potent inhibition

of bone turnover can impair bone biomechanics via changes in matrix mineralization parameters. Ultimately, even 5 years of denosumab therapy in postmenopausal women caused relatively modest absolute changes in matrix mineralization parameters, with no further changes between 5 and 10 years of therapy, despite extremely and persistently low remodeling rates (Dempster et al., 2018). Such findings may suggest the existence of self-regulatory mechanisms within bone that resist large excursions from biomechanically optimal matrix mineralization characteristics.

Clinical studies demonstrating the effects of denosumab (Table 73.1)

Osteoporosis indications

Postmenopausal osteoporosis

The efficacy and safety of denosumab administered as a 60 mg subcutaneous injection every 6 months was evaluated in several large clinical trials. Based on these data, described below, this regimen was approved by the FDA and EMA (trade name Prolia) for the treatment of postmenopausal women with osteoporosis at high risk for fracture.

The pivotal randomized, double-blind, placebo-controlled "FREEDOM" trial underscored the efficacy of denosumab treatment over 3 years to reduce the risk of new vertebral fractures by 68%, nonvertebral fractures by 20%, and hip fractures by 40% compared with placebo in postmenopausal women with osteoporosis (Cummings et al., 2009). Interestingly, the fracture reduction effect was independent of patient characteristics for vertebral fractures but was influenced by baseline body mass index and femoral neck T-score for nonvertebral fractures as depicted by a subgroup analysis (McClung et al., 2012). A post hoc analysis evaluating fracture incidence in women with known risk factors for fractures revealed that denosumab significantly reduced the risk of new vertebral and hip fractures in women at high fracture risk, whereas only new vertebral fractures were significantly reduced in women at low fracture risk (Boonen et al., 2011). Another post hoc analysis showed that the antifracture efficacy of denosumab was not dependent on renal function (Jamal et al., 2011). Long-term data support the antifracture efficacy of denosumab for up to 10 years according to data from the open-label extension of FREEDOM (Bone et al., 2017). Women originally randomized to denosumab (years 1−3) who remained on the drug during the extension (years 4−10) continued to exhibit low yearly rates of new vertebral, nonvertebral, and hip fracture, which were similar to the rates observed in denosumab-treated subjects during the first 3 years of the FREEDOM trial.

The effects of denosumab in FREEDOM were largely reproduced in the DIRECT study, which was a randomized, double-blind, placebo- and active comparator-controlled phase 3 trial in Japanese patients with osteoporosis (95% of whom were postmenopausal women) (Nakamura et al., 2014). Over 2 years, a 74% reduction in the risk of new vertebral fracture with denosumab versus placebo was noted, but the study was underpowered to assess differences in nonvertebral fracture risk. The antifracture benefit of denosumab was sustained in Japanese female and male patients with osteoporosis who continued to receive the drug in a 1-year open-label extension of DIRECT, while patients who switched from placebo to denosumab at the start of the extension had fracture rates similar to those of denosumab recipients in the original DIRECT trial (Sugimoto et al., 2015).

BMD, as evaluated by DXA, was significantly improved at various skeletal sites (total hip, lumbar spine, femoral neck) with denosumab treatment compared with placebo in the original FREEDOM trial (Bolognese et al., 2013). A substudy of FREEDOM analyzing changes in volumetric BMD as measured by quantitative CT yielded similar results (McClung et al., 2013). Furthermore, in the FREEDOM extension, BMD at the spine, hip, and femoral neck continued to progressively increase over a period of 10 years without reaching a plateau (Bone et al., 2017). Data from the 2-year DIRECT trial (Nakamura et al., 2014) conducted in Japan, and its 1-year extension (Sugimoto et al., 2015), were generally concordant with results of the FREEDOM trial while providing new evidence of a greater reduction in vertebral fracture risk with denosumab compared with open-label alendronate therapy. Several studies have investigated the effect of denosumab compared with bisphosphonates in improving BMD in postmenopausal women with osteopenia or osteoporosis. Denosumab significantly increased BMD at all sites when compared with once-weekly oral alendronate (Brown et al., 2009), once-monthly oral risedronate (Roux et al., 2014), and once-monthly oral ibandronate (Recknor et al., 2013). In a head-to-head study with once-yearly intravenous zoledronic acid in postmenopausal women with osteoporosis who were previously treated with oral bisphosphonates, denosumab significantly increased BMD at all skeletal sites compared with zoledronic acid (Miller et al., 2016).

Consistent with improved BMD, various subgroup analyses of the FREEDOM trial documented increased bone strength with denosumab treatment. In a subgroup of 99 patients in whom estimated bone strength was evaluated via QCT-based finite element analysis, denosumab treatment significantly increased bone strength in both trabecular and cortical

departments compared with the effects of placebo (Keaveny et al., 2014). Similar results were noted for estimated strength of the radius (Simon et al., 2013). Furthermore, denosumab treatment over 3 years led to a significant increase in cortical thickness and mass and reduced cortical porosity at the proximal femur, which also correlated with increased bone strength (Zebaze et al., 2016). Nevertheless, these QCT-based findings were not reproduced in histological and micro-CT-based analyses of 112 iliac crest biopsies from FREEDOM, where significant differences between denosumab and placebo with regard to cortical thickness and porosity were not consistently observed (Chapurlat, 2017; Reid et al., 2010).

Consistent with the mechanism of action of denosumab in inhibiting osteoclast formation, function, and survival, clinical studies revealed a rapid decrease in serum markers of bone resorption after denosumab administration that was followed by later reductions in serum markers of bone formation (Bekker et al., 2004). In the pivotal FREEDOM trial, denosumab was associated with median reductions of 86%, 72%, and 72% in concentrations of the bone resorption marker C-telopeptide of type 1 collagen at months 1, 6, and 36, respectively. Concentrations of the bone formation marker

procollagen type 1 N-terminal propeptide decreased by 18%, 50%, and 76% at months 1, 6, and 36, respectively (Cummings et al., 2009). Bone turnover marker reductions were sustained for up to 10 years in patients who continued to receive denosumab treatment in the FREEDOM extension trial (Bone et al., 2017). In 1-year active comparator-controlled trials conducted in postmenopausal women with low bone mass or osteoporosis, denosumab was generally more effective than oral or intravenous bisphosphonates at reducing bone turnover markers (Brown et al., 2009; Roux et al., 2014; Recknor et al., 2013; Miller et al., 2016).

These bone turnover findings were mirrored in data obtained from iliac crest biopsies from 92 participants of the pivotal FREEDOM trial, where denosumab reduced histomorphometric measures of bone resorption (e.g., eroded surface, erosion depth, and osteoclast number) and measures of bone formation (osteoid surface, width, and volume) without impairing bone mineralization or microarchitecture (Chapurlat, 2017; Reid et al., 2010). Normal bone microarchitecture and sustained reduced bone turnover were also documented in 22 biopsies of patients who continued denosumab treatment over 10 years in the FREEDOM extension (Bone et al., 2017; Dempster, 2018, p. 39).

Male osteoporosis

Although women are more commonly affected by osteoporosis than men, up to 30%−40% of all osteoporotic fractures worldwide occur in men (Johnell and Kanis, 2006), underlining the necessity of screening and treating male patients with osteoporosis. Despite the fact that BMD measurements are less well standardized in men than in women, men with low BMD are at risk for fragility fractures, as shown in the large prospective analysis of the MrOS cohort (Cummings et al., 2006). Most pharmacological treatments for male osteoporosis have been initially approved for postmenopausal osteoporosis and then replicated in smaller randomized controlled trials in men, with change in BMD as a primary endpoint (Gennari and Bilezikian, 2018).

The study that led to the approval of denosumab (Prolia) by the FDA and EMA for the treatment of male osteoporosis was a phase 3 randomized-controlled trial in men with low BMD that showed significant increases in BMD at the lumbar spine and total hip region (5.7% and 2.4% increases, respectively, at 12 months) versus placebo (Orwoll et al., 2012). Although antiresorptive drugs are generally currently recommended as first line pharmacotherapy in male osteoporosis (Watts et al., 2012), considering that primary male osteoporosis is predominantly characterized by impaired bone formation, a case for the early application of osteoanabolic substances can be made (Gennari and Bilezikian, 2013).

Use of denosumab in combination/sequence with other osteoporosis agents

The sequence in which osteoporosis therapies are utilized in patients can be critical to their impact on BMD (Cosman et al., 2017) and transitions to and from denosumab have been tested in numerous studies. The transition from alendronate to denosumab has been examined in both OVX cynos and humans. In OVX cynos that initially received 6 months of ALN, transition to denosumab further decreased bone resorption and cortical porosity, and increased BMD and bone strength, without deleterious effects on serum calcium or bone quality (Kostenuik et al., 2015). In postmenopausal women receiving alendronate for at least 6 months, transition to denosumab also resulted in further decreases in bone turnover by serum biomarkers and histomorphometry, while BMD increased (as measured by DXA) and cortical porosity decreased (as measured by HRpQCT) (Reid et al., 2010; Kendler et al., 2010; Zebaze et al., 2014). A separate clinical study demonstrated that transitioning from alendronate to denosumab yielded larger BMD changes than transitioning from alendronate to zoledronic acid (Miller et al., 2016). Some of these differences have been attributed to greater inhibition of intracortical remodeling with denosumab; this greater inhibition may reflect denosumab's effects on osteoclastogenesis and may also relate to the limited uptake of bisphosphonates in dense cortical bone, which could contribute to the more pronounced effects of denosumab in the cortex (Zebaze et al., 2014).

Transition from the anabolic agent teriparatide to denosumab was also examined, as antiresorptive therapy is generally thought to be necessary to maintain bone mass gains after teriparatide therapy is discontinued. In the DATA study, the transition to 24 months of denosumab after 24 months of teriparatide resulted in positive gains in BMD at all sites examined (Leder et al., 2015) in association with improvements in finite element−estimated bone strength at the distal tibia and radius as evidenced by HRpQCT (Tsai et al., 2017). In the same study, the transition *from* denosumab to teriparatide was detrimental to estimated bone strength at these sites, further demonstrating the importance of sequence in the use of osteoporosis therapies.

The addition of denosumab to teriparatide as a combination therapy was also examined in the DATA study. Previous studies suggested that the addition of antiresorptive agents (oral bisphosphonates) did not consistently improve BMD when combined with parathyroid hormone—PTH(1−84) and/or teriparatide, PTH(1−34)—in postmenopausal women

(Black et al., 2003) or men (Finkelstein et al., 2003). In contrast, the DATA study demonstrated that the combination of denosumab and teriparatide for 24 months increased BMD to a significantly greater extent than either monotherapy alone (Leder et al., 2014). Similar findings were observed in rodent models when RANKL inhibitors were combined with PTH (Samadfam et al., 2007; Kostenuik et al., 2001; Pierroz et al., 2010). Transition from denosumab to other antiresorptives has also been examined because most BMD gains are lost within the first 12 months after denosumab discontinuation if no follow-on osteoporosis therapy is taken (Bone et al., 2011; Miller et al., 2008; Popp et al., 2018), as discussed below. In general, follow-on bisphosphonate therapy after denosumab discontinuation appears to prevent or partially mitigate bone loss (Freemantle et al., 2012; Lehmann and Aeberli, 2017; Reid et al., 2017), though the effects of these and other follow-on therapies on fracture risk remain unknown.

Cancer indications

Denosumab for cancer treatment–induced bone loss

Maintenance of bone health and strength is a continuous challenge in the adjuvant setting of cancer patients. In particular, patients with prostate or breast cancer receiving sex hormone ablation therapies are prone to excessive bone loss and osteoporotic fractures (Hadji et al., 2017; Adler, 2011), and several studies have addressed the ability of denosumab at 60 mg every 6 months to preserve or increase bone mass and reduce fracture risk in such patients. Based on the data below, Prolia was approved by the FDA and EMA as a treatment to increase bone mass in men at high risk for fracture who are receiving androgen deprivation therapy for nonmetastatic prostate cancer and in women at high risk for fracture who are receiving adjuvant aromatase inhibitor therapy for breast cancer.

Androgen deprivation in men with prostate cancer

In men with prostate cancer undergoing adjuvant hormone ablation therapy via gonadotropin-releasing hormone analogues, denosumab increased lumbar spine BMD by 5.6% compared with a loss of 1% in the placebo group after 24 months. In addition, vertebral fractures were significantly reduced in the denosumab group (1.5%) compared with placebo (3.9%) after 36 months (Smith et al., 2009).

Aromatase inhibitors in women with breast cancer

Aromatase inhibitors are commonly used as adjuvant hormone ablation therapies for the treatment of hormone receptor–positive breast cancer in postmenopausal women. While aromatase inhibitors significantly improve the prognosis of affected patients (Burstein et al., 2014), they exert distinct negative effects on bone mass and increase the risk of fractures (Hadji, 2015). Denosumab was the first osteoporosis drug to undergo clinical trials to specifically assess its efficacy in fracture risk reduction in breast cancer patients treated with aromatase inhibitors, which is a growing population. In an initial smaller trial with 252 patients, denosumab was shown to have positive effects on BMD compared with placebo—BMD at the lumbar spine increased by 5.5% and 7.6% in the denosumab group compared with placebo after 12 and 24 months, respectively, and denosumab also increased BMD at all other measured sites (Ellis et al., 2008). The larger ABCSG-18 phase 3 trial ($n = 3425$ subjects) was designed to assess the effects of adjuvant denosumab versus placebo on fracture risk reduction in postmenopausal women with early hormone-responsive breast cancer receiving aromatase inhibitor treatment. Denosumab reduced the number of fractures compared with placebo (92 vs. 172) and significantly delayed the time to first clinical fracture. Notably, fracture risk reduction was observed independent of baseline T-score, with significant reductions in the patient subgroup with a T-score of -1 or higher as well as in the subgroup with a T-score lower than -1 (Gnant et al., 2015).

Treatment of hypercalcemia of malignancy refractory to bisphosphonate therapy

Hypercalcemia of malignancy is a complication of patients with advanced cancer that denotes a poor prognosis. It is caused by enhanced osteoclast activity through either a humoral mechanism or local cancer-induced osteolysis. Optimal therapy requires treatment of the underlying malignancy, but in case of extensive disease a palliative approach to alleviate patients' symptoms is warranted. In addition to the initial correction of volume depletion through intravenous saline infusions and loop diuretics to promote renal calcium excretion, intravenous bisphosphonates have been the treatment of choice (Stewart, 2005). Alternatively, in cases of severe renal insufficiency or refractory hypercalcemia despite bisphosphonate use, denosumab was shown to be effective in lowering serum calcium in a single-arm international study (Hu et al., 2014). That study involved the subcutaneous administration of 120 mg denosumab on days 1, 8, 15, and 29 and then every 4 weeks to

subjects with BP-refractory hypercalcemia of malignancy. Denosumab reduced serum calcium in 64% of patients within 10 days, with an estimated median response duration of 104 days. Based on those findings, denosumab (XGEVA) received regulatory approval from the FDA under an orphan drug designation for the treatment of BP-refractory hypercalcemia of malignancy.

Breast cancer

Bone metastases are a frequent and dire complication in breast cancer patients with advanced disease, leading to a variety of SREs that include pathological fractures, radiation and/or surgery to bone, and spinal cord compression (Irelli et al., 2016). A phase 3 noninferiority study in patients with breast cancer and bone metastases assessed the effects of monthly denosumab (120 mg, $n = 1026$) or zoledronic acid (4 mg, $n = 1020$), with the primary endpoint being the time to first on-study SRE (Stopeck et al., 2010). Denosumab was shown to be noninferior and also superior to zoledronic acid in delaying the time to first on-study SRE. Denosumab was associated with fewer renal adverse events and fewer acute-phase reactions compared with zoledronic acid, whereas there were no significant differences in overall survival, breast cancer disease progression, or the occurrence of ONJ between the two treatment groups (Stopeck et al., 2010).

Prostate cancer

Bone metastases in men with prostate cancer are also associated with substantial morbidity and significant adverse impacts on health-related quality of life (Saad et al., 2017). A phase 3 trial was conducted in men with castration-resistant prostate cancer and bone metastases who were randomized to receive denosumab ($n = 950$) or zoledronic acid ($n = 951$), with the primary endpoint being the time to first on-study SRE (Fizazi et al., 2011). Denosumab significantly improved the time to first on-study SRE by 3.6 months compared with zoledronic acid. Hypocalcemia was more common in the denosumab group, while osteonecrosis of the jaw (ONJ) occurred at similarly infrequent rates in the denosumab (2%) and zoledronic acid (1%) arms (Fizazi et al., 2011). Preclinical data suggest that at least some human cancer cells express functional RANK and that RANKL can promote the migration and invasion of various cancer cell types including prostate cancer cells (Jones et al., 2006; Mori et al., 2007), suggesting a potential role for RANKL in the promotion of metastasis, and bone metastasis in particular. A phase 3 trial was conducted to assess the ability of denosumab to prevent bone metastases in men with nonmetastatic castration-resistant prostate cancer at high risk of developing bone metastases (Smith et al., 2012). Denosumab improved bone metastases–free survival by 4.2 months compared with placebo (median 29.5 vs. 25.2 months). Overall survival remained unaffected by the treatment. ONJ developed in 5% of patients on denosumab compared with none on placebo (Smith et al., 2012). While these results suggest efficacy of denosumab in preventing bone metastases, there is currently no FDA- or EMA-approved indication for the adjuvant treatment of prostate cancer patients with denosumab.

Other solid tumors

A third phase 3 trial compared denosumab and zoledronic acid in patients with bone metastases secondary to solid tumors (excluding breast and prostate) and myeloma (Henry et al., 2011). The primary endpoint was time to first on-study SRE, and denosumab proved noninferior to zoledronic acid in delaying time to first SRE. There were no differences in overall survival between the groups. A subanalysis of the lung cancer cohort within this trial revealed a significant survival benefit for patients with any form of lung cancer receiving denosumab, with an overall survival of 8.9 months compared with 7.7 months for those receiving zoledronic acid. Survival benefits were more pronounced in the non-small-cell lung cancer group (9.5 vs. 8.0 months), with the most pronounced effect on overall survival seen in patients with squamous cell carcinoma (8.6 vs. 6.4 months) (Scagliotti et al., 2012).

Multiple myeloma

Osteolytic lesions are a hallmark of multiple myeloma, which can also lead to SREs. In contrast to solid tumors, multiple myeloma is a hematological disease, and as such the classic metastatic pathway is not required for bone manifestations to occur. For the assessment of denosumab, patients with multiple myeloma were first included in the above-mentioned trial in combination with patients who had bone metastases secondary to solid tumor malignancies other than prostate or breast (Henry et al., 2011). While the primary endpoint of this trial, reduction in first on-trial SRE, was successfully reached by showing noninferiority over zoledronic acid, an ad hoc analysis of the myeloma subgroup ($n = 180$) revealed a lower overall survival in the patients who received denosumab compared with those who received zoledronic acid. Based on these findings, denosumab was approved by the FDA and EMA for the treatment of bone metastases from solid tumors but not multiple myeloma.

Further assessment of the myeloma subgroup revealed imbalances between the groups with regard to baseline risk characteristics such as ECOG score, renal function, and form of treatment, such as stem cell transplantation. A higher rate of early withdrawals was also noted in the zoledronic acid group (Raje et al., 2016). These results prompted the initiation of a larger ($n = 1718$) trial specific to patients with multiple myeloma. Patients were randomized to receive denosumab ($n = 859$) or zoledronic acid ($n = 859$), and the primary endpoint of noninferiority of denosumab compared with zoledronic acid was met. Adverse events were comparable between groups, although fewer renal treatment-emergent adverse events were observed in the denosumab group. ONJ occurrence was 4% and 3% in the denosumab and zoledronic acid groups, respectively. Based on these results, denosumab was approved by the FDA and EMA in early 2018 for the treatment of skeletal complications arising from multiple myeloma.

Giant cell tumors

GCTBs are benign tumors associated with an osteolytic phenotype and substantial skeletal morbidity (Sobti et al., 2016). In a phase 2 trial, 120 mg of denosumab was given to 37 patients with unresectable or recurrent GCTBs at days 1, 8, 15, and 28 followed by additional doses every 4 weeks. A tumor response was observed in 30 of 35 patients (Thomas et al., 2010). In a larger subsequent trial, 163/169 (96%) of surgically unsalvageable GCBT patients had no disease progression after a median follow-up 13 months after denosumab administration. In a separate cohort of this study, 74% (74/100) of patients with salvageable GCTBs whose surgery was associated with severe morbidity did not require surgery a median of 9.2 months after denosumab initiation; 62% (16/26) of those that did require surgery underwent a less extensive procedure than initially planned prior to therapy. Osteonecrosis occurred in 1% of all patients (Chawla et al., 2013).

Denosumab for the treatment of metastatic bone disease, multiple myeloma, and giant cell tumors

The efficacy and safety of denosumab has been extensively studied in patients with malignancy-associated bone lesions administered denosumab subcutaneously at a dose of 120 mg every 4 weeks. Based on the data described below, the FDA and EMA approved this regimen of denosumab (trade name XGEVA) for the prevention of skeletal-related events (SREs) in patients with multiple myeloma and those with bone metastases from solid tumors as well as for the treatment of adults and skeletally mature adolescents with giant cell tumor of bone (GCTB) that is unresectable or where surgical resection is likely to result in severe morbidity. For the latter indication, additional 120 mg doses are administered subcutaneously on Days 8 and 15 of the first month of therapy.

Additional denosumab data

Glucocorticoid-induced osteoporosis

Glucocorticoids exert manifold adverse effects on bone tissue, and while physiological concentrations of glucocorticoids are indispensable for bone accrual and growth, supraphysiological concentrations, either endogenously or more commonly iatrogenically, have detrimental effects on bone (Hofbauer and Rauner, 2009). Glucocorticoids dose-dependently inhibit the differentiation and proliferation of cultured osteoblasts, promote apoptosis of cultured osteoblasts and osteocytes, and slow the rate of bone matrix mineralization. In addition, glucocorticoids transiently enhance the activity of osteoclasts through upregulation of RANKL (Hofbauer and Rauner, 2009). In vitro data show that the treatment of osteoblast-like cells with glucocorticoids upregulates their expression of RANKL and downregulates OPG expression (Hofbauer et al., 1999). Denosumab was shown to prevent reductions in bone mass and bone strength in a mouse model of glucocorticoid-induced osteoporosis (GIOP) (Hofbauer et al., 2009). Antiresorptive and osteoanabolic drugs constitute the current therapeutic options for patients with GIOP. Clinical studies show that bisphosphonates are effective in reducing the occurrence of fractures in patients with GIOP to a degree comparable to that observed in trials of patients with postmenopausal osteoporosis (Kanis et al., 2007). A recently published double-blind, active-controlled study investigated the efficacy of denosumab compared with risedronate in patients with osteoporosis either initiating or continuing glucocorticoid treatment (Saag et al., 2018). At 12 months, treatment with denosumab (60 mg every 6 months) led to a significant BMD increase at the lumbar spine (4.4% vs. 2.3%) and total hip (2.1% vs. 0.6%) compared with risedronate. Based on these results, denosumab was approved by the FDA and EMA in 2018 for the treatment of bone loss associated with long-term systemic glucocorticoid therapy.

Rheumatoid arthritis

Inflammation in arthritic joints leads to joint destruction, in part through increased RANKL expression by activated T cells (Kong et al., 1999a). Therefore, the effects of RANKL inhibitors have been examined in multiple models of rheumatoid arthritis (RA) and in clinical trials of patients with RA. In adjuvant- and collagen-induced arthritis models in rats, RANKL inhibition via OPG treatment inhibited bone loss in arthritic joints without affecting local or systemic inflammation parameters (Kong et al., 1999a; Romas et al., 2002; Stolina et al., 2009). In clinical studies, denosumab was effective at inhibiting the progression of bone erosions (via Sharp erosion score) in RA patients receiving methotrexate, though denosumab did not affect joint space narrowing or RA disease activity (Cohen et al., 2008; Takeuchi et al., 2016, 2017). The combined use of RA biologics and denosumab did not lead to greater rates of serious infection in this patient population (Lau et al., 2018), which had been a potential concern based on results from the FREEDOM trial in postmenopausal women with osteoporosis, as described below. Based on these studies, in 2017 Daiichi Sankyo received regulatory approval from Japan's PMDA for the use of denosumab to inhibit the progression of bone erosions associated with RA. Although the pathogenesis of osteoarthritis (OA) differs somewhat from that of RA, the OPG/RANKL axis has also been implicated in OA. Early changes in subchondral bone have also been hypothesized to contribute to OA joint pathology, and therefore the prevention of these changes via RANKL inhibition may affect OA progression. OPG was shown to ameliorate pain in the monosodium iodoacetate OA rat model but did not improve pathology in joints with established damage (Sagar et al., 2014). Clinical data of the effects of denosumab on OA are limited, though at least one clinical trial is ongoing to examine denosumab's effects on erosive OA (NCT02771860).

Other potential applications

The effects of RANKL inhibitors have been examined in other conditions affecting bone including immobilization-induced bone loss (disuse osteopenia), periprosthetic osteolysis, fracture repair, and osteogenesis imperfecta (OI). Mechanical loading affects RANKL expression in bone; increased loading-induced strain reduced RANKL expression in marrow-derived stromal cell cultures (Rubin et al., 2000), while in vivo studies indicate that immobilization resulted in increased RANKL expression in murine bone (Aliprantis et al., 2012). Inhibition of RANKL by genetic modification (Xiong et al., 2011) or administration of OPG (Bateman et al., 2000) protected against disuse osteopenia in mice. Similarly, OPG ameliorated bone loss due to sciatic nerve damage (Bateman et al., 2001), transient muscle paralysis (Aliprantis et al., 2012), and space flight (Lloyd et al., 2015). Limited clinical data are available regarding the effects of denosumab on bone mass in immobilized patients, though clinical studies are ongoing (NCT01983475 and NCT03029442). One year of denosumab reduced bone turnover markers and increased BMD in a cohort of 14 patients with recent spinal cord injury (mean: 15 months postinjury) compared with their baseline values (Gifre et al., 2016).

Aseptic loosening due to wear debris–induced osteoclastic bone resorption is the most common cause of implant failure, and increased production of RANKL likely plays a critical role in this process (Haynes et al., 2001). Administration of RANKL inhibitors was able to prevent wear debris osteolysis in a mouse calvarial model (Childs et al., 2002; Tsutsumi et al., 2008) and improve screw fixation strength in a nonosteolysis model in rats (Bernhardsson et al., 2015). Initial results from a clinical trial of denosumab in postmenopausal women undergoing cementless total hip replacement indicated that although treatment ameliorated the loss of periprosthetic BMD, it did not prevent stem migration or improve functional recovery indices (Aro, 2017). These data remain preliminary and did not specifically examine the effect of denosumab in patients with aseptic loosening, which remains undetermined. A small clinical study in patients with established aseptic loosening is ongoing (NCT02299817).

Bone resorption plays a key role in the fracture repair process, primarily through callus remodeling that restores the fractured bone's original mass and shape. Because denosumab is primarily used in patients at increased risk of fracture, it is important to understand the effect of RANKL inhibitors on fracture healing. Studies in rodent models indicated that RANKL inhibitors do not impair fracture union or reduce callus structural strength (Gerstenfeld et al., 2009; Delos et al., 2008; Ulrich-Vinther and Andreassen, 2005). High-dose denosumab administration to human RANKL knock-in mice with a closed femoral fracture led to near-total ablation of callus osteoclasts that was predictably associated with delayed callus remodeling, a finding also seen in fractured rodents receiving other RANKL inhibitors (Gerstenfeld et al., 2009; Delos et al., 2008; Ulrich-Vinther and Andreassen, 2005). Delayed callus remodeling in denosumab-treated mice was associated with greater callus structural strength (Gerstenfeld et al., 2009). A subset of patients that experienced nonvertebral fractures during the FREEDOM study showed no indication of increased incidence of delayed healing or nonunion in the denosumab group (Adami et al., 2012).

OI is a genetic disorder that results in increased bone fragility. The effects of RANKL inhibitors have been examined in animals and humans with OI. In young oim/oim mice treated from 2 to 14 weeks of age, RANK-Fc improved bone microarchitecture and decreased fracture incidence compared with controls (Bargman et al., 2012). To date, clinical reports of denosumab use in OI patients have been limited, though current data indicate that lumbar spine BMD is increased (Li et al., 2018). In children with OI type IV treated with 1 mg per kg body mass denosumab every 3 months, hypercalcemia and hypercalciuria ensued, indicating that the dosing strategy may need adjustment in rapidly growing children with this unique form of OI (Trejo et al., 2018). A larger Amgen-sponsored clinical study of denosumab in OI patients is ongoing (NCT02352753).

Bone marrow edema syndrome is a painful and often difficult-to-treat condition characterized by an increase of interstitial fluid within bone. Since this "bone bruise" condition is accompanied by local bone resorption (Thiryayi et al., 2008), the use of an antiresorptive agent seems reasonable. Intravenous bisphosphonates were shown to be effective in reducing bone marrow edema in professional athletes (Simon et al., 2014). More recently, denosumab was used in a case-series of 14 patients with bone marrow edema, with an overall treatment success rate of 93% based on MRI findings (Rolvien et al., 2017).

Denosumab also has been recently used to treat alveolar bone destruction, which characterizes periodontitis. In a rodent model of periodontitis, systemic delivery of OPG-Fc preserved alveolar bone volume and decreased bone resorption markers (Jin et al., 2007). Similarly, rats treated with OPG-Fc displayed enhanced postorthodontic tooth stability (Hudson et al., 2012).

Denosumab safety

As with any drug, the clinical benefits of RANKL inhibitors should be weighed against their potential risk. The warnings and precautions section of the US label for Prolia and XGEVA indicate potential risks including hypocalcemia, ONJ, atypical subtrochanteric femoral fractures (AFFs), multiple vertebral fractures following discontinuation, hypersensitivity, serious infections, dermatologic adverse reactions, and musculoskeletal pain (Prolia/XGEVA PI).

Hypocalcemia

Decreases in serum calcium with denosumab secondary to decreased bone resorption may lead to or exacerbate hypocalcemia (Prolia/XGEVA PI). Higher baseline bone formation may contribute to hypocalcemia after denosumab therapy is initiated (Kinoshita et al., 2016; Kostenuik et al., 2015). Clinical monitoring of serum calcium is recommended within 14 days of denosumab administration for patients predisposed to hypocalcemia or altered mineral metabolism, including patients with renal impairment. Denosumab is contraindicated in patients with preexisting hypocalcemia. In contrast, discontinuation of denosumab in XGEVA-treated patients with growing skeletons should involve monitoring for hypercalcemia, which has been reported.

Osteonecrosis of the jaw

ONJ has been reported in patients taking Prolia and XGEVA, with a higher incidence reported for XGEVA. ONJ, which can occur spontaneously, is generally associated with tooth extraction and/or local infection with delayed healing. Therefore, a dental examination is recommended prior to treatment in patients who may require such procedures or have other risk factors that may predispose them to ONJ (Prolia/XGEVA PI). During the long-term extension of the FREEDOM trial in postmenopausal women with osteoporosis, in which all subjects received open-label denosumab, 12 cases of ONJ occurred, all but 1 of which followed invasive oral dental procedures or events comprising scaling or root planning, tooth extraction, dental implant, natural tooth loss, or jaw surgery. A total of 11 subjects developed ONJ among the 1621 subjects who underwent or experienced such procedures or events, for a rate of 0.7%, compared with 1 ONJ case among the 1970 subjects who did not undergo or experience such procedures or events (0.05%) (Watts et al., 2017). The pathophysiology of the increased incidence of ONJ is not clear, though increased ONJ risk is also associated with other antiresorptive agents (i.e., bisphosphonates) (Khan et al., 2017). The recent development of nonclinical models demonstrating induction of ONJ in the presence of periapical disease may provide additional insights (Aghaloo et al., 2014).

Atypical femoral fractures

AFFs have also been reported with denosumab (Prolia/XGEVA PI). First reported in patients receiving bisphosphonates, these transverse fractures occur in the femoral diaphysis below the lesser trochanter and are associated with minimal

trauma or comminution. Prodromal pain and bilaterality are frequent or occasional features of AFFs, and therefore patients on denosumab who experience new thigh or groin pain should seek medical attention, and the contralateral limb should be assessed should an AFF occur. The pathophysiology of these fractures is not clear, though the evidence suggests they may occur as stress or insufficiency fractures (Shane et al., 2014). Large-scale studies have reported that most radiographically confirmed AFFs occur in patients who were never dispensed any potent antiresorptive therapies (Feldstein et al., 2012), and that long-term bisphosphonate use is not associated with an overall increased risk of fractures in the specific femoral region where AFFs occur (Abrahamsen et al., 2016). These observations have led to suggestions that potent antiresorptives may lead to an atypical radiographic fracture pattern without necessarily causing the fracture itself (Feldstein et al., 2012). In support of that possibility, tibiae from OPG-treated mice subjected to destructive biomechanical testing exhibited more transverse and distal failure patterns than vehicle-treated mice, and these shifts were associated with greater, not lesser, bone strength (Bonnet et al., 2016).

Denosumab discontinuation: effects on bone turnover, bone mass, and fracture risk

Cessation of therapy with denosumab is associated with rapid reversal of BMD gains and an increase in bone turnover markers to above pretreatment baseline levels from around month 8 to around month 24 after the last denosumab dose, followed by a return of turnover markers to baseline levels (Bone et al., 2011; Miller et al., 2008). BMD levels also tend to return to pretreatment baseline levels after discontinuing denosumab but generally remain above the levels of patients who never received denosumab (Bone et al., 2011; Miller et al., 2008). Recent post hoc analyses of patients from FREEDOM and its open-label extension indicate that for subjects who discontinue denosumab without any follow-on osteoporosis therapy, overall fracture risk resumes at levels similar to those of subjects who never received denosumab. One analysis showed that for subjects in FREEDOM who discontinued placebo or denosumab after having received at least two doses of study drug and continued to participate in the study for at least 7 months after the last dose received, the exposure-adjusted rates of new vertebral fractures were 9.3 vs. 5.6 per 100 subject-years, respectively (Brown et al., 2013). A subsequent analysis wherein subjects from the FREEDOM extension study were also included reported similar exposure-adjusted rates of new or worsening vertebral fractures after discontinuing denosumab or placebo (Cummings et al., 2018). However, the latter study also reported that the rate of multiple new or worsening vertebral fractures was somewhat higher for subjects discontinuing denosumab than for those who discontinued placebo (4.2 vs. 3.2 per 100 subject-years, respectively). And among subjects from FREEDOM and its extension who experience at least one new off-treatment vertebral fracture, 60.7% of those who discontinued denosumab experienced multiple vertebral fractures, compared with 34.5% of such subjects who discontinued placebo (Cummings et al., 2018). Several published case series have also described multiple vertebral fractures in patients discontinuing denosumab (Popp et al., 2016; Aubry-Rozier et al., 2016; Anastasilakis et al., 2017). Accordingly, professional committees and national guidelines have issued statements advising against cessation of denosumab without an alternative treatment, especially in patients at high fracture risk (Tsourdi et al., 2017; Meier et al., 2017).

Mechanisms underlying the risk of multiple vertebral fractures after denosumab discontinuation are unclear, but a cogent pathophysiological hypothesis should reconcile with observations that overall vertebral and nonvertebral fracture risks were similar after discontinuing denosumab or placebo. One potential hypothesis relates to the potential for perturbed spinal alignment after an index off-treatment (or prevalent) vertebral fracture. Altered spinal alignment in subjects with vertebral fractures has been associated with increased mechanical loading on the other vertebrae (Briggs et al., 2006), and for subjects experiencing high turnover after discontinuing denosumab therapy, those increased mechanical loads may act on vertebrae that bear microstructural hallmarks of high bone turnover, such as more extensive resorption cavities and trabecular disconnections. Microstructural features of high turnover can be particularly deleterious to bone strength when placed in regions of higher strain or lower bone volume (Hernandez et al., 2006; Slyfield et al., 2012). This hypothesis suggests that the risk of multiple vertebral fractures after denosumab discontinuation may abate to some degree as transiently higher turnover subsides and biomechanically detrimental resorption cavities are refilled. On the other hand, index or prevalent vertebral fractures may continue to adversely influence spine alignment and vertebral biomechanics independent of bone turnover rates, which could represent an ongoing risk for additional vertebral fractures.

Hypersensitivity, serious infections, and musculoskeletal pain

Hypersensitivity has been reported with denosumab use, and treatment should be discontinued if clinically significant allergic reactions occur. Increased risk of serious infection that required hospitalization including endocarditis and infections of the skin, abdomen, urinary tract, and ear were reported more frequently in the Prolia group in the FREEDOM

trial (Prolia PI). Higher rates of skin reactions such as dermatitis, eczema, and rashes also occurred with Prolia in FREEDOM. Severe bone, joint, and/or muscle pain has also been reported in patients taking Prolia.

Use in women of reproductive age

Denosumab is contraindicated in patients who are pregnant based on data from animal studies suggesting that denosumab may cause fetal harm (Prolia PI/XGEVA). Administration of high-dose denosumab to cynos throughout pregnancy resulted in increased fetal loss, stillbirths, and postnatal mortality with absent peripheral lymph nodes, abnormal bone growth, and decreased neonatal growth. Some of these abnormalities improved following a recovery period from birth through 6 months of age (Boyce et al., 2014). Nonetheless, for women of reproductive age receiving denosumab, contraception is recommended for at least 5 months after the last dose.

Theoretical impact of receptor activator of nuclear factor−kappa B ligand inhibition on insulin resistance and vascular calcification

Additional animal studies have suggested the potential for RANKL inhibitors to affect other pathological processes including insulin resistance and vascular calcification. In a series of experiments in mouse models of type 2 diabetes, genetic inhibition of RANKL signaling or OPG administration improved insulin sensitivity and glucose metabolism (Kiechl et al., 2013). These data were supported by the authors' observation that high serum RANKL concentration was as an independent risk predictor of T2DM in humans. A separate set of studies demonstrated that RANKL inhibitors could induce β-cell proliferation in vitro and in vivo (Kondegowda et al., 2015). A post hoc analysis of the FREEDOM study did not demonstrate a clear effect of denosumab on fasting serum glucose in postmenopausal osteoporotic women with prediabetes or diabetes; however, some improvement was observed in a subset of diabetic patients not receiving antidiabetic medication (Napoli et al., 2018).

Early genetic studies suggested a link between RANKL signaling and vascular calcification based on the presence of calcified arteries in osteoporotic OPG-deficient mice (Bucay et al., 1998). A subsequent study demonstrated that denosumab reduced aortic calcium deposition in mice receiving prednisolone (Helas et al., 2009). A post hoc analysis of the FREEDOM study did not show an effect of treatment on the progression of aortic calcification (by lateral spine X-ray) or the incidence of cardiovascular adverse events, compared with placebo (Samelson et al., 2014).

Summary

Denosumab is an effective therapeutic agent for increasing BMD and reducing vertebral and nonvertebral fracture risk in patients with postmenopausal osteoporosis, glucocorticoid osteoporosis, and male osteoporosis. Denosumab also delays SREs, reduces the onset of bone metastases, and prevents fractures in patients with bone metastases from breast and prostate cancer. Denosumab's subcutaneous mode of administration renders it a practical and well-tolerated drug because it circumvents the gastrointestinal tract, and no infusion equipment or facility is required for denosumab administration. A further advantage lies in the possible utilization of denosumab in patients with renal insufficiency, a common condition in the elderly and/or patients with cancer. Denosumab displays a favorable safety profile, and the risks of hypocalcemia and ONJ can be reduced by preventive measures. Since denosumab is not deposited in the skeleton, there is no sustained effect on bone metabolism after its discontinuation. Therefore, regular denosumab administration during therapy is warranted, and a long-term therapeutic strategy is recommended if denosumab is discontinued, particularly in patients at increased risk for fracture.

Chapter outline

Introduction

Insights gained from rare genetic conditions can be used to identify potential new targets and pathways for therapeutic intervention. The function of the *SOST* gene product, sclerostin, as an inhibitor of bone formation in humans was discovered by genetic mapping studies that pinpointed loss-of-function mutations in the *SOST* gene as causative in the high bone mass (HBM) disorder sclerosteosis (Balemans et al., 2001; Brunkow et al., 2001). In mice, deletion of the *SOST* gene causes an increase in bone mass and strength due to increased bone formation, while overexpression of a human sclerostin transgene results in low bone mass and decreased bone strength (Ke et al., 2012). Significant efforts have been directed toward the development of neutralizing antibodies to sclerostin as novel bone-forming therapies for osteoporosis and other conditions of low bone mass.

In this chapter, we focus on the biology of sclerostin and its pharmacologic inhibition by monoclonal antibodies (Scl-Ab). We describe the biochemistry of sclerostin and its interactions with low-density lipoprotein receptor-related proteins (LRP) 4/5/6, which facilitate sclerostin's function as an antagonist of the canonical wingless-related integration site (Wnt) signaling pathway. The mechanism of action of sclerostin inhibition and its consequences for skeletal tissue in a number of animal models, including models of osteoporosis, are discussed. Finally, we briefly summarize the findings from clinical trials of Scl-Ab in postmenopausal osteoporosis, male osteoporosis, osteogenesis imperfecta (OI), and adult hypophosphatasia.

Sclerostin biology and biochemistry

Human monogenic high bone mass conditions related to sclerostin: sclerosteosis and van Buchem disease

Two very rare, severe sclerosing bone dysplasias, each caused by a genetic deficiency in sclerostin expression—sclerosteosis and van Buchem disease—have yielded important insights into the importance of sclerostin as a regulator of bone metabolism in the human skeleton.

Sclerosteosis (OMIM: 269500) is a rare, autosomal recessive, HBM disorder found principally within the Afrikaner population of South Africa and in a few individuals in other parts of the world (Van Lierop et al., 2017). Sclerosteosis is caused by inactivating mutations in the *SOST* gene (Balemans et al., 2001; Brunkow et al., 2001). *SOST* is located on chromosome 17q12−q21 and encodes the protein sclerostin. The most frequent mutation (c.69G>T) introduces a premature stop codon immediately following the signal peptide, resulting in the loss of sclerostin protein expression. Table 74.1 summarizes the known *SOST* mutations and clinical characteristics that have been reported in patients with sclerosteosis. The earliest observed postnatal feature of sclerosteosis is syndactyly, which is present in approximately two-thirds of patients. From an early age, affected individuals are typically of tall stature, and high skeletal density and cortical thickening are readily apparent on X-ray examination (Hamersma et al., 2003). In the skull, progressive bone overgrowth occurs, leading to facial feature deformities due to excessive mandibular growth and forehead bossing. Bone overgrowth also causes cranial nerve entrapment, facial palsy, hearing loss, and raised intracranial pressure, the most severe and life-threatening complication of the condition. Measurement of bone mineral density (BMD) by dual-energy X-ray absorptiometry (DXA) in patients with sclerosteosis reveals extremely high BMD Z scores, ranging from +7.7 to +14.4 at the lumbar spine and +7.8 to +11.5 at the hip (Van Lierop et al., 2017).

The HBM observed in individuals with sclerosteosis is driven by excessive osteoblast-mediated bone formation, rather than by any defect in osteoclastic bone resorption. In adults with sclerosteosis, serum levels of the bone-formation marker procollagen type 1 N-terminal propeptide (P1NP) have been shown to be approximately four times higher than in healthy controls; in contrast, serum levels of the bone-resorption marker C-terminal telopeptide of type I collagen (CTX) were normal, or lower, compared with healthy controls (Van Lierop et al., 2017). Importantly, the high BMD present in patients with sclerosteosis translates into enhanced bone strength, indicating that the bone formed is intrinsically of good quality. The hyperostotic skeleton appears resistant to trauma and there are no reports in the literature of patients experiencing a fracture. Changes in mineralization kinetics, resulting in a reduction in matrix mineralization and an increase in proteoglycan content, are seen in patients with sclerosteosis, indicating that the high BMD does not reflect increased bone matrix mineralization, as has been observed in other HBM disorders such as pycnodysostosis (Hassler et al., 2014).

Within the Afrikaner population, the carrier rate for sclerosteosis has been estimated at 1/140 (Beighton et al., 1976). Serum sclerostin levels in sclerosteosis carriers are reported to be approximately 60% lower than in healthy control subjects, while serum P1NP and BMD at the lumbar spine and hip were higher in sclerosteosis carriers than in age- and sex-matched healthy controls (Van Lierop et al., 2017). These heterozygous individuals do not show signs or symptoms of sclerosteosis, which is indicative of a gene-dose effect of the *SOST* mutation. This supports the idea that pharmacologic inhibition of sclerostin may have potential for the development of bone-forming therapeutics for osteoporosis and other bone-related disorders.

Patients with van Buchem disease (OMIM: 239100) display skeletal changes similar to those of patients with sclerosteosis. However, the skeletal phenotype in van Buchem disease is milder and individuals tend to be of normal height and do not display syndactyly. The condition is mostly restricted to inhabitants of a single isolated fishing village in the Netherlands, which was an island until its reconnection to the mainland following land reclamation in 1940. In contrast with the *SOST* gene-coding region mutations found in sclerosteosis patients, van Buchem disease is caused by deletion of a 52-kb, noncoding, *SOST*-specific regulatory element located 35 kb downstream of the *SOST* gene. This region contains at least one enhancer element that is required for postnatal expression of sclerostin in bone (Balemans et al., 2002; Loots et al., 2005).

More recently, an additional sclerostin−bone axis was reported following the discovery of novel missense mutations in the gene for LRP4 (also known as multiple epidermal growth factor-like domain 7) in patients with the HBM condition termed sclerosteosis 2 (OMIM: 614305), a condition that bears striking similarities to sclerosteosis (Leupin et al., 2011). Individuals carrying homozygous or heterozygous mutations in LRP4 exhibit the typical characteristics of sclerosteosis,

TABLE 74.1 Summary of *SOST* mutations reported to be associated with sclerosteosis, and selected clinical characteristics.

cDNA mutation	Protein change	Type	Number of cases	Geographical origin	Tall stature	Syndactyly	Facial involvement (distortion or palsy)	Hearing loss	Raised intracranial pressure or headaches	Increased BMD

including syndactyly and cortical thickening of the skull and long bones. The causative mutations, R1170Q/W and W1186S, are located within the central pocket of the third β propeller of LRP4 (Leupin et al., 2011; Fijalkowski et al., 2016). These mutations impair sclerostin binding to LRP4, leading to increased BMD, and suggest that LRP4 may act as a chaperone to facilitate the action of sclerostin.

Expression of sclerostin protein

During embryogenesis, sclerostin is expressed in the skeletal anlage and limb bud (Loots et al., 2005). Expression of sclerostin is maintained throughout aging and is largely limited to the skeleton, where it is expressed by mature osteocytes but not by early osteocytes, osteoblasts, or bone-lining cells (Poole et al., 2005). Low levels of sclerostin expression are also detected in mineralized matrix-associated cells, including cementocytes (Lehnen et al., 2012), hypertrophic chondrocytes in the growth plate and articular chondrocytes (Chan et al., 2011; Van Bezooijen et al., 2009; Winkler et al., 2003), synovial tissue cells from patients with rheumatoid arthritis (Wehmeyer et al., 2016), and mineralized lesions within the vascular system and aortic valves (Brandenburg et al., 2013; Koos et al., 2013; Zhu et al., 2011). Low levels of sclerostin are also found in nonmineralizing tissues, including aorta, kidney, and some regions of the developing embryonic and neonatal heart (although not adult cardiac tissue) (Balemans et al., 2001; Fijalkowski et al., 2016; Poole et al., 2005; Lehnen et al., 2012; Chan et al., 2011; Van Bezooijen et al., 2009; Winkler et al., 2003; Wehmeyer et al., 2016; Brandenburg et al., 2013; Koos et al., 2013; Zhu et al., 2011; Didangelos et al., 2010; Krishna et al., 2017; van Bezooijen et al., 2007).

Osteocytes are thought to fulfill a mechanosensing role in the skeleton, and sclerostin is a candidate mediator of mechanotransduction. Sclerostin is detected in the canalicular network of bone (Poole et al., 2005); its expression by osteocytes is reduced following mechanical loading and it is at increased levels in unloaded bone (Robling et al., 2008). In common with most cells, osteocytes release extracellular vesicles (EVs) in vivo (McCormick et al., 2016; Brown et al., 2016) and EVs released from osteocyte cell lines cultured in vitro have been shown to contain sclerostin (Brown et al., 2016; Wang et al., 2017). Sclerostin is also detected in the circulation (Van Lierop et al., 2017), although the relevance of serum sclerostin in the context of skeletal homeostasis is currently unclear.

The *SOST* gene is subject to epigenetic regulation, and methylation of the *SOST* proximal promoter has been proposed as the mechanism by which *SOST* expression is regulated during osteoblast-to-osteocyte transition (Delgado-Calle et al., 2012). The histone deacetylases SIRT1 and HDAC4/5 are reported to repress *SOST* expression, and HDAC4/5 have been associated with transcriptional downregulation of *SOST* in response to parathyroid hormone (PTH) (Cohen-Kfir et al., 2011; Wein et al., 2016).

Structure and functional domains of sclerostin

The secreted glycoprotein sclerostin was first identified as a member of the DAN/Cerberus family and thus was predicted to contain a cysteine knot motif (Balemans et al., 2001; Brunkow et al., 2001). While most cysteine-knot proteins exist as dimers, sclerostin lacks the classical free cysteine that typically mediates dimerization in this class of protein. Hence, sclerostin exists as a monomer of approximately 21 kDa. In 2009, two research groups determined the structure of sclerostin in solution using nuclear magnetic resonance (NMR) spectroscopy (Veverka et al., 2009; Weidauer et al., 2009). In addition to highly flexible N and C termini, sclerostin contains a variety of structural features arranged around the cysteine knot, including a structured core, which can bind heparin, and the disordered "loop 2" region that is important for binding to the LRP5/6 Wnt coreceptors. Efforts to generate a crystal structure of sclerostin, either as the apo-protein or in complex with antibody fragments or the extracellular domain(s) of any of its cognate receptors, have so far been unsuccessful. This probably reflects the highly dynamic and flexible nature of sclerostin.

Sclerostin mechanism of action in the skeleton

Sclerostin interaction with LRP4/5/6

At around the same time that mutations in the *SOST* gene were discovered as the cause of sclerosteosis, the discovery of low and high bone mass mutations in the first β propeller of the LRP5 Wnt coreceptor revealed the importance of the Wnt signaling pathway as a central regulator of bone formation (Gong et al., 2001; Van Wesenbeeck et al., 2003). Subsequently, sclerostin was demonstrated to function as an antagonist of Wnt signaling through high-affinity binding to the extracellular domains of LRP5/6 (Li et al., 2005; Semenov et al., 2005); crucially, the link was made demonstrating that the

presence of HBM mutations in LRP5 impaired sclerostin binding and function (Semenov and He, 2006). The highly flexible loop 2 region of sclerostin contains an NxI motif (where N represents asparagine; x, any amino acid; and I, isoleucine), which interacts with the central region of the first β propeller of the LRP5/6 Wnt coreceptors (Bourhis et al., 2011; Holdsworth et al., 2012). This interaction echoes the classical "shutter-binding" mechanism that typically occurs between β-propeller-containing lipoprotein receptors and their ligands (Andersen et al., 2013).

Despite its structural similarity to LRP5/6, LRP4 is not believed to participate directly in canonical Wnt signaling, which is initiated following the formation of a ternary complex with Wnt and Frizzled (Fzd). The presence of HBM LRP4 mutations and the blockade of sclerostin binding using an LRP4 antibody are both associated with an increase in serum sclerostin, as well as an increase in bone mass (Fijalkowski et al., 2016; Chang et al., 2014). This suggests that the role of LRP4 in bone is to anchor sclerostin within osseous tissue. Similarly, mice with the LRP4 HBM R1170Q knock-in mutation show elevated serum sclerostin and a decrease in the proportion of osteocytes staining positive for sclerostin in the tibia (Boudin et al., 2017). Sclerostin binds LRP4 with high affinity in vitro and LRP4 overexpression in a Wnt reporter cell line has been shown to enhance the efficacy of sclerostin as a Wnt signaling antagonist (Leupin et al., 2011), while silencing of LRP4 impairs sclerostin function. Although the LRP4 HBM mutations have identified the central region of the third β propeller as the site of interaction with sclerostin, the reciprocal region of sclerostin that binds LRP4 and the molecular basis of this interaction remain to be fully defined.

Sclerostin inhibition of the canonical Wnt signaling pathway

Due to its sequence homology with other secreted bone morphogenetic protein (BMP) antagonists, sclerostin was originally thought to function as a modulator of the BMP pathway. High-affinity interactions between sclerostin and several BMP family members resulting in decreased BMP binding to type 1 and 2 BMP receptors have been reported (Winkler et al., 2003). Sclerostin has also been found to promote the intracellular degradation of BMP7 in vitro (Nusse and Clevers, 2017). However, compared with the well-established role of sclerostin as an antagonist of Wnt signaling, its effects on the BMP pathway are poorly understood and the physiological relevance of the described observations is unclear.

Following the discovery of the first mammalian Wnt family member in 1982, the Wnt signaling pathway is now recognized as an evolutionarily conserved cascade that is a central regulator of developmental processes, normal physiology, and disease (reviewed by Nusse and Clevers, 2017). Three major Wnt signaling pathways are recognized: the Wnt/β-catenin pathway (also called the canonical Wnt pathway), the noncanonical Wnt/planar cell polarity pathway, and the Wnt/calcium pathway. While both the canonical and the noncanonical Wnt signaling cascades play a role in bone homeostasis, the canonical pathway has emerged as the predominant regulator of bone metabolism (reviewed by Baron and Kneissel, 2013) and is the pathway upon which sclerostin acts. Increased canonical Wnt signaling favors osteogenic commitment and the differentiation of mesenchymal stem cells (MSCs), with concomitant repression of differentiation along the chondrogenic and adipogenic lineages (Baron and Kneissel, 2013).

The Wnt signaling pathway is highly complex, with multiple Wnt ligands and receptor subtypes and intricate intracellular regulatory mechanisms. It is beyond the scope of this chapter to address this pathway in detail; rather, a simplified overview of the pathway is provided to describe the role and mechanism of action of sclerostin. Activation of the canonical Wnt pathway is triggered by the binding of soluble Wnt ligands to the extracellular domains of the Fzd and LRP5/6 cell surface receptors. Formation of this ternary complex results in the stabilization and accumulation of β-catenin, which translocates to the nucleus and associates with transcription factors to regulate target gene transcription. Binding of osteocyte-secreted sclerostin to LRP5/6 prevents LRP5/6 from interacting with Wnt, thereby inactivating the canonical Wnt pathway and targeting β-catenin for proteasomal degradation. This leads to the inhibition of Wnt target gene transcription and decreased bone formation. Antibodies that bind sclerostin and prevent its interaction with LRP4/5/6 restore canonical Wnt signaling, leading to an increase in bone formation. Fig. 74.1 shows a simplified representation of the action of sclerostin as a secreted antagonist of canonical Wnt signaling, and the restoration of Wnt/β-catenin pathway activation in the presence of Scl-Ab.

Sclerostin effects on mesenchymal stem cells

Sclerostin directly modulates osteoblast function. In vitro, recombinant sclerostin inhibits the proliferation, alkaline phosphatase activity, and mineralization of human MSCs, while apoptosis is increased by sclerostin (Winkler et al., 2003; Sutherland et al., 2004). Similarly, ex vivo osteogenic cultures of MSCs, and primary calvarial osteoblasts from transgenic mice overexpressing sclerostin (hereafter, referred to as *SOST* transgenic mice), show a decrease in alkaline phosphatase expression and a decrease in mineralization compared with control cultures or wild-type littermate controls (Winkler et al., 2003; Yorgan et al., 2015). Of the different stages of osteogenic differentiation of MSCs, it is the late osteoblast/

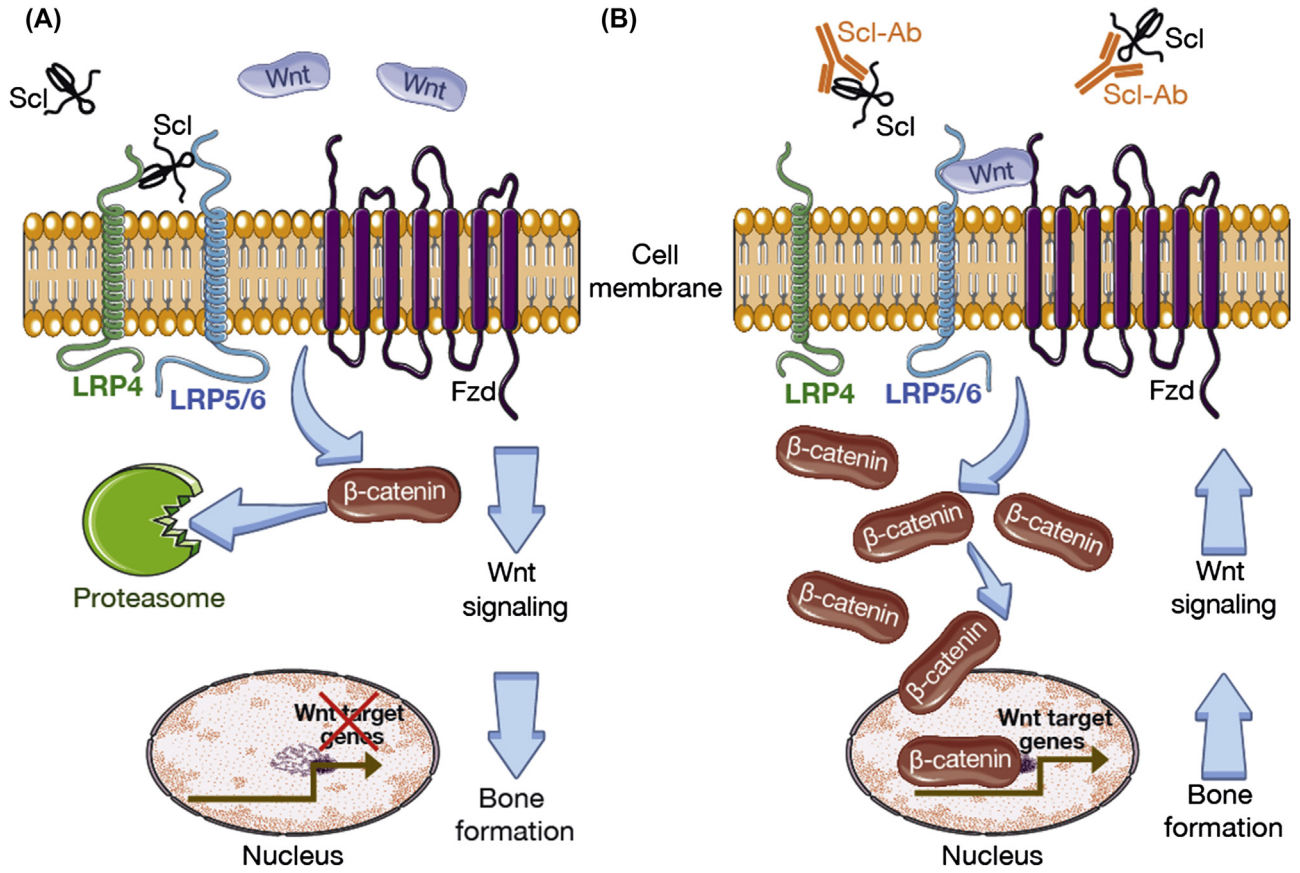

FIGURE 74.1 Mechanism of action of sclerostin as an antagonist of the canonical wingless-related integration site (*Wnt*) signaling pathway in bone tissue. (A) Sclerostin (*Scl*) binds the low-density lipoprotein receptor–related protein 4 (*LRP4*) and LRP5/6 cell surface receptors to block the interaction of Wnt with LRP5/6, thus preventing formation of the LRP5/6–Wnt–Frizzled (*Fzd*) ternary complex and inhibiting canonical Wnt signaling. Cytosolic β-catenin is targeted for proteasomal degradation and bone formation is inhibited. (B) Neutralizing antibodies to sclerostin (*Scl-Ab*) bind Scl to prevent the interaction between Scl and LRP4/5/6, thereby allowing Wnt to bind LRP5/6 and permitting formation of the LRP5/6–Wnt–Fzd ternary complex to stimulate canonical Wnt signaling. Cytosolic β-catenin accumulates and translocates to the nucleus, where it activates the transcription of Wnt target genes, leading to increased bone formation. This figure was produced using Servier Medical Art.

preosteocyte population that appears to be the most sensitive to sclerostin. Terminal differentiation of late osteoblasts into osteocytes is inhibited by sclerostin and in part reflects sclerostin-mediated regulation of the matrix extracellular phosphoglycoprotein (MEPE)–acidic serine aspartate-rich MEPE–associated motif axis, which is involved in mineralization of the newly formed bone matrix (Atkins et al., 2011). The action of sclerostin as an antagonist of Wnt signaling has also been shown in mouse preosteoblast MC-3T3 cells bearing a luciferase reporter of canonical Wnt pathway activation (Veverka et al., 2009).

Regulation of canonical Wnt signaling to control MSC differentiation has been demonstrated in vitro. In contrast to the widely studied effects of sclerostin on the osteoblast lineage, the action of sclerostin on chondrocytes and adipocytes is less well characterized. Addition of sclerostin to primary articular chondrocytes cultured in vitro reduces apoptosis and promotes chondrocyte homeostasis by inhibiting canonical Wnt signaling, decreasing expression of proteases implicated in cartilage degradation, and increasing expression of anabolic genes (Chan et al., 2011; Bouaziz et al., 2015). Inhibition of Wnt signaling by sclerostin was shown to induce adipogenesis in 3T3-L1 cells and bone marrow–derived MSCs (Fairfield et al., 2017), and promoted expression of UCP1, which is a marker of beige adipocytes (Fulzele et al., 2017).

Genetic manipulation of sclerostin expression in mice: *SOST* knockout and overexpression

Sclerostin is highly conserved across vertebrates and the amino acid sequences in rats and mice show at least 88% identity with the human sequence (Brunkow et al., 2001). Canonical Wnt signaling is an ancient and evolutionarily conserved pathway in metazoans. Animal models have proved to be highly informative translational models in which to study sclerostin function and have confirmed the significant role of sclerostin as an inhibitor of bone formation.

The sclerosteosis phenotype has been reproduced in mice through targeted deletion of the *SOST* gene. *SOST*-knockout (KO) mice exhibit increased BMD throughout the skeleton, which is apparent as early as 1 month of age (Kramer et al., 2010; Li et al., 2008; Lin et al., 2009). Progressive increases in leg and spine BMD have been observed from 1 to 4 months of age in male *SOST* KO mice, after which time leg BMD continues to increase, but at a slower rate, during months 4 to 12, with maintenance of peak BMD up to 18 months of age. Lumbar spine BMD in these mice peaks at 4 months of age and is sustained at this level up to 18 months (Ke et al., 2012). A similar profile of continuous increases in total and femoral BMD has also been observed in female *SOST*-KO mice compared with their wild-type littermates, with a rapid and progressive increase in BMD from 4 to 12 weeks of age, and a slower rate of BMD gain during weeks 12−40 (Lin et al., 2009).

Significant increases in trabecular thickness and bone volume fraction, as well as cortical thickness, have also been reported in *SOST*-KO mice (Ke et al., 2012; Kramer et al., 2010; Li et al., 2008; Lin et al., 2009). Dynamic histomorphometric analyses of bones from these mice demonstrated vastly greater mineralizing surface as a ratio to bone surface and markedly higher ratio of bone formation rate (BFR) to bone surface on trabecular bone surfaces. Elevated serum osteocalcin levels were also observed compared with wild-type littermates. The bones of *SOST*-KO mice display a normal lamellar bone structure, and the increased cortical thickness reflects accrual of bone on both endocortical and periosteal surfaces. Consistent with the increased bone formation and bone mass, bones from sclerostin-deficient male or female mice exhibited robust increases in mechanical strength upon testing of lumbar vertebral bodies and long bones (Li et al., 2008).

In agreement with the role of sclerostin as an antagonist of Wnt/β-catenin signaling, genetic deletion of *SOST* is associated with enhanced activation of this pathway in bone. A greater proportion of osteocytes show staining for β-catenin expression compared with osteocytes from wild-type mice. Furthermore, immunohistochemical staining revealed a significant reduction in apoptotic osteocytes in *SOST*-KO bone (Krause et al., 2010; Lin et al., 2009), suggesting a potential role for sclerostin in regulating osteocyte longevity. Bone composition analysis revealed that deletion of the *SOST* gene was associated with slower mineralization kinetics and a higher proteoglycan content of the endocortical bone matrix (Belkhribchia et al., 2014), which may contribute to the increased bone strength observed in the bones of *SOST*-deficient mice. Ovariectomy of female *SOST*-KO mice resulted in increased bone resorption, indicating that the impact of estrogen deficiency on bone resorption is maintained in mice lacking sclerostin (Ke et al., 2012).

As a counterpoint to the HBM phenotype in *SOST*-KO mice, *SOST* transgenic mice exhibit low bone mass and a reduction in bone strength due to decreased bone formation (Leupin et al., 2011; Winkler et al., 2003; Yorgan et al., 2015; Kramer et al., 2010). Three different approaches have been used to develop these models: one method expressed human sclerostin using a bacterial artificial chromosome (BAC) (Loots et al., 2005; Kramer et al., 2010), while other methods employed the mouse osteocalcin promoter, *OG2* (Winkler et al., 2003), or the mouse osteoblast-specific 2.3-kb *Col1a1* promoter (Yorgan et al., 2015) to overexpress human sclerostin in bone. Compared with their respective wild-type littermates, all three transgenic models exhibited reduced trabecular bone volume and cortical thickness within the axial and appendicular skeleton (lumbar spine, calvaria, and femur). The reduction in femoral cortical thickness was apparent in young mice and persisted through 8 months in the BAC−*SOST* model (Kramer et al., 2010), while vertebral trabecular bone volume was reduced at 6 weeks and persisted through 12 months in mice bearing the *Col1a1*−*SOST* transgene (Yorgan et al., 2015). Dynamic histomorphometry revealed a decreased BFR but no significant effect on bone resorption parameters in each transgenic model. Consistent with the reduction in bone formation and bone mass, the bones of *SOST* transgenic mice exhibit impaired mechanical strength and greater fragility compared with their wild-type littermate controls (Winkler et al., 2003).

Antibodies to neutralize sclerostin (Scl-Ab)

The concept of sclerostin inhibition has emerged as a potential approach for the treatment of osteoporosis and other skeletal disorders associated with low bone mass. Several Scl-Ab that block the function of sclerostin, including romosozumab (AMG785), blosozumab, and setrusumab (BPS804), have been tested in the clinical setting (Padhi et al., 2011; McColm et al., 2014; Seefried et al., 2017) and are briefly discussed later in this chapter. Various approaches have been used to generate Scl-Ab, including immunization-led antibody discovery campaigns and screening of synthetic human fragment antigen binding display libraries (Veverka et al., 2009; Back et al., 2012; Rothe et al., 2008). Neutralization of sclerostin function can be achieved by inhibiting its interaction with LRP4/5/6. NMR mapping experiments have revealed the binding sites of two research antibodies that interact with the sclerostin loop 2 region, the region that harbors the conserved NxI motif through which sclerostin binds LRP5/6 (Veverka et al., 2009; Boschert et al., 2016). While certain Scl-Ab, including romosozumab, block the interaction of sclerostin with LRP5/6 but not LRP4, other antibodies display the

converse effect and block binding to LRP4 but not LRP5/6 (Holdsworth et al., 2012; Gong et al., 2016). This may reflect differences in the epitopes recognized by individual Scl-Ab.

Pharmacologic inhibition of sclerostin by Scl-Ab: cell-level effects

Osteoblast lineage

Recombinant sclerostin inhibits mineralization of the mouse MC-3T3 osteoprogenitor cell line in vitro and addition of Scl-Ab to the culture medium reverses this effect (Li et al., 2009). In MC-3T3 cells modified to express a reporter of Wnt pathway activation, addition of Scl-Ab blocked the inhibitory effect of sclerostin on canonical Wnt signaling (Veverka et al., 2009). In vitro cultures of bone marrow stromal cells from mice treated with Scl-Ab form a greater number of alkaline phosphatase-positive colonies and mineralized nodules compared with cells from control mice (Shahnazari et al., 2012). Further evidence for the role of sclerostin on osteoblast lineage cells comes from in vivo experiments using Scl-Ab. For example, lineage tracing experiments show that Scl-Ab promotes the conversion of quiescent bone-lining cells into active osteoblasts on periosteal and endocortical surfaces in mice. This contributes to a rapid increase in osteoblast numbers and may involve activation of Wnt signaling in this cell population (Kim et al., 2017). Sclerostin may therefore contribute to the maintenance of bone-lining cells in a quiescent state on inactive bone surfaces.

In addition to the reactivation of bone-lining cells, administration of Scl-Ab in rodents increases osteoblast numbers concurrent with increased bone formation (Ominsky et al., 2015; Taylor et al., 2016), which is consistent with enhanced recruitment of osteoprogenitor cells to the bone surface (Greenbaum et al., 2017). The effects of Scl-Ab on individual osteoblasts were deduced through careful analysis of the time-dependent action of Scl-Ab on osteoblast lineage cells, characterized by the expression of runt-related transcription factor 2 (RUNX2) and neuroectodermal stem cell marker (Nestin) in osteoblasts and osteoprogenitors, respectively (Ominsky et al., 2015). In this study, at 4 and 26 weeks, the bone formation per osteoblast was higher in rats dosed with Scl-Ab compared with either the vehicle control or PTH(1−34). Both Scl-Ab and PTH(1−34) increased both osteoblast and osteoprogenitor number at the early (4-week) time point. While this effect was maintained in the PTH(1−34) group at the later (26-week) time point, it was attenuated in the Scl-Ab-treated group at this time point. This finding is indicative of the self-regulation of the bone-forming response, which occurs with prolonged Scl-Ab treatment in vivo. The mechanism for self-regulation of bone formation with longer-term treatment with Scl-Ab is a continuing area of investigation. As discussed later, the upregulation of other Wnt antagonists may contribute to this self-regulation.

Antibody-mediated inhibition of sclerostin promotes proliferation of osteogenic cells in the cambium layer of the periosteum in both young and geriatric (20-month-old) mice (Thompson et al., 2016). Lineage tracing approaches show that Scl-Ab promotes preferential differentiation of multipotent MSC-derived skeletal precursors toward early osteoblast precursors, increasing the number of osteoprogenitors through enhanced proliferation and decreased apoptosis (Trinh et al., 2017). Reduced apoptosis of osteoblasts and osteocytes was observed in mice treated with Scl-Ab following exposure to ionizing radiation, a finding that was associated with enhanced expression of DNA repair proteins by these cells in response to sclerostin inhibition (Chandra et al., 2017). Enhanced activity of individual osteoblasts ("osteoblast vigor") in response to Scl-Ab is reflected in studies performed in rats, where mineral apposition rate and bone formation per osteoblast were increased compared with controls (Ominsky et al., 2015).

Administration of Scl-Ab would be expected to cause enhanced Wnt signaling in target cells and, accordingly, treatment of male rats with Scl-Abs was found to increase β-catenin expression in endocortical osteoblasts (Suen et al., 2015). The temporal effects of Scl-Ab on the transcriptional profile of mature osteoblast lineage cells in bone samples enriched for bone-lining cells, osteoblasts, or osteocytes has been explored in vertebrae collected from ovariectomized (OVX) rats. In these studies, Scl-Ab rapidly increased expression of extracellular matrix genes and a subset of Wnt target genes. During the first week of treatment, bone-lining cells, osteoblasts, and osteocytes all displayed similar transcriptional patterns (Nioi et al., 2015). Longer-term treatment was associated with normalization of some Wnt target genes while the expression of secreted Wnt antagonists, including *SOST* and Dickkopf-related protein 1 (*DKK1*), was increased (Taylor et al., 2016; Holdsworth et al., 2017). Similar observations were made in femoral shafts collected from mice dosed with Scl-Ab. Interestingly, a synergistic bone-formation response has been observed when simultaneously inhibiting sclerostin and *DKK1*, further strengthening the role of additional Wnt regulators in the pharmacologic response to Scl-Ab (Florio et al., 2016). In addition to upregulation of *SOST* and *DKK1*, increased expression of mRNA transcripts encoding other secreted antagonists of Wnt signaling, including several secreted Fzd-related proteins and Wnt inhibitory factor 1, has been demonstrated (Holdsworth et al., 2017). Alterations in osteocyte expression of genes and pathways involved in the inhibition of cell cycle progression and mitogenesis, including activation of *p53* and inhibition of *c-Myc* signaling, occur

following chronic Scl-Ab treatment (Taylor et al., 2016). These changes are believed to contribute to self-regulation of the bone-forming response that occurs with longer-term Scl-Ab administration.

Further evidence for the effect of Scl-Ab on the osteocyte comes from observations that treatment with Scl-Ab restores osteocyte morphology and connectivity following spinal cord injury (Qin et al., 2015) or in the absence of periostin (Ren et al., 2015), and prevents the decrease in lacunar occupancy and osteocyte apoptosis following chronic exposure to glucocorticoids (Achiou et al., 2015).

Osteoclast lineage

Although sclerostin is not expressed by osteoclasts, there is evidence that it indirectly increases bone resorption by promoting osteoclast formation and activity. However, the mechanisms are not fully understood as of this writing. Experiments undertaken using in vitro cultures of mouse osteocyte-like MLO-Y4 cells suggest that sclerostin may regulate osteoclastogenesis by altering the ratio of receptor activator of nuclear factor-κB ligand (RANKL) to osteoprotegerin (OPG) expressed by these cells. In coculture of these cells with mouse splenocytes or human peripheral blood mononuclear cells, exogenous sclerostin enhanced osteoclastogenesis through RANKL-dependent formation of tartrate-resistant acid phosphatase form 5b (TRAP5b)-positive multinucleated cells that showed greater resorptive activity compared with control cocultures (Wijenayaka et al., 2011). Transcriptional analysis of osteoblast lineage cells in rats provides further evidence for Scl-Ab regulation of the RANKL/OPG ratio, as demonstrated by increased OPG expression and minimal effects on RANKL (Taylor et al., 2016). Ex vivo cultures of bone marrow osteoclast progenitors from OVX rats treated with Scl-Ab showed a reduction in the number of TRAP5b-positive osteoclast-like cells compared with controls, although serum concentrations of OPG and RANKL were unaffected in this study (Stolina et al., 2014). However, the expression of RANKL was reduced upon administration of Scl-Ab to in vitro organ cultures of mouse bones, with enhanced osteocyte Wnt signaling (Tu et al., 2015). Interestingly, mice with gain-of-function mutations in β-catenin resulting in elevated canonical Wnt signaling display increased bone resorption with enhanced expression of both *OPG* and *RANKL* (Tu et al., 2015). These data suggest that regulation of the OPG/RANKL balance is likely to play a pivotal role in the antiresorptive effect of Scl-Ab. In addition, increased expression of Wnt1-induced secreted protein 1 and decreased abundance of colony-stimulating factor 1 in osteoblast lineage cells (Taylor et al., 2016) may further contribute to the indirect inhibition of osteoclastogenesis by Scl-Ab. Fig. 74.2 illustrates the effects of Scl-Ab on osteoblast and osteoclast lineages within the bone microenvironment.

Pharmacologic inhibition of sclerostin by Scl-Ab in vivo

Effects of Scl-Ab in animal models of postmenopausal osteoporosis

Action of Scl-Ab on modeling- and remodeling-based bone formation

Scl-Ab promotes bone mass accrual with a unique mechanism of action resulting in increased osteoblast activity and decreased osteoclast activity. In OVX rats, a decrease in eroded and osteoclast surfaces is evident following 5 weeks of treatment with Scl-Ab (Li et al., 2009; Ominsky et al., 2014) and is maintained through 6 months of treatment (Li et al., 2014).

Increased bone formation, as indicated by transcriptional changes reflecting increased matrix production in osteoblast lineage cells, is observed soon (6 hours) after exposure to Scl-Ab in OVX rats (Nioi et al., 2015). These changes are later accompanied by further evidence of enhanced bone formation, including enlarged osteoblast surface, osteoid surface, and mineralization surface after 8 days. The process of osteoblast activation on quiescent surfaces results in an increase in modeling-based bone formation (MBF), defined as bone formation on bone surfaces where preexisting bone resorption is absent. An increase in MBF on the trabecular surfaces of vertebrae is observed in rats and cynomolgus monkeys following exposure to Scl-Ab for 5 and 10 weeks, respectively (Ominsky et al., 2014). Importantly, increases in MBF are not limited to the vertebrae, but are also detected within the long bones of the skeleton. For example, MBF is increased from 7% to 77% of the endocortical bone surface in the femur of cynomolgus monkeys (Ominsky et al., 2014). Furthermore, an increase in MBF in response to Scl-Ab is apparent on the periosteal surface, and the effect on each of these sites is dose-dependent (Ominsky et al., 2010). Similar bone formation events have been reported in the periosteal and endocortical regions of OVX rats (Li et al., 2014). Notably, promotion of MBF in the OVX rat has been documented with different sclerostin antibodies (Amgen, Inc./UCB Pharma, detailed above, and Eli Lilly and Company; Ma et al., 2017), further supporting the role of Scl-Ab in promoting bone formation.

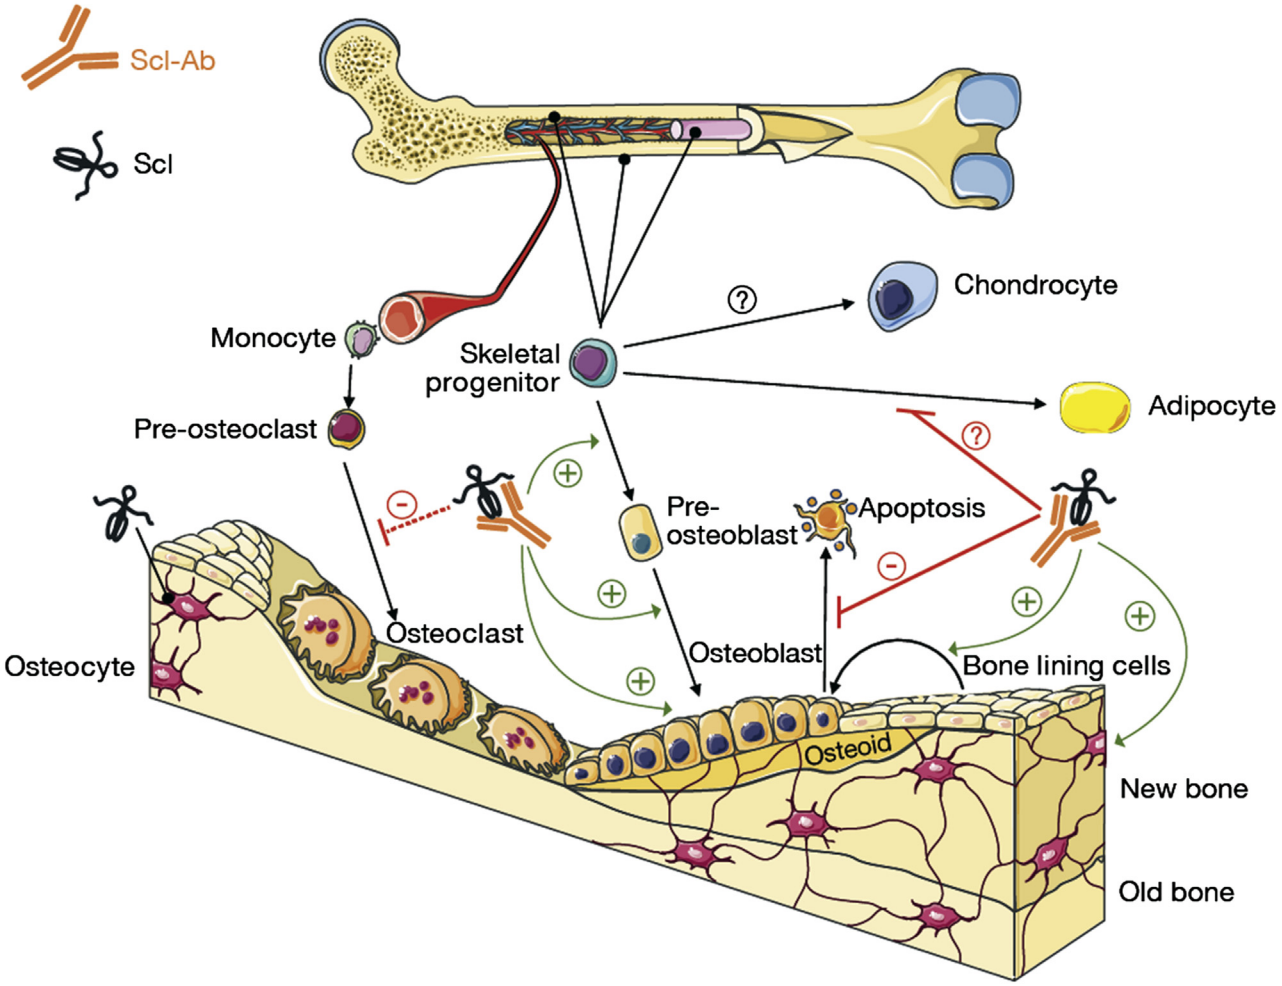

FIGURE 74.2 Effects of neutralizing antibodies to sclerostin (*Scl-Ab*) on bone formation and resorption. Inhibition of canonical Wnt signaling by sclerostin (*Scl*) in osteoblast lineage cells inhibits osteoblast-mediated bone formation and increases bone resorption by osteoclasts. Scl-Ab promotes bone formation via enhanced recruitment of osteoprogenitor cells, increased matrix production by osteoblasts, and reactivation of quiescent bone-lining cells. In addition, inhibition of osteoblast apoptosis by Scl-Ab contributes to the increased bone formation. Scl-Ab treatment also indirectly decreases bone resorption by modulating the expression of osteoclast regulators (produced by osteoblast lineage cells), including receptor activator for nuclear factor κB ligand/osteoprotegerin, colony-stimulating factor 1, and Wnt1-induced secreted protein 1. This figure was produced using Servier Medical Art.

The effects of Scl-Ab on remodeling-based bone formation (RBF) have been investigated in rat and cynomolgus monkey models. Scl-Ab increases the life span of the formative site (where walls of newly mineralized bone form following bone resorption) during RBF. This results in a positive net effect on bone volume at this site. However, this may be apparent only during the early stages of treatment, as shown in cynomolgus monkeys during weeks 2−10 of dosing, but not at week 28. Nevertheless, the remodeling sites in the vertebrae at the later time point did show a positive bone balance (increased wall thickness relative to resorption depth) (Boyce et al., 2017).

The positive effects on both modeling and remodeling bone formation lead to a large bone mass accrual; Fig. 74.3 summarizes the effects of sclerostin antibody on modeling- and remodeling-based bone formation. A transient bone formation response is observed following Scl-Ab treatment. Indeed, serum bone-formation markers, such as P1NP, bone-specific alkaline phosphatase (BSAP), and osteocalcin, are increased relative to vehicle control groups during the first 3 months of Scl-Ab treatment. Subsequently, these markers decrease toward baseline levels during months 6−12 of treatment (Ke et al., 2012; Li et al., 2014; Recker et al., 2015; Ominsky et al., 2012). The reduction in serum bone-formation markers correlates with a reduction in bone tissue formation, which is most evident within the lumbar vertebrae of OVX rats (Li et al., 2014) and intact cynomolgus monkeys (Ominsky et al., 2012). Interestingly, this attenuated response appears to be site specific; endocortical regions of the femoral diaphysis continue to display increases in bone

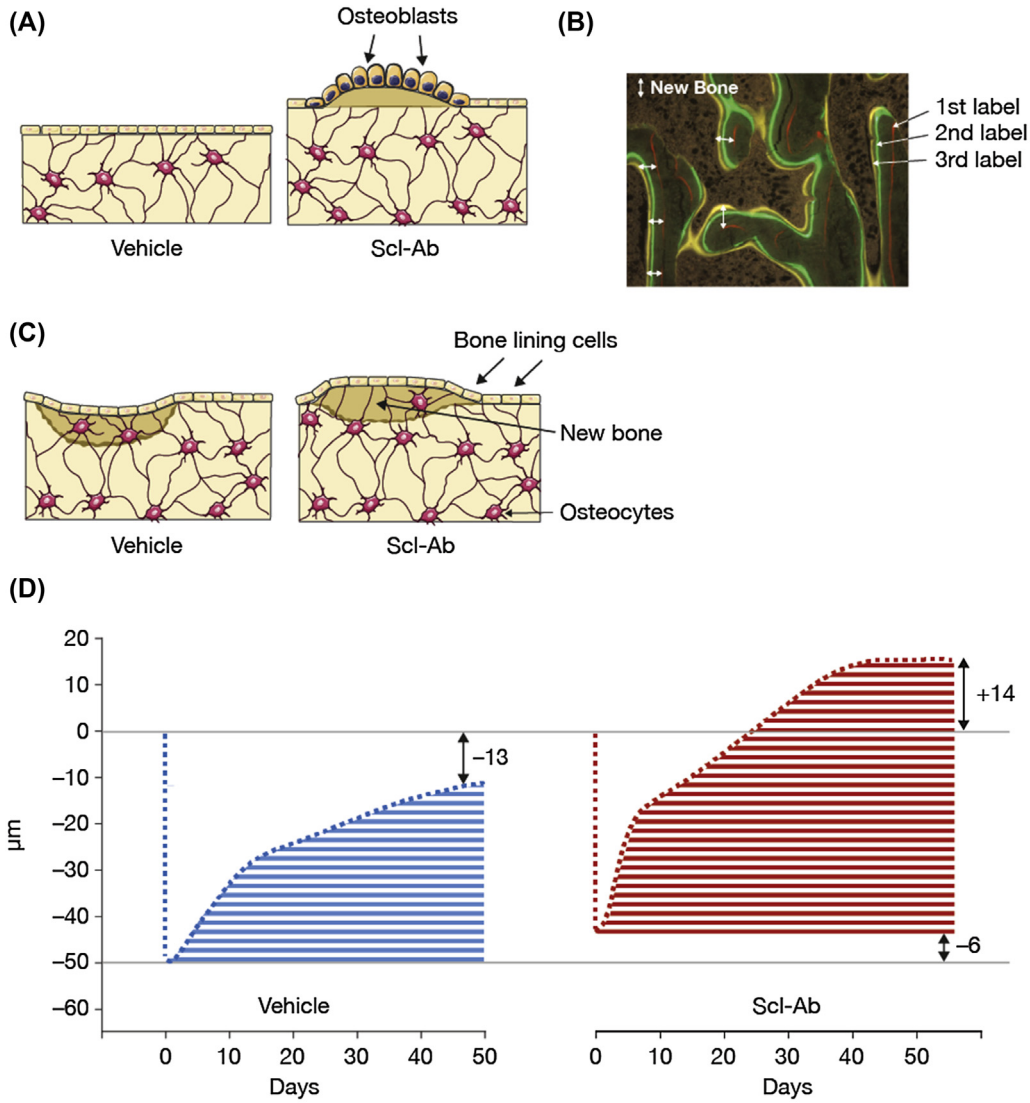

FIGURE 74.3 Tissue-level mechanisms of pharmacologic inhibition of sclerostin by sclerostin neutralizing antibody (*Scl-Ab*) on modeling-based bone formation and remodeling-based bone formation. (A) Modeling-based bone formation: illustration of bone formation by osteoblasts on a quiescent bone surface (i.e., without preexisting bone resorption) induced by Scl-Ab treatment. (B) An example of bone formation on a quiescent bone surface without preexisting bone resorption using dynamic histomorphometry. The fluorescence image shows an undecalcified 8-µm section of trabecular bone from the fifth lumbar vertebral body of an ovariectomized rat treated with Scl-Ab at 25 mg/kg, twice weekly by subcutaneous injection, for 5 weeks. The first fluorescent label was given on day 1 of Scl-Ab treatment, and the second and third fluorescent labels were given 12 and 2 days prior to autopsy. The first fluorescent label on the trabecular bone surface indirectly indicates bone formation on the quiescent surface without preexisting bone resorption. (C). Remodeling-based bone formation: illustration of bone formation following bone resorption. Scl-Ab treatment reduces the resorption pit depth and induces a greater extent of new bone formation than vehicle treatment. The amount of bone formed with Scl-Ab treatment exceeds that lost during the resorption phase of bone remodeling. Scl-Ab also extends new bone formation to include formation on the quiescent surface near the resorbed surface. (D) Illustration of the kinetic reconstruction of bone gain on the remodeling surface induced by Scl-Abs in a nonhuman primate model. The gray line at 0 µm represents the intact bone surface and the depth of the resorption site is shown by the vertical dashed lines. The filled area represents the formation of mineralized wall thickness at the formative site. Scl-Ab reduces the depth of the resorptive site (−6 µm compared with vehicle) and promotes greater wall thickness, resulting in a positive bone balance at the end of the resorption cycle (+14 µm compared with −13 µm in vehicle-treated animals). *(A and C) Modified from Ke, H.Z., Richards,W.G., Li, X., Ominsky, M.S., 2012. Sclerostin and Dickkopf-1 as therapeutic targets in bone diseases, Endocr. Rev. 33, 747−783. (D) Modified from Boyce, R.W., Niu, Q.T., Ominsky, M.S., 2017. Kinetic reconstruction reveals time-dependent effects of romosozumab on bone formation and osteoblast function in vertebral cancellous and cortical bone in cynomolgus monkeys, Bone 101, 77−87.*

formation beyond 6 months of treatment (Li et al., 2014). This extended response to Scl-Ab at cortical regions has also been documented in other studies with OVX rats (Ma et al., 2017).

Effects of Scl-Ab on bone mass and structure

The mechanism of action of Scl-Ab—increased bone formation and reduced bone resorption—leads to elevated bone mass and improved bone architecture in both cortical and trabecular compartments. In the OVX rat model, axial and peripheral BMD was restored following 5 weeks of Scl-Ab treatment versus sham treatment (Li et al., 2009). Furthermore, an increase in BMD was observed over 26 weeks at the lumbar vertebrae, which correlated with altered architecture, including increased trabecular thickness and thickness of the cortical shell (Li et al., 2014). These changes are not limited to the vertebral bones, as an increase in BMD and bone mineral content (BMC) at the femoral diaphysis was also noted. This is a direct result of increased periosteal and endosteal bone formation, with the net effect of increasing the cortical thickness. An increase in periosteal bone formation has also been reported at the femoral neck in response to Scl-Ab administration. Continued improvements in bone mass and geometry at the proximal tibial metaphysis and diaphysis were observed for up to 12 months of Scl-Ab treatment in OVX rats (Ominsky et al., 2017a). As in other animal models, bone-formation markers reached a plateau in the axial skeleton between months 6 and 12 despite continued administration of Scl-Ab.

Similar to the OVX rat model of osteoporosis, increases in bone formation have been reported in adolescent female (whole-body and distal radius metaphyseal BMC) and male cynomolgus monkeys (lumbar spine, femoral neck, and distal radius BMD) in response to treatment with Scl-Ab (romosozumab) (Ominsky et al., 2010, 2011). Interestingly, trabecular rods are converted to platelike structures because of increases in trabecular thickness (Matheny et al., 2017). This finding has great importance, as a low plate-to-rod ratio is known to be associated with increased fracture risk in osteoporosis (Wang et al., 2013; Liu et al., 2012).

Effects of Scl-Ab on bone strength and quality

The gains in bone mass and geometric bone changes in response to Scl-Ab improve bone strength at the lumbar vertebrae, femoral shaft, and femoral neck in OVX rats (Ominsky et al., 2017a). Increases in bone strength are also observed at the lumbar vertebrae, in male and female cynomolgus monkeys, in response to Scl-Ab treatment for up to 10 weeks (Ominsky et al., 2010, 2011). Consistent with this finding, adolescent cynomolgus monkeys display increased peak load strength at the lumbar vertebrae, femur midshaft, and neck following 6 months of treatment with Scl-Ab. Vertebral bone quality was maintained and a positive correlation between bone mass and bone strength (measured by peak load/force to failure) was observed with Scl-Ab at doses up to 100 mg/kg per week. Similarly, skeletally mature OVX cynomolgus monkeys dosed for 12 months with Scl-Ab displayed increased vertebral strength with maintenance of bone mass and strength relationship (Ominsky et al., 2017b).

Bone quality, as defined by the material properties and composition of the tissue, was maintained in cynomolgus monkeys dosed for 10 weeks with Scl-Ab (Ross et al., 2014). An important characteristic of bone matrix that reflects its ability to withstand mechanical strain is the level of mineralization within the tissue. Scl-Ab does not alter global mineralization of either cortical or trabecular bone tissue as assessed in male cynomolgus monkeys dosed for 10 weeks. The only change in the material properties of the matrix was an increase in lower mineralized areas due to enhanced new bone formation. No changes in tissue age-specific measurements of mineral-to-matrix ratio and no differences in hydroxyapatite crystallinity or collagen cross-linking in the endocortical, intracortical, or trabecular sites were detected. A significant increase in the trabecular compartment, of approximately 10% carbonate substitution for tissue older than 2 weeks, was observed. Interestingly, decreases in carbonate-to-phosphate ratios in bone are predictive of bone fragility fracture (Boskey et al., 2016). It is therefore unlikely that Scl-Ab treatment will negatively affect bone matrix quality or mineralization. The results from the 12-month bone quality studies using OVX rat and OVX cynomolgus monkey models (Ominsky et al., 2017a, 2017b) further demonstrated that Scl-Ab increased bone mass and strength, while maintaining bone quality in both trabecular and cortical bone compartments.

Probing Scl-Ab treatment regimens in preclinical models of osteoporosis

Clinical scenarios relating to Scl-Ab treatment have been investigated using preclinical models. The consequences of cotreatment with, or transition from and to, antiresorptive therapies have been tested in the OVX rat model. Transition from the bisphosphonate alendronate to Scl-Ab treatment did not alter the bone-forming capacity of Scl-Ab. Similar gains in mass and strength were observed in animals receiving Scl-Ab compared with those receiving vehicle alone (Li et al., 2011).

Furthermore, Scl-Ab maintained its bone-forming ability in the presence of alendronate when the agents were administered simultaneously. Similarly, when combined with zoledronate, Scl-Ab increased bone mass to a greater extent than either of the two agents alone when administered to OVX mice (Halleux et al., 2009).

It has been hypothesized that due to the attenuated response observed following 12 months of treatment with Scl-Ab, an initial Scl-Ab treatment period followed by an antiresorptive therapy may provide the optimal treatment strategy for patients with osteoporosis. Indeed, this strategy formed the treatment schedule for certain phase III clinical trials of romosozumab, a Scl-Ab in development by Amgen, Inc., and UCB Pharma. The consequences of follow-on treatment and discontinuation were deduced first in the OVX rat model. Following an initial 6-week treatment with Scl-Ab, the animals were transitioned to either vehicle or the antiresorptive RANKL inhibitor OPG-Fc for a further 20 weeks (Ominsky et al., 2017a). In this model, if transitioned to vehicle, bone mass was reduced to the level of the sham-operated controls in the Scl-Ab-treated group, but was still higher than that of OVX controls. However, transition to OPG-Fc treatment maintained the bone mass gains elicited by Scl-Ab treatment. Interestingly, the femoral diaphysis appeared to be more resistant to bone mass loss than the femoral neck or vertebrae following transition to vehicle, further underpinning the site specificity of the Scl-Ab response. The loss of bone due to transition from Scl-Ab to vehicle was also observed in OVX cynomolgus monkeys, where a gradual loss of bone mass was evident during the 6-month withdrawal period following 6 months of romosozumab treatment (Ominsky et al., 2017b). In addition to transition to OPG-Fc, transition to raloxifene and alendronate in the OVX rat (Ma et al., 2013), and zoledronate in the OVX mouse (Halleux et al., 2009), maintained Scl-Ab-mediated bone mass gains.

Re-treatment of OVX rats with Scl-Ab following withdrawal for 12 weeks restores bone mass to prewithdrawal levels, indicating restoration of pharmacologic response (Li et al., 2013). This has also been confirmed in mice, in which the bone-forming response to Scl-Ab is restored following treatment-free or "holiday" periods (Holdsworth et al., 2017) and in the clinical setting (Kendler et al., 2017). One caveat when interpreting these data is that bone loss occurs during the holiday period when all treatment is withdrawn. While it has not yet been shown that the bone-forming effects of Scl-Ab would be restored following the use of an antiresorptive agent during the Scl-Ab holiday, it has been shown that Scl-Ab treatment after alendronate effectively increases bone mass in preclinical and clinical settings (Li et al., 2011; Langdahl et al., 2017).

Effects of Scl-Ab in other animal models of low bone mass

In addition to the wealth of data generated in the OVX rat and cynomolgus monkey models of postmenopausal osteoporosis, inhibition of sclerostin by Scl-Ab has been shown to protect and restore bone mass and strength in several other animal models of low bone mass (Ke et al., 2012; Ominsky et al., 2017a). These include animal models of male osteoporosis, OI, immobilization-induced bone loss, glucocorticoid-induced osteoporosis, diabetic bone loss, radiation-induced bone loss, multiple myeloma bone diseases, and bone repair.

In an aged (16-month-old) male rat model with low bone mass, Scl-Ab treatment for 5 weeks significantly increased trabecular and cortical bone formation and restored trabecular and cortical bone mass and strength to the levels observed in young rats (Li et al., 2010). Similarly, Scl-Ab treatment for 6 weeks increased bone formation and decreased bone resorption, and completely restored bone mass and strength, in a male rat model of androgen deficiency induced by orchidectomy (Li et al., 2018). These data are consistent with the clinical observation that a dual effect of increasing bone formation and decreasing bone resorption results in significant gains in BMD at the spine and hip in men with osteoporosis following treatment with Scl-Ab (romosozumab) for 12 months (Lewiecki et al., 2016).

The efficacy of Scl-Ab in improving bone mass and bone strength has been tested in several animal models of OI, including Brtl/+ mice (a G349C point mutation on *Col1al*), Crtap$^{-/-}$ mice (a model of recessive OI), *Col1a2* G610C mice (mice with the Amish OI mutation), and *Col1a1*(Jrt)/+ mice (a model of severe dominant OI). Scl-Ab treatment showed improvements in bone formation, bone mass, and bone strength in these OI models (Little et al., 2017; Grafe et al., 2016; Sinder et al., 2013, 2014, 2016), although it may be less effective in a more severely affected model such as the *Col1a1(*Jrt)/+ mouse (Roschger et al., 2014). The efficacy of Scl-Ab in these models may be improved by use in combination with antiresorptive agents, such as bisphosphonates (Little et al., 2017), where bisphosphonates could preserve the bone gain upon cessation of Scl-Ab treatment (Perosky et al., 2016). It is worth noting that the improvements in bone mass and strength after treatment with Scl-Ab in these OI models are due to improvements in bone quantity, not bone quality. Importantly, the impaired bone quality in OI is unaffected by Scl-Ab (Sinder et al., 2016). Clinical trials to determine the benefits of Scl-Ab in patients with OI were ongoing at the time of writing.

Bone loss due to underloading—induced in animal models by hindlimb immobilization, tail suspension, neurotoxic protein (botulinum toxin)-induced muscle paralysis, and spinal cord injury—has been the subject of therapeutic agent testing. Sclerostin plays an important role in bone response to mechanical loading, as evidenced by increased sclerostin

expression with underloading and decreased expression with overloading (Robling et al., 2008; Moustafa et al., 2012). In addition, immobilization and underloading induce an increase in bone resorption and a decrease in bone formation, leading to rapid bone loss and structural damage. Scl-Ab may be a good choice of therapeutic agent for underloading-induced bone loss due to its dual action, increasing bone formation and decreasing bone resorption. Preclinical experiments of immobilization-induced bone loss models, including space shuttle-induced microgravity, demonstrate that Scl-Ab increases bone formation and decreases bone resorption, leading to increased bone mass, improved bone structure, and improved bone strength (Qin et al., 2015; Tian et al., 2011; Spatz et al., 2013; Beggs et al., 2015; Zhang et al., 2016; Bouxsein et al., 2012).

As with immobilization-induced bone loss, glucocorticoid treatment has also been shown to decrease bone formation and increase bone resorption. Scl-Ab impedes glucocorticoid-induced bone loss by preventing the decrease in osteoblast viability and bone formation, and the increase in bone resorption observed after glucocorticoid treatment (Achiou et al., 2015; Yao et al., 2016). Improvements in bone formation, bone mass, and bone strength after Scl-Ab treatment have been reported for several other forms of bone loss in animal models, including diabetic bone loss (Hamann et al., 2013), radiation-induced bone loss (Chandra et al., 2017), multiple myeloma bone diseases (Delgado-Calle et al., 2017; McDonald et al., 2017), and bone repair (see review by Ke et al., 2012).

Pharmacologic inhibition of sclerostin by Scl-Ab in humans

In humans, several Scl-Ab, namely romosozumab (AMG785), blosozumab (LY2541546), and setrusumab (BPS804), have been investigated in conditions associated with low bone mass and high risk of fragility fractures. These include postmenopausal osteoporosis (blosozumab and romosozumab), osteoporosis in men (romosozumab), adult hypophosphatasia (setrusumab), and adult moderate OI (setrusumab).

The most extensive clinical data sets have been generated in osteoporosis. These findings have been summarized in several reviews (Canalis, 2018; McClung, 2017; Lovato and Lewiecki, 2017) and will not be covered in depth in this chapter. Single- and multiple-dose phase I studies have been reported for both blosozumab and romosozumab in healthy volunteers with normal or low bone mass (Padhi et al., 2011, 2014; McColm et al., 2014). In these studies, each agent demonstrated dose-dependent increases in the serum bone-formation markers P1NP, osteocalcin, and BSAP; a dose-dependent decrease in the serum bone-resorption marker CTX; and an increase in BMD. In the follow-up phase II, dose-ranging studies in women with postmenopausal osteoporosis, administration of blosozumab or romosozumab dose-dependently increased BMD at the spine, total hip, and femoral neck, and recapitulated the rapid, dual effects on biochemical markers of bone formation and resorption reported in the phase I studies (Recker et al., 2015; McClung et al., 2014). Notably, the early response of serum markers of both bone formation and resorption to Scl-Ab is distinct from that seen following daily teriparatide (rhPTH(1−34)) or weekly alendronate treatment (McClung et al., 2014) (Fig. 74.4).

Results from phase III clinical studies evaluating the effect of romosozumab on reducing risk of fragility fractures in postmenopausal osteoporosis (Cosman et al., 2016; Saag et al., 2017) and the efficacy of the same molecule on markers of bone formation and resorption and BMD in men with osteoporosis have also been reported (Lewiecki et al., 2016). These results indicated that Scl-Ab increased bone formation and decreased bone resorption, which led to rapid and large increases in BMD in postmenopausal women and men with osteoporosis. Further, these studies also demonstrated that Scl-Ab decreased fragility fracture risk in postmenopausal women with osteoporosis compared with placebo and compared with alendronate. Increases in spine and hip BMD and estimated strength were also demonstrated versus teriparatide in postmenopausal women with osteoporosis who had transitioned from alendronate to romosozumab or teriparatide for 12 months (Langdahl et al., 2017).

In addition to the extensive clinical data generated for osteoporosis, preliminary clinical data for setrusumab have been reported following separate trials in patients with hypophosphatasia or adult moderate OI (Seefried et al., 2017; Glorieux et al., 2017). Consistent with the effects of other sclerostin antibodies in osteoporosis, administration of setrusumab to these patients resulted in increases in serum bone-formation markers and decreases in serum bone-resorption markers, leading to a mean increase in lumbar spine BMD.

Summary

Understanding the role of sclerostin in bone metabolism has led to the discovery and development of Scl-Ab as bone-forming agents for conditions associated with low bone mass, such as osteoporosis. In numerous animal models of bone loss, pharmacologic inhibition of sclerostin by Scl-Ab leads to a rapid increase in BMD and bone strength, while maintaining bone quality. The rapid bone gain induced by Scl-Ab arises from both an increase in bone formation and a

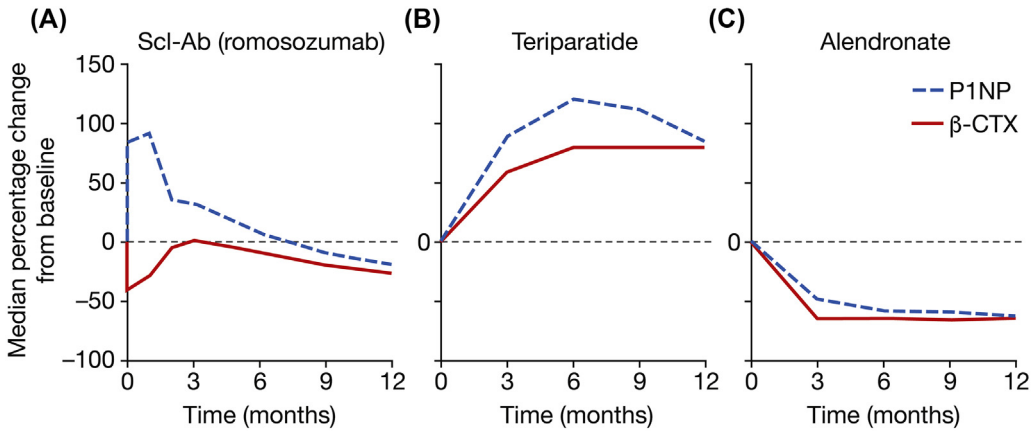

FIGURE 74.4 Effects of the sclerostin neutralizing antibody (*Scl-Ab*) romosozumab, teriparatide, and alendronate on serum markers of bone formation and bone resorption in postmenopausal women. Romosozumab increased bone formation and decreased bone resorption; teriparatide increased both bone formation and resorption, while alendronate decreased both bone formation and bone resorption. These data indicate differences in the mechanisms of action of the Scl-Ab romosozumab compared with teriparatide and alendronate. *β-CTX*, β-cross-linked C-terminal telopeptide of type I collagen; *P1NP*, procollagen type 1 N-terminal propeptide. *Modified and Reprinted from McClung, M.R., Grauer, A., Boonen, S., Bolognese, M.A., Brown, J.P., Diez-Perez, A., et al., 2014. decrease in bone resorption during the initial phase of treatment. Importantly, later gains in bone mass induced by Scl-Ab result primarily from a decrease in bone resorption, as the bone formation response is attenuated with continued treatment. The efficacy of Scl-Ab has been demonstrated in clinical trials of patients with osteoporosis, where treatment with Scl-Ab increases BMD and reduces vertebral, nonvertebral, and clinical fractures. The outcomes of trials investigating the efficacy of Scl-Ab in other indications such as OI, are ongoing at the time of writing and are eagerly awaited.

Chapter outline

Introduction

The association of vitamin D deficiency with a broad spectrum of common diseases, including breast, colorectal, and prostate cancers; cardiovascular disease; autoimmune conditions; and infections (Holick, 2007; Jones, 2007), has led to a renewed interest in using vitamin D metabolites and analogs to treat a host of clinical conditions. Since vitamin D regulates gene expression in functions as varied as calcium and phosphate homeostasis, cell growth regulation, and cell differentiation of a variety of cell types such as enterocytes, keratinocytes, and epithelial cells of the vasculature and gastrointestinal tract, it constitutes a valuable agent to modulate disease states. The discovery of the metabolites 25-hydroxyvitamin D_3 ($25(OH)D_3$; calcidiol) and 1α,25-dihydroxyvitamin D_3 ($1\alpha,25(OH)_2D_3$; calcitriol) in the early 1970s led to their chemical synthesis and, since the 1980s, the development of several generations of calcitriol analogs (Jones et al., 1998). The pharmaceutical industry has attempted to separate the *calcemic properties* of $1\alpha,25(OH)_2D_3$ from its *cell-differentiating properties* (Miyaura et al., 1981) so as to develop vitamin D analogs with specialized "calcemic" or "noncalcemic" (cell-differentiating) uses (Bouillon et al., 1995; Jones, 2008b). Several agents in the form of calcipotriol, 22-oxacalcitriol (OCT), 19-nor-$1\alpha,25\text{-}(OH)_2D_2$, and $1\alpha(OH)D_2$, with "reduced calcemic activity" have resulted, finding widespread use in the treatment of psoriasis and secondary hyperparathyroidism. Other vitamin D analogs, e.g., ED-71 and 2-MD, primarily targeted to bone, have been touted as drugs for treatment of osteoporosis. Research has also focused on the synthesis of vitamin D compounds with multiple transcriptional targets in addition to the vitamin D receptor (VDR), VDR antagonists, and cytochrome P450 family 24 (CYP24) inhibitors, which block VDR-mediated action or the catabolism of 25(OH)D and $1\alpha,25(OH)_2D$, to provide agents with possible utility in metabolic bone diseases, osteoporosis, and cancer (Jones et al., 1998; Masuda and Jones, 2006). Our perception of the importance of vitamin D/25(OH)D repletion has been modified by the concept that some $1\alpha,25(OH)_2D_3$ is produced locally by target cells, making this molecule an endocrine *and* a paracrine factor (Holick, 2007; Jones, 2007). This review will discuss the full spectrum of vitamin D compounds currently available and some of their possible uses and potential mechanisms of action.

Pharmacologically important vitamin D compounds

Vitamin D compounds can be subdivided into four major groups, listed in Tables 75.1—75.4 and described in the following sections.

Vitamin D and its natural metabolites

Table 75.1 shows the structures of vitamin D_3 and some of its important metabolites. Somewhat paradoxically, vitamin D_3, the natural form of vitamin D, is not approved for use as a drug in the United States, whereas it is found increasingly as an over-the-counter natural food supplement in the United States and is used in both roles in virtually every other country in the world.

TABLE 75.1 Vitamin D and its natural metabolites.

Vitamin D metabolite (ring structure)[a]	Side chain structure	Site of synthesis	Relative vitamin D receptor—binding affinity[b]	Relative vitamin D-binding protein—binding affinity[c]	References
Vitamin D_3 [1]		Skin	~0.001	3180	(Mellanby and Cantag, 1919; McCollum et al., 1922)
25(OH)D_3 [1]		Liver	0.1	66,800	(Blunt et al., 1968)
1α,25(OH)$_2D_3$ [3]		Kidney	100	100	(Fraser and Kodicek, 1970; Holick et al., 1971)
24(*R*),25(OH)$_2D_3$ [1]		Kidney	0.02	33,900	(Holick et al., 1972)
1α,24(*R*),25(OH)$_3D_3$ [3]		Target tissues[d]	10	21	(Holick et al., 1973)
25(*S*),26(OH)$_2D_3$ [1]		Liver?	0.02	26,800	(Suda et al., 1970)
25(OH)D_3-26,23-lactone [1]		Kidney	0.01	250,000	(Horst, 1979)

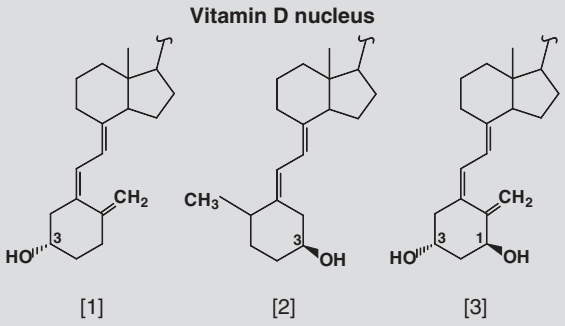
TABLE 75.2 Vitamin D prodrugs.

Vitamin D prodrug (ring structure)[a]	Side chain structure	Company	Status	Possible target diseases	Mode of delivery	References
25(OH)D_3)[1]		Generic	In use, Europe	Vitamin D deficiency	Rapid release, oral	US patent no. 3565924
		OPKO —Renal	In use, USA	CKD stage 3/4 Hyperparathyroidism	Controlled release, oral	
1α(OH)D_3 [3]		Leo	In use, Europe	Osteoporosis	Systemic	(Barton et al., 1973)
1α(OH)D_2 [3]		Genzyme	In use, USA	Secondary hyperparathyroidism	Systemic	(Paaren et al., 1978)
Dihydrotachysterol [2]		Duphar	Withdrawn	Renal failure	Systemic	(Jones et al., 1988)
Vitamin D_2 [1]		Various	In use, USA	Rickets Osteomalacia	Systemic Systemic	(Park, 1940)
1α(OH)D_5 [3]		Various	In use, USA	Cancer	Systemic	(Mehta et al., 2000)

CKD, chronic kidney disease.
[a]*Structure of the vitamin D nucleus (secosterol ring structure).*



During the late 1960s and early 1970s, most of the principal vitamin D metabolites were first isolated and identified by gas chromatography—mass spectrometry and then their exact stereochemical structure was determined (Jones et al., 1998). This led to the chemical synthesis of the naturally occurring isomer and its testing in various biological assays in vitro and in vivo. Indeed all the major metabolites, namely, 25(OH)D_3 (Calderol, Rayaldee), 1α,25$(OH)_2D_3$ (Rocaltrol), and 24,25-dihydroxyvitamin D_3 (24*R*,25$(OH)_2D_3$; Secalciferol), are currently or have been available for use as drugs globally.

Vitamin D prodrugs

Table 75.2 lists some of the important prodrugs of vitamin D. All of these compounds require a step (or more) of activation in vivo before they are biologically active. Included here is vitamin D_2 (ergocalciferol), which is derived from the fungal sterol, ergosterol, by irradiation. When the nutritional basis of rickets and osteomalacia became apparent in the first half of the 20th century, vitamin D (particularly vitamin D_2 because it was less expensive and could be made by simply irradiating yeast) became the treatment of choice for these diseases. In North America, low-dose prophylactic vitamin D (400 IU) in the form of dietary supplements or fortification of milk, margarine, bread, or other food products replaced much of the need for therapeutic vitamin D to abolish overt rickets and osteomalacia. Florid vitamin D deficiency rickets has become

TABLE 75.3 Analogs of $1\alpha,25(OH)_2D_3$.

Vitamin D analog (ring structure)[a]	Side chain structure	Company	Status	Possible target diseases	Mode of delivery	References
Calcitriol, $1\alpha,25(OH)_2D_3$ [3]		Roche Duphar	In use worldwide	Hypocalcemia Psoriasis	Systemic Topical	(Baggiolini et al., 1982)
26,27-F6-$1\alpha,25(OH)_2D_3$ [3]		Sumitomo Taisho	In use, Japan	Osteoporosis Hypoparathyroidism	Systemic Systemic	(Kobayashi et al., 1982)
19-Nor-$1\alpha,25(OH)_2D_2$ [5]		Abbott	In use, USA	Secondary hyperparathyroidism	Systemic	(Perlman et al., 1990)
22-Oxacalcitriol (OCT) [3]		Chugai	In use, Japan	Secondary hyperparathy-roidism Psoriasis	Systemic Topical	(Murayama et al., 1986)
Calcipotriol (MC903) [3]		Leo	In use worldwide	Psoriasis Cancer	Topical Topical	(Calverley, 1987)
$1\alpha,25(OH)_2$-16-ene-23-yne-D_3 (Ro 23-7553) [6]		Roche	Preclinical	Leukemia	Systemic	(Baggiolini et al., 1989)
EB1089 [3]		Leo	Clinical trials	Cancer	Systemic	(Binderup et al., 1991)
20-Epi-$1\alpha,25(OH)_2D_3$ [3]		Leo	Preclinical	Immune diseases	Systemic	(Calverley et al., 1991)
2-Methylene-19-nor-20-epi-$1\alpha,25(OH)_2D_3$ (2MD) [7]		Deltanoid	Preclinical	Osteoporosis	Systemic	(Shevde et al., 2002)

2-Methylene-22-dehydro-19-nor-1,24*R*,25(OH)3D_3 (WT-51) [7]		Deltanoid	Preclinical	Osteoporosis	Systemic	US patent application no. 2014/0206655
19-Nor-14-epi-23-yne-1,25$(OH)_2D_3$ (inecalcitol, TX-527) [8]		Hybrigenics	Clinical trials	Prostate cancer Leukemia	Systemic	(Medioni et al., 2014)
Eldecalcitol (ED-71) [4]		Chugai	In use, Japan	Osteoporosis	Systemic	(Nishii et al., 1993)
1α,24(*S*)-$(OH)_2D_2$ [3]		Sanofi	Preclinical	Psoriasis	Topical	(Strugnell et al., 1995)
1α,24(*R*)-$(OH)_2D_3$ (TV-02) [3]		Teijin	In use, Japan	Psoriasis	Topical	(Morisaki et al., 1975)

VDR, vitamin D receptor.

uncommon in North America because of adherence to public health guidelines and the fact that vitamin D food fortification is required by law, in contrast to prior to fortification and it is still more prevalent in the world where food fortification is not practiced. In the United States, vitamin D_2 is the form of vitamin D used exclusively in pharmaceutical preparations, whereas vitamin D_3 is being increasingly incorporated into over-the-counter supplements. Vitamin D_2 differs only in that it possesses two specific modifications of the side chain (see Table 75.2) but these differences do not preclude the same series of activation steps as vitamin D_3, these giving rise to 25(OH)D_2, 1α,25(OH)$_2D_2$, and 24,25(OH)$_2D_2$, respectively. There has been controversy regarding the relative utility of dietary vitamin D_2 and vitamin D_3 to raise the circulating 25(OH)D level (Vieth et al., 2005). Evidence suggests that monthly oral pharmacological doses of vitamin D_3 are significantly more effective than equivalent doses of vitamin D_2 for increasing the 25(OH)D level into the sufficient range (20−50 ng/mL) (Armas et al., 2004), while there is ample evidence vitamin D_2 compounds are less toxic than their vitamin D_3 counterparts (Roborgh and de Man, 1960; Sjöden et al., 1985). On the other hand, other studies using smaller, daily oral dosing of vitamins D_2 and D_3 suggest a rough bioequivalence (Rapuri et al., 2004; Holick et al., 2008; Thacher et al., 2009).

25(OH)D_3 was developed and approved as the pharmaceutical preparation Calderol in the 1970s but was withdrawn in the United States in 2000 and at this writing is available only in Europe. A novel modified-release version of 25(OH)D_3 has been developed in the United States by OPKO−Renal (Miami, FL) and approved by the US FDA under the name Rayaldee and is approved for the treatment of stage 3/4 chronic kidney disease. Two other prodrugs, 1α(OH)D_3 and 1α(OH)D_2, were synthesized in the 1970s (Barton et al., 1973; Paaren et al., 1978) as alternative sources of 1α,25(OH)$_2D_3$ and 1α,25(OH)$_2D_2$, respectively, which in the process circumvent the renal 1α-hydroxylase enzyme, which was shown to be tightly regulated and prone to damage in renal disease. The prodrug 1α(OH)D_5 has been in clinical trials for the treatment of breast cancer (Mehta et al., 2000). The 1α-hydroxylated prodrugs have also been used in the treatment of osteoporosis. While the etiology of osteoporosis is complex and likely to be multifactorial (Seeman et al., 1995), there have been consistent claims that serum levels of 1α,25(OH)$_2D_3$ are low in osteoporosis (Riggs and Melton, 1992). In addition, evidence that certain VDR genotypes correlate with bone mineral density (Morrison et al., 1994; Uitterlinden et al., 2005) suggests that some genetically inherited basis involving vitamin D exists, leading to increased susceptibility to osteoporosis. As a consequence, it is not surprising that clinical trials of 1α(OH)D_3 (Orimo et al., 1987), 1α(OH)D_2 (Gallagher et al., 1994), and 1α,25(OH)$_2D_3$ (Gallagher et al., 1989; Ott and Chesnut, 1989; Tilyard et al., 1992) have led to reports of modest gains in bone mineral density and reductions in fracture rates in osteoporotic patients, a topic reviewed by Seeman et al. (1995).

The final compound in Table 75.2, dihydrotachysterol (DHT), lived a complex history as a prodrug. Originally it was believed to be "active" when converted to 25(OH)-DHT by virtue of an A ring rotated 180 degrees such that the 3β-hydroxyl function assumes a pseudo-1α-hydroxyl position (Jones et al., 1988). The mechanism of action of DHT has become less clear with the description of the extrarenal metabolism of 25(OH)-DHT to 1α,25(OH)$_2$-DHT and 1β,25(OH)$_2$-DHT, two further metabolites that have greater biological activity than either 25(OH)-DHT or DHT itself (Qaw et al., 1993).

Calcitriol analogs

Table 75.3 lists some of the most promising vitamin D analogs of 1α,25(OH)$_2D_3$ approved by governmental agencies, under development by various industrial/or university research groups as of this writing, or abandoned at various stages of the development process. Since the number of vitamin D analogs synthesized now lists in the thousands, the table is provided mainly to give a flavor of the structures experimented with thus far, the worldwide scope of the companies involved, and the broad spectrum of target diseases and uses.

The first generation of calcitriol analogs included molecules with fluorine atoms placed at metabolically vulnerable positions in the side chain and resulted in highly stable and potent calcemic agents such as 26,27-F_6-1α,25(OH)$_2D_3$. A second generation of analogs focused on features that make the molecule more susceptible to clearance, such as in calcipotriol (MC903), where a C22−C23 double bond, a 24-hydroxyl function, and a cyclopropane ring have been introduced into the side chain, or in OCT, where the 22-carbon has been replaced with an oxygen atom. Both modifications have given rise to highly successful analogs, calcipotriol and maxacalcitol, marketed in Europe and Japan, respectively (Kragballe et al., 1991; Nishii et al., 1993).

The C-24 position is a favorite site for modification, and numerous analogs contain 24-hydroxyl groups, e.g., 1α,24(*S*)-(OH)$_2D_2$ and 1α,24(*R*)-(OH)$_2D_3$ (Strugnell et al., 1995). Other analogs contain multiple changes in the side chain in combination, including unsaturation; 20-epimerization, 22-oxa replacement; homologation in the side chain; or terminal methyl groups. The resultant molecules such as EB1089 and KH1060 attracted the strong attention of researchers because of their increased potency in vitro and were pursued as possible anticancer and immunomodulatory compounds, respectively, but their development seems to have been stalled.

Attempts have been made to modify the nucleus of calcitriol. The Roche compound 1α,25(OH)$_2$-16-ene-23-yne-D$_3$, touted as an antitumor compound in vivo, possesses a D-ring double bond (Baggiolini et al., 1989). Declercq and Bouillon have made a novel 14-epi,19-nor-23-yne derivative with the same 23-yne feature (inecalcitol; TX-527), which also holds promise in the treatment of prostate cancer and various adult leukemias (Table 75.3; Medioni et al., 2014), and the same researchers have introduced a series of biologically active analogs without one of the other of the C/D rings but with a rigid backbone to maintain the spatial arrangement of the A-ring hydroxyl groups and the side chain (Table 75.4; Verstuyf et al., 2000). The A-ring-substituted 2-hydroxypropoxy-derivative ED-71 (Eldecalcitol), which by virtue of an A-ring substituent at C-2 and tighter binding affinity to vitamin D-binding protein (DBP) has a longer $t_{1/2}$ in the plasma (Nishii et al., 1993), is in use in Japan as an anti-osteoporosis drug. ED-71 performed well at restoring bone mass without causing hypercalcemia in long-term studies involving ovariectomized (OVX) rats and in phase I and II clinical trials (Matsumoto and Kubodera, 2007). Other bulky modifications at the C-2 position of the A ring are accommodated well by the VDR, as indicated by modeling and biological activity studies (Suhara et al., 2001; Shevde et al., 2002). Another C-2-substituted bone-specific analog is 2-MD (Shevde et al., 2002), at an early stage of pharmaceutical development, as of this writing, for the treatment of osteoporosis. It has a related 24-hydroxylated successor known as WT-51, which is (22E)-2-methylene-22-dehydro-1,24,25-trihydroxy-19-nor-vitamin D$_3$ and which markedly increases bone mass in OVX rats without causing hypercalcemia.

19-Nor-1α,25(OH)$_2$D$_2$ lacks a 19-methylene group and is similar to the in vivo active metabolite 1α,25(OH)$_2$-DHT$_2$, formed from DHT, because it lacks a functional group at the pseudo C-19 position. Many other compounds have been developed with rigid or altered *cis*-triene structures or modifications of the 1α-, 3β-, or 25-hydroxyl functions for use as drugs, but to allow us to establish minimal requirements for biological activity in structure/activity studies (Bouillon et al., 1995). BXL-628 combines 1-fluorination, 16-ene and 23-ene unsaturations, 26,27-homologation, and 20-epimerization, all found in earlier generations of analogs to make an antiproliferative agent used in clinical trials for the treatment of prostate cancer and prostatitis (Crescioli et al., 2004; Adorini et al., 2007).

Miscellaneous vitamin D analogs and associated drugs

One series of compounds depicted in Table 75.4 are the substituted biphenyls originally developed by Ligand, representing nonsteroidal scaffolds selected by high-throughput screening, which show weak VDR binding but good transactivation through vitamin D response element (VDRE)-driven, vitamin D-dependent genes and produce hypercalcemia in vivo (Boehm et al., 1999). This family has been extended by the synthesis of some highly potent, tissue-selective non-secosteroidal VDR modulators with nanomolar affinity (e.g., LY2109866) (Ma et al., 2006). This is the first class of vitamin D mimics that lack the conventional *cis*-triene secosteroid structure while maintaining the spatial separation of the A-ring and side-chain hydroxyl functions needed to bind to certain key residues of the ligand-binding pocket of the VDR. Although these nonsecosteroidal compounds are purported to exhibit an improvement of the therapeutic index over calcitriol in animal models, they are still to be tested clinically. In addition, Table 75.4 also shows the structures of two different classes of VDR/calcitriol antagonists. The former compounds, including TEI-9647, are dehydration products of the metabolite 1α,25(OH)$_2$D$_3$-26,23-lactone (Table 75.1) and have been used in the treatment of Paget's disease (Ishizuka et al., 2005; Saito and Kittaka, 2006; Toell et al., 2001).

Another group of compounds important to the vitamin D field that are under development are the CYP24A1 inhibitors. By blocking CYP24A1, the main catabolic pathway within the vitamin D-target cell, these agents extend the life of the natural agonist, calcitriol, giving rise to a longer lasting biological effect (Prosser and Jones, 2004). Sandoz/Novartis developed a group of molecules that exhibit greater specificity toward CYP24A1 and CYP27B1 compared with the general CYP inhibitor, ketoconazole, that showed utility in blocking cell proliferation in vitro, but these compounds were discontinued after early clinical trials (Schuster et al., 2001). Cytochroma (now OPKO—Renal) has developed a library of CYP24A1 inhibitors synthesized by Gary Posner based upon vitamin D templates, some of these being pure CYP24A1 inhibitors, while others are mixed VDR agonist/CYP24A1 inhibitors (Table 75.4). Some of these drugs have reached phase IIB human clinical trials for the treatment of psoriasis (Posner et al., 2004) and are now being tested systemically in the treatment of secondary hyperparathyroidism (Posner et al., 2009). Their promise stems from their ability to block the attenuating action of CYP24A1 on calcitriol-mediated prepro-parathyroid hormone (PTH) gene suppression.

There are several other compounds under development that have attracted interest because they have dual targets. James Gleason and John White have synthesized compounds with combined VDR-agonist and transcriptional histone deacetylase inhibitor activity for use as possible growth regulators in cancer therapy (Bijian et al., 2018), while Andrzej Kutner has developed vitamin D—retinoid combinations (retiferols), which target both VDR and their related retinoic acid/retinoid X nuclear receptors, where both agents are known to modulate cell differentiation and reduce cell division.

Clinical applications of vitamin D compounds

The clinical potential of vitamin D analogs has been covered comprehensively by others (Bikle, 1992; Bischoff-Ferrari et al., 2006) in published reviews. This section of the review focuses only on diseases currently treated with vitamin D analogs.

Secondary hyperparathyroidism

Chronic renal disease (CKD) is accompanied by a gradual fall in serum 1α,25$(OH)_2$D levels over the five-stage natural history of the disease, stages being defined by the decline in glomerular filtration rate (GFR). CKD culminates in the need for dialysis (stage 5). For 3 decades this reduction in serum 1α,25$(OH)_2$D has been assumed to be the result of a decline in 1α-hydroxylase (CYP27B1) activity, due in turn to loss of the protein itself, but the elucidation of the fibroblast growth factor 23 (FGF23)-regulated phosphate homeostatic pathway has opened up an alternative explanation. Since FGF23 triggers downregulation of CYP27B1 and upregulation of the catabolic 24-hydroxylase (CYP24A1), this hormone may also contribute to the progressive reduction in circulating 1α,25$(OH)_2$D levels (Quarles, 2008). Furthermore, FGF23 rises as early as CKD stage 1, preceding the decline in the 1α-hydroxylase activity, which occurs in CKD stage 2, and well before the hypocalcemia and secondary hyperparathyroidism that characterize the later stages of this disease. Unchecked, these biochemical events, together with the other sequelae of renal failure such as phosphate retention, can result in renal osteodystrophy. Active vitamin D analogs, such as 1α$(OH)D_3$ and 1α,25$(OH)_2D_3$, raise plasma Ca^{2+} concentrations and, in addition, lower PTH levels by direct suppression of PTH gene transcription at the level of the PTH gene promoter. Slatopolsky and colleagues (Delmez et al., 1989) showed that intravenous infusion of "active" vitamin D preparations results in a more effective suppression of plasma PTH levels without such a profound increase in plasma [Ca^{2+}] in end-stage renal disease (ESRD). Subsequent work has employed "low-calcemic" vitamin D analogs such as 1α$(OH)D_2$ (doxercalciferol), OCT, or 19-nor-1α,25$(OH)_2D_2$ (paricalcitol) as substitutes for the more calcemic natural hormone. The US FDA has approved both oral and intravenous versions of these drugs for the treatment of secondary hyperparathyroidism at stages 3 and 4 of the disease, as well as hemodialysis and peritoneal dialysis patients.

In 2003, a body of nephrologists released guidelines (National Kidney Foundation, 2003) recommending more aggressive use of vitamin D preparations and "active" vitamin D analogs in the treatment of secondary hyperparathyroidism in CKD. KDOQI guidelines suggested that treatment as early as stage 3 (GFR <60) might benefit the patient by limiting the extreme rises in plasma PTH levels and preventing the parathyroid gland resistance to vitamin D treatment often observed in ESRD. KDOQI guidelines also recognized the high frequency of vitamin D deficiency (25(OH)D <10 ng/mL) and vitamin D insufficiency (25(OH)D 10−30 ng/mL) in the CKD and ESRD population (Gonzalez et al., 2004) and made the opinion-based recommendation to make an initial attempt at vitamin D repletion with escalating doses of vitamin D_2 prior to administration of "active" vitamin D analog replacement therapy. This initial intervention to boost 25(OH)D levels has proven to be successful in stage 3 CKD patients in that it increases 1α,25$(OH)_2$D and mildly suppresses PTH levels but the strategy fails to produce the desired effects in stage 4 CKD patients due to reduced renal 1α-hydroxylase activity (Al-Aly et al., 2007; Zisman et al., 2007). As of this writing, both oral and intravenous formulations of various active vitamin D analogs are available for use in stage 3−5 patients to take over when vitamin D repletion fails to regulate PTH levels.

The emergence of the potential importance of the extrarenal 1α-hydroxylase in normal human physiology has led to a reevaluation of the vitamin D repletion and "active" hormone replacement arms of the CKD therapy (Jones, 2007). The value of vitamin D repletion is now seen as providing the substrate 25(OH)D for both the renal 1α-hydroxylase, which is the main determinant of circulating 1α,25$(OH)_2D_3$, and the extrarenal 1α-hydroxylase, which is postulated to augment 1α,25$(OH)_2D_3$ synthesis for local or intracrine actions around the body. While the decline of the renal enzyme during CKD is well established, the fate of the extrarenal 1α-hydroxylase in the face of uremia is largely a matter of conjecture. Evidence from anephric patients treated with large doses of 25$(OH)D_3$ (Dusso et al., 1988) suggests that the extrarenal enzyme survives in CKD patients, arguing that provision of a source of 25(OH)D to vitamin D-deficient and -insufficient patients throughout all stages of CKD is warranted. It also argues for the more judicious use of "active" vitamin D analogs as hormone replacement therapy layered on top of conventional vitamin D repletion therapy. Early attempts at this type of combined vitamin D/"active" vitamin D analog approach in a pediatric population have resulted in a more efficient PTH control without many of the usual problems of soft-tissue calcification observed in patients treated only with "active" vitamin D analogs (Fournier et al., 2007). The threefold higher susceptibility of CKD patients to cardiovascular disease (Teng et al., 2005; Tentori et al., 2006) may also point to the deleterious effects of untreated vitamin D deficiency on the vasculature and highlight the beneficial effects of both renally and locally produced 1α,25$(OH)_2$D for maintaining normal

blood pressure, for antiproliferative effects on myocardial cell hypertrophy, and for direct suppressive effects on vascular epithelial cell "osteoblastic" gene expression, e.g., Runx2 and Osterix (Mathew et al., 2008; Judd and Tangpricha, 2009).

On the other hand, a decade of availability of "active" vitamin D analogs has led some to question whether the overuse of such potent vitamin D compounds has contributed to accelerated calcification of the vascular tree and the increased incidence of cardiovascular disease in CKD patients (Razzaque, 2011). A new "milder" analog, in the form of Rayaldee (controlled-release $25(OH)D_3$) (Table 75.2), has been approved for use in stage 3/4 CKD patients for the treatment of secondary hyperparathyroidism. Clinical trial data show that Rayaldee suppresses serum PTH levels by over 30% (Sprague et al., 2016; Galassi et al., 2017) in such patients. Whether the same drug can be as successful in dialysis patients is still unknown.

Hyperproliferative conditions: psoriasis and cancer

The demonstration that $1\alpha,25(OH)_2D_3$ is an antiproliferative, prodifferentiating agent for certain cell types in vivo and many cell lines in vitro suggested that vitamin D analogs might offer some relief in hyperproliferative disorders such as psoriasis and cancer. Early psoriasis trials with systemic $1\alpha,25(OH)_2D_3$ were moderately successful but plagued with hypercalcemic side effects. Modifications to the protocol included:

(a) administration of calcitriol overnight when intestinal concentrations of $[Ca^{2+}]$ were low;
(b) substitution of low-calcemic analogs for the calcitriol.

Although oral calcitriol can be an effective treatment for psoriasis when administered using an overnight protocol, by far the most popular treatment for psoriasis is the topical administration of the low-calcemic analog calcipotriol, formulated as an ointment, which results in an improvement in over 75% of patients (Kragballe et al., 1991). Both $1\alpha,25(OH)_2D_3$ and calcipotriol are effective in psoriasis because they block hyperproliferation of keratinocytes, increase differentiation of keratinocytes, and help suppress local inflammatory factors through their immunomodulatory properties. Calcipotriol has now been marketed worldwide for use in psoriasis for over 25 years.

Several thousands of vitamin D analogs have been tested in vitro and in vivo with some degree of success in controlling the growth of tumor cells and thus offering potential for use as anticancer drug therapies (Masuda and Jones, 2006). Many vitamin D compounds are extremely effective antiproliferative or prodifferentiation agents in vitro, acting through a variety of mechanisms involving alterations in cell cycle genes and proapoptotic genes to produce their effects. Preclinical studies in laboratory animals have also resulted in promising data (Masuda and Jones, 2006). With the analog EB1089, the promising antiproliferative effects observed in vitro and in the NMU-induced mammary tumor and in LNCaP prostate cancer xenograft models (Colston et al., 2003) were also extended into the clinic. Early trials in limited numbers of breast cancer patients have been followed up with more extensive ongoing phase II and III clinical trials in a number of different cancers (Gulliford et al., 1998; Evans et al., 2002; Dalhoff et al., 2003). Several other analogs have entered clinical trials for the treatment of a variety of hyperproliferative diseases, usually involving VDR-positive tumors (see Masuda and Jones, 2006).

Despite the enormous promise of vitamin D analogs as anticancer agents, this has yet to result in an approved vitamin D analog for use in any type of cancer (Masuda and Jones, 2006). The principal problem in anticancer studies involving orally administered vitamin D compounds is hypercalcemia. Although the newer analogs appear to be less calcemic than calcitriol itself, they still retain some ability to raise serum calcium; they are not noncalcemic, as is sometimes claimed. Another problem emerging from experience with clinical trials is that effective doses needed to retard cell growth ($\sim$1 nM or higher) cannot be attained in vivo due to low bioavailability (Beer et al., 2004; Trump et al., 2004; Deeb et al., 2007). One of the determinants of tumor cell vitamin D analog levels is the catabolic enzyme CYP24A1, which is upregulated in vitamin D-target cells and limits the effective drug concentration reached. Thus, another approach to effective vitamin D therapy in cancer patients is the potential use of a CYP24-inhibitor (Table 75.4) with or without calcitriol or a calcitriol analog (Masuda and Jones, 2006). Nevertheless, it remains uncertain if a vitamin D compound can be developed that is sufficiently devoid of calcemic activity while retaining significant antiproliferative activity to be effective against tumors and also survive the catabolic processes that operate in vivo.

Criteria that influence pharmacological effects of vitamin D compounds

Three decades of work on vitamin D analogs have shown us that several factors play a role in dictating the success of synthetic compounds made to mimic some or all of the actions of calcitriol. These factors are discussed briefly next.

Activating enzymes

In vitro models show that some vitamin D compounds lacking 1α-hydroxylation (25(OH)D_3, 24(*R*),25(OH)$_2D_3$) are capable of interacting with VDR and transactivating reporter genes, but this occurs only at high (μM) concentrations of ligand (Uchida et al., 1994). It seems unlikely that these concentrations will be reached in vivo except in hypervitaminosis D (Jones, 2008a). Consequently, most of the compounds described in Tables 75.1 and 75.2 lack vitamin D biological activity *unless* they are activated in vivo. This is particularly the case for the parent vitamin D_3 itself, for its main circulating form 25(OH)D_3, or for any of the prodrugs listed in Table 75.2. Vitamins D_2 and D_3 depend upon both the liver 25-hydroxylase and the kidney 1α-hydroxylase enzyme systems to be activated, whereas most prodrugs require only a single step of activation. In particular, the 1α(OH)D drugs were designed to overcome the tightly regulated 1α-hydroxylase step, which is defective in chronic renal failure. In essence, prodrugs depend on the weakly regulated 25-hydroxylase step in the liver for activation. CYP27A1, the cytochrome P450 originally thought to be responsible for 25-hydroxylation of vitamin D_3, has been shown to be a bifunctional enzyme that can execute both activation of vitamin D_3 and the 27-hydroxylation of cholesterol during bile acid biosynthesis (Okuda et al., 1995). However, CYP27A1 has a relatively low affinity for vitamin D, does not 25-hydroxylate vitamin D_2, and when mutated results in cerebrotendinous xanthomatosis, not rickets. Consequently, the more "physiologically relevant" 25-hydroxylase within the group of candidate orphan P450s (Prosser and Jones, 2004) is likely to be CYP2R1 (Cheng et al., 2004), since this is a high-affinity microsomal enzyme with a known human mutation causing rickets and has been shown to 25-hydroxylate a D_2 prodrug, 1α(OH)D_2 (Jones et al., 2006). CYP2R1 has been crystallized with several vitamin D substrates in the active site, making it likely that it is the physiologically-relevant isoform (Strushkevich et al., 2008). Mutations of CYP2R1 result in vitamin D-dependency rickets type 1B (Thacher et al., 2015; Molin et al., 2017).

The role of extrarenal tissues in 1α-hydroxylating various 25-hydroxylated metabolites and analogs in normal physiology has always been a controversial story. However, it was widely accepted that extrarenal 1α-hydroxylase activity is pathologically relevant in granulomatous conditions (e.g., sarcoidosis) (Adams and Gacad, 1985). In sarcoid patients, 25(OH)D can be converted to 1α,25(OH)$_2$D in monocytes/macrophages, a step that, unlike the renal case, is not subject to tight regulation and thus potentially is more likely to result in hypercalcemia. Exposure of such patients to sunlight or administration of 25(OH)D can result in excessive plasma levels of 1α,25(OH)$_2$D. Following the cloning of the cytochrome P450 representing the 1α-hydroxylase (officially known as CYP27B1) (St. Arnaud et al., 1997; Takeyama et al., 1997), it was quickly shown that CYP27B1 can also be expressed extrarenally in skin, colon, and lung cancer cells (Fu et al., 1997; Jones et al., 1999). Our knowledge has been extended since 2005 with studies of CYP27B1 mRNA levels using real-time PCR and specific anti-CYP27B1 antibodies (Hewison et al., 2005) to show a widespread distribution of this enzyme in many normal tissues as well as pathological situations. Work using mouse models lacking positive and negative regulatory elements for the renal CYP27B1 suggest that in the absence of renal CYP27B1, serum levels of 1,25(OH)$_2D_3$ are reduced but do not disappear totally. This result is probably due to a failure to sufficiently suppress CYP27B1 activity in the kidney and to a corresponding complete suppression of renal CYP24A1, although it is possible that residual blood 1,25(OH)$_2D_3$ levels in these mice could be derived from extrarenal sources of CYP27B1 as well (Meyer et al., 2017). As alluded to earlier, the concept of the extrarenal 1α-hydroxylase suggests that this enzyme plays an important physiological as well as pathological role (Jones, 2007) and this has raised the level of importance given to ensuring maintenance of adequate 25(OH)D levels by vitamin D or direct 25(OH)D_3 supplementation in CKD patients.

Most of the calcitriol analogs listed in Table 75.3 are thought to be active as such, not requiring any step of activation prior to their action on the transcriptional machinery.

Vitamin D-binding protein

The DBP provides transport for all lipid-soluble vitamin D compounds, from vitamin D to 1α,25(OH)$_2D_3$, so it is not surprising that DBP also carries vitamin D analogs. Most of the analogs of calcitriol designed as of this writing contain modifications to the side chain, and this is usually detrimental to binding to DBP. Several analogs (e.g., calcipotriol, OCT, and 19-nor-1,25(OH)$_2D_2$) have very weak affinities for DBP, reduced by as much as 2−3 orders of magnitude relative to 1α,25(OH)$_2D_3$. This property has important implications for metabolic clearance rates, delivery to target cells, and tissue distribution (Bouillon et al., 1991; Kissmeyer et al., 1995). Detailed studies with one analog, OCT, have shown it to bind primarily to β-lipoprotein and exhibit an abnormal tissue distribution in vivo, with disproportionally high concentrations (ng/g tissue) in the parathyroid gland (Tsugawa et al., 1991). It was thus proposed that this unusual distribution may make OCT a useful systemically administered drug with a selective advantage in the treatment of hyperparathyroidism. Another vitamin D analog with a modified side chain is 20-epi-1α,25(OH)$_2D_3$, in which the 20-*S* configuration of the side chain is

opposite to the normal 20-*R* configuration. The DBP binding affinity of this analog is virtually unmeasurable as it does not displace [^{3}H]25(OH)D_3 from the plasma binding protein (Dilworth et al., 1994). Reporter gene transactivation assays show that 20-epi-1α,25$(OH)_2D_3$ transactivates equally well in COS cells incubated in the presence and absence of fetal calf serum (as a source of DBP), whereas 1α,25$(OH)_2D_3$-induced reporter gene expression is sensitive to DBP in the external growth medium, requiring two log units less hormone in the absence of DBP as in its presence (Dilworth et al., 1994). It therefore appears that analogs that bind DBP less well than 1α,25$(OH)_2D_3$ derive a target cell advantage over the natural hormone, *if they are able to find alternative plasma carrier proteins to transport them to their target cells.* However, these same alternative plasma carriers presumably result in changes in the tissue distribution and hepatic clearance of analogs over the natural metabolites of vitamin D. The development of a DBP-knockout mouse (Safadi et al., 1999) suggests that 25(OH)D_3 clearance is more rapid in the absence of DBP.

Vitamin D receptor/retinoid X receptor/vitamin D response element interactions

Three decades of work have established that 1α,25$(OH)_2D_3$ is able to work through a VDR-mediated genomic mechanism to stimulate transcriptional activity at vitamin D-dependent genes (Whitfield et al., 2005). Cloning of the VDR and elucidation of the 3D structure of its ligand-binding domain have provided a huge boost to delineating the precise conformational changes that take place when the natural ligand binds to the VDR (Rochel et al., 2001) and the nature of the post-ligand-binding transcriptional events that occur thereafter, particularly the nature of the coactivator proteins involved (Rachez and Freedman, 2000). Basic knowledge of the mechanism of action of vitamin D has also been aided by the opportunity to observe the lack of effects of calcitriol and its analogs in the VDR-knockout mouse (Yoshizawa et al., 1997; Li et al., 1997). These studies have largely refuted claims of alternative non-VDR-mediated mechanisms to produce physiologically relevant effects that might complicate our understanding of the pharmacological effects of vitamin D analogs.

Much evidence exists to support the viewpoint that vitamin D analogs mimic 1α,25$(OH)_2D_3$ and use primarily a genomic mechanism. In early work, Stern (1981) showed that there exists a strong correlation between chick intestinal VDR binding of an analog and its potency in a ^{45}Ca rat bone resorption assay, suggesting that a vitamin D analog is only as good as its affinity for the VDR. More recent work has suggested that this a highly simplified viewpoint and that VDR binding affinity may not even be the major factor; other factors may be transactivation activity stemming from a series of parameters such as conformation of the ligand/VDR complex, binding of the RXR partner, stability of the VDR/RXR/ligand complex, or even the nature of the coactivator proteins recruited to the complex. Data from the "superagonist" analogs (Yang and Freedman, 1999; Dilworth et al., 1997; Zella et al., 2009) suggest that 20-epi compounds including KH1060 are consistently only 1−2 orders of magnitude more potent than 1α,25$(OH)_2D_3$ in gene transactivation assays and/or differentiation assays. Thus it appears that the quantitative advantages claimed for some of the calcitriol analogs are modest. But it should also be pointed out that part of this advantage can also be explained by other factors such as differences in DBP binding or analog clearance.

Perhaps more important is whether analogs can be qualitatively different from 1α,25$(OH)_2D_3$ in their actions and work selectively in either calcium and phosphate homeostasis or cell differentiation. Freedman's group reported that the ability of various analogs to transactivate vitamin D-dependent genes or to stimulate differentiation of cells is best correlated with their ability to recruit the coactivator DRIP-205, one of the many components of the DRIP complex isolated by Freedman's group (Cheskis et al., 1995; Rachez et al., 1999). Among the other coactivators/transcription factors implicated in vitamin D analog action is GRIP-1 (TIF-2), which has been purported to have a particular propensity to interact with the analog OCT (Takeyama et al., 1999). In another study by Issa et al. (Issa et al., 2000), a broad panel of vitamin D analogs showed that GRIP-1 was more consistently recruited at levels closer to those of 1α,25$(OH)_2D_3$ than was another coactivator, AIB-1. Work by Peleg et al. (2003) offers an insight into the purported bone tissue selectivity of the Roche analog Ro 26-9228 (Table 75.3; renamed BXL-628) by showing recruitment of GRIP-1 in osteoblasts but not in CaCo-2 colon cancer cells; although paradoxically BXL-628 is now being pursued clinically for prostatic disease rather than osteoporosis treatment (Marchiani et al., 2006). Nevertheless, it appears that there is a fairly strong basis for the hypothesis that differences in the biopotency advantage of certain vitamin D analogs over 1α,25$(OH)_2D_3$ are due in part to changes in the recruitment of the RXR dimerization partner and/or coactivators (e.g., Eelen et al., 2008), but there is no consensus on which of these coactivator proteins is the important one or if these different coactivators can explain tissue/cell selectivity. Work using chromatin immunoprecipitation assays (Pike et al., 2007), which show temporal changes in coactivator recruitment at vitamin D-dependent gene promoters, may aid in our understanding of this complex transcriptional story.

The proposition that the interaction of analogs with the VDR might alter the receptor's conformation and therefore underlie its ability to interact with VDRE DNA sequences, to form RXR heterodimers, and/or to recruit coregulators such as DRIP, SRC, or any one of the other 300 or more coregulators that are now known, as has been described earlier, has been an attractive hypothesis since the 1990s (McKenna et al., 1999; O'Malley et al., 2008). This idea is supported by the discovery, through early proteolytic digestion studies and more recently through crystallography studies of the VDR, that receptor conformations may be different from that seen with $1,25(OH)_2D_3$ when complexed with certain analogs (Peleg et al., 1995; Orlov et al., 2012; Rochel et al., 2000, 2011; Tocchini-Valentini et al., 2001). These differences are extremely modest, however, and their actual effects on the transcription of specific genes as has been suggested is largely speculative. Consistent with these uncertainties is the observation that almost all of these effects of VDR mechanistic activity have been determined through either biochemical assays or highly modified cell-based assays that did not use endogenous gene output as an activity measure, and were rarely conducted in vivo. Indeed, even our most basic determination of the differential affinity of an analog for the VDR when bound to complex sites of DNA action in the cell has never been assessed. These and many additional uncertainties have prevented any definitive conclusions as to the underlying mechanisms that may be responsible for the differential actions of most analogs, which may include gene selectivity, tissue selectivity, or disease selectivity, which are the most sought-after features that have driven therapeutic analog development. Perhaps more importantly, these proposed mechanisms frequently neglect the possibility that the primary determinants of analog selectivity are due to other features described in this section, including aspects of metabolism and differential transport, as well as the unique pharmacokinetic and pharmacodynamics features of virtually every analog when tested in vivo. Returning to the VDR, it is also important to note that the VDR, like many transcription factors, binds to sites of action on cellular genomes that are highly chromatinized, dynamically active, and uniquely individualized for each of the genes with which they linked (Meyer et al., 2010, 2012). Thus, the uniqueness of each vitamin D target gene has also been neglected in assessing analog action in most if not all earlier studies. In a following section, we consider many of these newly emerging concepts, made possible through the use of new technical approaches that have enabled the investigation of VDR action in cells and tissues both in vitro and in vivo on a genome-wide scale. While none of these principles has been examined yet for their impact on vitamin D analog action, it seems very likely that they will play a central role as major determinants of the unique actions of these synthetic vitamin D ligands.

Target cell catabolic enzymes

Much evidence has accumulated to show that $1\alpha,25(OH)_2D_3$ is subject to target cell catabolism and side chain cleavage to calcitroic acid via a 24-oxidation pathway catalyzed by CYP24A1 (Makin et al., 1989). CYP24A1 is vitamin D inducible, since its gene promoter contains a double VDRE; carries out multiple steps in the side chain modification process; and is present in most (if not all) vitamin D-target cells (Prosser and Jones, 2004; Akiyoshi-Shibata et al., 1994); and its role appears to desensitize the target cell to continuing hormonal stimulation by $1\alpha,25(OH)_2D_3$ (Lohnes and Jones, 1992). The CYP24A1-knockout mouse shows 50% lethality at weaning and death resulting from hypercalcemia and nephrocalcinosis, and surviving mice show an inability to rapidly clear a bolus dose of $1\alpha,25(OH)_2D_3$ from the bloodstream and tissues (St-Arnaud et al., 2008; Masuda et al., 2005). CYP24A1-knockout mice also exhibit a metabolic bone disease reminiscent of the excessive osteoid bone pathology observed in rodents given excessive amounts of $1\alpha,25(OH)_2D_3$ (Hock et al., 1986). Moreover, work crossing the CYP24A1-knockout mouse with the VDR-knockout mouse rescues this bone defect (St Arnaud et al., 2000), suggesting that excessive VDR-mediated signaling is the cause, although the bone lesion can also be relieved by administration of $24,25(OH)_2D_3$ (Arnaud, 2009). The conclusion from the knockout mouse experiments that CYP24A1 primarily exists to catabolize $1,25(OH)_2D_3$ and its precursor $25(OH)D_3$ has now been reinforced by the finding that mutations of the human CYP24A1 gene result in hypercalcemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis, in a syndrome known as idiopathic infantile hypercalcemia (IIH) (Schlingmann et al., 2011).

Given the demonstrated importance of CYP24A1 to $1\alpha,25(OH)_2D_3$ clearance, one must ask the question of whether vitamin D analogs might be subject to the same catabolic processes that determine their pharmacokinetics. Certainly there are vitamin D analogs such as calcipotriol, OCT, EB1089, and KH1060 that are metabolized by vitamin D-target cells to clearly defined and unique metabolites (Dilworth et al., 1997; Masuda et al., 1994, 1996; Shankar et al., 1997), which resemble products of the 24-oxidation pathway for $1\alpha,25(OH)_2D_3$. Furthermore, some of these metabolites are products only of vitamin D target cells and are calcitriol inducible, implying that CYP24A1 is involved in their formation, this having been confirmed with some analogs such as calcipotriol (Jones et al., 2006). Even in the cases of several analogs blocked at C-24 and subject to metabolism elsewhere on the side chain, the involvement of CYP24A1 is strongly implicated or proven, including 23-hydroxylation of 26,27-hexafluoro-$1\alpha,25(OH)_2D_3$, 26-hydroxylation of 24-difluoro-$1\alpha,25(OH)_2D_3$, 26-hydroxylation of $1\alpha,25(OH)_2$-16ene-23yne-D_3, and 26- and 28-hydroxylation of $1\alpha,25(OH)_2D_2$. Since

many of these same products are observed in vitro and in vivo and since pharmacokinetic parameters often parallel target cell metabolic parameters (Kissmeyer et al., 1995), one concludes that target cell metabolism of vitamin D analogs must contribute to the pharmacokinetics and biological activity observed in vitro and in vivo. Even studies such as that of Eelen et al. (2008), which claimed differences in VDR-mediated gene expression at the coactivator level, also show that a CYP24A1 inhibitor, VID-400 (Table 75.4), narrowed potency differences between 23yne analogs and 1α,25$(OH)_2D_3$ by blocking catabolism of the latter and revealed that analogs derive advantages at metabolic and transcriptional levels. Unfortunately, this metabolic blockade approach has not always been used in analog screening and there is little doubt that poor performance during in vivo testing is the result of poor metabolic stability of the studied analog.

Some of the calcitriol analogs with modifications in the vicinity of C-23, namely, 20-epi-1α,25$(OH)_2D_3$ (Dilworth et al., 1994), 1α,25$(OH)_2$-16ene-D_3 (Siu-Caldera et al., 1999), and 20-methyl-1α,25$(OH)_2D_3$ (Shankar et al., 2001), undergo 24-oxidation pathway metabolism that stalls at the level of the 24-oxo metabolite, seemingly because the enzyme CYP24A1 cannot efficiently carry out the usual 23-hydroxylation step and complete the catabolic sequence to the inactive cleaved product. The consequence, at least in vitro, is that the 24-oxo metabolite accumulates, and there have been claims that this metabolite retains significant biological activity (Siu-Caldera et al., 1999). This hypothesis has received a boost by the work of Zella et al. (2009), who have found that the superagonist 20-epi-1α,25$(OH)_2D_3$ exhibits a prolonged duration of action on intestinal calcium-regulating genes selectively, and these researchers have proposed that this advantage over 1α,25$(OH)_2D_3$ stems from a reduction in its catabolic rate.

Hepatic clearance or nonspecific metabolism

The poor DBP-binding properties of many side chain modified calcitriol analogs open up the possibility of alternative plasma carriers and accelerated degradation. The liver plays a major role in such metabolic clearance and a small number of detailed studies performed have included in vitro incubation with liver preparations. Calcipotriol (Sorensen et al., 1990), OCT (Masuda et al., 1996), EB1089 (Kissmeyer et al., 1997), and KH1060 (Rastrup-Anderson et al., 1992) are all subject to metabolism by liver enzymes. One such liver enzyme capable of nuclear and 23- and 24-hydroxylation of 1α,25$(OH)_2D_3$, and possibly some of its analogs, is the abundant general cytochrome P450, CYP3A4 (Xu et al., 2005). Indeed, this enzyme is upregulated by 1α,25$(OH)_2D_3$ in the duodenum, suggesting that a physiologically relevant loop exists (Thummel et al., 2001). Since over the years there have been frequent reports of drug-induced osteomalacia associated with coincidental use of anticonvulsants (e.g., diphenylhydantoin) or barbiturates with vitamin D preparations (Onodera et al., 2001), the direct association between CYP3A4 and 1α,25$(OH)_2D_3$ is potentially important to explain the putative accelerated clearance of some vitamin D metabolites (Gascon-Barre et al., 1984). One such phenomenon that might be explained by intestinal CYP3A4 action is the purported lower toxicity of vitamin D_2 compounds compared with their D_3 counterparts referred to earlier. Microsomes from an intestinal cell line and supersomes enriched in recombinant human CYP3A4 catabolize 1α,25$(OH)_2D_2$ at a significantly faster rate than 1α,25$(OH)_2D_3$ (Helvig et al., 2008). The implication of this finding is that 1α,25$(OH)_2D_2$ and possibly other synthetic analogs, such as the mixed VDR agonist/CYP24A1 inhibitor CTA-018 (Posner et al., 2009), are selectively broken down in intestine, potentially reducing their gene expression effects on intestinal calcium and PO_4 absorption but not on other tissues.

A 2017 demonstration that CYP3A4 might play a backup role to CYP24A1 in vitamin D catabolism was the use of rifampin in the treatment of IIH patients (Hawkes et al., 2017). Recall that IIH patients with mutations of CYP24A1 cannot catabolize 25$(OH)D_3$ or 1,25$(OH)_2D_3$ to 24-hydroxylated products efficiently, and the metabolites accumulate, causing hypercalcemia. Rifampin is a potent CYP3A4 inducer (Wang et al., 2013) and results in the appearance of biologically inactive 4α,25$(OH)_2D_3$ and 4β,25$(OH)_2D_3$ catabolites in the serum from 25$(OH)D_3$ metabolism. The IIH patients treated with rifampin have an alternative catabolic mechanism and show fewer hypercalcemic episodes (Hawkes et al., 2017).

The potential role of gene targets and the unique features of their regulation as major determinants of analog action

The previous section described studies suggesting that the differential actions of many vitamin D analogs in cells in vitro and in vivo may be due to metabolism, transport, tissue uptake, and/or the differential impact of certain analogs on VDR conformation, particularly as it relates to the receptor's ability to interact with RXR and/or to recruit and interact with the coregulator class of transcription factors. In the last case, however, almost all of the data used to support this idea that analogs promote unique VDR conformations with altered functional outcomes were derived using highly biased cellular techniques that were in vogue at the time but were simply incapable of delivering this type of mechanistic information. Since 2010, however, new approaches have emerged, which include chromatin immunoprecipitation linked to parallel

TABLE 75.5 Overarching principles of vitamin D action in target cells.

Vitamin D receptor (VDR) binding sites (the cistrome): 2000−8000 $1,25(OH)_2D_3$-sensitive binding sites/genome whose number and location are chromatin dependent and a function of cell-type
Active transcription unit for induction: the VDR/retinoid X receptor (RXR) heterodimer
Distal binding site locations: dispersed in *cis*-regulatory modules (CRMs or enhancers) across the genome; located in a cell-type-specific manner near promoters, but predominantly within introns and distal intergenic regions; frequently located in clusters of elements
VDR/RXR binding site sequence: induction mediated by classic hexameric half-sites (AGGTCA) separated by 3 bp; repression mediated by divergent sites
Mode of DNA binding: predominantly, but not exclusively, $1,25(OH)_2D_3$ dependent
Modular features of CRMs: contain binding sites for multiple transcription factors that facilitate either independent or synergistic interaction
Epigenetic CRM signatures: defined by the dynamically regulated posttranslational histone H3 and H4 modifications
VDR cistromes: dynamic alterations in the cellular epigenome during differentiation, maturation, and disease provoke changes to the VDR cistrome that qualitatively and quantitatively affect the vitamin D-regulated transcriptome

DNA sequencing (ChIP-seq) and derivative techniques, that have not only facilitated the study of gene transcription on a genome-wide scale, but have also begun to uncover novel roles for the epigenomic landscape that surrounds genes and defines their regulatory regions at levels of detail that are currently unparalleled (Hoffman et al., 2013; Ernst and Kellis, 2010; Ernst et al., 2011; Thurman et al., 2012; Bernstein et al., 2010; Kellis et al., 2014; Stamatoyannopoulos, 2012). This approach, as well as the striking ability to modify these regulatory regions easily both in cells in culture and in mice in vivo using gene editing techniques such as CRISPR/Cas9, now facilitates the study of gene regulation in an unprecedented fashion, providing new mechanistic insights that are of high significance (Cong et al., 2013; Hille and Charpentier, 2016; Singh et al., 2016). Perhaps most importantly, they have revealed that each gene, and often gene networks as well, represents a unique entity, and must therefore be studied in intact cells and tissues entirely in that context. This new approach has been applied to the vitamin D system, revealing a number of fundamental findings, as summarized in Table 75.5 and discussed briefly next. Unfortunately, none of these new concepts have been evaluated for their possible mechanistic contribution to analog-based gene-, cell-, or disease-based selectivity. Thus, while they represent only conceptual possibilities at present, they will have to be assessed in the future.

As summarized in Table 75.5, genome-wide studies have revealed that VDR binding to the genome is largely $1,25(OH)_2D_3$ dependent, is primarily colocalized to sites of RXR binding, and comprises from 2000 to 8000 sites per cell type (termed a VDR cistrome) (Pike et al., 2007; Meyer et al., 2014a, 2016; Heikkinen et al., 2011). While these sites often partially overlap, a subset is always highly cell-type specific, and all are highly enriched for the classic VDRE described in an earlier section of this review (Kerner et al., 1989; Ozono et al., 1990). Surprisingly, there is frequently more than one VDRE located within a given binding region, and thus more than one VDR/RXR complex exists within many of these regulatory segments, much like that first observed at the *Cyp24a1* gene (Zierold et al., 1995). Evidence that more than one VDRE leads to a facilitated response to $1,25(OH)_2D_3$ is prevalent (Kim et al., 2006; Stamatoyannopoulos et al., 2012). Given the fact that most genomes contain well over 100,000 typical VDRE-like sequences, ChIP-seq data clearly indicate that legitimate binding sites for the VDR/RXR heterodimer are highly chromatin restricted. We now know that these "functional" sites are determined by the presence of additional regulatory complexes that are essential for establishing sites of vitamin D regulation. This feature is well supported by parallel determinations of sites of DNase I hypersensitivity (Meyer et al., 2014b). Perhaps one of the most important discoveries is the observation that, while VDR binding sites can be located near gene promoters, most are located at intergenic and intronic sites frequently 10's if not 100's of kilobases from the genes they regulate (Meyer et al., 2014a, 2017). Even more profound is the fact that genes are modulated by multiple regulatory regions (termed enhancers), and that these enhancers are modular, and therefore typically capable of direct interaction with not only DNA-binding proteins like the VDR but also multiple additional transcription factors as well. A subset of these are likely to be determinants of enhancer structure, but others mediate regulation via additional signaling pathways, providing a mechanism at target genes that facilitates the integration of external signals at specific genes. These and many additional observations of the features of endogenous gene targets provide compelling support for much important detail that was never accounted for in the earlier studies of vitamin D analogs.

A second observation described in Table 75.5 is the finding that genomes and the individual genes within are maintained and regulated by an epigenetic chromatin environment that is both active and dynamic (Ernst and Kellis, 2010; Ernst et al., 2011). This environment is location specific and comprises, in part, distinct modifications to histone tails within nucleosomes that are preferentially enriched at gene transcription units, at the regulatory regions of genes, and at gene promoters. Virtually all binding sites for the VDR across individual genomes are located within epigenetic regions that are highlighted by the presence of epigenetic histone modifications that represent signatures of enhancer structure (Meyer et al., 2014b, 2016, 2017). These signatures are important, because they also reflect the presence of additional protein complexes that contribute to the type of response elicited by $1,25(OH)_2D_3$. The classes of proteins prebound to these sites are numerous; some are pioneering factors, others are lineage-determining factors and/or master regulators, and all are participants either in facilitating VDR binding or in enabling the assembly of a functional complex of which the VDR is a part (Meyer et al., 2014a, 2015; Lupien et al., 2008; Bi et al., 2012; Gosselin et al., 2014; Heinz et al., 2015). Thus, the overall activities of $1,25\text{-}(OH)_2D_3$ at these sites are fully framed within these enhancer environments, leading to activation, suppression, or qualified response. Previous analog studies would have been incapable of addressing these issues. Finally, given the frequency of multiple regulatory regions, and the often central roles of master regulators in gene output, enhancers frequently exhibit hierarchical activity in their ability to drive transcription. This occurs as a result of ubiquitous enhancer−enhancer interactions that enable one enhancer to dominate the activity of the others at a promoter. In some cases, this hierarchical activity prevails despite the fact that the dominant enhancer may be located many kilobases distal to the gene. This is illustrated by the *Mmp13* gene (Meyer et al., 2014c). These and other recently described features within genes are almost certain to influence the potential gene- and cell-specific biological actions of vitamin D analogs.

A final observation listed in Table 75.5 is that epigenomes are highly dynamic at numerous sites across the genome. Thus, this regulatory layer at many genes undergoes striking changes as a consequence of development, cellular differentiation, and maturation and, perhaps most importantly, as a function of disease. VDR cistromes are likewise highly dynamic and prone to substantial changes (Meyer et al., 2016; Ding et al., 2013a, 2013b). These changes in the epigenome lead to significant alterations in the availability of binding sites for transcription factors, thereby altering the regulatory potential of many genes within the entire genome (Meyer et al., 2014a). The consequences of this dynamism are significant alterations in cellular transcriptomes and, more importantly, in function. In the case of vitamin D, response to the VDR can be increased, decreased, prevented, or qualitatively modified, thereby altering the functional response to $1,25(OH)_2D_3$ in a temporal or spatial manner. Interestingly, while these changes occur typically in many disease states that are the focus of vitamin D analog therapy, they are particularly prevalent in cancer cells, a significant target of the antiproliferative activities identified for the vitamin D hormone. While the overall dynamism of the epigenome increases complexity, it also highlights the impact of disease in the selection of gene targets relevant to vitamin D as a therapeutic. Virtually none of these issues were addressable in earlier vitamin D analog studies. Future exploration of the mechanisms of action of novel vitamin D analogs will require the use of the aforementioned techniques and approaches if we are to fully understand exactly how vitamin D analogs operate in vivo.

Many of the basic principles of vitamin D-regulated gene expression as outlined in the foregoing section and in Table 75.5 are illustrated in a series of in vivo studies of the regulation of genes such as *Tnfsf11* (RANKL), the *VDR* itself, *LRP5*, *Mmp13*, *Cyp27b1*, and *Cyp24a1* (Meyer et al., 2017; Kim et al., 2006; Onal et al., 2015, 2016; Pike et al., 2016, 2017; Fretz et al., 2007). Details of the regulation of the *Tnfsf11* gene are illustrated in Fig. 75.1.

Proposed molecular mechanisms of action of vitamin D compounds

Fig. 75.2 contains a general model to predict how vitamin D analogs work. It allows for consideration of both prodrugs (those requiring 25-hydroxylation by CYP27A1 or CYP2R1 and those requiring 1α-hydroxylation by the kidney or extrarenal 1α-hydroxylase) and $1\alpha,25(OH)_2D_3$ analogs. This model therefore makes a distinction between those target cells that express an extrarenal 1α-hydroxylase (CYP27B1), and therefore have the ability to make and respond to their own "local" $1\alpha,25(OH)_2D_3$, and those that simply respond through their VDR with altered transcription. This model features a conventional VDR/RXR heterodimer working through a VDRE in most genes. Crucial parameters for each new analog include:

(1) affinity for DBP,
(2) affinity for VDR,
(3) ability to recruit RXR and coactivators followed by transactivation of genes,
(4) rate of target cell metabolism (reflected partly in pharmacokinetic parameters),
(5) rate of hepatic or nonspecific clearance (reflected partly in pharmacokinetic parameters).

Our view is that all listed parameters contribute significantly to the overall biological activity of any given analog.

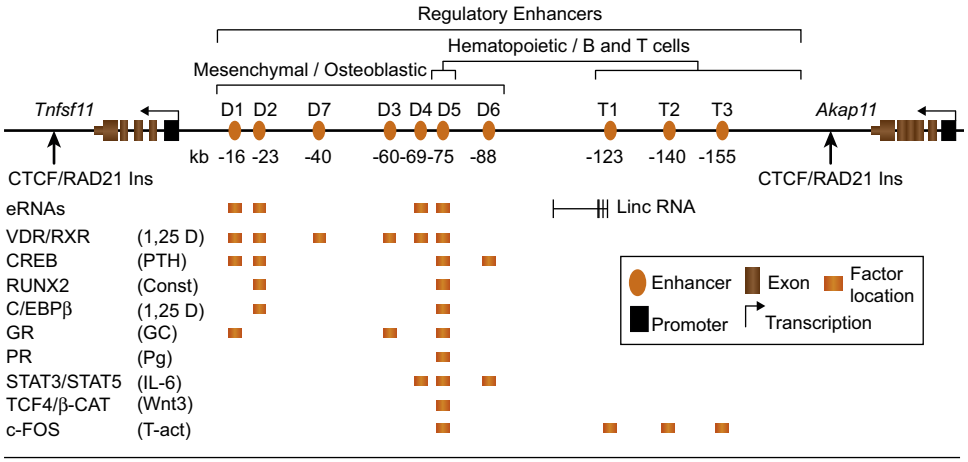

FIGURE 75.1 Regulatory enhancers involved in the regulation of the *Tnfsf11* gene. The *Tnfsf11* gene locus and its osteoblastic and hematopoietic regulatory regions are shown. *Arrows* indicate the CCCTC-binding factor (*CTCF*)/*RAD21*-defined boundaries of the locus that includes the transcription unit and its upstream noncoding regulatory control regions. Enhancers that mediate osteoblast lineage regulation (*D* regions) and hematopoietic regulation (*T* regions) are numbered and indicated by *orange ovals* (light gray in print version). Their distance from the *Tnfsf11* TS Snscription start site in kilobases is indicated below the oval. The *D5* enhancer is active in both cell lineage types. Factors that have been shown to bind to each enhancer by chromatin precipitation (ChIP)—chip and/or ChIP sequencing analysis are indicated below the gene locus by *orange blocks* (light gray in print version).

Future prospects

The elucidation of new details of the genomic mechanism of action of $1\alpha,25(OH)_2D_3$ will probably reveal novel post-VDR coactivator-based approaches by which the vitamin D signaling cascade can be exploited. Certainly, the significant progress made in characterizing the coactivator proteins and the rest of the transcriptional apparatus will continue and will benefit from parallel work on other transcriptional modulators (e.g., other steroids). The attempts to combine deacetylase inhibitors with VDR agonists (Bijian et al., 2018) will be followed with interest.

Studies of the vitamin D-binding pockets of VDR, DBP, and the three (or more) vitamin D-related CYPs will continue to be a major goal now that all these specific proteins have been cloned, overexpressed, and crystallized. Work on the ligand-binding domain of the VDR (Rochel et al., 2001; Rachez and Freedman, 2000; Tocchini-Valentini et al., 2001) will be extended to new analogs and coactivator complexes and the other major proteins in the vitamin D signal transduction pathway.

The wide availability of recombinant proteins for hundreds of CYPs from species across the phylogenetic tree, including 58 CYPs in the human genome, has allowed for the elucidation of some crystal structures and also modeling studies of the enzymes involved in vitamin D metabolism (Prosser et al., 2006; Hamamoto et al., 2006). Current models are starting to reveal key substrate side-chain contact residues (e.g., Ala326 within CYP24A1) associated with 24- and 23-hydroxylation that lead to bifurcation of the catabolic pathway into either calcitroic acid or 26,23-lactone production (Prosser et al., 2007). The crystallization and structural determination of the microsomal CYP2R1, the putative vitamin D 25-hydroxylase, is a harbinger of what is to come in this field (Strushkevich et al., 2008).

Access to full-length CYP24A1 and CYP27B1 has also permitted a more efficient search for potential inhibitors. Specific inhibitors of CYP24A1 (Schuster et al., 2001, 2003; Posner et al., 2004, 2009) may be of value in blocking $1\alpha,25(OH)_2D_3$ catabolism in certain clinical conditions where excessive breakdown is suspected (e.g., cancer therapy). CYP27B1 inhibitors (Schuster et al., 2001, 2003; Posner et al., 2004, 2009) might be useful in situations where $1,25(OH)_2D_3$ synthesis is excessive and serum levels are elevated. Alternatively, the development of specific or even nonspecific inducers of CYP24A1, or surrogates such as CYP3A4 (Hawkes et al., 2017), might aid in the treatment of $1,25(OH)_2D_3$ excess. In general, modeling of VDR and CYPs is expected to lead to more rational vitamin D analog design to take advantage of structural idiosyncrasies of all of these key proteins. Meanwhile, the not-so-rational synthesis of new analogs is likely to continue. The list of applications for these new vitamin D analogs continues to increase (Holick, 2007; Jones, 2007), making synthesis a worthwhile exercise.

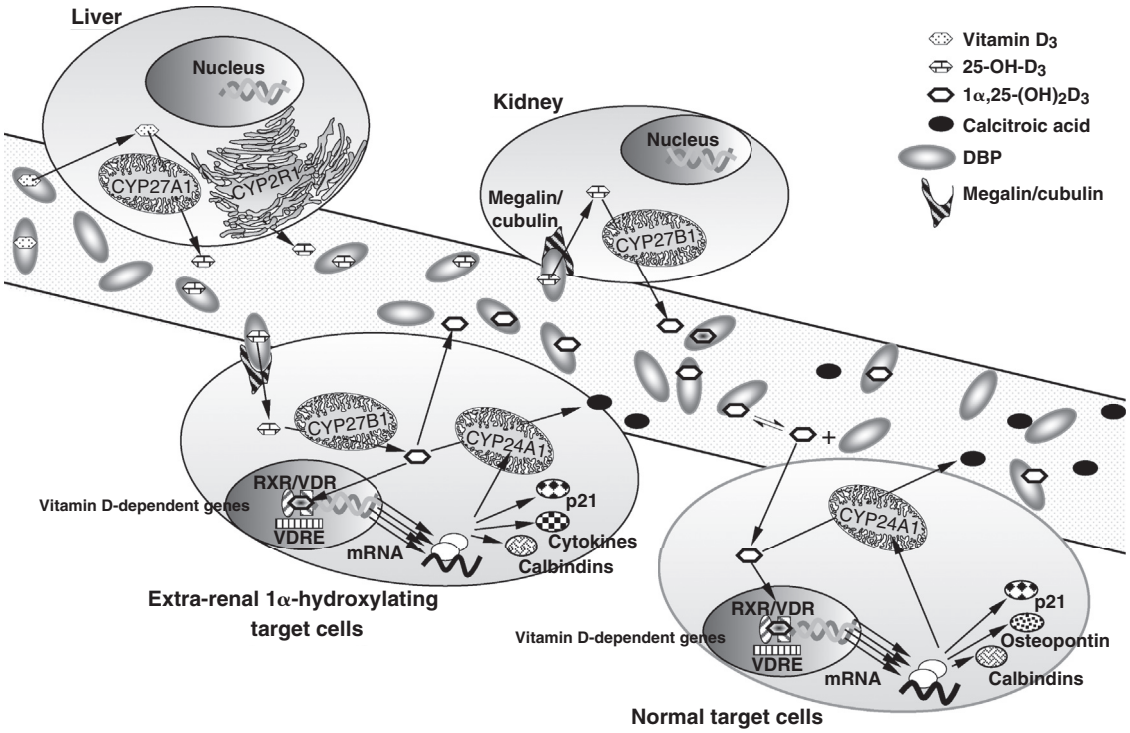

FIGURE 75.2 Current concepts of the activation, mechanism of action, and catabolism of vitamin D. The model incorporates a plasma-binding protein (vitamin D-binding protein, *DBP*), which acts as a carrier of vitamin D metabolites and analogs; activating enzymes (cytochrome P450s, CYPs) involved in activation of vitamin D or prodrug; target cell transcriptional machinery (vitamin D receptor, *VDR*; retinoid X receptor, *RXR*; coactivators) involved in the biological actions of $1\alpha,25(OH)_2D_3$ or its analogs; and a target cell catabolic enzyme system (CYP24A1) involved in the degradation of $1\alpha,25(OH)_2D_3$ or its analog. The metabolism of vitamin D in the context of the cells involved is shown. Going clockwise, top left: hepatocyte showing some of the candidate CYPs shown to 25-hydroxylate vitamin D and its prodrugs; note that VDR is believed to be absent from liver cells. Top middle: proximal tubular cell showing the key elements in the uptake of $25(OH)D_3$ and its conversion to $1\alpha,25(OH)_2D_3$. Megalin/cubulin are cell surface receptors that execute endocytosis of the DBP/$25(OH)D_3$ complex, while CYP27B1 is the main component of the 1α-hydroxylase, responsible for synthesis of circulating $1\alpha,25(OH)_2D_3$. Lower right: conventional target cell, which lacks megalin/cubulin and takes up only the free ligand, $1\alpha,25(OH)_2D_3$, and not the DBP originally involved in transporting the ligand to the target cell. The key elements of the transcriptional machinery are shown, including VDR/RXR as well as representative gene products such as cell division protein p21, the bone matrix protein osteopontin, the calcium transport protein calbindin, and the autoregulatory protein CYP24A1. The role of the highly inducible CYP24A1 is to convert the hormone (or analog) into inactive degradation products, such as calcitroic acid, which enter plasma and are excreted in bile. Lower left: target cell, which expresses extrarenal 1α-hydroxylase (CYP27B1) and the megalin/cubulin machinery to take up $25(OH)D_3$, and thus capable of making $1\alpha,25(OH)_2D_3$ locally. The cell can also respond in a likewise manner to the conventional target cell because it also possesses the VDR and other transcriptional machinery. The expectation is that cells involved in cell differentiation or controlling cell division require higher concentrations of $1\alpha,25(OH)_2D_3$ to modulate a different set of genes, and CYP27B1 boosts local production to augment that *circulating* $1\alpha,25(OH)_2D_3$ arriving from the kidney in the bloodstream. Under normal physiological processes, locally produced $1\alpha,25(OH)_2D_3$ would not enter the general circulation, although in pathological conditions (e.g., sarcoidosis) this could occur. At this time, it is not clear how many cell types can be considered simple target cells and how many possess the CYP27B1 and megalin/cubulin to allow for local production of hormone. *VDRE*, vitamin D response element. *Reproduced from* Jones, G., 2007. Expanding role for vitamin D in chronic kidney disease: importance of blood 25-OH-D levels & extrarenal 1α-hydroxylase in theclassical and non-classical actions of 1α,25-dihydroxyvitamin D3. Semin. Dial. 20, 316–324.

Acknowledgments

The authors acknowledge the contributions of Drs. David Prosser and Martin Kaufmann to the compilation of tables and Fig. 75.2 generated for this review. We thank Dr. Mark B. Meyer for his contribution to some of the work presented.

Chapter outline

Introduction

Weight-bearing exercise is an essential part of a comprehensive strategy to treat and prevent osteoporosis (Sinaki et al., 2010). The National Osteoporosis Foundation recommends both high- and low-impact weight-bearing exercises for 30 min per day 5−7 days a week to load the skeleton. Muscle-strengthening exercises, as complementary to weight-bearing exercises, improve posture and promote musculoskeletal anabolism (Kelly and Gilman, 2017), and help to coordinate

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00076-2

movement and prevent falls. A principal component of these exercises—mechanical signals—is anabolic to both bone and muscle, yet inhibitory to fat formation. This suggests that cells resident on and in the bone tissue are critical to the adaptive response, as well as cells in the bone marrow, including mesenchymal stem cells (MSCs), the shared progenitor for bone and fat cells, interpreting mechanical signals as stimulatory and inhibitory, respectively (Krishnan et al., 2006; Menuki et al., 2008; David et al., 2007; Luu et al., 2009a).

With exercise, dynamic ground-reaction forces transduce a range of signals across the skeleton (Martin et al., 2015; Nilsson and Thorstensson, 1989) and musculature, subjecting cells, tissues, and organs to mechanical strain (deformation) and acceleration. Key salutary outcomes of exercise include increased lean muscle, increased bone mineralization and turnover rate, decreased inflammation (Sakurai et al., 2009), and inhibition of marrow adipose tissue volume (Styner et al., 2014), improving health outcomes that combat the progression of osteoporosis and delay the onset of obesity.

Exercise represents a nondrug strategy to increase bone mass as well as decelerating bone loss, salutary outcomes achieved through bone tissue's sensitivity to its mechanical loading environment. A host of human-based studies have worked toward quantifying the impact of general and specific exercise regimens on bone mass and morphology, taking into account interdependent variables such as gender, age, and nutritional status of the individuals. Although some studies have provided encouraging results, the large majority of data have been equivocal, perhaps a reflection of our limited understanding of which specific components of the mechanical signal are perceived as influential by the resident bone cell populations (e.g., osteocytes, osteoblasts, lining cells, osteoclasts, bone marrow stem cells) and which are irrelevant by-products of loading. The design of an "optimal" exercise intervention (e.g., least amount of physical exertion for the greatest gain in skeletal strength) requires many critical questions to be addressed: should the exercise protocol incorporate large loads or could they be small if they are applied rapidly? How long does an individual have to exercise to maximize benefits? Are the attributes of mechanical loading accumulated, or is there a threshold past which additional challenges no longer are perceived as regulatory influences to the skeleton? Does an exercise program that works in one cohort (e.g., adolescents) translate to another (e.g., the elderly)?

Here, we first define the functional loading environment of bone to demonstrate that the ability of physical signals to influence bone morphology strongly depends on the character of the signal, and we provide an overview of the molecular and cellular events that play a role in transducing the mechanical signal into a biochemical message. Establishing a first-order approximation of the physical and molecular factors of the mechanically derived signal is critical toward developing exercise prophylaxes that are clinically feasible, enjoy high compliance, and can prevent the bone loss leading to osteoporosis.

Bone's sensitivity to mechanical signals

The skeleton's ability to adapt to altered levels and patterns of mechanical loading is well established but the difficulty lies in defining the specific regulatory component(s) that is embedded within the bone's complex loading environment. Numerous clinical exercise studies have been unable to correlate adaptive changes in bone to specific aspects of a particular exercise regimen, including exercise mode (e.g., running, swimming, weight lifting), intensity (e.g., percentage of maximal heart rate), duration, and repetition (number of times per month, week, day), emphasizing the need to characterize bone's mechanical environment generated by the prescribed exercise regimen.

At the organ level, the site specificity of exercise-induced bone adaptation is clear in tennis players, who display significant bone hypertrophy in the playing extremity but not in the contralateral arm that simply throws the ball into the air (Jones et al., 1977). During physical activity, changes in the loading environment are not uniform across the skeleton or bone. Reflecting this nonuniform environment, adaptation within a bone is also site specific, as some bone surfaces will change their osteoblastic or osteoclastic activity but others will not (Judex et al., 1997).

Since the early 1980s, specific components of the mechanical milieu have been proposed as the dominant stimulus for bone adaptation, including strain magnitude (Rubin and Lanyon, 1985), strain rate (O'Connor et al., 1982), electrokinetic streaming currents (Pollack et al., 1984), piezoelectric currents (Bassett, 1968), fluid shear flow (Weinbaum et al., 1994), and strain energy density (Fyhrie and Carter, 1986). Although several of these parameters correlate with specific skeletal morphologies, few have validated their regulatory role with an accurate, prospective prediction of adaptation as stimulated by changes in loading conditions (Gross et al., 1997). The difficulty in identifying a unifying principle that can anticipate the mechanical control of bone adaptation may be aggravated by an underlying "structural" presumption that tissue efficiency (minimal skeletal strain/minimal skeletal mass) is itself the driving stimulus that regulates the remodeling process.

Alternatively, bone cells may be responding to "biologically relevant" parameters of the functional milieu that are not necessarily linked to minimizing deformation of the structure under load. In support of "other than peak" signals regulating bone adaptation, examples of biological systems that perceive and respond to exogenous stimuli, such as vision, hearing,

and touch, are regulated in this fashion. It is also well accepted that too much loading will damage the bone matrix and predispose the skeleton to failure, just as too much light, noise, or pressure will overwhelm sight, hearing, and touch. To identify the criteria by which bone tissue responds to loading, it is important to look beyond the material consequences of a structure subject to dangerous levels of load and consider the biological benefit of a viable tissue/cell system subject to exercise.

Bone's mechanical milieu elicited by physical activity

Strains in bone

To gain insight into the structural demands that are placed onto the skeleton during daily activities, the mechanical environment that bone is subjected to can be characterized. In stark contrast to the notion that bone is purely loaded under compression, these experiments have definitively demonstrated that the long bones of the appendicular skeleton are also subject to a complex array of forces and moments produced by torsion and bending even during very simple activities such as steady-state locomotion (Rubin et al., 2013).

The mechanical state in the bone matrix is commonly quantified by spatial and temporal measures that are based on mechanical strain (ε), the dimensionless expression of deformation (ε = change in length, ΔL, normalized to the original length, L, of any given specimen). Because of the very small deformations that bone experiences during physiological loading, strain is typically expressed as microstrain (1% deformation = 0.01 strain = 10,000 $\times$ 10^{-6} strain = 10,000 $\mu\varepsilon$ = 10,000 microstrain).

Strain of a material is an inescapable product of load, regardless of its specific design or function. Pull a rubber band and it stretches, sit on a seat cushion and it compresses. Bend a pencil, and the concave surface is undergoing compression while the convex is stretching, undergoing tension; bend it too much, past the yield strain, and it snaps. In the case of bone, mechanical strain and its derivatives are considered an efficient means of translating mechanical load, including intensity, duration, and manner (e.g., twisting, bending), into a site-specific regulatory signal that can be recognized by the cell system that controls bone adaptation. One obvious goal of this strain-mediated form/function adaptation is to avoid catastrophic failure, or bone fracture. This requires that bone architecture is designed to control loading to avoid the tissue's yield strain of 0.7% (7000 $\mu\varepsilon$). Through strain gauges surgically implanted onto bone's surface, strain magnitudes have been determined during functional activities in a variety of species, including humans, dogs, primates, roosters, horses, sheep, and rats (Burr et al., 1996; Gross et al., 1992; Lanyon, 1971; Rubin and Lanyon, 1982). Although these gauges record deformation only from the specific sites they are attached to, engineering models can be used to extrapolate measured deformations to other sites within the bone.

Peak strain magnitudes measured in diverse vertebrates range from 2000 to 3000 microstrain (Rubin and Lanyon, 1984b). Whether measured in the third metacarpal of a galloping horse, the tibia of a running human, the humerus of a flying goose, the femur of a trotting sheep, or the mandible of a chewing macaque, this "dynamic strain similarity" suggests that skeletal morphology is adjusted such that functional activity elicits a very specific (and perhaps beneficial) level of strain to the bone tissue (Rubin et al., 1990). That strains of this magnitude are at least a factor of 2 below the yield point of bone material emphasizes that bone has a "safety factor to failure" of about 2−3 to defend against aberrant loading events. However, the realization of a mechanism by which the skeleton anticipates being loaded to about half its yield strength seems overly complex and unlikely. Instead, in vivo and in vitro data suggest that the functional criteria that regulate adaptation, and the means by which bone cells perceive and respond to their functional milieu, are more sophisticated than a mechanism that simply focuses on the magnitude of the deformation generated in the tissue.

Locomotion induces a nonuniform strain environment

During locomotion, bending is the dominant form of loading in the middiaphysis of limb bones; more than 85% of the strain measured in diaphyseal long bones is accounted for by bending moments (Rubin and Lanyon, 1982). These mid-diaphyseal bending moments are promoted, not negated, by bone curvature, and like the pencil, applied bending moments generate compressive strains on one side of the cortex and tensile strains on the opposite side (Fig. 76.1). The dominance of bending in the functional loading environment is somewhat counterintuitive because far less bone mass would be required to support the same loads if the bone were loaded axially. Bending fosters consistent, predictable loading conditions under which specific regions within the cortex are loaded in a similar fashion independent of the functional activity.

To demonstrate the stability of the functional strain environment, roosters were subjected to three distinct loading environments engendered by treadmill walking, treadmill running, or drop jumps for which roosters were released from a

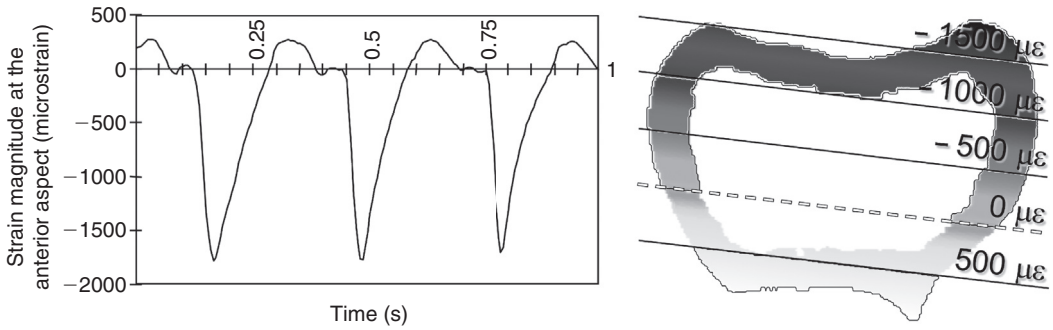

FIGURE 76.1 (Left) Recording from a strain gauge attached to the anterior aspect of the middiaphyseal tarsometatarsus while the animal is running on a treadmill at a high speed. (Right) The distribution of longitudinal normal strain magnitude about the middiaphysis of the rooster tarsometatarsus. The distribution was recorded at that point in the stride in which peak strain is achieved. While the distribution of peak strain is spatially very nonuniform, the manner in which the bone is loaded remains constant (i.e., the site of peak strain varies very little during the stance phase of a gait cycle). *Adapted from Judex, S., Gross, T.S., Zernicke, R.F., 1997. Strain gradients correlate with sites of exercise-induced bone-forming surfaces in the adult skeleton. J. Bone Miner. Res. 12(10), 1737–1745.*

50- to 60-cm height. Tarsometatarsal middiaphyseal strain magnitudes and distributions were determined via strain gauges and linear beam theory (Judex and Zernicke, 2000b). We found that peak compressive strains produced by these three activities increased from −1570 με for walking to −1870 με for running and −2070 με for jumping (nb, a negative strain denotes compression). Despite this increase in peak strains, the relative distribution of strain across the middiaphysis was essentially identical across the three activities.

With bending causing tension on one surface and compression on another, the transition between these two areas creates a region of the cortex that experiences very low peak strain magnitudes. Even though this neutral axis of zero strain is far removed from the area of the cortex subject to the peak strains, somehow tissue is retained in this low-magnitude strain state. It might be suggested that bone cells in different regions of the cortex are differentially sensitive to strain (e.g., some cells strive to 3000 με in compression, some to 1500 με in tension; others—near the neutral axis—are content with strains of 50 με). Although appealing in its simplicity, the apparent limitations of a spatially specific strain sensitivity are apparent with respect to the required genetic logistics.

Alternatively, it is possible that strain information is spatially integrated in three dimensions via a cell network facilitated by the osteocyte's canalicular network (Weinbaum et al., 2001) and gap junction intercellular communication (Donahue et al., 1995), such that the area of the cortex subject to 50 με resists resorption owing to sufficient homeostatic signals received from neighboring areas subject to higher strains. This "information integration" perspective is supported by the observation that the bone loss that parallels disuse occurs uniformly about the cortex and through the diaphysis, even though the net change in bone strain caused by the absence of function varies widely (Gross and Rubin, 1995). Since the early 2000s, many studies have confirmed the role of gap junction communication in signal transduction across osteocyte networks when bone cells are subjected to external mechanical cues (Jorgensen et al., 2000; Ishihara et al., 2013; Cherian et al., 2003, 2005).

The influence of muscle on bone's strain environment

The symbiotic relationship between muscle and bone is inherently obvious, and the musculoskeletal system might be considered in the context of one defining the other. In the absence of ground-reaction forces, the spectral components of muscle contraction typically impose smaller strains on the skeleton than those caused by functional impact loading. Even though muscle-induced strains may be small, they are sustained for extended periods of time (e.g., in postural muscle activity) and thus, over time, may dominate a bone's characteristic "strain history." Examining this hypothesis, strain data from a variety of animals reveal the existence of a broad frequency range of strains in the appendicular skeleton, even during activity such as quiet standing (Fritton et al., 2000; Fig. 76.2).

From a stimulus standpoint, these persistent, low-amplitude, high-frequency signals may, when summed, be at least as important as the seldom occurring, and somewhat unpredictable, peak strain events. If there is an age- or pathologically induced change in the dynamics of these muscle oscillations, it could be argued that bone mass may deteriorate, because these muscle-based signals also attenuate. To determine the role of muscle dynamics in the etiology of osteopenia, the spectral characteristics of muscle activity as a function of age were obtained through measurements of muscle surface vibration (Huang et al., 1999).

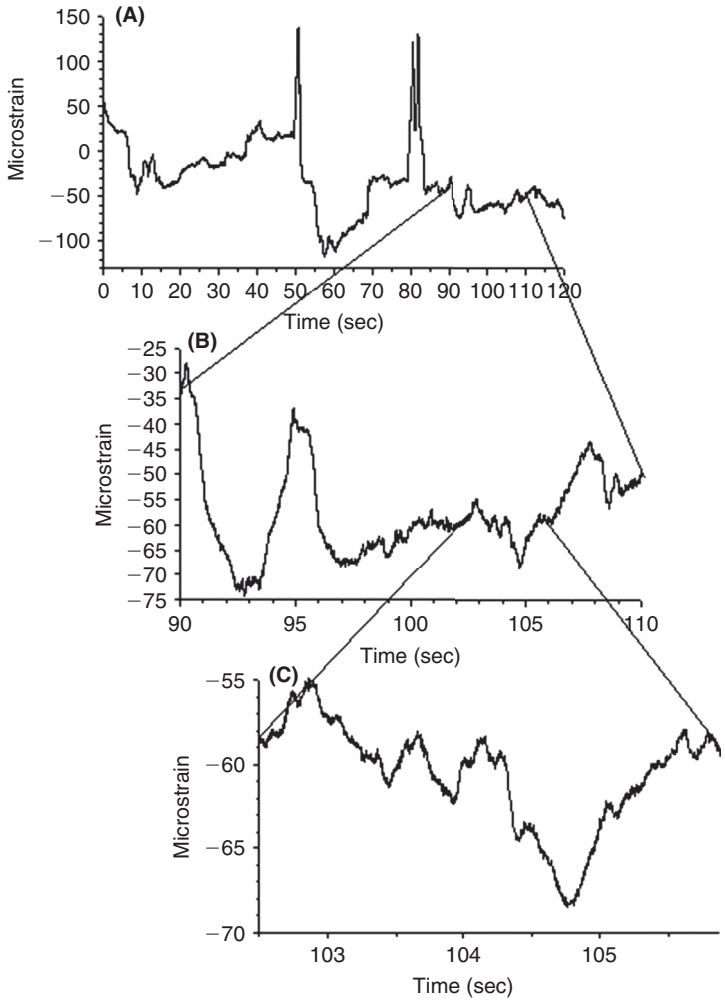

FIGURE 76.2 (A) A 2-min strain recording from the caudal longitudinal gauge of the sheep tibia while the animal took a few steps with peak strains on the order of 200 με. (B) A 20-s portion of that strain record shows peak strain events as large as 40 με. (C) Further scaling down to a 3-s stretch of the strain recording illustrates events on the order of 5 με. *Adapted from Fritton, S.P., McLeod, K.J., Rubin, C.T. 2000. Quantifying the strain history of bone: spatial uniformity and self-similarity of low-magnitude strains. J. Biomech. 33(3), 317–325.*

During the contraction of a muscle, radial expansion of the individual fibers results in fiber collisions and the production of muscle sound or acoustic vibrations of the muscle body. The frequency of these vibrations reflects the firing rate of the motor units and, correspondingly, the force output of the motor unit. When recorded in 40 volunteers (20–83 years of age) using a low-mass accelerometer, the spectra of the acoustic vibrations normal to the surface of the soleus muscle showed that muscle activity in the frequency range above 20 Hz decreased by a factor of 3 in the elderly compared with that seen in young adults, a sarcopenia consistent with loss of fast oxidative-type fibers. Simultaneous with the decay of high-frequency signals, there is a marked decrease in the amount of type IIa and IIb fibers (Lee et al., 2006), compounding the suppression of the source of the signal.

As the high-frequency components seen in bone during load bearing almost certainly arise through muscle activity, the deterioration of the muscle contraction spectra with age would consequently decrease the spectral content of bone strain above 20 Hz. From this perspective, it can be argued that the sarcopenia of aging may be a principal etiological factor in osteoporosis, as this portion of the strain spectrum is demonstrably osteogenic (see later). If aging leads to the loss of specific muscle fibers critical to the maintenance of bone mass, osteoporosis could presumably be inhibited by providing a "surrogate" for the lost spectral strain history.

Regulation of bone morphology by mechanical stimuli

Toward identifying the osteogenic parameters of the strain milieu

It is clear that the skeleton is subject to a wide range of mechanical signals, including low- to high-frequency strains, normal and shear strains, and compressive and tensile strains. It is also clear that the cells on and within the mineralized matrix are subject not only to mechanical parameters such as strain, but also to derivatives of tissue deformation such as fluid flow and electrokinetic currents, parameters that may represent an important physiological pathway in mediating an adaptive response. But which physical parameters are most important to regulating the adaptive response?

Models that have been used to investigate bone's adaptive response to its mechanical environment include overloads by osteotomies (Lanyon et al., 1982), vigorous exercise (Judex and Zernicke, 2000a), or exogenous loading models in which external forces are applied to the bone. Exercise represents a physiological means of enhanced mechanical loading, but the limited exercise repertoire of most laboratory animals makes it difficult to generate and control distinct mechanical milieus. Exogenous loading models such as the functionally isolated avian ulna (Rubin and Lanyon, 1984a), the axially loaded rat ulna (Torrance et al., 1994), or the rat tibia placed in a four-point bending apparatus (Turner et al., 1991) allow the generation of relatively controlled mechanical environments.

Strain magnitude

When holding strain frequency and number of loading events constant, longitudinal normal strain magnitude (strain in the direction of bone's longitudinal axis) is highly related to the osteogenic response. In other words, the larger the maximal deformation that is generated in the bone, the larger the overall response of the bone. Strains, when applied at 1 Hz (cycles per second) and that fail to reach a certain magnitude are permissive to bone loss. This relationship was first demonstrated in the functionally isolated turkey ulna preparation to which strains in the range of 400−500 με were applied at 1 Hz for 100 cycles per day. In this model, strains smaller than 1000 με caused bone loss, with strains larger than 1000 με leading to new bone formation in a dose-dependent relationship (Qin et al., 1998).

The question as to how much strain in bone has to be generated to obtain an osteogenic effect depends on the interrelationship between strain magnitude, strain rate, and strain frequency. While 100 loading cycles per day at 1 Hz inducing 1000 με prevented bone loss from occurring, this threshold can be reduced to 700 με when 600 loading cycles are applied at 1 Hz, to 270 με when 36,000 loading cycles are applied at 60 Hz, or to 100 με when 108,000 loading cycles are applied at 30 Hz. This demonstrates that the search for a particular strain (loading) threshold has to take other mechanical parameters into account as well and that this relationship can be exploited to design safer exercise regimens using smaller loads. Nevertheless, when considered in the clinic, a fascinating study has showed that higher intensity training has been shown to be more effectual than low intensity in peri- and postmenopausal women (Watson et al., 2018).

Differential bone remodeling to distinct components of the strain tensor

The goal of investigating the osteogenic effects of different aspects of the strain tensor has been approached using the turkey ulna model of disuse osteopenia, in which the modeling and remodeling response was quantified following 4 weeks of either axial or torsional loading or disuse (Rubin et al., 1996). Each of the two load groups was subjected to peak principal strains of 1000 με (predominately normal strain in the axial case, and shear strain when subjected to torsion). Of the three distinct groups, only disuse caused a significant change in gross areal properties compared with controls (13% loss of bone). This suggests that both axial and torsional loading conditions are substitutes for the functional signals normally responsible for retention of bone mass, leaving the periosteal and endosteal envelopes unfazed by disparate components of the strain tensor.

The intracortical response, however, was found to depend strongly on the manner in which the bone was loaded. Disuse failed to increase the *number* of sites within the cortex actively involved in bone turnover (intracortical events), yet significant area was lost within the cortex owing to a threefold *increase in the mean size* of each porotic site. Axial loading increased the degree of intracortical turnover compared with intact controls, yet the average size of each porotic event remained identical to that of controls. Conversely, torsion elevated neither the number of porotic events, the area of bone lost from within the cortex, nor the size of the porotic event. It appears that bone tissue can readily differentiate between distinct components of the strain tensor, with strain per se necessary to retain coupled formation and resorption, shear strain achieving this goal by maintaining the status quo, whereas normal strain elevates intracortical turnover, but retains coupling.

Strain rate

Although strain magnitude appears to be an important determinant of bone mass, it is critical to realize that dynamic but not static strains have osteogenic potential. At the extreme, static loading (strain rate = 0) at strain magnitudes capable of stimulating formation when applied dynamically produces a remodeling response similar to that to disuse, resulting in bone resorption (Lanyon and Rubin, 1984). Several studies support the notion that bone is sensitive to the applied strain rate, with higher strain rates being more osteogenic (LaMothe et al., 2005; O'Connor et al., 1982).

Extrapolated for the design of exercise interventions, these results imply that loads should be applied rapidly. Although exercise studies have been unable to identify a specific exercise intervention that is most effective in producing beneficial skeletal effects, a trend has emerged with high-impact exercise being more efficient than low-impact exercises in terms of stimulating new bone formation (Gabel et al., 2017). This trend may support the notion that high strain rates have a critical impact on bone morphology, as high-impact exercises ostensibly induce higher strain rates (MacKelvie et al., 2003).

Cycle number

A threshold behavior exists for the number of loading cycles, with the full response being triggered after only a limited number of loading cycles (Umemura et al., 1997; Rubin and Lanyon, 1984a). Focusing on the turkey ulna preparation, a loading regimen inducing peak strains of approximately 2000 με maintained bone mass with only 4 cycles a day. When the cycle number was increased, this loading regimen stimulated new bone formation. Thirty-six load cycles saturated the osteogenic response, with as many as 1800 cycles failing to be more effective than 36 cycles. Once the system is "on," additional information appears to be ignored.

Studies have indicated that the manner in which loading cycles are distributed plays an important role in defining the magnitude of the anabolic response. Partitioning a given bout of loading cycles into several loading sessions can increase bone's response to the mechanical intervention (Robling et al., 2002). Going one step further, studies have shown that this concept can be exploited to produce a mechanical intervention that is more efficacious despite providing fewer loading cycles (Gross et al., 2004), achieved by inserting a 10- to 15-s rest period between loading cycles to increase the osteogenic response in both young and aged mice (Srinivasan et al., 2002, 2003). This loading strategy can transform an otherwise ineffective loading regimen into a highly osteogenic stimulus. Specifically, varying the peak strain magnitudes (at a fixed cycle number) and varying cycle numbers (at a fixed strain magnitude) both result in increased bone formation rate (BFR) when a 10-s rest is inserted between loading cycles, compared with cyclic loading (Srinivasan et al., 2007). The mechanism by which the sensitivity of cells to mechanical signals is increased by rest-inserted loading may be associated with high cell refractory periods that, upon the application of a single loading event, impose a "time out" to the cell during which it cannot respond to another cycle (Sen et al., 2011). Translated to the human, perhaps incorporating rest periods into training regimens could increase the salutary response to exercise.

Strain distribution

Although a relation between bone's peak strain magnitude and the adaptive response has been proposed, bone also appears to be sensitive to how the strains are distributed across a bone section. Simply imposing a strain distribution that produces peak strain magnitudes similar to those of habitual loading conditions—but at different locations within the section (i.e., rotating the strain distribution)—may initiate new bone formation (Rubin and Lanyon, 1987). Thus, unusual strain events (strain errors) have been suggested to drive bone adaptation. Running, for instance, may not be the optimal exercise for bone formation, partly because it may generate strain distributions that are very similar to strain distributions induced by walking. Interestingly, sports that involve a great variety of changes in loading directions, such as squash, aerobic dancing, and speed skating, lead to site-specific benefits in bone mineral density in the areas that are subjected to loads during a given activity (Heinonen et al., 1995). Specifically, squash players had increased bone mineral density at lumbar spine (13.8%), femoral neck (16.8%), distal femur (11.2%), patella (6.7%), proximal tibia (12.6%), calcaneus (18.5%), and distal radius (11.3%), compared with sedentary controls. The speed skaters had a higher bone mineral density only at the distal femur (7.2%).

Sport-induced enhancement in bone has also been shown to be dependent on the intensity of the sport, such that high-impact sports (i.e., football) are more effective in increasing bone mass compared with low-impact sports (i.e., swimming and cycling) (Vlachopoulos et al., 2017). In addition, exposing the skeleton to the mechanical forces from childhood may also aid in maximizing the potential gains, as evident by the correlation between physical activity and bone strength from childhood to early adulthood (Gabel et al., 2017). Hence, physical activity that varies in loading directions has been shown

to result in enhanced osteogenic responses, although it has not been confirmed that these changes in loading directions actually cause altered bone strain distributions.

Strain gradient

Rather than exclusively considering the peak magnitude of the stimulus and averaging the morphological response through a given cross section, one could investigate whether new bone is actually deposited in those regions where the applied stimulus is the largest (i.e., does bone adaptation correlate with strain distribution?). If such a site-specific relationship exists, then the knowledge of this specific osteogenic component may provide information about a mechanism by which bone cells perceive their mechanical environment.

To a degree, this issue was addressed in an exercise study in which young adult roosters were run on a treadmill for 9 min per day (~1500 gait cycles) for 3 weeks. The brief daily running regimen activated periosteal surfaces, but the amount of periosteal mineralizing surfaces per sector was only weakly associated with strain magnitude ($R^2 = 0.24$, negative correlation). In contrast, circumferential strain gradients (changes in strain magnitude across a volume of tissue) correlated strongly ($R^2 = 0.63$) with the sites of periosteal activation, consistent with earlier results from an external loading model (Judex et al., 1997). In general, circumferential strain gradients are largest where strains (deformations) are the smallest.

Although counterintuitive from a structural perspective, activating bone formation at sites subjected to low strains rather than large strains, strain gradients drive fluid flow in bone in the matrix, a process that has been suggested to play an important role in mechanotransduction in bone. These data further emphasize that bone adaptation is not necessarily guided by form–function relations, rather that bone cells respond to a biological signal resulting from the application of mechanical loads.

Fluid flow

Cells on and within the mineralized matrix are subject to mechanical parameters such as strain, as well as derivatives of tissue deformation such as fluid flow and electrokinetic currents, parameters that may represent an important physiological pathway in mediating an adaptive response. Bone cells, in particular osteocytes, are surrounded by extracellular fluid (Weinbaum et al., 1994). The driving force for fluid to flow is a differential pressure between two ends of a lacunar–canalicular system that experience different amounts of mechanical strain, both temporally and spatially. Fluid flow is thus a direct by-product of mechanical strain, and a large body of in vitro studies has shown the sensitivity of bone cells to flow (Rubin et al., 2006; Bancroft et al., 2002). Because of the tight coupling between mechanical strain and fluid flow under physiological conditions in vivo, only few studies have successfully increased fluid flow in controlled animal models (Qin et al., 2003). Similar to in vitro data, raising intramedullary pressure, and thus enhancing interstitial bone fluid flow, can increase bone formation (Stevens et al., 2006). The in vivo mechanism(s) by which bone cells sense and respond to fluid flow may be related to one of the following processes: (1) fluid pressurization that directly stimulates cells, (2) interstitial fluid flow that excites osteocytes through fluid shear stresses, (3) drag forces that perturb the osteocytic processes in the pericellular matrix, (4) fluid flow that aids in the transport of nutrients to bone cells, or (5) electrokinetic effects such as streaming potentials (Bonewald and Johnson, 2008).

Evidence of this is provided by a novel fluorescence recovery after photobleaching technique, combined with synchronized mechanical loading and imaging, used to show a 31% increase in real-time solute transport within the lacunar–canalicular system following cyclic end compression of mouse tibia (400 με of surface strain at 0.5 Hz, 4 s rest between adjacent loading cycles) (Price et al., 2011). This model provides a foundation through which the effect of mechanical stimulation of osteocytic cellular responses could be quantified in vivo. Together, in vitro and in vivo studies clearly demonstrate that bone fluid flow is capable of transducing mechanical signals from the matrix to the cell.

Low-magnitude, high-frequency mechanical signals

A common theme of the exercise-induced adaptation in bone is that only peak events are considered (e.g., exercise intensity, peak strain magnitude, peak strain rate). From this, one could conclude that mechanical modulation of bone physiology depends on large signals to have any morphological impact. However, the weak correlation of new bone formation with exercise intensity or with the specific sites of peak strain magnitudes suggests that other factors may also help define bone mass and morphology.

As discussed earlier, in vivo data suggest a nonlinear interdependence between cycle number, strain frequency, and strain magnitude. When the turkey ulna was loaded at 1 Hz, peak strains larger than 700 με were necessary to maintain bone mass. This loading threshold can be reduced to 400 με at 30 Hz and to 270 με at 60 Hz. Although the reduction in strain threshold could be associated with an increase in cycle number, it is also possible that the increase in frequency at which loading occurred played a large role, just as the eye sees color based on frequency and the ear hears pitch based on frequency. Indeed, since the early 2000s, we and others have demonstrated that bone can sense and respond to even extremely small mechanical signals if they are applied at frequencies considered "high" based on typical locomotion (walk at 1 Hz, run at 3 Hz).

Low-level mechanical signals increase bone quantity and strength

To examine the long-term influence of applying short bouts of extremely low magnitude, high-frequency signals, adult sheep stood in a chute where only the hindlimbs were subjected to a vertical ground-based vibration, oscillating at 30 Hz, to create peak−peak accelerations of 0.3*g* (Rubin et al., 2001a). When the animals were not being treated, they pastured with controls. After 1 year of stimulation, peripheral quantitative computed tomography of the femur demonstrated a 34.2% increase in trabecular density in mechanically stimulated sheep ($P < .01$). Micro-computed tomography indicated that not only the quantity of trabecular bone had benefited but also its microarchitecture (Rubin et al., 2002b). The trabecular bone pattern factor, an index of connectivity, decreased 24.2% in animals subjected to the noninvasive stimulus ($P < .03$), reflecting an increase in connectivity of the trabecular struts. Histomorphometry emphasized that the increase in volume fraction was achieved through an anabolic stimulus (Rubin et al., 2002a). The elastic modulus and stiffness of the bone subject to the low-level mechanical stimulus also increased significantly (Fig. 76.3) and analyses of the tissue-level stresses and strains indicated that, micromechanically, the bone had to adapt to become a mechanically more efficient structure (Judex et al., 2003).

Translating this to the human, a pilot study in children with low bone density showed a similar trend wherein a 30-min vibration intervention (30 Hz, 0.3*g*) for 8 weeks led to 6.2% increase in cancellous bone density, 2.1% increase in cortical bone density, and 16.6% increase in bone-specific alkaline phosphatase, an indicator for increase in bone formation (Pitukcheewanont and Safani, 2006). Low-level leisure time physical activity such as walking or bicycling for less than 20 min per day has also been shown to reduce the risk of hip fracture (hazard ratio = 0.77) and any fracture (hazard ratio = 0.87) in both men and women (Stattin et al., 2017). These studies suggest that bone may be "tuned" to higher frequency loading, and it may represent a sort of "surrogate" for strenuous exercise (Ozcivici et al., 2010).

Low-level mechanical signals normalize bone formation

Disuse osteopenia models have been used to determine whether resorptive remodeling, as stimulated by disuse, could be suppressed with brief exposure to these low-level vibrations. A single-element strain gauge, attached to the tibia of

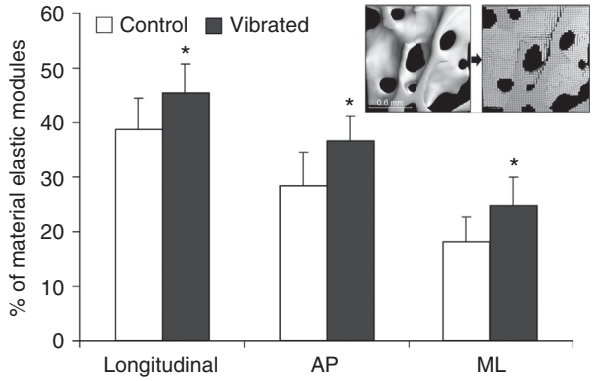

FIGURE 76.3 Finite element modeling was used to convert the trabecular structure into a mechanical model. Simulated mechanical testing in all three orthogonal loading directions indicated that the application of short bouts of high-frequency mechanical signals increased trabecular stiffness. Shown is the apparent tissue elastic modulus expressed as percentage of the tissue elastic modulus for control and experimental sheep in the three directions (mean + SD). *AP*, anterior−posterior direction; *ML*, medial−lateral direction. *$P < .05$. *Adapted from Judex, S., Boyd, S., Qin, Y.X., Turner, S., Ye, K., Muller, R., Rubin, C. 2003. Adaptations of trabecular bone to low magnitude vibrations result in more uniform stress and strain under load. Ann. Biomed. Eng. 31(1), 12−20.*

calibration rats, showed that the oscillation, at 0.3*g*, generated strains less than 5 με at 45 Hz, more than 2 orders of magnitude below the strains that can protect bone when induced at 1 Hz. Compared with long-term controls, 28 days of tail suspension caused mineralizing surface (MS/bone surface (BS)) of the tibiae to drop 52% ($P < .004$) and BFR per bone volume (BFR/BV) to drop 72% ($P < .0002$) (Rubin et al., 2001b). The suppression of formation was not significantly different from that in the animals subjected to disuse for most of the day (23 h, 50 min) and then allowed to freely bear weight for 10 min per day. However, 10 min/day of weight bearing on an active vibration platform normalized mineralizing surfaces and BFRs to normal weight-bearing levels.

Translating this to humans, a 6-month vibration intervention (90 Hz, 0.3*g*, 10 min/day, 5 days/week) in children with immobility-induced disability resulted in 6.3% increase in trabecular bone mineral density of the proximal tibia, compared with children who did not receive a vibration treatment, who had a 12% decrease in bone mineral density relative to baseline (Ward et al., 2004). Taking this to an extreme, negative implications of a prolonged 56-day bed rest, in terms of reduced bone mass and increased bone resorption, were mitigated with a twice-daily resistive vibration exercise for 4−6 min per bout, ranging in frequency from 18 to 26 Hz (Armbrecht et al., 2010), although the *g* forces were much higher.

Vibrations can decrease resorptive activity

To test the effects of these higher frequency mechanical signals in the growing skeleton in which resorptive activity is relatively high, 8-week-old mice were subjected to daily 15-min bouts of whole-body vibrations at 45 Hz and 0.3*g*. After 3 weeks, osteoclastic activity in the trabecular metaphysis and epiphysis of the tibia was ~30% lower ($P < .05$) in vibrated mice than in age-matched controls. BFR/BS on the endocortical surface of the metaphysis was 30% greater ($P < .05$) in whole-body vibration than in age-matched control mice, but trabecular and middiaphyseal BFRs were not significantly altered (Xie et al., 2006).

Translated to humans, 8 weeks of whole-body vibration intervention (15 min/day, 30 Hz, 0.3*g*) in postmenopausal women reduced the hip fracture risk by mitigating the bone loss at the trochanter and lumbar spine (Beck and Norling, 2010). In addition, whole-body vibration (frequency ranging from 25 to 35 Hz) combined with exercise also resulted in increased bone mineral density at the lumbar spine and decreased fall risk in postmenopausal women (von Stengel et al., 2011).

Genetic variations modulate bone's response to mechanical signals

It is well accepted that the genetic makeup of any given individual is a strong predictor of risk of osteoporosis (Deng et al., 2001). What is not as clear is if the genetic template can account for variability in the response to bone's ability to adapt to mechanical signals. To address this question, inbred mouse strains with distinct bone phenotypes (Judex et al., 2004) were used to examine whether they were differentially sensitive to changes in their habitual mechanical environment (Judex et al., 2002). Adult female mice, with relatively thin (C57BL/6J), medium (BALB/cByJ), and robust (C3H/HeJ) skeletons were subjected to 10 min/day of low-level, high-frequency mechanical signals (0.25*g* at 45 Hz). After 3 weeks, BFR, with tissue volume as referent of C57BL/6J mice subjected to the low-level mechanical signal, was 69% greater ($P < .04$) than in intrastrain control mice. Increased trabecular BFRs coincided with an 85% ($P < .01$) larger BV (BV/TV) and 50% larger trabecular thickness ($P < .009$) in the vibrated mice. In BALB/cByJ mice, the low-level mechanical signals increased BFR/BV by 34% ($P < .02$), but bone structural indices, including BV/TV, remained unaffected. In contrast to the responsiveness of the C57BL/6J and BALB/cByJ strains, no significant effects of mechanical stimulation were measured in tibial trabecular bone of C3H mice. Extrapolating these results to the human skeleton may provide insight into the preferential efficacy of mechanical interventions, such as exercise or low-level vibrations. The results of this study also suggest that some people who benefit from a genetically predetermined higher bone mass may ultimately be less sensitive to any form of physical intervention (Torvinen et al., 2003).

Inhibition of postmenopausal bone loss by low-level vibrations

With the demonstration that mechanical factors can be anabolic and anticatabolic to the skeleton, a challenge becomes whether these "regulatory factors" can be safely and effectively administered in the clinic to inhibit or reverse osteopenia. Many animal studies have shown the efficacy of low-level whole-body vibration intervention in mitigating ovariectomy-induced bone loss (Flieger et al., 1998; Rubinacci et al., 2008; Butezloff et al., 2015; Krishnamoorthy et al., 2016). However, the effect of whole-body vibration in postmenopausal women in the clinic remains ambiguous. The ability of a

low-magnitude (0.2g), high-frequency (30 Hz) mechanical stimulation to inhibit postmenopausal osteopenia was evaluated in a prospective, randomized, double-blind, placebo-controlled clinical trial (Rubin et al., 2004). Sixty-two postmenopausal women were enrolled in the study. Thirty-one women underwent mechanical loading of the lower appendicular and axial skeleton for two 10-min periods per day, induced via floor-mounted devices that produced the mechanical stimulus, whereas 31 women received placebo devices and underwent daily treatment for the same period of time.

An intention-to-treat analysis of dual-energy X-ray absorptiometry data of the spine (L1−4), proximal femur, and nondominant radius showed little effect of the intervention. In a post hoc analysis of those subjects who used the device at least 60% of the prescribed time, a linear regression of the means was used to show that lumbar spine bone mineral density declined by 3.3% (±0.83) in the placebo group compared with only 0.8% (±0.82) in the treated group ($P < .03$), reflecting a 2.5% benefit of the biomechanical intervention. A 3.3% treatment benefit was observed in the trochanter region of the hip, with a 2.9% (±1.2) loss observed in the placebo group, yet with a 0.4% (±1.2) gain in the treated group ($P < .03$). At the distal radius, no significant differences were observed as a function of time or between groups, emphasizing the mechanical influence to be locally delivered.

On the other hand, another randomized controlled trial on 202 osteopenic postmenopausal women showed no significant improvement in overall trabecular, femoral neck, total hip, or lumbar spine bone mineral density after 1 year of whole-body vibration intervention (20 min/day, 37 or 90 Hz, 0.3g) (Slatkovska et al., 2011). This clinical trial, however, had some limitations including low patient compliance and a lack of subjects with low bone density, and the placebo group did not lose significant bone density over the course of 1 year. Hence, more studies are needed to determine the efficacy of low-intensity whole-body vibration intervention in tackling postmenopausal bone loss. In any case, physical activity has been independently shown to be associated with thicker cortex and higher bone strength at the distal tibia in elderly women, suggesting that physical activity in old age may aid in mitigating bone loss (Nilsson et al., 2017). However, low-magnitude, high-frequency mechanical signals failed to reverse osteoporosis in the frail elderly (Kiel et al., 2015).

Low-level mechanical signals mitigate bone loss due to cancer

Cancer progression, along with the treatment strategies such as chemotherapy, irradiation, and immunosuppressive therapies, can put a tremendous stress on the musculoskeletal system, leading to rapid bone loss and increased fracture risk. Multiple studies have shown the efficacy of low-magnitude whole-body vibration in tackling the bone loss and osteopenia resulting from cancer and radiation therapies. In an ovarian cancer murine model, a 1-year intervention with whole-body vibration (15 min/day, 5 days/week, 90 Hz, 0.3g) increased BV by 25% in proximal tibia and by 16% in L5 vertebrae, compared with age-matched control mice (Pagnotti et al., 2012).

Similarly, in a murine model of multiple myeloma, 8 weeks of whole-body vibration intervention (15 min/day, 5 days/week, 90 Hz, 0.3g) resulted in a 76% increase in trabecular BV fraction, 30% increase in cortical BV, and 45% reduction in tartrate-resistant acid phosphatase 5b activity, compared with mice with multiple myeloma (Pagnotti et al., 2016).

Extending this to the clinic, pediatric cancer survivors who had a bone mineral density Z score of ≤ -1 improved their Z score by 0.25 ± 0.78 after 1-year of whole-body vibration intervention (2 × 10 min/day, 7 days/week, 32−37 Hz, 0.3g), while the placebo group's Z scores reduced by −0.19 ± 0.79 ($P = .05$) (Mogil et al., 2016). Improvement in bone mineral density was correlated with circulating osteocalcin ($P = .02$), suggesting increased bone formation as a result of whole-body vibration.

Low-level mechanical signals are anabolic to the musculoskeletal system

Susceptibility to osteopenia is present early in life, the amount of bone gained during adolescence is a main contributor to peak bone mass in the young adult, and peak bone mass in the young adult is a determinant of osteoporosis in the elderly (Loro et al., 2000). A study was designed to establish if brief, daily exposure to extremely low level mechanical stimuli (10 min/day, 30 Hz, 0.3g) was anabolic to musculoskeletal development in young females, 15−20 years of age, each in the lowest quartile of bone density in this age cohort and who had already sustained a fracture (Gilsanz et al., 2006). Using an intention-to-treat analysis, cancellous bone in the lumbar vertebrae and cortical bone in the femoral midshaft of the experimental group were 2.0% ($P = .06$) and 2.3% ($P = .04$) greater, respectively, compared with controls. Cross-sectional area of paraspinous musculature was 4.9% greater ($P = .002$) in the experimental group versus controls. When a per-protocol analysis was performed, gains in both muscle and bone were strongly correlated to a threshold in compliance, where the benefit of the mechanical intervention compared with controls was realized once the device was used for at least 2 min per day ($n = 18$), as reflected by a 3.9% increase in cancellous bone of the spine ($P = .007$), 2.9% increase in

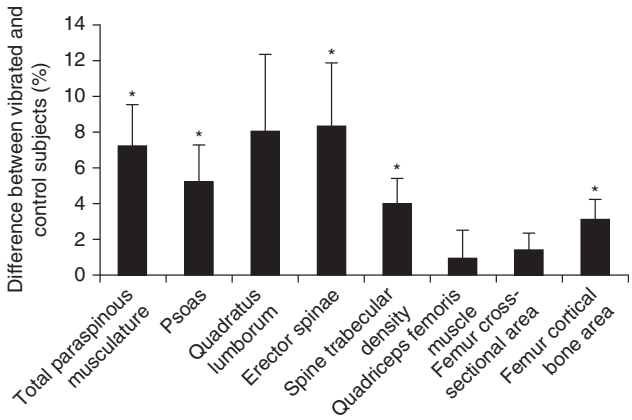

FIGURE 76.4 The difference in the change (mean + SE) in musculoskeletal parameters measured over 1 year for young women who used the device for more than 2 min per day, compared with controls and women who stood on the vibrating plate for less than 2 min per day. With the exception of musculature around the femur and femoral cross-sectional area, the musculoskeleton of the experimental group benefited significantly (*$P < .05$) from the brief low-level mechanical intervention. *Adapted from Gilsanz, V., Wren, T.A., Sanchez, M., Dorey, F., Judex, S., Rubin, C. 2006. Low-level, high-frequency mechanical signals enhance musculoskeletal development of young women with low BMD. J. Bone Miner. Res. 21(9), 1464–1474.*

cortical bone of the femur ($P = .009$), and 7.2% increase in musculature of the spine ($P = .001$), compared with controls plus the low compliers (Fig. 76.4).

Short bouts of extremely low level mechanical signals, several orders of magnitude below that associated with vigorous exercise, increased both trabecular and cortical bone in weight-bearing regions of the skeleton. Further, muscle mass of the paraspinous region increased, suggesting that risk factors for fracture beyond bone quantity and quality could be mitigated. Low-level, high-frequency mechanical signals, even lower than those used in this study, have also been shown to preserve postural stability in an aging population (Gravelle et al., 2002), providing evidence that physical signals can serve to reduce risk factors of osteopenia, falling, and sarcopenia.

Low-level mechanical stimulation has also been shown to aid in muscle strength loss during extended bed rest (Muir et al., 2011). During a 90-day bed rest, healthy adults were subjected to either low-magnitude whole-body vibration (10 min/day, 30 Hz, 0.3g or 0.5g) or no treatment. Subjects that underwent whole-body vibration intervention retained their postural stability as quantified by 73% reduction in displacement and 97% reduction in velocity after 60 days of bed rest, compared with controls. In addition, although vibration did not mitigate loss in muscle extension strength, it resulted in 46.2% improved retention in flexion strength, compared with controls ($P = .01$). Preserving postural control and improving muscle strength, whole-body vibration can aid in reducing the risk of debilitating falls and represent a system-level approach to controlling fractures due to low bone density.

The reason for improvement in muscle strength and postural stability due to whole-body vibration is not yet clearly understood. Satellite cells are quiescent myogenic cells that are capable of differentiating into skeletal muscle cells in response to injury or an external stimulus (Morgan and Partridge, 2003). A study utilizing a murine model of ovariectomy demonstrated depletion in the satellite cell population (−21%, $P < .05$) in the muscle compared with control. The depletion of muscle satellite cells was mitigated when the mice were subjected to whole-body vibration (−11% compared with control, $P > .05$) (Frechette et al., 2015), suggesting a possible mechanism through which low-level vibration can preserve muscle mass and muscle strength, and possibly mitigate fall risk. Should these musculoskeletal enhancements be preserved through adulthood, this intervention may prove a deterrent to osteoporosis in the elderly.

How can bone sense a signal so small?

The aforementioned studies, contrasting with a more-is-better principle, suggest that bone strains 2 orders of magnitude below a previously suggested threshold (Frost, 1987) can be anabolic to bone. The means by which such low-level mechanical signals can be anabolic to a tissue such as bone is not clear. If cortical matrix deformations of less than 0.001% strain, measured at the periosteum, were transduced directly to the resident osteoblast or osteocyte population, the deformation of the cell itself would be less than 1 Å. Given that such deformations may be too small to be recognized by cells (Han et al., 2004), by-products of matrix deformation, such as fluid flow–induced shear stresses, streaming potentials, fluid drag on pericellular processes, or enhanced nutrient transport, may contribute to a cell's responsiveness to mechanical

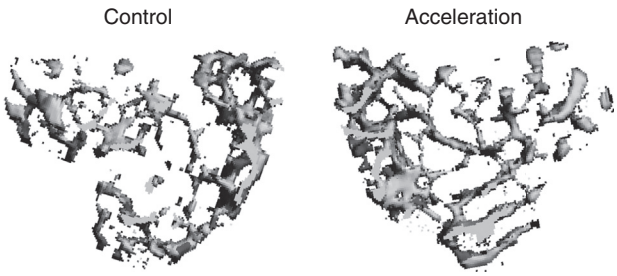

FIGURE 76.5 By applying very low level oscillatory accelerations to one leg of the anesthetized mouse while the other leg serves as a contralateral control, the efficacy of very small and unconstrained motions that do not directly apply deformation to the matrix can be tested. *Adapted from Garman, R., Gaudette, G., Donahue, L.R., Rubin, C., Judex, S. 2007a. Low-level accelerations applied in the absence of weight bearing can enhance trabecular bone formation. J. Orthop. Res. 25(6), 732–740.*

signals (Malone et al., 2007a). Yet even these alternative pathways are dependent on matrix deformation and therefore will be very small in magnitude during low-level mechanical stimulation.

In contrast to a matrix deformation–dependent pathway for mechanotransduction, the frequency sensitivity of the adaptive system points toward a more fundamental, perhaps unrecognized, pathway by which physical signals interact with the tissues and cells (Luu et al., 2009b). Indeed, a mechanism that would allow a cell to sense mechanical signals directly without reliance on matrix strain would obviate the need for compensatory tissue-level amplification mechanisms and reduce complexity in the system, and may provide cells with mechanical information without the potential for damaging the surrounding tissue. Physical acceleration of a cell may present such a signal that can transmit physical challenges to a receptive cell population in an efficient and safe manner (Garman et al., 2007a). This hypothesis was tested by removing bone's habitual loading environment and imposing very small amplitude oscillatory accelerations that induce motion but no direct deformation (Garman et al., 2007b).

To this end, a device was developed that can deliver high-frequency accelerations to skeletal segments in the absence of weight bearing (Fig. 76.5). In an anesthetized murine model, the left tibia of each mouse was subjected to oscillatory 0.6*g* accelerations at 45 Hz for 20 min/day and the right tibia served as control. Oscillatory accelerations, applied in the absence of weight bearing, resulted in 70% greater BFRs in the trabeculae of the metaphysis but similar levels of bone resorption, compared with contralateral controls. Quantity and quality of trabecular bone also improved as a result of the acceleration stimulus. As expected, the matrix deformations induced by these motions are extremely small, indicating that mechanosensory elements of resident bone cell populations can perceive and respond to acceleratory signals, and point to an efficient means of introducing subtle physical signals into a biological system without putting the matrix at risk of overloading.

Biochemical modulation of mechanical signals

Which cells sense the stimulus?

It is clear that bone cells are able to sense their mechanical environment via a number of proposed mechanisms, including direct matrix deformations, pressure and transient pressure waves, accelerations, fluid shear stresses, fluid drag forces, or even dynamic electric fields as interstitial fluid flows past charged bone crystals (Fig. 76.6). It is much less clear, however, which of the cells within a bone are the key sensory elements in mechanotransduction. Mechanical responses of

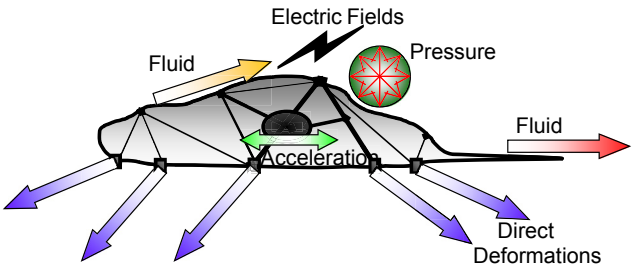

FIGURE 76.6 Proposed mechanisms by which bone cells may sense the application of mechanical forces to the skeleton.

osteoprogenitor cells, including stromal cells, osteoblasts, and osteocytes, have all been documented without identifying the critical responding cell: for example, exposure to microgravity results in a decreased number of osteoblasts—but what cell senses and responds to the loss of gravity, the undifferentiated mesenchymal precursor, the differentiated osteoblast, or the distant, entombed osteocyte?

Bone marrow mesenchymal stem cells

Bone marrow stromal cells change their proliferation rate and gene expression patterns in response to mechanical stimulation (Li et al., 2004; Baskan et al., 2017) and alter lineage selection as well, moving toward osteoblastogenesis and away from adipogenesis (David et al., 2007; Luu et al., 2009a). Low-level mechanical stimulation has also been shown to suppress adiposity and adipogenesis in vivo as evident by 27.4% reduction in fat volume in the torso and 19% lower ratio of adipocytes to marrow-based MSCs in the epididymal fat pad in mice that underwent whole-body vibration treatment (15 min/day, 5 days/week, 90 Hz, 0.2*g*), compared with controls (Rubin et al., 2007a).

Returning to the importance of "timing" of the signal, when low-magnitude vibration was separated into multiple bouts throughout the day, separated by a refractory period between bouts of stimulation, the suppression of adipogenesis was enhanced in MSCs in vitro. Following 7 days of low-magnitude whole-body vibration treatment (90 Hz, 0.7*g*), the cells that were vibrated 40 min/day failed to suppress adipogenesis. On the other hand, the cells that were vibrated for two bouts of 20 min per day suppressed adipogenesis by 30 ± 8% ($P < .05$) and 70 ± 5% ($P < .01$) when the bouts were separated by 1 and 3 h, respectively (Sen et al., 2011). When the length of the refractory period was increased from 3 to 6 h, there was no further improvement in adipogenesis suppression in MSCs.

These studies suggest that not only are the stromal cells in the body responsive to low-level mechanical stimulation, but their response is also dependent on how the signals are delivered, in terms of the bout duration, number of bouts delivered per day, and length of the refractory period between bouts of stimulation. Indeed, similar response is demonstrated in vivo such that when adult C57BL/6 mice are subjected to 6 week of low-magnitude whole-body vibration (90 Hz, 0.2*g*), the visceral adiposity is suppressed when the vibration was delivered in two bouts of 15 min per day, separated by a 5-h refractory period, but not when the vibration was delivered in one bout of 30 min per day (Patel et al., 2017). Again, timing may be as important as the signal itself.

Osteoblasts

Low-magnitude high-frequency mechanical stimulation at 35 Hz and 0.3*g* for 10 min/day has been shown to restore mineralization and osteogenic gene expression (alkaline phosphatase, RUNX2, osteomodulin, osteoglycin, parathyroid hormone receptor 1) in preosteoblast cells (2T3) that were exposed to a random positioning machine, which can mimic disuse and microgravity conditions in vitro (Patel et al., 2009). In another preosteoblast cell line, MC3T3-E1, subjecting the cells to low-magnitude mechanical stimulation (35 Hz, 0.25*g*) for either 30 min per day or two bouts of 15 min per day (separated by 0.5, 1, 2, 3, or 6-h refractory periods) has been shown to increase the expression of osteogenic proteins (alkaline phosphatase, osteocalcin, and collagen type I) (Zhao et al., 2018). The osteogenic protein expression was the highest when the mechanical loading was delivered in two bouts of 15 min per day, separated by a 0.5-h refractory period.

Osteoclasts

With respect to osteoclasts and bone resorption, stromal cell expression of the osteoclast differentiation factor is sensitive to mechanical force (Rubin et al., 2000), suggesting that the number of osteoclasts present is controlled through mechanical regulation sensed by stromal cells. Osteocytes are another mechanosensitive cell embedded in the bone that can affect osteoclast activity. Low-level mechanical stimulation (1 h/day, 60 Hz, 0.3*g*) of MLO-Y4 osteocyte-like cells led to 55% reduction ($P < .01$) in receptor activator of nuclear factor κB ligand (RANKL), 36% attenuation ($P < .05$) of formation of large osteoclasts (≥10 nuclei), and 20% reduction ($P = .07$) in osteoclastic resorption, compared with control (Lau et al., 2010). In addition, low-magnitude high-frequency vibration has also been shown to inhibit RANKL-induced differentiation of monocyte-like cells (RAW264.7) into mature osteoclasts (Wu et al., 2012), adding another layer of control by which mechanical force might limit bone resorption and influence the system level of bone turnover.

Osteocytes

Finally, the majority of cells in cortical bone are osteocytes, and owing to their pervasive, three-dimensional distribution throughout both trabecular and cortical bone, these cells are potentially well placed to sense the magnitude and direction of

mechanical strain within the tissue (Bonewald, 2011). Osteocytes, although enclosed in calcified tissue, are interconnected through a network of canaliculi through which these cells cast long cell processes. Osteocytes respond to strain in vivo as shown by increased glucose-6-phosphate dehydrogenase activity (Skerry et al., 1989) or earlier response of c-*fos* mRNA (Inaoka et al., 1995) after loading. As well, unloading causes osteopontin expression in osteocytes (Gross et al., 2005). Dentin matrix protein 1, which is a secreted matrix protein expressed in late osteoblasts and osteocytes, has been shown to increase in osteocytes after tooth movement in the jaw (Gluhak-Heinrich et al., 2003).

If we consider that strain signals of even very low magnitude can stimulate an anabolic response in bone tissue, the osteocyte may be best placed to sense such a signal (Santos et al., 2009). This might occur through fluid flow through canaliculi, as well as through deformation, both of which have been shown to cause changes in osteocyte function (Plotkin et al., 2005). It has also been suggested that, owing to the modulus mismatch of the bone material and the lacunae, the osteocytes within the cavity would be subject to strains as high as 30,000 με, even though the bulk material was strained only to 3000 με (Nicolella et al., 2006). In other words, the microarchitecture of the bone tissue could serve to indirectly (fluid pressure through canaliculi) or directly (strain amplification via the lacunae and then again via membrane to nucleus via linker of nucleoskeleton and cytoskeleton [LINC]) amplify the strain signal.

Bone marrow vasculature

Other cells present in bone, such as endothelial and smooth muscle cells in the penetrating vasculature, might also contribute to the skeleton's adaptive response to loading. After all, endothelial cells respond to shear stress and tensile strain generated by increased heart rate during exercise, by producing nitric oxide (Boo and Jo, 2003). Nitric oxide is an important humoral factor to transduction of mechanical input in vascular cells (Lane and Gross, 1999). Increased vascular release of nitric oxide is likely to regulate bone cell response: nitric oxide has pleiotropic effects in bone cells and potently decreases resorption by decreasing osteoclast formation and activity (Fan et al., 2004). But bone stromal cells also release nitric oxide as a result of mechanical input (Rubin et al., 2003), providing a secondary cell target for mechanical induction of this freely diffusible antiresorptive agent. Thus, targets of skeletal loading may include extraskeletal cells and systems. In any case, cells contributing to bone remodeling directly (osteoblasts and osteoclasts), indirectly (osteoprogenitor cells and osteocytes), and distantly (muscle and vascular systems) are all known to be mechanosensitive.

Mechanoreceptors in bone cells

The ability of cells to read their biomechanical environment requires either that their mechanoreceptors be in contact with the outside, through the cell membrane and its attachment to substrate, or that the mechanoreceptor be able to sense changes in a loading-induced physical intermediary such as fluid shear on the apical membrane. Although there are examples of channels that are regulated by movement of mechanosensory bristles (Sukharev and Corey, 2004), or by tension waves (Morris, 1990), a unified model of the most proximal events that lead to intracellular signal transduction in nonsensory tissues does not yet exist.

Theoretical considerations may be moving toward an architectural/spatial concept that integrates positional changes between signaling proteins, scaffolds, membrane domains, and structural components of the cell. All can be perturbed by mechanical force. Whether each aspect is a mechanoreceptor in itself or works in a holistic context combining many aspects of cell architecture and response is yet to be determined. With the multiplicity of mechanical signals presented to the cell, it is at least likely that no single mechanosensor or receptor mechanism is responsible for all of the integrated cell response to the mechanical environment.

Integrins and integrin-associated proteins

Membrane deformation and shear across the membrane, as well as pressure transients, can be transmitted to the cytoskeleton and ultimately to the cell-matrix adhesion proteins that anchor the cell in place (Katsumi et al., 2004). Thus, the cell represents a load transmission network whereby surface forces will affect proteins that span or are associated with the plasma membrane, including the cytoskeleton, linker proteins at sites of cell attachment, and membrane-spanning integrin adhesion proteins. In this way, mechanotransduction might be expected to depend on the mechanical integrity of this network with constituents of this network serving as molecular mechanotransducers.

Indeed, in particular the β1-integrin subunit has been implicated in mechanotransduction on osteocytes and osteoblasts (Bennett et al., 2001). In osteoblasts, steady fluid flow can upregulate β1 expression (Kapur et al., 2003), even though blocking β3 with RGD-containing peptides did not affect extracellular signal-regulated kinase (ERK) activation (Weyts et al., 2002). Other focal adhesion proteins such as focal adhesion kinase (FAK) may be critical to integrin clustering as

well as molecular signaling in bone cells (Rezzonico et al., 2003). Mechanical stimulation stimulates tyrosine phosphorylation, predominantly in FAK, in osteoblasts (Boutahar et al., 2004). Upon phosphorylation, FAK contributes to mitogen-activated protein kinase (MAPK) activation via interaction with c-src, Grb2, and the small GTPase Ras (Schlaepfer et al., 1999). This is significant because MAPK activation is also one of the effectors of oscillatory flow in bone cells and this pathway has been observed in response to fluid flow in endothelial cells (Berk et al., 1995). More molecular definition has lately been assigned to this pathway: involvement of a β1-integrin-linked kinase is stimulated through mechanical input via, leading to AKT activation (Nho et al., 2005), a pathway that links to downstream processes regulated by canonical Wnt/catenin.

Connexins

Connexins are membrane-spanning proteins that form regulated channels that allow the direct exchange of small molecules with adjacent cells resulting in intercellular communication between cells. Intercellular communication via gap junctions has been suggested to be central to the transmission of information about the mechanical environment of a given cell and ultimately allowing a sensing cell to elicit a change in behavior at an actor cell some distance removed from the mechanosensing event (Yellowley et al., 2000). Interconnected cells have also been proposed to form a cellular network that can exhibit an enhanced sensitivity to biophysical stimuli than occur in individual cells. This application might occur owing to the larger area occupied by a cell network, and therefore larger net effect of the biophysical signal than by individual cells. Indeed, when the communication of an ensemble of cells is interrupted, a reduced sensitivity has been observed in response to biophysical signals such as electric fields (Vander Molen et al., 2000) or fluid flow (Saunders et al., 2001). In addition, mechanical signals may increase the expression of connexins in vitro and in vivo, increasing the gap junction intracellular communication and becoming better connected with their neighbors, perhaps acting as a sort of positive feedback loop (Alford et al., 2003; Uzer et al., 2014). Fluid shear stress has been shown to result in opening and phosphorylation of connexin 43 in osteocytic cells, following increased level of active AKT (Batra et al., 2014).

Channels

Alterations in ion channel activity in osteoblasts have been associated with bone cell activation, whether through alteration in conductance stimulated by parathyroid hormone (Ferrier et al., 1986) or by stretch/strain (Duncan et al., 1992). There are at least three classes of mechanosensitive ion channels in human osteoblasts (Davidson et al., 1990). Through this set of channels, a mechanical stimulus could induce membrane hyper- and depolarization or a complex multiphasic response. Cyclical strain has been shown to modulate the activity of certain channels: chronically strained osteoblasts had significantly larger increases in whole-cell conductance when subjected to additional mechanical strain than unstrained controls (Duncan and Hruska, 1994). More recently, radial membrane strains of 800% were shown to be necessary to open half of the mechanosensitive channels in bone cells (Charras et al., 2004). Mechanosensitive channels have also been implicated in the response of bone cells to fluid shear stress (Ryder and Duncan, 2001). In addition to direct activation of intracellular signaling cascades, influx of a charged species such as calcium can also alter membrane potential and activate voltage-sensitive channels that are not directly mechanosensitive (Li et al., 2002). Studies have identified activation of piezo-type mechanosensitive ion channel component 1 as a driving factor for enhanced osteoblastogenesis and suppressed osteoclastogenesis in human periodontal ligament cells and suppressed adipogenesis in MSCs when the cells are subjected to compressive loading or hydrostatic pressure, respectively (Sugimoto et al., 2017; Jin et al., 2015). Further studies are needed to identify the exact channel(s) in different types of cells that responds to external mechanical cues.

Membrane structure

Cells possess a complex organizational structure that supports compartmentalization of signals within an equally complex plasma membrane. Certain proteins are integral to membrane structure while creating docking positions for signaling complexes. Caveolins 1 and 2 have been described in human fetal osteoblasts and in murine MC3T3-E1 cells along with multiple caveolar flasks in the membrane (Solomon et al., 2000) and in osteoblasts in adult bone (Lofthouse et al., 2001). Bone cell caveolae are associated with important signaling molecules, including G proteins, Ras, nitric oxide synthase (NOS), and tyrosine kinases. These membrane domains, whether caveolae or noncaveolar lipid rafts, provide a microenvironment that modulates efficiency and fidelity of mechanical signal transduction.

The organized membrane may have greater significance for mechanical response than for parsing signals arising from liganded receptors. Noncaveolar and caveolar organized membranes have been shown to be critical for mechanically induced signals in a variety of cells. In the vascular endothelium, for instance, increased flow causes the translocation of

signaling molecules to caveolae; if caveolae are disassembled, both proximal and downstream signaling events, including activation of the MAPK pathway, are abrogated (Rizzo et al., 1998). Stretch activation of small GTPases in cardiac myocytes has, as well, been associated with caveolae: the stretch activation of the guanine nucleotide exchange factors (GEFs) RhoA and Rac1 fails to occur when caveolae are disrupted by treatment with methyl-β-cyclodextrin (Kawamura et al., 2003).

The role of caveolae in processing signals in bone is being studied: caveolin-1-null mice have bigger bones, perhaps resulting from accelerated development (Rubin et al., 2007b). The accumulation of β-catenin, following mechanical stimulation, has been shown to be dependent on the cross talk between caveolin-1 and ERK, emphasizing the interaction between caveolin-1/ERK and Wnt/β-catenin signaling pathways in transducing mechanical cues for osteocytic survival and bone formation (Bilic et al., 2007; Case et al., 2008; Gortazar et al., 2013).

Primary cilium

Another potential avenue for mechanical signal transduction has arisen with the reevaluation of the role of the primary cilium, a microtubule-based structure extending from almost every mammalian cell studied. The primary cilium has been known to function as a sensory organelle, but is now recognized as receiving both mechanical and chemical signals from the environment (Michaud and Yoder, 2006). Epithelial cells in the kidney have been shown to recognize fluid shear stress in the lumen of the nephron through their primary cilium, and mutations leading to abnormal cilia, such as are found in polycystic kidney disease, lead to gross abnormalities in function (Nauli and Zhou, 2004). Indeed, when ciliary polycystin-1 is knocked out, in addition to developing polycystic kidney disease, mice have delayed endochondral and intramembranous bone formation (Xiao et al., 2006). Further, interesting data have shown that bone cell primary cilia translate fluid flow into calcium signals (Malone et al., 2007b).

Nuclear connectivity

Considering a means of translating mechanical information to the nucleus, studies suggest that the MSC response to low-level mechanical stimulation is dependent on cytoskeletal remodeling, rather than fluid-induced shear stress, as evident by enhanced cell proliferation and mineralization following actin remodeling (Uzer et al., 2012, 2013). Specifically, cell mechanosensitivity is enabled by mechanical coupling between the nucleus and the cytoskeleton through LINC complexes. When LINC complexes were disrupted, cells' response to low-level mechanical stimulation diminished. Interestingly, cells' response to high-magnitude mechanical stimulation did not alter when LINC complexes were disrupted, suggesting LINC as a novel and specific mechanism for cells' response to low-level mechanical stimulation (Uzer et al., 2015). The role of LINC complexes in controlling the sensitivity of cells to mechanical cues is further demonstrated in enucleated cells that showed lower contractile energy and lower traction tress values when the LINC complexes were disrupted in the cells (Graham et al., 2018).

Mechanically activated intracellular signaling

Application of mechanical force to bone cells causes modulation of cell function, including changes in proliferation and function. Indeed, most aspects of cell behavior can be elucidated by a number of mechanical forces. Thus, straining osteoprogenitor cells can cause them to proliferate (Zhuang et al., 1996) and to secrete extracellular matrix (Harter et al., 1995). Similarly, shear stress, in addition to strain-induced effects, can induce β-catenin signaling (Norvell et al., 2004) and secretion of osteopontin (You et al., 2001). To achieve these ends, it is quite clear that multiple classical signaling pathways are activated after force application.

Because the distal responses to mechanical factors are similar to those elicited by ligand−receptor pairing, and result in changes in gene expression, mechanotransduction must eventually end up utilizing similar intracellular signaling cascades. In essence, mechanical forces have been shown to activate every type of signal transduction cascade, from increases in intracellular cAMP (Lavandero et al., 1993) to inositol trisphosphate and intracellular calcium, guanine regulatory proteins (Gudi et al., 2003), and MAPK (Waterman et al., 2002). Next, rather than reviewing each mechanosignaling cascade, we provide four examples.

MAPK signaling

Mechanical force can activate MAPK in every cell type studied to date. In bone cells many groups have shown activation of ERK1/2, in particular. Mechanical activation of ERK1/2 is required for certain measurable responses to strain in bone

stromal and osteoblast-like cells. The strained bone cell downregulates its expression of RANKL, and upregulates expression of endothelial NOS. Although strain also activates c-jun kinase (JNK), JNK inhibition does not prevent strain effects on either RANKL or endothelial NOS. Reduced display of RANKL by cells present in bone diminishes the local osteoclastogenic potential. As a result of increased endothelial NOS expression, nitric oxide synthesis is enhanced.

ERK1/2 activation by mechanical stress has been linked to other specific genes, such as strain induction of collagenase-3 (Yang et al., 2004), as well as to proliferation. Both FosB and its spliced variant, ΔFosB, which has been shown to stimulate increases in bone density in vivo, are induced by mechanical loading of the mouse hindlimb and by fluid shear stress in mouse calvarial osteoblasts (Inoue et al., 2004). The ERK1/2-dependent increase in the fos gene targets a CRE/AP-1 type element in the promoter that binds CREB. The proximal events leading to ERK1/2 activation are the subject of much continued research. This may certainly involve integrins (Whedon, 1984) as well as multiple other effectors, including small GEFs (Jin et al., 2005) or changes in membrane structure (Boyd et al., 2003).

MAPK has been also shown to play a role in adipogenic differentiation of multipotent stromal cells during low-magnitude high-frequency vibration (15 min/day, 40 Hz, 0.3*g*). Under the influence of adipogenic medium and vibration, phosphorylation of p38 MAPK was enhanced, leading to increased secretion of PPARγ, C/EBPα, and adiponectin, and increased number of oil droplets. The adipogenic differentiation of stromal cells was inhibited when p38 inhibitor was added to the cells (Zhao et al., 2017). Interestingly, in the absence of adipogenic medium, vibration has been shown to promote osteogenic differentiation in MSCs in vitro as evident by increased alkaline phosphatase activity, matrix mineralization, and osteogenic gene expression (Runx2, collagen type I, alkaline phosphatase, osteocalcin, and osteopontin). Vibration-mediated increase in osteogenic differentiation is driven by phosphorylation of p38 MAPK, and inhibition of p38 MAPK leads to reduction in alkaline phosphatase activity and osteogenic gene expression (Lu et al., 2018).

Activation of Wnt/catenin signals

Increased expression of Wnt/β-catenin target genes is another response of osteoblasts to mechanical loading (Robinson et al., 2006). Multiple known genes with catenin response elements are quickly transcribed when strain is applied to osteoblast cells in culture, or when bone cells are studied after whole-animal loading; these are probably related to the anabolic response of bone tissue to exercise. Increased canonical β-catenin signaling through a gain-of-function mutation in low-density lipoprotein−related protein 5 (G171V) has further been shown to increase the response of osteoblasts to mechanical loading (Sawakami et al., 2006). The Wnt/β-catenin signaling pathway also plays a role in bone marrow MSC adhesion and osteogenic differentiation on a hydroxyapatite-coated surface, as evident by increased alkaline phosphatase activity and osteogenic gene expression, following low-level vibration (Chen et al., 2016).

β-Catenin regulation in the cytoplasm has been well studied, but its nuclear trafficking and function are not yet well studied. A 2018 study suggests that inactivation of glycogen synthase kinase-3β leads to β-catenin association with the nucleoskeleton following low-level vibration or substrate strain. However, concurrently depleting LINC complex elements (SUN1 and SUN2) leads to reduced nucleoskeleton association and nuclear entry of β-catenin, suggesting that nucleus access of β-catenin is one of the mechanisms through which mechanical signals are transmitted by the cytoskeleton to the nuclear surface (Uzer et al., 2018). Mechanical activation of catenin signaling, of crucial importance to osteoprogenitor proliferation and lineage selection, will continue to be of great interest to this field.

Nitric oxide signaling

Nitric oxide has pleiotropic effects on bone cells (Ralston, 1997), and may have a role in mechanical signaling in bone. Nitric oxide is released shortly after shear stress from osteoblasts and osteocytes (Smalt et al., 1997) probably owing to activation of endothelial NOS (Klein et al., 2004), similar to known effects of shear in vascular cells. The rapid activation of nitric oxide in endothelial cells requires, in part, an intact plasma membrane, including lipid rafts (Park et al., 1998) and cytoskeleton (Knudsen and Frangos, 1997), and this is likely to be true for the mechanical release of nitric oxide in bone cells.

Endothelial NOS is the predominant NOS isoform in adult bone (Helfrich et al., 1997), and expression of this gene with subsequent increase in nitric oxide production is upregulated by strain in marrow stromal cells. Nitric oxide has also been independently shown to induce osteogenic differentiation in osteoprogenitor cells in the absence of osteogenic growth factors (Mostafa et al., 2015). Downstream nitric oxide signaling can depend on activation of guanylate cyclase or on direct actions of the molecule to nitrosylate proteins as has been shown for nitric oxide action to decrease the RANKL/osteoprotegerin ratio in stromal cells (Fan et al., 2004). Nitric oxide has also been shown to be necessary for the response to

in vivo loading in rodents, although whether the nitric oxide derives from bone or the vasculature in bone is not yet clear (Kunnel et al., 2004).

Prostaglandins

In bone's anabolic response to loading, prostaglandins may be important as indicated by their increased levels during loading (Rawlinson et al., 1991). Indeed, a variety of mechanical signals, including direct stretch (Zaman et al., 1997), pressure (Burger et al., 1992), and fluid flow (Klein-Nulend et al., 1997), can markedly upregulate prostaglandin production, whereas the disruption of the osteocyte cytoskeleton, and thus the transmission of the signal to the nucleus, completely disrupts the responsiveness of the cell (Ajubi et al., 1996). Although greater detail of the mechanism of action of prostaglandins is provided elsewhere in this book, it is important to note that administration of prostaglandin E_2 to rodents will increase the stiffness of trabecular bone (Akhter et al., 2001), and that perhaps the EP2 receptor is most important in coordinating the prostaglandin response to mechanical signals into improved bone strength. Indeed, strain-induced upregulation of osteocalcin has been shown to be mediated by the EP2 receptor, whereas strain-induced downregulation of sclerostin, which is a potent inhibitor of bone formation, has been shown to be mediated by the EP4 receptor (Galea et al., 2011). Considering the role of prostaglandins as potent regulators of bone remodeling (Raisz, 1995), and their responsiveness to both mechanical and humoral signals, it will ultimately be important to more definitively understand the physiological responses of the skeleton to exercise and mechanical signals and the role of biochemical messengers such as prostaglandins that can modulate bone quantity and quality.

Summary

The critical contribution of exercise in general, and mechanical stimuli in particular, to the achievement and maintenance of bone quantity and quality is clear. In contrast to systemic, pharmaceutical interventions, the attributes of such mechanical strategies are that they are native to the bone tissue, are safe at low intensities, incorporate all aspects of the remodeling cycle, and will ultimately suppress osteopenia. Further, these signals appear to influence tissues beyond "simply" bone, with evidence that they can help retain musculature and postural stability, thus providing a more "systems-based" intervention for osteoporosis. However, the design and widespread use of effective and clinically acceptable exercise prophylaxes and treatments that are based on bone's sensitivity to mechanical stimuli will be delayed until we achieve a better understanding of the operative mechanisms at the levels of the tissue, cell, and gene. Until that time, it is safe to conclude that you should get up and run around your office a few times, to stimulate your brain and your skeleton.

Chapter outline

Introduction

Studies involving genetically manipulated animals have contributed enormously to our understanding of cellular and molecular mechanisms controlling skeletal development, homeostasis, and disease progression. The mouse and zebrafish have been the most widely utilized organisms for genetic studies. The zebrafish has been used to great advantage in forward genetic screens to identify novel genes that affect skeletal patterning and development, and it is possible to generate defined mutations in zebrafish that enable the development of human skeletal disease models (reviewed in Luderman et al., 2017). However, the mouse is the most widely used organism for genetic studies of bone biology and thus will be the focus of this review. Public repositories of genetically modified embryonic stem (ES) cells and mice have greatly facilitated the genetic analysis of bone biology. The adaptation of CRISPR/Cas9 technology has made the production of genetically modified animals more feasible and enabled the generation of mouse models carrying disease-causing mutations found in humans. Large-scale publicly supported phenotyping efforts include assessments of bone morphology and bone density, enabling investigators to screen through public databases for novel genes that may have an impact on bone formation and/or maintenance.

Large-scale phenotyping resources and repositories

Several large-scale government-sponsored research programs including the Knockout Mouse Project (USA), European Conditional Mouse Mutagenesis Program, North American Conditional Mouse Mutagenesis project (Canada), and Texas

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00077-4

A&M Institute for Genomic Medicine (USA) are coordinated into the International Mouse Phenotyping Consortium (IMPC) (www.mousephenotype.org). The goal of the IMPC is to produce loss-of-function alleles for 20,000 known and predicted genes in the mouse genome and provide high-throughput initial phenotypic assessments. The IMPC has provided access to targeting vectors, ES cells, and mice harboring a large number of mutated alleles. Some of the alleles have been created by gene targeting, while others have been generated through gene-trapping technologies or large-scale chemical mutagenesis screens. The IMPC publishes a searchable list of all available vectors, ES cell clones, and mice (http://www.knockoutmouse.org).

The phenotyping pipeline includes an assessment of body weight, bone mineral density (DEXA), and bone morphology (X-ray). The database can be searched by gene name or phenotype. For example, at the time of this writing, the IMPC database contains over 200 mutant alleles that lead to abnormal appendicular skeleton morphology. There are nearly 200 entries for abnormal bone mineral density and nearly 100 for abnormal autopod morphology. Many of the genes have not been implicated previously in skeletal biology. Modified ES cells and mice can be obtained from the IMPC, greatly accelerating the process of generating and characterizing mutant mouse strains. The IMPC bone phenotype screen is designed for high throughput and therefore cannot identify subtle morphological alterations or abnormalities in bone mechanical properties, material properties, or structure. The Origins of Bone and Cartilage Disease (OBCD) project (www.boneandcartilage.com), affiliated with IMPC, performs micro-CT, biomechanical testing, and digital X-ray microradiography on a subset of mice generated through the IMPC (Freudenthal et al., 2016; Kemp et al., 2017). As of March 2018, some micro-CT data were available on the OBCD website for 620 conventional knockout strains.

Overexpression approaches to assess gene function in skeletal tissues

The production of transgenic mice that overexpress target genes in specific skeletal tissues is a widely employed strategy. Different transgenic lines that display variable levels of transgene expression can be generated from a single DNA construct, which can enable the discovery of dose-dependent effects on target cells. However, a major caveat of this approach is that these transgenic models often yield nonphysiological levels of gene expression, confounding interpretations of the role(s) of the gene under normal conditions. Moreover, the site of transgene integration and variability in transgene copy number insertion can have significant consequences on tissue specificity and levels of expression. Although this can be exploited to examine dose-dependent effects, the levels and sites of expression must be documented carefully.

A common limitation of standard transgenic approaches is that the overexpression of genes can lead to embryonic lethality, prohibiting the establishment of stable transgenic lines. Furthermore, this can lead to selection for lines expressing only low levels of the transgene, which can confound interpretations of the function of the gene under investigation. This limitation can be addressed by the generation of inducible transgenic strains. The most widely used method is to generate a construct that contains a strong transcriptional stop sequence flanked by LoxP sites located upstream of the gene of interest. By crossing such strains to mice expressing Cre recombinase (discussed later), transgene expression can be activated in a tissue-specific or inducible manner in skeletal cells (Liu et al., 2015).

In addition to overexpressing genes of interest, the transgenic approach can be used for loss-of-function studies. For some genes, it is possible to design and express a dominant-negative variant in order to block its activity (see, e.g., Hiramatsu et al., 2011). The use of transgenics to drive overexpression of dominant-negative variants or natural antagonists leads to loss of function and thus targets pathways in their normal physiological contexts.

The overexpression of siRNA targeting a gene of interest is another transgenic loss-of-function approach that has been used to interrogate gene function in skeletal tissues (e.g., Guo et al., 2016). Although not widely utilized, this strategy can reveal aspects of gene function that are not evident using Cre-loxP technology (discussed later) to delete specific genes. For example, Mutsaers et al. compared osteosarcoma features using osteoblast-restricted Cre-loxP-mediated loss of the tumor suppressor Trp53 (p53) with osteoblast-restricted expression of shRNA against Trp53 (Mutsaers et al., 2013). The two approaches yielded distinct subtypes of osteosarcoma, likely due to differences in the acute versus gradual loss of p53 in knockout and shRNA models, respectively.

Transgenic-overexpression approaches to ablate specific skeletal cell populations can be achieved by driving overexpression of the diphtheria toxin receptor (DTR); this strategy has been used to indicate that osteocytes are transducers of mechanical signals in bone (Tatsumi et al., 2007). However, another study reported effects in multiple organs using the same transgenic construct (Al-Jazzar et al., 2017), highlighting the importance of analyzing tissue specificity in different background strains and experimental contexts when using these transgenic approaches.

Over the past decade, transgenic strains in which marker genes such as *LacZ, GFP,* and/or *ALP* are expressed under the control of tissue-specific promoters (discussed below) have been extensively characterized and are now widely employed

to track gene expression and specific cell lineages in skeletal tissues. These transgenic lineage tracers allow visualization of specific cell types and their descendants in vivo and permit the isolation of these cells for more detailed analyses of gene expression and functional characteristics (Roeder et al., 2016). Most lineage-tracing approaches utilize promoters that drive the expression of Cre recombinase (discussed below).

Several promoter constructs, discussed following, have been well characterized and widely used to drive gene expression in skeletal tissues.

Tendon and ligament

Tendon patterning and differentiation have been difficult to study using transgenic overexpression approaches due to a lack of tendon-specific promoters. This is because there are no genes expressed at high levels, such as those encoding matrix components, whose expressions are restricted specifically to tendon. Tendon-specific enhancers of more widely expressed genes have not been described. *Scleraxis* (*Scx*) encodes a transcription factor expressed in developing tendons and ligaments, although expression has also been reported in cartilage and nonskeletal tissue (Sugimoto et al., 2013). An *Scx* promoter capable of driving high levels of tendon-specific gene expression has not yet been reported. *Scx-Cre* strains (discussed later) provide a potential strategy for inducing the expression of Cre-inducible transgenes with reasonable specificity in tendon.

Chondrocytes

The most commonly used cartilage-specific promoter is derived from the mouse *pro a1(II) collagen* gene *(Col2a1).* This promoter drives expression in the sclerotomic compartment prior to the migration of these cells to become vertebral bodies and in nascent chondrocytes beginning during the condensation stage in appendicular elements (Ovchinnikov et al., 2000). The *Col11a2* promoter has also been used, but some *Col11a2*-based promoters drive expression in perichondrium and osteoblasts in addition to doing so in chondrocytes (Horiki et al., 2004).

Osteoblasts/osteocytes

Proximal promoter fragments (2.3 kb) derived from rat or mouse *Col1a1* genes have been used extensively to drive overexpression in osteoblasts. Strong activity is seen in fetal and adult mature osteoblasts and osteocytes (Dacquin et al., 2002). The 3.6 kb proximal *Col1a1* promoter drives robust expression earlier (in preosteoblasts) but is also active in tendon, skin, muscle, and brain (Liu et al., 2004; Scheller et al., 2011). Promoters based on osteocalcin have been used extensively because they exhibit excellent specificity for osteolineage cells. The 3.5−3.9 kb human osteocalcin promoter fragments drive expression in the majority of mature osteoblasts and osteocytes (Zhang et al., 2002).

The identification of a promoter whose activity is restricted to mature osteocytes has been a challenge. A 10 kb *dentin matrix protein 1 (Dmp1)* promoter has been described, but reportedly drives gene expression in osteoblasts and myoblasts in addition to osteocytes; an 8 kb *Dmp1* promoter appears to have higher specificity for osteocytes (reviewed in Kalajzic et al., 2013).

Osteoclasts

A variety of promoters drive high levels of gene expression in osteoclasts and their progenitors. These include *Cd11b,* expressed in monocytes, macrophages, and along the osteoclast differentiation pathway from mononucleated progenitor cells and into mature osteoclasts (Ferron and Vacher, 2005), and *Tracp,* expressed in mature osteoclasts and their precursors (Kim et al., 2016).

Transgenic mouse reporters of signaling pathways

Transgenic reporter lines can also be used to monitor signaling pathway activity. For example, WNT pathway activity has been monitored in vivo using TOPGAL mice to track β-catenin activity during endochondral bone formation (Day et al., 2005). Specifically, this transgene harbors the *LacZ* gene cassette under the control of a promoter consisting of three TCF/LEF consensus binding sites that serve β-catenin-dependent enhancers positioned upstream of a minimal *Fos* promoter. Tools have also been developed to monitor canonical BMP pathway activity in vivo (Monteiro et al., 2004; Javier et al., 2012). These mice carry a SMAD1/5-specific response element derived from the *Id1* promoter coupled to *lacZ* or luciferase reporters. Similar approaches have been employed to monitor canonical or RBPJ-dependent Notch signaling

activity. For example, one such reporter consists of an open reading frame for the histone H2B-Venus fusion protein under the control of four tandem copies of the RBPJ-binding consensus sequence from the Epstein−Barr virus major latency C promoter upstream of a basal Sv40 promoter (Nowotschin et al., 2013).

Other approaches, such as gene targeting (described later), have also been utilized to monitor signaling pathway activity. For example, a *LacZ* cassette has been targeted to both *Ptch1* and *Gli1* loci, which are direct transcriptional targets of Hedgehog signaling, and β-galactosidase staining can then be used to monitor Hedgehog-responsive cells. While these "knockin" approaches ablate one allele of the targeted gene, heterozygotes have been used to monitor Hedgehog signaling in several skeletal cells (Mak et al., 2008; Zhao et al., 2015). These represent just a few genetic reporter tools being utilized to study cell signaling during normal skeletal development, disease, and repair.

Gene targeting

Gene targeting in mouse ES cells is the most widely used technique for genetic manipulation. Basic methodologies can be found in review articles (Bouabe and Okkenhaug, 2013). The International Mouse Knockout Consortium (IMKC) maintains a searchable list of all available vectors, ES cells, and mice (http://www.knockoutmouse.org). The goal of the consortium is to generate conditional loss-of-function alleles for 20,000 genes, with new mouse strains being added weekly. The Jackson Laboratories Mouse Genome Informatics website (www.informatics.jax.org) provides information on all published genetic modifications, results of ongoing phenotypic analysis, and links to publicly available ES and mouse resources. Since all genetic modifications are included on this website, one can request strains that have not been deposited into a public repository by contacting the investigator directly.

Advantages and disadvantages of conventional gene deletion

Phenotypes caused by conventional gene deletion and loss of function can be used to generate animal models of human disease. As discussed previously, skeletal analysis performed on conventional loss-of-function mutants by the IMKC has revealed previously unknown skeletal phenotypes. However, deletion of genes essential for early embryonic development may lead to lethality, thus precluding analysis of skeletal tissues. Moreover, it is often challenging to discriminate direct effects in skeletal tissues from indirect ones related to the roles of targeted genes in metabolic, cardiovascular, neuroendocrine, or other systems and/or processes. On the other hand, conventional gene knockouts play an essential role in detecting the indirect effects of genes on skeletal tissue formation and maintenance.

Conditional loss-of-function approaches

The ability to ablate or overexpress genes in a tissue-specific manner has revolutionized our understanding of gene function in distinct cell types and lineages, at specific stages of development, and in adults in response to disease or injury. Most methods used to realize tissue-specific gene knockout or activation rely on site-specific recombinases from yeast (Flp) or bacteriophage (Cre) (Birling et al., 2009). These recombinases recognize specific short palindromic sequences in DNA; the target gene is modified to add these sequences (Birling et al., 2009). For the most widely used Cre-loxP system, two mouse strains are required: the "floxed" strain, in which a region of the gene under investigation is flanked by loxP sites, and a second transgenic or "knockin" strain in which Cre recombinase is expressed under the control of an inducible and/or tissue-selective promoter/enhancer sequence. In mice carrying both the floxed alleles and Cre transgene, the Cre recombinase deletes the sequence located between the loxP sites. LoxP sites are placed in noncoding regions, often within introns flanking important exons (i.e., the exon is "floxed"); often the exon containing the translational start site of the encoded protein is chosen. The floxed target gene usually functions normally in the absence of Cre. Fig. 77.1 shows a typical IMKC vector design and various targeting strategies used by the IMKC to generate mice and ES cells carrying conditional alleles that can be obtained from this repository.

Most studies have employed constitutively active forms of Cre. However, ligand-regulated forms that enable inducible control of Cre activity are rapidly gaining precedence. This approach enables simultaneous tissue and temporal control of gene deletion or activation. The most popular strategy for regulating Cre activity involves fusion of the Cre recombinase to a ligand binding domain derived from a mutated estrogen receptor (ER) (Metzger and Chambon, 2001). The mutated ER domain recognizes the synthetic estrogen antagonist 4-OH tamoxifen (T) but is insensitive to endogenous β-estradiol. In the absence of T, the Cre-ER(T) fusion protein is retained in the cytoplasm. Binding of T to the ER domain permits the fusion protein to enter the nucleus and catalyze recombination. Sensitivity to T is greatly improved in mice expressing a Cre-ER(T2) fusion protein in which additional point mutations were introduced into the ligand binding domain of ER

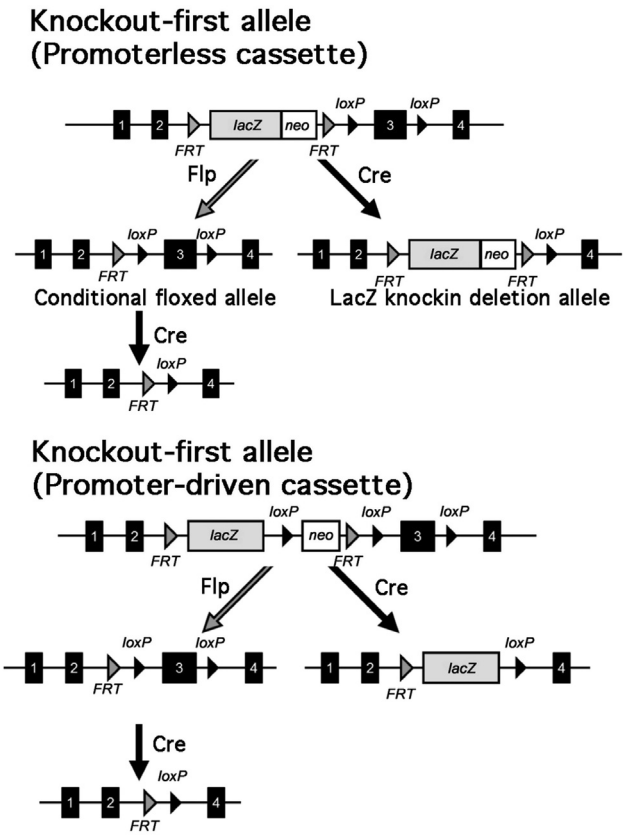

FIGURE 77.1 Schematic of a Knockout-first allele generated by the International Mouse Knockout Consortium (IMKC). The targeting strategies used by IMKC rely on the identification of a "critical" exon. The generation of the knockout-first allele is flexible and can produce reporter knockouts, conditional knockouts, and null alleles following exposure to site-specific recombinases Cre and Flp (Osterwalder et al., 2010).

(Indra et al., 1999). A complete list of Cre lines can be obtained by downloading the Jackson Laboratories Mouse Genome Informatics *MGI Recombinase Alleles Report* (www.informatics.jax.org/home/recombinase). The Jackson Laboratories website also includes a link with expression data for some of these lines (www.creportal.org).

The Cre-loxP system permits exploration of gene function in distinct tissues at multiple time points. However, there are some important considerations. Depending on the Cre line used, excision of the target gene may not be complete; this is highly dependent on the floxed allele. Floxed alleles also vary with respect to the kinetics of Cre-mediated recombination. This must be born in mind when attempting to compare phenotypes caused by excision of different genes using the same Cre transgenic line, especially at prenatal stages.

As discussed following, the promoters most widely used for analysis of skeletal phenotypes often exhibit expression in multiple skeletal cell types, at multiple stages of differentiation within a lineage, and for some genes, in nonskeletal cell types as well. For this reason, every study should verify the extent and location of Cre-mediated recombination of the floxed line of interest. Lineage controls and activity reporters are discussed briefly in the following section.

T can have effects on cartilage, bone, and osteoclasts independently of target gene deletion. Even low doses of T used to catalyze Cre-ER(T)-mediated excision can affect osteoblast function (Starnes et al., 2007). Hence, a control group of Cre-negative mice treated with T may be needed to examine the impact of this variable on the mutant phenotype.

Some of the constitutive and inducible Cre lines most widely used to study skeletal biology are discussed in the following and outlined in Table 77.1.

Uncondensed mesenchyme and precartilage condensations

Prrx1-Cre utilizes a 2.4 kb region of the *Prrx1* promoter to drive Cre expression in early uncondensed mesenchyme largely restricted to the limbs and head (Logan et al., 2002). This mesenchyme eventually gives rise to differentiated chondrocytes, osteoblasts, adipocytes, and vessel-associated pericytes within these anatomical regions. Two *Prrx1-CreERT2* mouse

TABLE 77.1 Commonly used Cre lines for skeletal analysis.

Precondensed mesenchyme	Description	Primary sites of expression
Dermo1-Cre (Twist2-Cre) Twist2$^{tm1.1(cre)Dor}$	Cre knockin that abolishes function of *Twist2* allele	Craniofacial and splanchnic mesenchyme; skeletal condensations
Prrx1-Cre Tg(Prrx1-Cre)1Cjt	Transgene insertion	Limb bud mesenchyme, skull vault
Prrx1-CreER-GFP Tg(Prrx1-cre/ERT2,-GFP)1Smkm	Transgene insertion Inducible, GFP activity tracer	Limb bud mesenchyme, skull vault
Prrx1-CreERT2 Tg(Prrx1-cre/ERT2)1Mlgn	Transgene insertion Inducible Cre activity	Limb bud and skull mesenchyme
Cartilage		
Sox9-Cre Sox9$^{tm3(cre)Crm}$	IRES-Cre cassette inserted into 3′UTR of Sox9	Skeletal condensations; other sites: intestine, testes, etc.
Sox9-CreERT2	IRES-CreERT2 cassette inserted into 3′UTR of *Sox9*	Skeletal condensations; other sites: intestine, testes, etc.
Col2a1-Cre Tg(Col2a1-cre)1Bhr	Transgene insertion	Differentiating chondrocytes in appendicular elements, sclerotome Other sites: heart valves, notochord
Col2a1-CreERT Tg(Col2a1-cre/ERT)KA3Smac	Transgene insertion Inducible; not responsive in adults	Tamoxifen-inducible in differentiating chondrocytes
Col2a1-CreERT2 Tg(Col2a1-cre/ERT2)1Dic	Transgene insertion Inducible in embryos and adults	Tamoxifen-inducible in differentiating chondrocytes
Aggrecan-CreERT2 Acan$^{tm1(cre/ERT2)Crm}$	CreERT2 knockin into 3′ UTR of *Acan* locus Inducible in embryos and adults	Growth plate and articular cartilage, ligament, fibrocartilage of meniscus, trachea, intervertebral disc
Col10a1-Cre Tg(Col10a1-cre)1421/1427/1465Vdm	Transgene insertion of a bacterial artificial chromosome (BAC) encoding *Col10a1* modified by insertion of a Cre cassette	Hypertrophic chondrocytes and descendants in bone marrow regions; detected in skin
Col10a1-Cre Col10a1$^{tm2.1(cre)Ksec}$	Transgene insertion containing a 10.5 kb *Col10a1* promoter/enhancer region upstream of Cre recombinase	Hypertrophic chondrocytes and descendants in bone marrow regions
Col10a1-CreERT2 Col10a1$^{tm3.1(cre/ERT)Ksec}$	Transgene insertion containing a 10.5 kb *Col10a1* promoter/enhancer region upstream of CreERT2 inducible recombinase	Tamoxifen inducible in hypertrophic chondrocytes; lineage traces to descendants in bone marrow regions
GDF5-Cre Tg(Gdf5-cre-ALPP)1Kng	Transgene insertion of a BAC encoding *Gdf5* modified by insertion of a Cre-IRES-ALPP cassette into the translational start site	Joint interzone in embryos; derivatives contribute to synovium and articular cartilage
Prg4-CreERT2 Prg4$^{tm1(GFP/cre/ERT2)Abl}$	GFP/CreERT2 cassette inserted into translation initiation codon of the Prg4 gene; abolishes function of the modified Prg4 locus Inducible in embryos and adults	Superficial zone cartilage; descendant cells contribute extensively to full thickness articular cartilage
FSP1-Cre Tg(S100a4-cre)1Egn	Transgene insertion	Broadly in a subset of fibroblasts; fibrous periosteum/perichondrium

Bone		
Prrx1-CreER-GFP Tg(Prrx1-cre/ERT2,-GFP)1Smkm	Transgene insertion Inducible, GFP activity tracer	Osteochondroprogenitors
Prrx1-CreERT2 Tg(Prrx1-cre/ERT2)1Mlgn	Transgene insertion Inducible Cre activity	Osteochondral progenitors; periosteal cells; bone marrow mesenchymal progenitors
Grem1-CreERT Tg(Grem1-cre/ERT)3Tcw	Transgenic insertion of a BAC encoding Gremlin-1 modified by insertion of CreERT	Osteochondroreticular progenitors
Sp7-Cre (Osx-Cre) g(Sp7-tTA,tetO-EGFP/cre)1Amc	Transgene insertion. A tetracycline-regulated transactivator (tTA) upstream of a tetracycline-responsive element (tetO)-controlled EGFP/Cre fusion protein placed in exon 1 of a BAC construct encoding Sp7 (Osterix) Inducible in embryos and adults	Neonatal mesenchymal stromal cells that give rise to osteochondroprogenitors and bone marrow adipocytes; the transgene itself impacts bone mass and causes a craniofacial defect
LepR-Cre $LepR^{tm2(cre)Rck}$	A cre inserted into the endogenous LepR gene, generating a loss-of-function allele of Lepr	Adult mesenchymal stromal cells that give rise to osteochondroprogenitors and bone marrow adipocytes
Col1a1(2.3 kb)-Cre Tg(Col1a1-cre)1Kry	Transgene insertion of 2.3 kb promoter	Mature osteoblasts throughout differentiation
Col1a1(3.6 kb)-Cre Tg(Col1a1-creBek	Transgene insertion of 3.6 kb promoter	Immature osteoblasts throughout differentiation
Col1a1(2.3 kb)-CreERT2 Tg(Col1a1-cre/ERT2)1Crm	Transgene insertion of 2.3 kb promoter Inducible	Mature osteoblasts throughout differentiation
Col1a1(3.2 kb)-CreERT2 TG(Col1a1-cre/ERT)#Hmk	Transgene insertion 3.2 kb promoter	Immature osteoblasts throughout differentiation
Bglap-Cre (Oc-Cre) Tg(BGLAP-cre)1Clem	Transgene insertion	Mature osteoblasts
Dmp1-Cre Tg(Dmp1-cre)1Jqfe	Transgene insertion; 14 kb promoter	Odontoblasts, osteoblasts, osteocytes
Dmp1-Cre Tg(Dmp1-cre)1Btm	Transgene insertion; 8 kb promoter	Odontoblasts, osteoblasts, osteocytes
Dmp1-CreERT2 Tg(Dmp1-cre/ERT2)D77Pdp	Transgene insertion; 10 kb promoter Inducible in embryos and adults	Mature osteoblasts and osteocytes
Osteoclasts		
LysM-Cre $Lyz2^{tm1(cre)Ifo}$	A Cre inserted into the ATG start site of the endogenous *Lyz2* gene	Myeloid lineage cells
CD11b-Cre Tg(ITGAM-cre)2781Gkl	Transgene insertion	Myeloid lineage cells
TRAP-Cre Tg(Acp5-cre)4Rda	Transgene insertion containing promoters 1B and 1C of *Acp5* gene	Myeloid lineage cells

Continued

TABLE 77.1 Commonly used Cre lines for skeletal analysis.—cont'd

Precondensed mesenchyme	Description	Primary sites of expression
Ctsk-Cre Ctsktm1(cre)Ska	Targeted insertion of the Cre cassette into the endogenous *Ctsk* locus replacing first 4 exons	Myeloid lineage cells
Ctsk-Cre Tg(Ctsk-cre)1Rda	Transgene insertion of a 5 kb *Ctsk* promoter driving Cre expression	Myeloid lineage cells
Cre reporters and ROSA locus tools		
R26R Gt(ROSA)26Sor^{tm1Sor}	Targeted insertion of a loxP-flanked stop cassette upstream of a lacZ coding sequence within the Rosa26 locus between exons 1 and 2	LacZ expressed in all cells where Cre is active and in their descendants
R26R-Confetti Gt(ROSA)26Sor$^{tm1(CAG-Brainbow2.1)Cle}$	Targeted insertion of a strong CAGG promoter, a loxP site, a PGK-Neo-pA cassette (serving as a transcriptional roadblock), and the Brainbow 2.1 construct inserted between exons 1 and 2 of the Gt(ROSA)26Sor locus	Individual cells and their descendants can be tracked upon Cre activation
R26-tdTomato (Ai9) Gt(ROSA)26Sor$^{tm9(CAG-tdTomato)Hze}$	Targeted insertion of a CAGG promoter upstream of a loxP-flanked stop cassette and the coding sequence for a DsRed protein (tdTomato)	Cellular tdTomato-derived red fluorescence in all cells where Cre is active and in their descendants
R26-ntdTomato (Ai75D) Gt(ROSA)26Sor$^{tm75.1(CAG-tdTomato*)Hze}$	Targeted insertion of a CAGG promoter upstream of a loxP-flanked stop cassette and coding sequences for a DsRed protein (tdTomato) containing a nuclear localization signal	Nuclear tdTomato-derived red fluorescence in all cells where Cre is active and in their descendants
mTmG Gt(ROSA)26Sor$^{tm4(ACTB-tdTomato,-EGFP)Luo}$	Targeted insertion of a CAGG promoter upstream of a loxP-flanked coding sequence for a DsRed protein (tdTomato) and poly adenylation sequence, which is followed by a membrane-tagged EGFP protein	Red fluorescence in all tissues; EGFP in Cre-expressing cells and in their descendants
nTnG Gt(ROSA)26Sor$^{tm1(CAG-tdTomato*,\ -EGFP)Ees}$	Targeted insertion of a CAGG promoter upstream of a loxP-flanked coding sequence for a nuclear localized DsRed protein (ntdTomato), which is followed by a nuclear localized EGFP protein	Red fluorescence in nuclei of all tissues; EGFP in the nuclei of Cre-expressing cells and in their descendants
R26-rtTA Gt(ROSA)26Sor$^{tm1(rtTA,\ -EGFP)Nagy}$	Targeted insertion of a loxP-flanked stop cassette upstream of a reverse tetracycline trans-activator coding sequence, internal ribosomal entry site (IRES), and EGFP coding sequence	A doxycycline inducible transactivator protein is expressed in all Cre-expressing cells and in their descendants; rtTA interacts with transgenic promoters containing tet-responsive elements to drive expression of exogenous transgenes only in the presence of doxycycline
R26-iDTR Gt(ROSA)26Sor$^{tm1(HBEGF)Awai}$	Targeted insertion of a loxP-flanked stop cassette upstream of the simian diphtheria toxin receptor coding sequence	Diphtheria toxin receptor (DTR)-inducible expression in all Cre-expressing cells; DTR-expressing cells are susceptible to ablation following administration of diphtheria toxin
R26-DTA Gt(ROSA)26Sor$^{tm1(DTA)Lky}$	Targeted insertion of a loxP-flanked stop cassette upstream of the diphtheria toxin alpha chain (DTA) coding sequence	Inducible expression of diphtheria toxin and cell death/toxicity in all Cre-expressing cells

strains utilizing the same promoter region have been developed, and these mice also demonstrate expression within the previously mentioned mesenchymal progenitor populations (Hasson et al., 2007; Kawanami et al., 2009). One of the two *Prrx1-CreERT2* strains (Kawanami et al., 2009) contains a CreERT2-GFP fusion protein, allowing for both Cre activity and the detection of cells with an active *Prrx1* transgene promoter. The *Dermo1-Cre* (*Twist2*-Cre) is a "knockin" mouse line used in heterozygosity that exhibits Cre expression within mesenchymal condensations (Yu et al., 2003); however, it is not restricted to the skeletal mesenchyme and can be observed more broadly in the mesenchyme of other organs. A *Sox9-Cre* "knockin" that targeted an internal ribosomal entry site (IRES)-Cre to the *Sox9* 3′UTR successfully drives Cre-mediated excision within precursors of osteoblasts and chondrocytes in skeletogenic condensations (Akiyama et al., 2005; Chan et al., 2011); however, it is also active in other sites of endogenous *Sox9* expression.

Chondrocytes

The most widely used Cre strain for chondrocyte-mediated gene deletion/activation is *Col2a1-Cre* (Ovchinnikov et al., 2000). Transgene expression of the *Col2a1-Cre* line is robustly driven in chondrocytes; however, most lines exhibit Cre activity in joint mesenchymal and perichondrial cells that give rise to many if not most osteoblasts (Long et al., 2001; Ono et al., 2014). Three *Col10a1-Cre* lines permit gene deletion specifically within hypertrophic chondrocytes of the developing growth plate (Yang et al., 2005, 2014bbib_Yang_et_al_2005; Golovchenko et al., 2013bib_Yang_et_al_2014b). These *Col10a1-Cre* lines were derived using transgenic approaches: one using a transgenic approach including a 10.5 kb *Col10a1* promoter region (Yang et al., 2005), the second using a bacterial artificial chromosome (BAC) transgene containing much of the *Col10a1* gene (Gebhard et al., 2008; Golovchenko et al., 2013), and the third by knockin of Cre into the endogenous gene (Tsang et al., 2007; Yang et al., 2014b). Several of these mouse lines have been used to demonstrate that hypertrophic chondrocytes give rise to a great number of osteoblasts and osteocytes during endochondral bone development, thereby illustrating that "chondrocyte-specific" gene deletion/activation is transient at best, while the growth plate actively contributes cells to the osteoblast lineage within the bone marrow.

T-inducible recombination in chondrocytes is enabled via the use of transgenic lines expressing a CreERT or CreERT2 cassette under the control of *Col2a1* promoter/enhancer fragments. These mice permit efficient ablation or activation of genes in prenatal cartilage up to 2 weeks after birth; however, for most lines, efficiency is significantly lower in adults. One more widely used *Col2a1-CreERT2* line is more efficient in adult mice (e.g., Grover and Roughley, 2006; Chen et al., 2007). To overcome these issues, *aggrecan-CreERT2* mice were developed in which an IRES-CreERT2 cassette has been "knocked in" to the *aggrecan* gene 3′UTR. These mice exhibit robust inducible Cre expression in both prenatal and adult growth plate and articular chondrocytes as well as chondrocytes within fibrocartilage (Henry et al., 2009). Finally, a *Col10a1-CreERT2* mouse line was generated using a transgenic approach similar to that of the *Col10a1-Cre* mouse line that utilizes a 10.5 kb Col10a1 promoter/enhancer sequence. This line has been important in lineage-tracing hypertrophic chondrocytes into cells within the bone marrow (Zhou et al., 2014b). However, since *Col10a1*-expressing hypertrophic chondrocytes are a transient population, continuous delivery of T would be required to examine the long-term skeletal effects of hypertrophic chondrocyte and descendant gene deletion/activation.

No Cre lines drive Cre-mediated recombination specifically within articular chondrocytes alone. However, transgenic mice in which a Cre-IRES-ALPP (alkaline phosphatase used as a reporter of Cre expression) cassette was inserted into a *Gdf5* BAC clone (*Gdf5-Cre*) drive Cre expression within joint interzone cells, synovial cells, and articular chondrocytes (Koyama et al., 2008). More recently, a *Prg4GFPCreERT2* strain, in which GFP and CreERT2 have been introduced into the *Prg4* locus, has been shown to drive Cre expression in superficial zone cartilage in young mice. This work also demonstrated that superficial zone cells give rise to descendants that end up spanning the depth of articular cartilage in adults (Kozhemyakina et al., 2015).

Osteoprogenitors/osteoblasts/osteocytes

In addition to the lateral plate mesoderm and skull mesenchyme of embryos, *Prrx1-CreERT2* activity can be induced in osteochondroprogenitors of postnatal mice within the cranial suture mesenchyme, the periosteum, and bone marrow (Ouyang et al., 2014). Similarly, the *Grem1-CreERT2* mouse, which was generated by BAC recombineering techniques utilizing the *Grem1* gene, marks a skeletal stem cell population with chondrogenic, osteogenic, and reticular potential (Worthley et al., 2015). BAC recombineering approaches utilizing a clone containing the *Sp7 (Osterix)* locus and a doxycycline regulatable Cre-GFP fusion cassette was generated to create an inducible "Tet-OFF" *Sp7-Cre* mouse line (Rodda and McMahon, 2006). Originally characterized as a marker of osteoprogenitors, *Sp7* and Cre-GFP are now known to be expressed in cells that give rise to chondrocytes, osteoblasts, stromal cells, adipocytes, and perivascular cells in bone

marrow (Chen et al., 2014). Similar to *Sox9-Cre* mice, *leptin receptor* Cre *(LepR-Cre)* utilized a "knockin" approach positioning an IRES-Cre cassette in the *LepR* 3′UTR. *LepR-Cre* drives Cre-mediated excision within most mesenchymal progenitor cells of late embryonic and adult bone marrow (Zhou et al., 2014a). Over the course of weeks to months, these *LepR-Cre* expressing progenitors give rise to most osteoblasts and many osteocytes in adult mouse bone.

Unlike previous Cre-expressing mice that initiated gene recombination in mesenchymal or osteochondral progenitors, the *Col1a1(3.6 kb)-Cre* utilizes a 3.6 kb *Col1a1* promoter transgene to drive Cre expression in more committed osteoblasts; however, it also targets tendon and fibrous cells in cranial sutures, skin, and other organs (Liu et al., 2004). A smaller 2.3 kb *Col1a1* promoter transgene permits *Col1a1 (2.3 kb)-Cre* to have a restricted pattern of expression in mature osteoblasts; however, ectopic expression has been noted in the brain (Dacquin et al., 2002; Scheller et al., 2011). A fragment of the human *bone gamma carboxyglutamate* protein or *osteocalcin* promoter/enhancer has been used to direct expression of Cre to mature osteoblasts in the *Bglap-Cre* (or *Oc-Cre*) transgenic mouse line, which is activated in mature osteoblasts just prior to birth (Zhang et al., 2002). Several transgenic Cre lines have been developed utilizing the *Dmp1* promoter to drive Cre expression in osteocytes; however, they are not specific to these cells (reviewed in Kalajzic et al., 2013). Lines containing 10 kb or longer *Dmp1* proximal promoter regions exhibit expression in osteoblasts in addition to osteocytes. An 8 kb *Dmp1-Cre* strain is reported to have more osteocyte-selective expression (Bivi et al., 2012). Several inducible Cre transgenic strains have been developed for committed osteoblast-derived gene deletions or activations in postnatal mice. These include the *Col1a1* (2.3 kb)-*CreERT*, *Col1a1* (3.2 kb)-*CreERT*, and 8 kb *Dmp1-CreERT2* strains (Maes et al., 2010, p. 1471; Kim et al., 2012).

Osteoclasts

Several Cre strains permit ablation in myeloid cells of the hematopoietic lineage. LysM-Cre mice, in which a Cre was targeted to the endogenous *Lys2* gene locus, demonstrate constitutive Cre expression in the myeloid cell lineage including monocytes, granulocytes, mature macrophages, and osteoclasts (Clausen et al., 1999). The *Cd11b-Cre* transgenic mouse line utilizes a 1.7 kb promoter fragment of the human *ITGAM* (*CD11b*) gene to drive Cre expression in murine macrophages and osteoclasts (Nakamura et al., 2007). Additional transgenic lines expressing Cre under the control of *Acp5* (*TRAP-Cre*) and *Ctsk* (*Ctsk-Cre*) promoters have been generated and characterized (Nakamura et al., 2007); however, each line exhibits promiscuous Cre expression in nonmyeloid cells. An excellent review compares the most commonly used myeloid-specific promoters (Hume, 2011).

Lineage tracing and overexpression tools of the *Rosa26* locus

Lineage tracing

Genetically modified mice have enabled the elucidation of cell lineage relationships in bone with unprecedented resolution, as illustrated in Fig. 77.2. These studies employ strains carrying a floxed reporter gene, such as *LacZ, GFP,* or *RFP* (*tdTomato*), whose expression is activated in specific cells and maintained in their descendants. The reporter allele *R26R* carries a LacZ cassette under the control of a floxed strong transcriptional stop sequence that has been introduced into the ubiquitously expressed *Rosa26* locus. When bred to a Cre-expressing strain, β-galactosidase is expressed in all cells in which the Cre is expressed. The use of R26R in bone is limited by the fact that osteoblasts express endogenous LacZ, but major insights have been made using R26R and other lineage tracers to study osteoprogenitors. These are discussed in several comprehensive reviews (Roeder et al., 2016; Scott and Underhill, 2016). Examples are the previously discussed demonstrations that immature osteoblasts move into developing bone along with invading blood vessels (Maes et al., 2010) and that hypertrophic chondrocytes give rise to osteoblasts (Ono et al., 2014; Yang et al., 2014b). More recently, multiple lines have been generated that permit live imaging of the expression of fluorescent proteins in specific organelles (cell membrane, nucleus, etc.) in a tissue-specific and inducible manner (Abe and Fujimori, 2013).

Overexpression using the *Rosa26* locus

The *Rosa26* locus has also been exploited to conditionally express a variety of genes that serve as useful tools to study skeletal biology. Conditional overexpression of diphtheria toxin alpha chain (DTA) or diphtheria toxin receptor (DTR) is often used to study the function of specific cell populations when R26-DTA or R26-DTR mice are crossed with Cre-expressing or inducible Cre−expressing mice. R26-DTA mice were developed by inserting a loxP-flanked stop cassette upstream of the DTA coding sequence (Voehringer et al., 2008) that when Cre-activated induces cell toxicity and cell

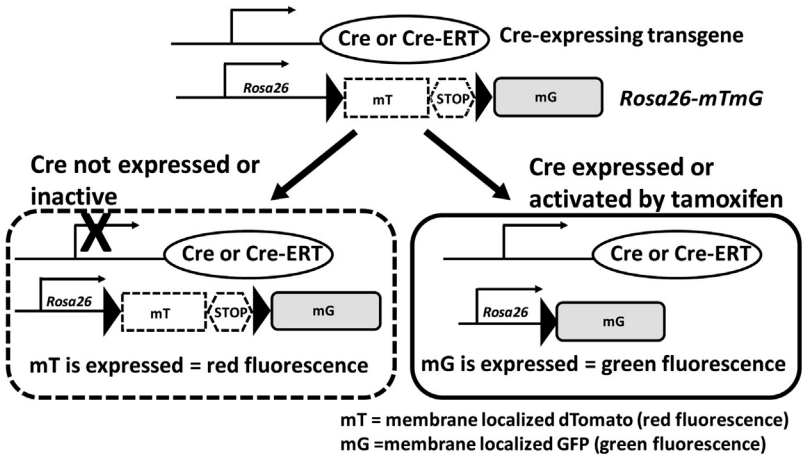

FIGURE 77.2 Lineage tracing with Cre strains and the *Rosa26-mTmG* reporter line. Schematic depicting the general principle behind Cre/lox-mediated lineage tracing. *Rosa26-mTmG* mice (*top*) are crossed with a Cre-expressing or CreERT—expressing strain. Double-heterozygous offspring will produce Cre recombinase in cells in which the promoter driving Cre (or CreERT) expression is active. If the Cre is unmodified, it will be active in these cells. If a CreERT is used, Cre will be expressed but will be inactive unless tamoxifen is supplied. In cells in which Cre is not present or is inactive, cells will be red due to the expression of membrane-bound dTomato (mT), which is expressed from the *Rosa26* reporter allele *(bottom left).* Expression of Cre or administration of tamoxifen to CreERT-expressing mice will lead to Cre-mediated excision of the mT-STOP cassette (*bottom right*). This removes the strong transcriptional STOP sequence and enables expression of membrane-bound GFP (mG). Because the Cre-mediated switch is genetic, it is permanent and will remain for the life span of the recombined cell. It will be passed on to the cell's offspring, allowing its lineage (i.e., the cell types to which the recombined cell gives rise to) to be traced.

death. R26-iDTR mice contain a loxP-flanked stop cassette upstream of the DTR coding sequence that when Cre-activated induces DTR expression (Buch et al., 2005); however, cell death induction requires the delivery of diphtheria toxin, affording temporal control of cell death induction. A recent study investigated the importance of surface chondrocyte death in articular cartilage by overexpressing diphtheria toxin within surface chondrocytes using *Prg4-GFPCreERT2* (Zhang et al., 2016). Although cell death has been proposed as a contributor to the onset or progression of osteoarthritis, this study revealed that the death of surface chondrocytes did not initiate joint cartilage degeneration.

Finally, inducible and tunable overexpression of genes can be achieved utilizing a reverse tetracycline transactivator (rtTA) and tetracycline-inducible transgene overexpression system. In this approach, a Rosa26 mouse line containing a loxP-flanked stop cassette upstream of an rtTA, IRES, and GFP cassette allows for doxycycline-inducible rtTA and GFP protein expression when crossed with a Cre-expressing mouse line. Upon Cre-mediated activation and delivery of doxycycline, the rtTA interacts with additional transgenic promoters containing tet-responsive elements to drive the expression of exogenous transgenes only in the presence of doxycycline. This model has been used recently to study transient versus sustained Notch signaling in chondrocytes and their descendants (Liu et al., 2015).

Genomic engineering using CRISPR/Cas9

The development of CRISPR/Cas9 technology has revolutionized genomic engineering. CRISPR/Cas9 is a genome editing technique in which the generation of 20-nt guide RNA sequences (gRNAs) determines the site of genomic editing. Error-prone DNA repair mechanisms are exploited to introduce insertions or deletions. The technology can also be used to generate specific point mutations or conditional alleles. In addition to the efficiency of the technique, CRISPR/Cas9 gRNAs can be injected directly into fertilized eggs to generate mutant offspring, bypassing the need to inject ES cells into blastocysts. Thus, genetically modified mice can be produced in as few as 4 weeks compared with homologous recombination using ES cells, which typically requires 6—12 months. Detailed methodologies for generating mutant animals using CRISPR/Cas9 are rapidly evolving but can be found in work by Yang et al. (2014a). Many core facilities and commercial groups cost-effectively generate mouse models using CRISPR/Cas9 technology.

Conclusions

With all of the successes in genetic manipulation and the rapidly growing number of modified mouse strains available in public repositories, the real bottleneck is phenotyping. Many knockout and mutant strains exhibit no obvious skeletal

phenotypes due to functional redundancy. Therefore, the creation of double or even triple knockouts may be necessary to discover gene function. Furthermore, inbred strains vary considerably in their peak BMD. ES cells from the 129 strain have been frequently used. However, 129 mice exhibit abnormal immunological characteristics that could impact bone density (McVicar et al., 2002). Genetically modified mice frequently have 129, C56Bl/6, and C3H backgrounds, but unmodified mice of these strains have different BMD profiles (Rosen et al., 2001) and different responses to mechanical loading (Li et al., 2005) that need to be considered when interpreting skeletal phenotypes. Moreover, environmental factors such as housing, diet, and intestinal microbiota can have a significant impact on metabolic parameters and BMD (Nagy et al., 2002; Li et al., 2016).

Finally, it is well recognized that caution must be taken when extrapolating findings in mouse models to functions in humans. Biomechanical loading and hormonal effects on bones are clearly different in mice and humans. Nonetheless, similarities outweigh the differences by far, and genetic models are likely to play an increasingly prominent role in every aspect of research within the field of skeletal biology.

Chapter outline

Introduction

Bone metabolism is characterized by an intimate cooperation of bone cells including osteoblasts, osteoclasts, and osteocytes in order to maintain bone tissue quantity and the integrity of bone structure. In metabolic bone diseases such as osteoporosis, bone metabolism is altered, leading to bone loss that is often accompanied by changes in the microarchitecture that result in bone fragility and ultimately fracture. The development of serum and urinary assays for biochemical markers, reflecting either enzymatic activities of osteoblasts and osteoclasts or breakdown products of bone tissue, has been very useful for investigating the complex pathways of bone metabolism and their alterations in bone diseases. Novel biological markers have been developed, and studies suggest that they may be valuable research tools for investigating the mechanisms of bone metabolism and assessing the activity of osteocytes, and some of them may be of value for the management of patients with osteoporosis and other bone diseases. In this chapter we will present briefly the established biochemical markers, review the new data on emerging biomarkers, and then discuss their clinical utility in osteoporosis and other metabolic bone diseases.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00078-6

Established biochemical markers of bone metabolism

The structure, biology, and clinical utility of classical biochemical markers in different diseases including osteoporosis has been reviewed in several recent review papers (Naylor and Eastell, 2012; Eastell and Szulc, 2017). At present, the most specific and sensitive markers of bone formation (Table 78.1) are serum total osteocalcin; the bone isoenzyme of alkaline phosphatase (bone ALP); and the procollagen type I N-terminal propeptide (PINP), this last marker reflecting the rate of synthesis of the main constituent of bone tissue. For the evaluation of bone resorption, most currently available assays are based on serum or urine detection of breakdown products of type I collagen, the most abundant protein of bone matrix. These include the intermolecular cross-links pyridinoline (PYD) and deoxypyridinoline (DPD); cathepsin K−generated C-terminal telopeptide of collagen type I (CTX) and cross-linked N-terminal telopeptide of type I collagen (NTX); and matrix metalloproteinase (MMP)-generated cross-linked carboxyterminal telopeptide of type I collagen (CTX-MMP or ICTP); all of which are type I collagen fragments. Serum 5b isoenzyme of tartrate-resistant acid phosphatase (TRACP5b) is also a valuable biochemical marker reflecting mainly the number and activity of osteoclasts. An expert group from the International Osteoporosis Foundation (IOF) and the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has performed a comprehensive review of the available data, and based on this assessment has recommended the systematic use of serum PINP and serum betaCTX as biochemical reference markers of bone formation and bone resorption, respectively, but only in clinical research studies in osteoporosis (Vasikaran et al., 2011; Johansson et al., 2014).

A study performed in 371 untreated postmenopausal women with osteoporosis aged between 50 and 84 years analyzed the correlation of bone markers including PINP and serum CTX with static and dynamic histomorphometric parameters measured on iliac crest biopsies (Chavassieux et al., 2015). PINP was found to be significantly associated with both static and dynamic parameters of formation ($0.21 \leq r \leq 0.36$, $.01 \geq P \geq .0001$), whereas serum CTX correlated with all resorption parameters ($0.18 \leq r \leq 0.24$, $.02 \geq P \geq .0001$). These associations are rather modest, but this is not surprising, as systemic bone markers reflect the turnover of the entire skeleton including the periosteal, cortical, endocortical, and cancellous compartments, whereas histomorphometric parameters assess a small part of the iliac crest. A combined calcium balance and tracer study in women with osteoporosis (Eastell et al., 1997) also showed positive correlation between the estimated resorption and concentration of bone resorption markers, with DPD having the highest correlation coefficient. The available studies of bone turnover marker (BTM) validation have shortfalls including limitations of the reference methods such as availability, cost, and small sample size.

BTM selection depends on the clinical context. In metabolic bone diseases such as Paget's disease of bone and patients with bone metastases (BMs), some type I collagen degradation markers are more sensitive than serum beta CTX. These include urinary NTX and the nonisomerized form of CTX (αCTX) (Garnero et al., 1997; Leeming et al., 2006). Bone ALP, intact PINP (bone formation), and TRAP5b (bone resorption) would be appropriate for assessing bone disorders in chronic kidney disease (because these markers are excreted not by the kidney but by the liver), and osteocalcin (bone formation) or CTX (bone resorption) would be appropriate for assessing glucocorticoid-induced osteoporosis.

However, the established biochemical markers, including serum CTX and PINP, have some limitations. These include (1) a lack of tissue specificity for bone, as type I collagen is widely distributed in different organs, (2) an inability to distinguish the metabolic activity of the different skeletal compartments even though they can be differently affected by

TABLE 78.1 Established markers of bone turnover.

Bone formation (serum marker)	Bone resorption (serum or urine marker)
Osteocalcin: intact, total, or undercarboxylated	*Serum* and urine ***cross-linked C-telopeptide of type I collagen (S-βCTX,*** CTX)
Bone alkaline phosphatase	Serum and urine cross-linked N-telopeptide of type I collagenS
Procollagen type I N-terminal propeptide	Serum cross-linked C-telopeptide of type I collagen generated by matrix metalloproteinases (CTX-MMP or ICTP[a])
Procollagen type I C-terminal propeptide	Urinary free and total deoxypyridinoline
	Serum tartrate-resistant acid phosphatase isoenzyme 5b
	Urinary free and total deoxypyridinoline

The markers recommended by the IOF−IFCC as reference markers for use in clinical studies are indicated in bold italic.
[a]CTX-MMP *is the official abbreviation;* ICTP *is the most commonly used abbreviation.*

diseases and treatments, (3) reflecting mainly the function of osteoblasts or osteoclasts and not the activity of osteocytes even though these cells are the most abundant of bone tissue and play a pivotal role in the maintenance of skeletal integrity, and (4) all of them being single protein-based markers, although circulating proteomic, metabolomic, or microRNA (miRNA generally; miR for specific numbers) signature could provide an earlier and/or a more integrated view of bone remodeling alterations. The new biochemical markers described in the following section may overcome some of these limitations (Table 78.2).

Novel biological markers of bone metabolism

The novel markers can be classified in different groups as shown in Table 78.2. These include the measurements of some noncollagenous proteins, osteoclastic enzymes other than TRACP5b, osteocyte-secreted factor, molecules involved in coupling between osteoclast−osteoblasts, hormones, and "omics" markers such as proteomic and metabolomic patterns and circulating miRNAs. The most promising candidates in each category and their clinical relevance for the investigation of patients with osteoporosis and other metabolic bone diseases are discussed next.

Periostin

The periosteum covers long bones, and although in adults its metabolism is considered low, it plays an important role for controlling the diameter of bones and thus bone strength (Seeman, 2007). Currently, however, there are no available noninvasive biological tools allowing the assessment of periosteal metabolism, as current bone markers reflect mainly endosteal bone remodeling (Szulc et al., 2005). Periostin (POSTN) may be a candidate marker of periosteal metabolism. Detailed reviews of the structure, regulation, and involvement of this protein in bone metabolism have been recently published (Merle and Garnero, 2012; Bonnet et al., 2016).

POSTN is mainly expressed by periosteal osteoblasts and osteocytes—although osteoclasts may also express low levels (Merle et al., 2014). At the protein level, it is composed of a signal sequence followed by an Emilin domain rich in cysteine, four repeated and conserved Fasciclin-1 (FAS-1) domains, and a C-terminal hydrophilic and variable domain. Alternative splicing of the C-terminal domain gives rise to at least five different human isoforms. Each FAS-1 domain is rich in glutamate residues and contains an N-terminal recognition site for the vitamin K-dependent enzyme γ-glutamyl carboxylase (γ-carboxylase recognition sites) responsible for posttranslational modification of glutamic residues to γ-carboxyglutamate. This protein belongs to the matricellular protein family because it contains binding sites for extracellular matrix proteins, such as type I and type V collagens, and the cell surface receptor integrins. In adults, POSTN has been shown to be overexpressed at the periosteal surface as well as in other collagen-rich tissues subjected to mechanical strain such as periodontal ligaments, heart valves, and tendons (Merle and Garnero, 2012; Bonnet et al., 2016).

The most informative data on the function of POSTN in bone metabolism have been obtained from studies using POSTN-deficient mice. These mice develop periodontitis and osteoporosis with lower bone mineral density (BMD), altered microarchitecture, and decreased bone strength (Bonnet et al., 2009). These studies have also shown POSTN to be an important mediator of the effects of mechanical factors and parathyroid hormone (PTH) on cortical BMD and bone strength by modulating the canonical Wnt signaling pathway via downregulation of sclerostin (SOST) expression (Bonnet et al., 2009, 2012).

POSTN not only is involved in regulating bone formation and BMD but also could have an effect on bone strength by regulating collagen cross-linking (Kii et al., 2010). POSTN interacts in bone tissue with bone morphogenic protein 1, which catalyzes the lysyl oxidase activation that promotes collagen cross-linking (Maruhashi et al., 2010).

Circulating periostin as a potential clinical biomarker

Because POSTN is a secreted protein, it can be measured in peripheral biological fluids including serum. Several clinical studies have been performed using various research enzyme-linked immunosorbent assays (ELISAs) based on polyclonal or monoclonal antibodies with different specificities. There are several commercially available immunoassays but the most widely used are the following three. The USCN (China) assay uses a polyclonal antibody raised against the FAS-1 domain of POSTN and is expected to detect all POSTN isoforms (Rousseau et al., 2014, 2015). This assay has been used in most published clinical studies. Two other ELISAs, from Adipogen (Switzerland) and Biomedica (Austria), were more recently developed. These two site assays use a combination of a monoclonal and polyclonal antibodies raised against human recombinant POSTN. However, the exact specificity of the antibodies is unknown, and it remains unclear which molecular forms they are detecting in the serum. Because research and commercial assays are not standardized, it is difficult to compare the results between studies, and this could influence the interpretation of the data. In young adults, serum POSTN measured by the Biomedica assay was shown to correlate with serum insulin-like growth factor 1 (IGF-1) and high-resolution peripheral quantitative computed tomography (HR-pQCT) measures of cortical bone. This suggests that POSTN could have a role in IGF-1-driven cortical modeling and consolidation (Walsh et al., 2017). In postmenopausal women, serum POSTN had zero or weak correlation (Rousseau et al., 2014, 2015; Walsh et al., 2017; Anastasilakis et al., 2014) with spine and hip areal BMD. Similarly, serum POSTN was not or only slightly associated with conventional markers of bone formation and bone resorption (Rousseau et al., 2015; Walsh et al., 2017; Anastasilakis et al., 2014). These data indicate that when assayed in serum, POSTN levels reflect biological processes different from those captured by static (BMD) or dynamic (bone marker) indices of bone metabolism. In a cohort of healthy elderly men and women, a positive correlation between serum POSTN and HR-pQCT-assessed cortical bone thickness was observed; it correlated negatively with cortical porosity, although these associations were no longer significant after adjusting for gender and age. In the same individuals, serum POSTN was not correlated with trabecular bone volume fraction (BV/TV) after adjustment by PINP, serum CTX, BMD, gender, or age (Bonnet et al., 2015). There was also an association of POSTN levels between parents and adult offspring, with an estimated heritability of 50%, and a genetic covariance was found between serum POSTN and bone microarchitecture. In a cohort of postmenopausal women, the highest quartile of serum total POSTN measured by the USCN assay was associated with an increased risk of all incident fractures independently of BMD and conventional bone markers (Rousseau et al., 2014). These data were more recently confirmed in another case−control study of postmenopausal women from Korea (Kim et al., 2015). A positive association was found between serum POSTN and all incident fractures independently of BMD (Kim et al., 2015). When vertebral and nonvertebral fractures were analyzed separately, POSTN levels were associated only with the latter type of fracture, which is in agreement with the predominant role of POSTN on cortical bone metabolism (Kim et al., 2015). Altogether, available clinical data suggest that serum total POSTN could be a new biological marker of fracture risk, and more specifically nonvertebral fracture in postmenopausal women. The fact that it is independent of both BMD and bone markers suggests that the measurement of serum POSTN could be useful in combination with these two key risk factors to improve risk assessment. These data, however, need to be confirmed in larger independent studies.

Because POSTN has been shown to be an important mediator of the anabolic activity of PTH in animal studies, circulating POSTN may be useful in assessing the effects of PTH and its derivatives in humans. A recent open-label single-arm study showed that serum POSTN was moderately but significantly increased after 52 weeks of treatment with teriparatide in postmenopausal women with osteoporosis (Gossiel et al., 2018). In addition, the change in serum POSTN was significantly and positively associated with changes in lumbar spine and hip BMD after 1 and 2 years, respectively.

Total serum POSTN as measured by commercially available immunoassays is not specific, however, as serum levels represent the additional contribution of the metabolism of other tissues. It is possible that bone-specific isoforms or POSTN fragments could be a more sensitive index of fracture risk. In that respect, it is interesting to note that specific POSTN isoforms have been described in other tissues such in fibrotic lung, heart and skin (Kuhn et al., 2007; Uchida et al., 2012; Masuoka et al., 2012). Thus, it may be possible to identify bone-specific POSTN isoforms or POSTN bone-specific fragments. It has recently been shown that mouse and human POSTN are efficiently degraded by the osteoclast-specific enzyme cathepsin K (Garnero et al., 2017). Cathepsin K−generated POSTN fragment(s) may thus be a candidate of such a bone-specific biochemical marker. Based on these assumptions, we recently developed a competitive ELISA that specifically detects a fragment of POSTN generated by the catalytic action of cathepsin K (Garnero et al., 2017). We found that serum levels of this new marker (so-called K-POST) was not associated with areal hip BMD, serum PINP, and CTX, but was negatively correlated with cortical bone parameters of the tibia assessed by HR-pQCT in a cohort of elderly women. Interestingly, increased levels of this marker were also significantly associated with the risk of low-trauma clinical fracture even after multiple adjustments including serum CTX, PINP, areal BMD, and the Fracture Risk Assessment Tool index, whereas total POSTN measured by the USCN commercial assay was not predictive (Bonnet et al., 2017).

Receptor activator of NF-kB ligand and osteoprotegerin

Measurements of regulators of osteoclastic and osteoblastic differentiation and activity have been suggested as useful in assessing bone metabolism in osteoporosis, arthritis, and metastatic bone diseases. The receptor activator of *NF-kB ligand (RANKL)/RANK/osteoprotegerin (OPG)* system is one of the main regulators of osteoclast formation and function as demonstrated by a series of preclinical and clinical studies (for a review, see Kearns et al., 2008). It has been shown that serum RANKL levels were increased in patients with systemic autoimmune diseases before glucocorticoid therapy compared with healthy controls (Kaneko et al., 2012). Patients with high baseline RANKL levels demonstrated an increase in BMD after therapy, whereas BMD decreased in those with lower RANKL values. This suggests that serum pretreatment RANKL may be useful for predicting the response to glucocorticoid in patients with systemic autoimmune diseases. In order to increase the sensitivity of systemic measurements, OPG and RANKL expression have been measured in peripheral blood mononuclear cells (PBMCs). No changes in OPG or RANKL expression could be demonstrated in PBMCs of postmenopausal women after treatment with either ibandronate or strontium ranelate (Stuss et al., 2013). Measuring circulating RANKL and OPG remains challenging, especially RANKL, because their levels are very low. It is also unlikely that circulating levels of OPG and RANKL adequately reflect local bone marrow production. These limitations explain the conflicting data on the association of circulating OPG and RANKL with BMD and biochemical BTMs in postmenopausal women and elderly men (Findlay and Atkins, 2011). The OPG/RANKL system is also likely to play a role in the bone−vascular axis. Indeed, in postmenopausal women with osteoporosis and hypercholesterolemia, statin treatment leads to a significant increase of serum OPG and RANKL expression in T cells (Rattazzi et al., 2016).

Dickkopf-related protein 1

The Wingless (Wnt) signaling pathway plays a pivotal role in the differentiation and activity of osteoblastic cells (Day et al., 2005). The primary receptors of Wnt molecules are the seven-transmembrane Frizzled-related proteins (FRPs), each of which interacts with a single transmembrane low-density lipoprotein receptor-related protein 5/6 (LRP5/6). Different secreted proteins including soluble FRPs (sFRPs), Wnt inhibitory factor 1, and Dickkopf (Dkk) 1 to Dkk4 prevent ligand−receptor interactions and consequently inhibit the Wnt signaling pathway. Alterations of the Wnt signaling pathway and its regulatory molecules including Dkk1 and sFRPs play an important role in bone turnover abnormalities associated with osteoporosis, arthritis, multiple myeloma (MM), and BMs from prostate and breast cancer. Immunoassays for circulating Dkk1 have been developed. Serum Dkk1 levels have been reported to be increased in clinical situations characterized by depressed bone formation such as MM (Tian et al., 2003) but also in diseases characterized by focal osteolysis such as MM (Tian et al., 2003), BMs from breast or lung cancer (Voorzanger-Rousselot et al., 2007), and rheumatoid arthritis (Diarra et al., 2007). Conversely, in patients with osteoarthritis of the hip, a clinical situation characterized by focal sclerosis of subchondral bone, lower serum Dkk1 levels have been associated with a decreased risk of joint destruction (Lane et al., 2007; Voorzanger-Rousselot et al., 2009a). In postmenopausal osteoporosis, a negative association of Dkk1 with BMD has been reported (Butler et al., 2011; Anastasilakis et al., 2010). Dkk1 was decreased after 12 months of glucocorticoids (Gifre et al., 2013). Interestingly, serum Dkk1 has been reported to increase after 12 and 18 months of teriparatide treatment in women with postmenopausal osteoporosis, which may explain the waning of the anabolic effect of this drug (Gatti et al., 2011). After treatment with yearly zoledronic acid, serum Dkk1 transiently increases within 1 month and declines thereafter (Gatti et al., 2014; Anastasilakis et al., 2013), whereas with an intramuscular monthly injection of a non-nitrogen-containing bisphosphonate such as clodronate, the level of Dkk1 is not affected (Gatti et al., 2012a). Dkk1 serum levels are unaffected 3 months after treatment with denosumab (Anastasilakis et al., 2013). In another longer-term study, serum Dkk1 decreased within the first 6 months of denosumab treatment and reached statistical significance compared with placebo at 18 months. The changes in Dkk1 were significantly and positively related to serum CTX and bone ALP (Gatti et al., 2012a). In patients with active RA, it was shown that 6-month anti-TNF therapy induces a small but significant decrease of serum Dkk1 (Adami et al., 2016). As for the assessment of OPG and RANKL, circulating Dkk1 might not adequately reflect local bone contribution. One way to increase the sensitivity of circulating Dkk1 measurements may be to use an assay based on the binding of Dkk1 on LRP6, or so-called functional Dkk1. Circulating functional Dkk1 was associated with radiological progression in patients with ankylosing spondylitis (AS), whereas total Dkk1 was not predictive (Heiland et al., 2012). In AS, it was also shown that increased serum Dkk1 is associated with low BMD and a higher prevalence of vertebral fracture (Rossini et al., 2016).

From a practical point of view, measurements of Dkk1 in plasma are recommended, as platelets activated during the clotting process to obtain serum are major contributors to circulating Dkk1 (Voorzanger-Rousselot et al., 2009b).

Sphingosine-1-phosphate

Sphingosine-1-phosphate (S1P) is a lipid mediator that acts on different functions of cells through S1P receptors (SP1R, SP1R1, and SP1R2) of the G-protein-coupled receptor family (During et al., 2015; Meshcheryakova et al., 2017). Although S1P may affect the proliferation, survival, and migration of osteoblasts (Grey et al., 2002, 2004; Roelofsen et al., 2008), the dominant effect of this protein on bone metabolism seems to be on osteoclastogenesis. Indeed, in vitro and in vivo experiments have shown that S1P significantly potentiates osteoclast differentiation by increasing RANKL in osteoblasts (Ryu et al., 2006). When substantial gradients exist between S1P concentrations in blood and bone, the migration of osteoclast precursors from blood (high S1P state) to bone (low S1P state) is facilitated (Ishii et al., 2009, 2010). The deletion of SP1R1 in monocyte cells leads to an accumulation of osteoclast precursors and a resultant increase in bone resorption (Lee et al., 2012). Conversely, SP1R2-deficient mice exhibit moderate osteopetrosis as a result decreased osteoclastic bone resorption (Ishii et al., 2010). Thus, SP1R1 exerts positive chemotaxis to an S1P gradient, whereas SP1R2 induces migration in the inverse direction—so-called chemorepulsion. Increased serum S1P levels were found to be associated with high levels of bone resorption—but not bone formation—markers, low BMD, and a higher risk of prevalent vertebral fractures in postmenopausal women (Lee et al., 2012; Kim et al., 2012). The predictive value of plasma S1P was investigated in 248 postmenopausal women who were either untreated or receiving HRT or bisphosphonate and followed prospectively over 3.5 years. It was reported that women with baseline levels of S1P in the highest tertile had a 5.5-fold increased risk of incident vertebral fracture compared with women with levels in the two lower tertiles, independently of BMD and prevalent fracture (Bae et al., 2016). A case–control study also reported that in patients with hip fracture, the plasma/bone marrow ratio of S1P was elevated compared with controls, whereas neither plasma nor bone marrow level alone could discriminate the two groups (Kim et al., 2016). Thus, the effect of S1P on bone fragility may depend on the ratio between levels in the peripheral circulation and bone marrow compartment. Altogether, these data suggest that the measurement of circulating S1P levels and/or its plasma/bone marrow ratio could be a new biological marker of fracture risk, although these data obtained in small number of Asian subjects require confirmation in larger prospective studies and other ethnicities.

Sclerostin

SOST is a 22 kD secreted protein that binds LRP5 and LRP6 and thereby inhibits the Wnt signaling pathway and consequently bone formation (Li et al., 2005; Semenov et al., 2005). SOST can also stimulate the secretion of osteocyte-derived RANKL, thereby activating directly osteoclast activity (Wijenayaka et al., 2011; Xiong and O'Brien, 2012). Placebo-controlled studies in postmenopausal women demonstrated that injection of monoclonal blocking antibodies against SOST, romosozumab, and blosozumab transiently increased bone-formation markers and BMD and was associated with decreased bone resorption markers (McClung et al., 2014; McColm et al., 2014; Recker et al., 2015; Appelman-Dijkstra and Papapoulos, 2016).

Different immunoassays including three commercially available tests have been developed to detect SOST changes in blood. The two ELISAs from Biomedica and TECOmedical, and the Meso Scale Discovery (MSD) electrochemiluminescence assay, use antibodies recognizing different epitopes on the SOST molecule. They are likely detecting different circulating immunoreactive forms (Durosier et al., 2013). The MSD test recognizes only the intact molecule, whereas the two ELISAs also measure fragments from SOST and possible other structurally similar but unrelated molecules. It has been shown that although all three assays were highly correlated, especially the two ELISAs (Costa et al., 2014), absolute levels can differ markedly, and their association with bone turnover and PTH may also vary (Durosier et al., 2013). Because circulating SOST highly correlates with bone marrow plasma values, serum level is likely to reflect local bone production (Costa et al., 2014).

SOST levels are slightly higher in girls prior to puberty, tend to decrease in both sexes during puberty, but remain significantly higher in boys than in girls after puberty (Kirmani et al., 2012). SOST was found to be significantly higher in postmenopausal women than in premenopausal controls (Mirza et al., 2010). In healthy women and men, SOST levels increased over lifetime by respective averages of 2.4-fold and 4.6-fold (Modder et al., 2011a; Ardawi et al., 2011). In postmenopausal women, SOST correlated negatively with total and free estradiol and with intact PTH (Modder et al., 2011b).

The association of SOST with fracture risk has been investigated in elderly women and men, with discordant data (Arasu et al., 2012; Ardawi et al., 2012; Garnero et al., 2013; Szulc et al., 2013) between studies. This suggests that the clinical utility of this marker to predict fracture risk in osteoporosis is probably limited. SOST levels are higher in patients with type 2 diabetes (T2D) (Gennari et al., 2012; Garcia-Martin et al., 2012; Ardawi et al., 2013; Yamamoto et al., 2013).

In these subjects, serum SOST was negatively associated with BTMs and positively with BMD. Postmenopausal women with T2D and increased serum SOST had a higher risk of prevalent fractures independently of BMD and bone turnover. These findings suggest that SOST could be a determinant of skeletal fragility in patients with T2D (Starup-Linde et al., 2016), although they require confirmation by longitudinal studies. SOST expression has been reported in the wall of calcifying arteries (Caira et al., 2006; Roman-Garcia et al., 2010), and serum SOST is associated with vascular calcification in postmenopausal women (Hampson et al., 2013), patients with T2D (Morales-Santana et al., 2013), patients with rheumatoid arthritis (Paccou et al., 2014), and chronic kidney disease subjects (Thambiah et al., 2012; Evenepoel et al., 2015; Lv et al., 2016a). Thus, serum SOST could be a new biological marker of vascular calcification.

Fibroblast growth factor 23 and klotho

Fibroblast growth factor 23 (FGF-23) is a circulating factor expressed predominantly in osteocytes that negatively regulates serum levels of inorganic phosphorous and 1,25-dihydroxyvitamin D_3 (Riminucci et al., 2003; Liu et al., 2003; Shimada et al., 2004). The release of FGF-23 by both young and old osteocytes may be a mechanism whereby osteocytes can control mineralization (Wang et al., 2008) and phosphate homeostasis. A cofactor, α-klotho, is needed for FGF-23 to bind to FGF receptors (Kuro-o, 2013). α-Klotho heterodimerizes with the FGFR1 receptor in the parathyroid tissue and distal convoluted tubule of the kidney, yielding a high-affinity receptor for FGF-23 (Urakawa et al., 2006). Several clinical skeletal disorders that result in mineralization abnormalities and elevated FGF-23 serum levels have been reported and include autosomal-dominant hypophosphatemic rickets, tumor-induced osteomalacia, and X-linked hypophosphatemic rickets (Wang et al., 2008; Bonewald and Wacker, 2013). Moreover, mice overexpressing FGF-23 have low cortical and trabecular BMD (Larsson et al., 2004). Given the importance of FGF-23 as a regulator of phosphate homeostasis, it is possible that this osteocyte factor could be associated with bone strength and fracture risk.

FGF-23 is synthesized as a molecule of 251 amino acids including a leader sequence coding for a signal peptide of 24 amino acids. During secretion, FGF-23 can be proteolytically cleaved between Arg179 and Ser180 to generate N-terminal and C-terminal fragments. Thus, in circulation, FGF-23 can be present as the intact form and C- and N-terminal fragments (Komaba and Fukagawa, 2012). Circulating FGF-23 can be measured by immunoassays that detect only the intact molecule, or with a C-terminal assay that detects both intact FGF-23 and C-terminal fragments. Currently it remains unclear whether the C-terminal assay will give results comparable to the intact one in different clinical situations.

Two prospective studies have analyzed the relationships between serum intact FGF-23 and fracture risk in elderly men. Mirza et al. (2011) measured baseline intact FGF-23 in 2868 elderly Swedish men (mean age 75 years) followed prospectively for more than 3 years. They found that increased baseline intact FGF-23 was associated with increased risk of all fractures and vertebral fractures. For nonvertebral and hip fracture, the relationship was not linear—only patients with serum levels of FGF-23 in the highest quartile have increased risk of fracture. Interestingly, the association remained significant after adjustment for several potentially confounding factors such as BMD, PTH, and glomerular filtration rate (GFR). Lane et al. (2013) performed a case–control investigation in 387 men with incident nonvertebral fractures including 75 hip fractures and a random sample of 1385 elderly men (>65 years, mean 74 years) participating in the US MrOS study. In contrast to the findings in Swedish men, they overall found no significant association of serum FGF-23 analyzed in quartiles and the risk of nonvertebral or hip fracture. When subjects were stratified according to renal function, however, there was a twofold higher risk of nonvertebral fracture for patients with levels of serum FGF-23 in the highest quartile—only among those with a GFR <60 mL/min/1.73 m^2. The reasons for the discrepancy between these two studies remain unclear, and additional data in prospective studies in men and postmenopausal women with various degrees of renal function would be helpful. Recently, the association of serum klotho with BMD loss and incidence of fracture was investigated in the Health, Aging and Body Composition Study (commonly known as the Health ABC Study) comprising 2776 older individuals followed prospectively for 5 years. There was no association of baseline serum klotho with spinal and hip bone loss nor with the risk of vertebral, nonvertebral, and hip fracture (Chalhoub et al., 2016).

Proteomic signature

As reviewed previously, conventional biochemical marker studies focus on a limited number of molecules and are usually based on previously established biological relevance. Proteomic studies, on the other hand, allow for an unconstrained approach to the analysis of a broad array of proteins or their fragment peptides without the need for a priori knowledge of their involvement in a particular disease state. Such an approach has been utilized particularly in the cancer field (Petricoin et al., 2002; Liotta and Petricoin, 2006). More recently, serum proteomic analyses have expanded to other diseases such as metabolic syndrome (Lamers et al., 2011) and type 1 diabetes (Moulder et al., 2015). Proteomic analysis is usually

performed on serum samples that are first depleted of abundant proteins such as albumin. Samples are subsequently digested by trypsin, and the tryptic peptide samples are analyzed using an LC−MS−MS platform (Baker et al., 2014). Detection and quantification of LC−MS−MS features with characteristics (mass, charge, LC elution time, MS drift time, and abundance) are performed using specific software. The detected features are then identified by mapping their mass, elution time, and drift time using other software tools (Crowell et al., 2013; Zimmer et al., 2006).

This proteomic approach has been used recently to predict hip bone loss and the incidence of hip fracture in MrOS study (Nielson et al., 2017). Twenty proteins were found to be significantly associated with accelerated BMD loss, and among them, five were also predictive of hip fracture risk. Some of these proteins have been previously associated with fracture risk (e.g., CD14 and SHBG), whereas others have roles in cellular senescence and aging (B2MG and TIMP1) and complement activation and innate immunity (CO7, CO9, CFAD). Selective reaction monitoring allows detection of multiple proteins in a single sample and can thus be used to easily assess a proteomic signature provided that it can be replicated in other studies, reliably yielding more robust predictions of outcomes than do the measurements of single molecules.

Metabolomic signature

Metabolomic is an emerging "omics" science that involves comprehensive and systematic profiling of low-molecular-weight end product metabolites from tissues, cells, or biological fluids (Wilson et al., 2005). This is a potentially powerful technology, as small changes in gene and protein expression could be amplified at the metabolic level. Alterations in the composition and concentration of metabolites may also enable the screening of potential biomarkers closely related to diseases. Up to now, metabolomics has found applications in many chronic metabolic disorders, such as diabetes, lung disease, neurodegenerative diseases, cancer, hypertension, and cardiovascular diseases (Tan et al., 2016; Wang et al., 2012a; Blekherman et al., 2011). The application of metabolomics in osteoporosis has just begun.

From a technical point of view, metabolomics is a method of systematic, qualitative, and quantitative analysis of metabolites in organism. Proton nuclear magnetic resonance (1H NMR) and mass spectrum (MS)-based techniques used in metabolomics exhibit properties of relatively high sensitivity, high resolution, and high throughout. However, metabolomic data are influenced by several preanalytical factors—including how samples are collected and processed—that need to be carefully controlled.

Metabolomics has been used in several preclinical osteoporosis studies as reviewed recently (Lv et al., 2016b). A few studies investigated serum metabolic profiles in osteoporosis clinical studies. The study from Qi et al. (2016) involved 364 female subjects from China divided into four groups (premenopausal women with normal BMD, postmenopausal women with normal BMD, postmenopausal women with osteopenia, and postmenopausal women with osteoporosis) (Qi et al., 2016). It was reported that women with low BMD had increased linoleic acid, oleic acid, arachidonic acid, 11,14-eicosadienoic acid, eicosapentaenoic acid, and tryptophan as well as lower 3-hydroxy-L-proline, which suggests alterations in lipid, amino acid, and energy metabolism. You et al. (2014) performed a cross-sectional metabolomic study in 601 Taiwanese women separated into two groups of postmenopausal women with high or low BMD (You et al., 2014). This study demonstrated that women with low BMD are characterized by increased acetate and glutamine and decreased glucose, VLDLs, lactate, acetone, and lipids, suggesting alteration in the metabolism of pyruvate, fatty acid, carbohydrate, D-glutamine, and D-glutamate. Sheedy et al. (Sheedy et al., 2014) used a 1H NMR-based metabolomics approach to analyze urine samples from participants recruited for an 18-month randomized controlled trial of a multicomponent progressive resistance training exercise program and calcium−vitamin D3-fortified milk consumption in healthy middle-aged and older men (Sheedy et al., 2014). There was no change in urinary metabolome in response to calcium−vitamin D3 intervention, while significant metabolite alterations following exercise intervention were observed, notably a reduction in creatinine and an increase in choline, guanidinoacetate, and hypoxanthine. Finally, Miyamoto et al. (2017) compared serum metabolome analyzed using capillary electrophoresis/MS in postmenopausal women with low and normal BMD. They could detect 57 different serum metabolites. Compared with women with normal BMD ($n = 42$), women with low BMD ($n = 5$) had significantly lower levels of Gly-Gly dipeptide and cystine, whereas hydroxyproline was increased. However, because the number of subjects was very limited, these data should be interpreted cautiously and need to be replicated in larger studies.

To date, metabolomic-based osteoporosis studies have been performed using the untargeted metabolomic approach. While the untargeted metabolomics method can provide comprehensive information on molecular weight and sample composition, it has limitations including poor specificity, large fluctuations from the instrument, and poor reproducibility of results. To improve selectivity and accuracy, it would be important in the future to combine targeted metabolomic studies with untargeted metabolomics.

MicroRNAs

The miRNAs are a class of small (~22 nucleotides), single-stranded noncoding RNAs (Hobert, 2008). They induce either translational repression or cleavage of target messenger RNAs (mRNAs) by imperfect or perfect base-pairing with specific sequences in the 3′ untranslated regions (UTRs) of target mRNAs. Interactions between mRNAs and miRNAs demonstrate two important characteristics: (1) a single miRNA is capable of binding to 100 or more distinct mRNA species, and (2) UTRs of most mRNAs contain binding sites for several miRNAs. The resulting pleiotropy of interactions and cooperative activities of miRNAs enables the regulation of complex gene expression networks in a fashion similar to that of transcription factors. Several in vitro and a few in vivo animal studies have shown that miRNAs play important roles in osteoblast (Lian et al., 2012) and osteoclast (Sugatani and Hruska, 2009) differentiation and function. As recently reviewed, miRNAs are not only involved in normal osteoblast and osteoclast function but also can be deregulated in bone disease states including osteoporosis (van Wijnen et al., 2013; Hackl et al., 2016; Wang et al., 2013).

A study showed that miR-214 levels are elevated in bone tissue specimens from older individuals with fracture, and that levels correlated with several biological and histological indices of bone formation (Wang et al., 2013). The target gene of miR-214 was identified; it is *ATF4*, which codes for an important transcription factor required for osteoblast function (Wang et al., 2013). miRNAs are released from cellular cytoplasm into biological fluids within extracellular vesicles (Valadi et al., 2007) or vesicles formed by high-density lipoproteins (Vickers et al., 2011) as well as in association with RNA-binding proteins such as nucleoplasmin or proteins of the argonaut family (Wang et al., 2010; Arroyo et al., 2011).

From a diagnostic point of view, measuring circulating miRNAs would be very attractive, as they may provide valuable information about alterations of bone metabolism and possibly earlier than protein-based biomarkers. The vesicular or protein association of circulating miRNAs accounts for their remarkable stability in biological fluids. They are resistant to RNase activity in the peripheral blood and thus may serve as excellent biomarkers (Gilad et al., 2008; Mitchell et al., 2008). However, as protein-based biomarkers, measurement of circulating miRNAs has some limitations. Blood levels may vary significantly with lifestyle and comorbidities, circadian rhythm (Shende et al., 2011), liver and kidney functions, smoking habits, and diet (Witwer, 2012). Thus, measurements of circulating miRNAs require a strict definition of inclusion and exclusion criteria in order to minimize the impact of these sources of variability and maximize the signal/noise ratio. For example, miRNA assessment can be improved by limiting measurements to patients with normal renal function (>30 mL/min/1.73 m^2) and the use of samples taken early in the morning after overnight fasting. Analytical factors can also substantially affect miRNA measurement variability. The different qPCR platforms are not standardized and can introduce variability. Similarly, levels can vary according to PCR protocols even on the same platform. In addition, most miRNA data are relative expression values rather than absolute levels, and there is currently no consensus on which selected reference gene, global mean normalization, or other approach performs best.

Although many studies have analyzed circulating miRNAs in different diseases including cancer, data on osteoporosis are limited. The first attempt to identify circulating miRNAs as biomarkers of osteoporosis focused on measuring them in monocytes, which are a circulatory reservoir of osteoclast precursors. Wang et al. (Wang et al., 2012b) showed that miR-133a was upregulated in peripheral monocytes from 10 patients with low BMD compared with 10 healthy controls, although such a difference could not be found when miRNA was isolated from B cells. CXCL11, CXCR3, and SLC39A1, which are involved in osteoclast differentiation, were identified as putative target genes. Li et al. (2014) replicated the upregulation of miR-133a in cell-free plasma samples of osteoporotic compared with osteopenic women from a cohort of 120 Chinese postmenopausal women. Besides miR-133a, Li et al. (2014) also reported a downregulation of circulating miR-21-5p. Both miRNA levels correlated with spinal and hip BMD (Li et al., 2014). Conversely, levels of miR-503 were reported to be decreased in CD14+ monocytic PBMCs of 10 untreated postmenopausal women with osteoporosis compared with those of 10 women with normal BMD (Chen et al., 2014). In ovariectomized mice, the authors showed that silencing of miR-503 using a specific antagomir increased RANK protein expression, promoted bone resorption, and decreased bone mass. Conversely, the overexpression of miR-503 with agomir inhibited bone resorption and prevented bone loss. Cell-free miRNAs were analyzed in the serum of 60 patients with hip fracture who were categorized as osteoporotic and nonosteoporotic based on dual-energy X-ray absorptiometry (DXA) BMD assessments (Seeliger et al., 2014). Nine miRNAs were found to be upregulated in patients with osteoporosis, and among those, six [miRs 21, 23a, 24, 25, 100, and 125b] were also significantly increased in the corresponding hip bone tissue. Weilner et al. (2015) compared the serum miRNA of patients who had recent fractures with that of healthy controls and identified 10 miRNAs differentially expressed including miRs let-7g, 10b, 133b, 22, and 328. Two other studies analyzed circulating miRNA in patients with osteoporosis compared with controls. Panach et al. (2015) reported 12 differently expressed miRNAs among the 179 analyzed in patients with fractures compared with subjects with osteoarthritis used as controls. They confirmed that among those, miRs 122, 125, and 21 were upregulated in an independent validation sample. Interestingly, these miRNAs

were also identified by Seeliger (Seeliger et al., 2014), and miR-21 levels were significantly correlated with the bone-resorption marker CTX. The regulation of 331 miRNAs in whole blood samples was investigated in 48 postmenopausal women stratified according to BMD levels (Meng et al., 2015). The investigators initially identified six miRNAs differently expressed between 25 osteoporotic women and 23 women with osteopenia. In a replicative study, five (miRs 130b, 151a, 151b, 194, and 590) of six miRNAs were confirmed to be increased in patients with osteoporosis. miR-194 expression levels were found to be significantly different between 24 postmenopausal women with normal BMD values, 32 osteopenic subjects, and 32 individuals with osteoporosis, with values correlating with BMD T-scores. Finally, Yavropoulou et al. (2017) analyzed the serum level of 14 targeted miRNAs in 35 women with fracture, 35 women with low BMD and no fracture, and 30 healthy controls. Among them, 2 were found to be increased in cases versus controls (miRs 124 and 2861), whereas 3 others were downregulated (miRs 21-5p, 23a, and 23a-3p).

A recent study investigated circulating miRNA expression according to the presence and absence of fracture in 80 postmenopausal women with T2D (Heilmeier et al., 2016). The identification of new risk factors for fragility fracture in T2D is critically needed, as BMD and conventional protein-based biochemical markers are poorly predictive. Using miRNA−qPCR arrays, the investigators showed that 48 miRNAs can differentiate fracture status in T2D women, and that several combinations of four miRNAs were able to discriminate diabetes-related fractures with high specificity and sensitivity (AUCs: 0.92−0.96; 95% CI: 0.88−0.98). Among the most discriminative miRNAs, in vitro studies showed that miR-382 significantly enhanced osteogenic differentiation, while miR-550a inhibited this process. These two miRNAs impaired adipogenic differentiation.

Other situations where new predictive biomarkers are awaited are in men with idiopathic osteoporosis, premenopausal women, and postmenopausal women with osteopenia (Kocijan et al., 2016). A recent study investigated serum miRNA profiling in 10 premenopausal women, 10 postmenopausal women, 16 men with idiopathic osteoporosis, and 39 age-matched controls. It was found that among the 187 circulating miRNAs investigated, expression was altered in 19 of them in patients compared with controls. Interestingly, a combination of eight of them was highly predictive with an area under the ROC greater than 0.9. Some of these miRNAs—including miR-29b-3, which has been found to be involved in the regulation of extracellular matrix formation via collagen type I expression—correlated with PINP, a marker of type I collagen synthesis.

As shown from Table 78.3, the available studies that investigated blood levels of miRNAs are all cross-sectional and included a limited number of subjects. Data between studies are difficult to compare, as the criteria to classify cases and controls were different and the technical platforms were not standardized. Before these candidate miRNAs can be used clinically to investigate alterations of bone metabolism in osteoporosis, data need to be confirmed in substantially larger studies, ideally prospective in design with fracture incidence as an outcome. It can be foreseen that in the future this field will markedly expand and may lead to the discovery of a signature of circulating miRNAs, thus demonstrating clinical utility for the investigation of patients with osteoporosis.

Variability of biochemical markers of bone turnover

The measurement of established protein bone markers is subject to variability that is important to consider when interpreting data. Different sources of variability have been identified including preanalytical conditions, assay technical precision, and biological variability. Among the sources of preanalytical variability that have been reviewed in detail elsewhere (Naylor and Eastell, 2012; Garnero, 2008; Hlaing and Compston, 2014), the most important are (1) the circadian variation, which is of greater magnitude for markers of bone resorption—except serum TRACP and CTX-MMP—than for markers of bone formation, (2) diet and food intake, especially for markers such as serum CTX (Qvist et al., 2002; Clowes et al., 2002), and (3) recent fracture. Indeed, bone marker levels are markedly increased during fracture healing starting from month 1 and remain elevated for about 6 months, with a return to levels before the fracture by the end of 1 year (Ivaska et al., 2007). The extent of increase differs between markers (highest for serum PINP) and according to the size of the fractured bone (Ivaska et al., 2007). For example, BTMs increase more after trochanteric fracture than femoral neck fracture (Ikegami et al., 2009). Recently, the National Bone Health Alliance published recommendations to standardize sample handling and patient preparation to reduce preanalytical variability of the two reference markers CTX and PINP (Szulc et al., 2017).

Commercial CTX assays include manual ELISA (Immunodiagnostic Systems [IDS], Boldon, UK), automated electrochemiluminescence immunoassays (ECLIA; Roche Diagnostics, Mannheim, Germany), and automated chemiluminescence immunoassay (CLIA; IDS). PINP measurements include intact PINP by radioimmunoassay (Orion Diagnostica, Espoo, Finland), which measures only native trimeric peptide; total PINP with ECLIA by automated Roche Diagnostics platforms, which measures both trimeric PINP peptide and the low-molecular-weight peptides of α1 and α2

TABLE 78.3 Circulating/bone miRNA in osteoporosis studies.

chains; and intact PINP with CLIA by automated IDS platform, which measures native trimeric peptides only. To obtain the most precise measurements of these two reference markers, the recommendation is to collect blood fasting between 7:30 and 10:00 a.m., although random sampling is acceptable for PINP because it is only slightly affected by diet and circadian variability. Other factors that should be considered when interpreting the results of bone markers include age, gender, ethnicity, underlying diseases such as kidney insufficiency (which may alter renal excretion of the markers and thus serum levels), concomitant medications, such as glucocorticoids, that induce a rapid decrease of markers of bone formation, and geographical location (Naylor and Eastell, 2012; Hlaing and Compston, 2014; Szulc et al., 2017). Although such influences cannot be modified, having their effects on biomarker data in mind is important. When biochemical BTMs are measured on adequately collected samples and with a well-performing assay, the within patient variability is in the range of 8%−12% for serum bone formation markers and 15% (serum based) to 40% for markers (urinary assays) of bone resorption. Such figures are used to determine the least significant change (LSC) when evaluating the efficacy of bone active therapy (see below).

Reference ranges

Each laboratory should establish reference intervals (RIs) for cutoff levels that identify subjects at risk for fracture or for assessing response to treatment (see later). However, when this is not feasible, laboratories can refer to published RIs that have been determined specifically for a given bone marker measured by a given assay platform—because the different assays are not standardized—in the same type of specimen. Interestingly, in the last decade several studies have been performed to establish these reference ranges for most assays (Glover et al., 2008, 2009; Adami et al., 2008; de Papp et al., 2007), which were recently reviewed (Morris et al., 2017). Because bone marker levels vary with age with a marked increase at the time of the menopause, healthy untreated premenopausal women from 30 or 35 to 40 years of age should be selected. The subjects must have optimum vitamin D status, the number of subjects must be large enough, and geographical variation should be considered when reference ranges are established.

Clinical uses of bone markers in osteoporosis

The IOF and IFCC recommend the use of a marker of bone formation (serum PINP) and bone resorption (serum CTX) as reference analytes in clinical studies (Vasikaran et al., 2011). In osteoporosis, the main potential uses for BTMs are for monitoring the treatment and assessment of fracture risk, although some studies have reported an association with the level of BMD and rate of bone loss.

Diagnosis of osteoporosis and prognosis of bone loss

Bone marker levels have been shown to correlate negatively with BMD assessed by DXA at different skeletal sites (Biver et al., 2012), with a higher association with advancing age in postmenopausal women (Garnero et al., 1996a). The association is too weak, however, to accurately identify women at low BMD, and thus bone markers are not recommended for diagnosing osteoporosis. However, if levels are substantially raised (more than 1.5 times higher than the upper limit of the RI), causes of high bone turnover other than osteoporosis should be investigated including myeloma, BMs, kidney disease, primary hyperparathyroidism, thyrotoxicosis, or recent fracture.

Several studies have also shown that increased BTMs, and especially markers of bone resorption, are associated with a higher magnitude of bone loss in the 2−5 years that follow (Garnero et al., 1999; Chopin et al., 2012). Although this association is significant at a cohort level, it is not strong enough to predict the rate of bone loss at the individual level with a single assessment of bone markers. One approach to improve the predictive value of BTMs is to combine indices of bone formation and bone resorption into a single integrated measure reflecting the bone balance index at the level of the whole body. Such an index has been recently proposed and based on the relationship between resorption (urinary NTX) and formation (osteocalcin) seen in a patient cohort with stable BMD (premenopausal women more than 5 years before final menstrual period) (Shieh et al., 2016). Then patients are assessed relative to this regression standard to investigate whether their level of NTX relative to osteocalcin is above or below the amount expected to correspond to stable BMD. Initial validation in early postmenopausal women suggests that this bone balance index may be more useful than urinary NTX alone in predicting BMD loss at the lumbar spine over the subsequent 3−4 years. However, further large studies are required to see whether this approach is useful in predicting bone loss in individual subjects. Such a bone balance index should also be developed using the IOF−IFCC recommended serum markers, CTX and PINP.

Prediction of fracture risk

Several prospective studies have shown that some bone markers predict the risk of osteoporotic fractures over the next 2–5 years, including spinal, hip, and nonvertebral fractures in postmenopausal women (reviewed in Garnero, 2000). The association is somewhat inconsistent for bone formation markers—except bone ALP—whereas stronger and more consistent relationships were observed for bone resorption markers including serum CTX. The association between resorption markers and fracture is largely independent of BMD, and when combined, these two risk factors allow for the prediction of fracture risk more accurately than one parameter alone (Garnero et al., 1996b; Johnell et al., 2002). In 2011, Vasikaran et al. (2011) reviewed all prospective studies of bone markers for fracture prediction in untreated men and women. They confirmed that several studies found that bone markers can identify early and late postmenopausal women at increased risk for fracture. The value of markers to predict fracture appears to decrease with longer follow-up (Ivaska et al., 2010). In healthy elderly men, the association seems to be weaker than it is in postmenopausal women. For example, in a case–control study of the large US MrOS study, it was reported that serum PINP—but not serum CTX or TRAP—predicted the risk of nonvertebral and hip fracture, but this association was was no longer significant after adjustment for BMD (Bauer et al., 2009). However, the association of bone formation markers including PINP in men and women may be not linear. A study in elderly men and women followed prospectively for 7.3 years found no significant association overall between baseline PINP and the risk of hip fracture (Finnes et al., 2014). However, spline analysis suggested a U-shaped curve association, with increased risk of hip fracture for very high or very low PINP levels. A recent meta-analysis including six prospective studies in elderly men and postmenopausal women confirmed a modest but significant association of both reference markers—serum CTX and PINP—with the risk of fracture (Chavassieux et al., 2015). This study reported that each SD increase in serum PINP and CTX was associated with a hazard ratio of fracture of 1.2. Since the publication of this meta-analysis, three additional prospective studies have been reported. In the Australian Health in Men study, which included 100 men with incident hip fracture and 3896 subjects with no fracture, it was found that each SD increase in serum total osteocalcin was associated with a 1.2-fold increased risk of fracture independent of multiple variables including age and glucocorticoid use (Chubb et al., 2015). In contrast, neither serum CTX, nor PINP were independent predictors of fracture in this study. Yoshimura et al. (2011) analyzed 400 men and women participating to the Taiji cohort followed prospectively for 10 years. They reported no significant association between a panel of different bone markers including osteocalcin, bone ALP, procollagen type I C-terminal propeptide (PICP), PINP, serum CTX, serum NTX, serum ICTP, urinary PYD and DPD, and fracture risk. However, this study was performed in relatively young subjects, resulting in only 32 incident fractures, and thus was insufficiently powered to use fracture as an endpoint. Finally, the predictive value of bone markers was analyzed in a nested case–control analysis of the Singapore Chinese Health Study, a 5-year prospective study in healthy women and men (45–74 years) (Dai et al., 2016). It was found that both serum PINP and serum CTX were significantly associated with the risk of hip fracture, with ORs (95% CI) of 6.63 (2.02–21.18) and 4.92 (1.67–14.51), respectively, for the highest versus lowest quartile. Interestingly, when subjects at risk were identified as those with both high serum PINP and high serum CTX, the odds ratio of fracture increased to 7.5 (2.53–21.41).

Predicting and monitoring treatment efficacy

It has been hypothesized that the response to antiresorptive therapy and anabolic treatment could be related to pretreatment levels of bone markers. For example, in the Fracture Intervention Study, it was shown that patients with high pretreatment levels of bone ALP or PINP had a greater response to alendronate in terms of reduction of nonspine fracture than that shown by subjects with lower levels (Bauer et al., 2006). In postmenopausal osteoporosis, lower PINP was associated with slower bone loss before treatment and lower response to treatment with zoledronate (Eastell et al., 2015). With anabolic therapies such as PTH and PTH analogs, one could argue that these drugs will particularly benefit patients with low turnover. However, randomized studies indicate that teriparatide increases BMD and reduces fracture risk whether pretreatment levels of bone markers are suppressed or not (Delmas et al., 2006). In fact, in that study it was shown that the reduction in absolute risk of spinal fracture was larger in those women with high pretreatment bone turnover (Delmas et al., 2006). However, because the association in these studies was modest, nonconsistent (Seibel et al., 2004), and may vary according to the drugs even within the same class, it is still unclear whether the baseline levels of bone markers predict which individual patients will benefit more from one treatment or another. The role of bone markers to identify patients who are candidates for new therapies with novel and unique mechanisms of action such as cathepsin K or SOST inhibitors remains to be investigated.

Treatment for osteoporosis primarily aims to prevent bone loss and reduce fracture risk. The magnitude of change in BMD in response to antiresorptive therapy is small, and taking the precision of the measurement into account, it is

necessary to wait 2 years to determine efficacy. The level of BTMs changes rapidly with therapy and can help to identify nonresponse and/or poor adherence to therapeutic regimens. It has been shown that larger changes in bone marker levels are associated with better adherence to bisphosphonate treatment and subsequent reduction in fracture risk (Eastell et al., 2011a). However, other studies did not show any difference in the persistence of oral bisphosphonate between women receiving the feedback of bone markers and subjects with no feedback (Clowes et al., 2004; Silverman et al., 2012). The IOF and the European Calcified Tissue Society have proposed that the BTMs CTX and PINP be used to identify non-adherence to oral bisphosphonate therapy (Diez-Perez et al., 2017). The recommendation was based on the results of the TRIO study, which compared the effects of oral alendronate, ibandronate, and risedronate on BMD and bone markers in postmenopausal women with osteoporosis. The working group recommends measuring PINP and CTX at baseline and 3 months after starting therapy to check for a decrease greater than the LSC (a decrease of more than 38% for PINP and 56% for CTX). If a significant decrease is observed, treatment can continue. If no significant decrease is observed, the clinician should reassess to identify problems with the treatment, mainly low adherence. However, it remains to be seen whether this screening strategy has a direct effect on adherence in real-life settings.

Several randomized placebo controlled studies have shown that antiresorptive therapies including estrogens, selective estrogen-receptor modulators, bisphosphonates, the anti-RankL antibody, denosumab, and cathepsin K inhibitors induce a dose-dependent decrease of resorption markers within 1−3 months. The decrease in bone formation markers is delayed and reaches a plateau after 3−6 months, reflecting the physiological coupling of bone resorption and formation (for a review, see Cremers and Garnero, 2006; Fig. 78.1A and B). The onset and magnitude of decrease in BTMs with antiresorptive therapy depends on the mechanism of action of the drug, the category of bisphosphonate, the route of administration (faster for intravenous than for oral bisphosphonate), and the marker used. For example, although serum TRACP5b levels decrease significantly with bisphosphonate and the anti-RANKL denosumab, they remain stable or even increase with cathepsin K inhibitors (Eisman et al., 2011). Indeed, both bisphosphonates and denosumab markedly suppress the differentiation and number of osteoclasts reflected by serum TRACP5b, whereas cathepsin K inhibitors do not interfere with osteoclast formation. With cathepsin K inhibitors, ICTP concentrations increase, which could be due to a compensatory increase in MMP activity and/or the decrease of cathepsin K−mediated degradation of the ICTP peptide. In contrast, the other collagen markers of bone resorption, such as NTX and CTX, are suppressed by these agents (Eisman et al., 2011).

The relationships between changes of BTMs and fracture risk have been investigated in several placebo-controlled studies. These include investigations of bisphosphonates and raloxifene and were reviewed by Vasikaran et al. (2011). In this review, there was a significant relationship between the magnitude of change of bone markers over 3−12 months and the reduction in spinal fracture risk at 3 years. The changes in bone markers explained from 27% to 77% of the antifracture efficacy. Since then, two additional randomized trials of antiresorptive drugs have been reported. Jacques et al. (2012) looked at the relationships between change in bone marker and BMD and the risk reduction of new vertebral fracture risk at 3 years in postmenopausal women receiving 5 mg intravenous injection of zoledronic acid once a year (the Horizon trial). Among the 7736 women randomized to zoledronic acid or placebo injection, PINP data were available at baseline and at 1 year for 1132 of them. The changes in absolute levels of PINP explained up to 58% of the antifracture efficacy, which was largely independent of changes in BMD. Thus, with this drug, changes in both BMD and bone markers could be useful in predicting its clinical efficacy. Bruyere et al. (2012) analyzed the relationships between BMD or BTM changes and vertebral fracture incidence in women treated with the selective estrogen receptor modulator bazedoxifene in a post hoc analysis of a 3-year randomized, placebo-controlled study. Data for serum CTX and osteocalcin were available in all 5244 randomized subjects at baseline. It was found that the 1-year change in CTX and osteocalcin explained 16% and 6%, respectively, of the reduction in the 3-year risk of new vertebral fracture (both significant). Thus, all these studies with antiresorptive treatments are consistent and show that bone marker monitoring effectively predicts clinical efficacy, at least as well as prediction based on changes in BMD.

From a clinical point of view, it would be very helpful to determine whether there is a threshold level of bone markers under treatment that will translate into optimal antifracture efficacy. In the risedronate study, it was shown that the relationship between vertebral fracture risk and the levels of CTX reached after 3−6 months was not linear and that there may be a level of bone resorption reduction below which there are no further fracture benefits (Eastell et al., 2003). Two methods of assessing bone marker response have been proposed, and both have limitations. The LSC approach signifies the minimum change in the bone marker that can be attributed to treatment effect rather than random variation of the marker (usually with 95% certainty). This is most commonly expressed as a percentage change or alternatively as absolute units. The approach, which has only a statistical and not a clinical basis, requires that a sample be taken before starting therapy. This could be overlooked, or the patient may have low turnover due to previous treatment. In these cases, the RI approach, established in young healthy women who do not lose bone, is particularly useful. However, this also has its limitations. Some untreated women may already be in the lower half of the reference for some bone markers (e.g., serum CTX) at baseline. In that case, another bone marker (e.g., PINP) could be measured for comparison. Interestingly, a recent head-to-head study (TRIO study) of three oral bisphosphonates (ibandronate, alendronate, and risedronate) in postmenopausal women with osteoporosis compared the response at 12 weeks of serum CTX and PINP using both LSC and the pre-menopausal women's RI (Naylor et al., 2016). It showed that the proportion of bone marker responders was high (70% −100%) with these bisphosphonates and similar in the two approaches (LSC and RI). Ultimately, however, optimal cutoffs will need to be validated in prospective studies using incidence of fracture as an endpoint.

Biochemical BTMs are also useful for monitoring the efficacy of anabolic treatment including teriparatide (Fig. 78.2), a synthetic form of PTH, and possibly new drugs such as abaloparatide, a synthetic peptide analog of PTH-related protein

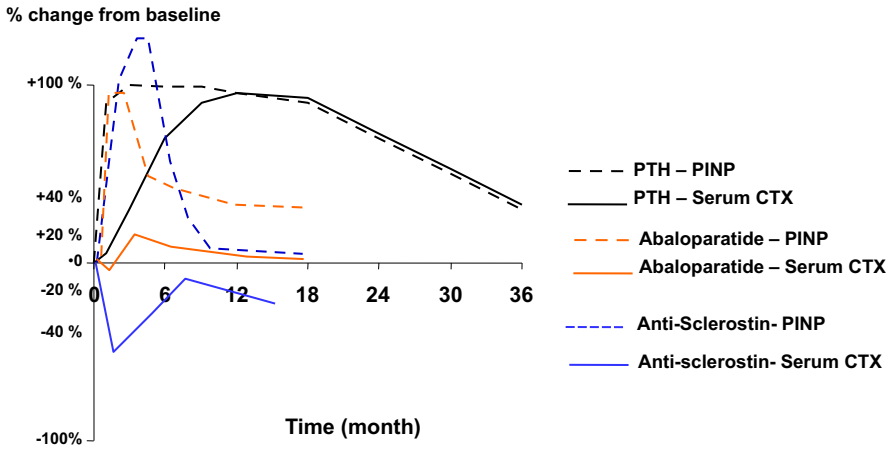

FIGURE 78.2 Schematic changes of bone turnover with anabolic treatments. *PINP*, procollagen type I N-terminal propeptide; *PTH*, parathyroid hormone*; serum CTX*, serum C-terminal telopeptide of collagen type I.

and the anti-SOST romosozumab (McClung et al., 2014). As reviewed recently (Krege et al., 2014), serum PINP appears to be the most useful bone marker for monitoring and predicting the efficacy of teriparatide for the following reasons: (1) it increases markedly within 1 month of therapy and has the highest signal-to-noise ratio compared with other bone formation (PICP, bone ALP) and bone resorption (urinary NTX, DPD) markers (Chen et al., 2005), (2) at the individual level it has a great specificity and sensitivity to differentiate patients treated with teriparatide versus placebo when a positive response is defined as an increase of 10 ng/mL in PTH (Tsujimoto et al., 2011) (3) levels during teriparatide therapy highly correlate with bone formation, defined by the mineralizing surface of transiliac bone biopsies ($r = 0.85$) (Dempster et al., 2012) or by the increase in skeletal uptake of technetium-99m methylene diphosphonate on a bone scan (Moore et al., 2010), confirming that PINP concentration is related to bone formation at the skeletal level, (4) changes at 1 and 3 months are strongly predictive of spinal BMD increase at 12 and 18 months as shown in several clinical studies reviewed by Krege et al. (2014), and (5) changes at 1−3 months correlated with changes of bone strength at 18 months as estimated from quantitative computed tomography scans with finite element modeling of the spine (Keaveny et al., 2007; Farahmand et al., 2013). Data validating the use of PINP for predicting fracture risk reduction during teriparatide treatment are not yet available. Abaloparatide stimulates bone formation and bone resorption rapidly and dose-dependently in women with postmenopausal osteoporosis, but less and more transiently than does teriparatide (Fig. 78.2), leading to a greater increase in BMD compared with the effect of teriparatide (Miller et al., 2016). Differences in the effects of teriparatide and abaloparatide may be related to differences in biologic effects. The differential binding of abaloparatide compared with teriparatide leads to parathyroid type 1 receptor conformation binding selectivity that favors anabolic activity. As a result, abaloparatide may provide more transient stimulation of osteoblast cyclic adenosine monophosphate production and result in lower expression of osteoblast-derived RANKL. This could result in less stimulation of bone resorption. A recent study comparing the effects of teriparatide and abaloparatide on BMD and bone markers in postmenopausal women with osteoporosis showed that an early change in PINP correlates with a change in lumbar spine BMD more strongly with abaloparatide than it does with teriparatide (Eastell, 2017).

Monitoring side effects of osteoporosis therapies

Severe bone resorption suppression—e.g., at the beginning of the treatment with denosumab—might induce hypocalcemia. In postmenopausal women, hypocalcemia was more frequent in patients with increased BTM concentrations before treatment (Ishikawa et al., 2016). Long-term suppression of bone turnover during treatment with bisphosphonates or denosumab is associated with increased risk of osteonecrosis of the jaw. However, no study has shown a difference in BTMs between patients with osteonecrosis of the jaw and controls or a predictive value for low BTMs (Khan et al., 2015). Long-term suppression of bone turnover might also be associated with increased risk of subtrochanteric and femoral shaft fractures—so-called atypical femur fractures. In patients with atypical femur fractures, BTMs were within the RI for healthy young premenopausal women (Franceschetti et al., 2013). Because BTMs increase substantially after fracture, however, measurements after atypical femur fractures are difficult to interpret (Black et al., 2012; Adler et al., 2016).

Treatment holiday monitoring

The possibility of drug holidays has been suggested because of concern over long-term harm with antiresorptive therapy (Bone et al., 2011). Denosumab withdrawal results in a rebound in BTMs, accelerated bone loss, and increased vertebral fracture risk (Aubry-Rozier et al., 2016; Tsourdi et al., 2017). Consequently, a discontinuation is not appropriate with denosumab without considering an alternative treatment to prevent bone loss (Tsourdi et al., 2017).

With bisphosphonates, however, suppressed bone turnover is observed for several years after treatment is stopped (Black et al., 2012). However, a recent assessment of the extension studies of the pivotal FLEX (with alendronate) and Horizon (with zoledronate) trials reported that after stopping alendronate or zoledronate for 3 years, 53% and 34% of patients, respectively, had either total hip BMD loss exceeding the LSC cutoff or PINP levels above the target premenopausal range (Kim, 2017). This supports the ASBMR task force's recommendation to reassess risk 3 years after drug discontinuation.

In postmenopausal osteoporosis, BTM concentrations after 5 years of treatment with alendronate or 3 years of treatment with zoledronate did not predict the rate of bone loss after stopping treatment (McNabb et al., 2013; Cosman et al., 2014), but bone loss was small, decreasing the power of the study. Furthermore, 1-year changes in bone ALP and urine NTX after treatment discontinuation did not predict fracture rates, although the power of this study was limited due to the low rate of clinical vertebral fractures (Bauer et al., 2014). Based on these findings, measuring bone markers after treatment is not recommended at the present time, although this issue remains of great interest and deserves additional prospective studies.

Diagnosis and monitoring of treatment in Paget's disease of bone

BTMs are used for diagnosis, monitoring of treatment, and monitoring for relapse in patients with Paget's disease of bone (Singer et al., 2014; Muschitz et al., 2017; Paul Tuck et al., 2017). BTMs are sensitive but not specific enough to diagnose Paget's, which is usually diagnosed by imaging (Al Nofal et al., 2015). Levels are significantly elevated in the majority of pretreatment patients but can be in the upper range of normal in patients with monostotic disease. A recent systemic review and meta-analysis demonstrated moderate to strong correlations between most BTMs in untreated patients (Al Nofal et al., 2015). In addition, moderate to strong correlations were found with scintigraphic assessment of disease activity. There were no statistically significant differences between the various BTMs in terms of their correlation with scintigraphic activity. The Endocrine Society recommends that basically all BTMs can be used in patients with Paget's disease of bone with the exception of osteocalcin, which seems less useful in these patients (Singer et al., 2014). Because of its low costs and adequate performance, total ALP is mostly recommended (Singer et al., 2014). Abnormalities in the RANKL/OPG dipole have been implicated in the pathogenesis of Paget's disease (Ralston et al., 2008; Vega et al., 2007; Idolazzi et al., 2017). However, two of the circulating Wnt antagonists, SOST and Dkk1, did not differ between untreated patients with Paget's disease of bone and gender- and age-matched controls (Idolazzi et al., 2017). To our knowledge, other newer BTMs such as POSTN have not yet been explored in Paget's disease of bone.

Dkk1 and SOST have been described to increase in response to BP treatment (Gatti et al., 2012b), but to our knowledge these have not been explored as markers for response to BP treatment in patients with Paget's disease of bone. Other BTMs have been explored and have been found very useful in the monitoring of oral and IV BP therapy as well as monitoring of denosumab therapy (Singer et al., 2014; Muschitz et al., 2017; Paul Tuck et al., 2017), with rapid decreases in bone resorption markers followed by decreases in bone formation markers. The time scale of the decrease depends on the drug, the dose, and the mode of administration. The earlier mentioned systemic review also demonstrated good correlations between BTMs and between BTMs and disease activity in Paget patients assessed using scintigraphic imaging a few months after treatment (Al Nofal et al., 2015). The biochemical target of pharmacotherapy in patients with Paget's disease of bone is usually normalization of the BTMs (Singer et al., 2014; Muschitz et al., 2017; Paul Tuck et al., 2017), and BP therapy combined with BTM monitoring is indeed generally seen as a best practice. However, it must be mentioned that studies such as the PRISM study (with all its caveats) failed to demonstrate differences in bone pain between BP-treated patients and symptomatically treated patients with Paget's disease of bone (Langston et al., 2010). Retreatment of patients with Paget's disease of bone is either based on symptoms or an increase in BTM levels. Most BTMs seem useful for this purpose (Singer et al., 2014; Muschitz et al., 2017; Paul Tuck et al., 2017).

Bone turnover markers for rare bone diseases

The last couple of years have been characterized by exciting developments in the diagnosis and treatment options for rare metabolic bone diseases. While the investigation of some rare bone diseases such as van Buchem disease, sclerosteosis, and pycnodysostosis has led to the development of potential compounds for osteoporosis such as the SOST antibody romosozumab and the cathepsin K inhibitors (Costa and Bilezikian, 2012; Bandeira et al., 2017; Stoch and Wagner, 2008), investigation of other rare bone diseases has led to the development of compounds that will probably be applicable only to those diseases, such as an activin A antibody for *fibrodysplasia ossificans progressiva (FOP)* (Upadhyay et al., 2017). Much credit goes to the regulatory authorities that have enabled these life-changing developments for the few patients seriously affected by these diseases. BTMs can be helpful in diagnosis and treatment monitoring in some of these diseases and may also be useful during various stages of drug development. The following gives a brief overview of the value of BTMs in some of the more than 400 rare metabolic bone diseases (Masi et al., 2015).

Fibrous dysplasia

In a relatively large group of patients with fibrous dysplasia and McCune–Albright syndrome (MAS) studied retrospectively, BTMs (total ALP, PINP, and CTX) were elevated prior to treatment, and levels correlated with skeletal involvement (as determined by imaging using 99mTc-skeletal scintigraphy and skeletal burden scores as described by Collins et al., 2005 of the disease) as well as pain scores (Majoor et al., 2017). BTMs were successfully used to monitor BP therapy in these patients with normalization of BTM levels as the target (Majoor et al., 2017). Correlating with higher skeletal involvement, BTM levels in MAS were higher than in polyostotic fibrous dysplasia (PFD). This study and others clearly suggest that BTMs seem useful in determining the skeletal involvement and monitoring of BP treatment in MAS and PFD.

Hypophosphatasia

BTMs seem to have a limited role, if any, in the diagnosis or monitoring of the treatment of hypophosphatasia (HPP). A consensus document reports that in adult patients, bone biopsies might be considered for patients with additional skeletal risk factors beyond HPP such as chronic kidney disease, history of fractures, or very low BMD (Kishnani et al., 2017). BTMs may provide support in deciding whether bone biopsies are indicated; albeit that is left to the discretion of the clinician (Kishnani et al., 2017). A case−control study investigating the predictive value of the ALP:PINP ratio for a loss-of-function mutation in the gene that encodes for the "tissue-non-specific" isoenzyme of ALP (TNSALP) is currently ongoing in adult untreated patients (NCT02796885). In various forms of HPP (infantile, severe childhood, mild childhood, and "odonto"), total ALP and bone ALP were found to be invariably below control ranges (Whyte, 2017a). Recently, a recombinant bone-targeted ALP, called asfotase alpha, has become available to correct the inborn error caused by a loss-of-function mutation of the TNSALP (*ALPL* gene) (Whyte, 2017b). To our knowledge, the effects of asfotase alpha on BTMs, and the potential role of BTMs in the development of the drug as well as monitoring of treatment, have not yet been published.

Fibrodysplasia ossificans progressiva (FOP)

Little is known for the role of BTMs in FOP, although it has been reported that, for example, total ALP might increase during flare-ups. Three drugs are currently in clinical development for this disease: palovarotene, ACE-011, and REGN2477. BTMs are part of the various clinical studies for the development of these drugs (Kaplan, 2017). Given the limited data on the BTMs in these patients, interpretation of the markers collected during these trials will be challenging. At the same time, these studies will provide us with a wealth of BTM data in these patients, even pretreatment and during placebo treatment.

Osteogenesis imperfecta

Compared with controls, BTMs do not seem to be altered in untreated osteogenesis imperfecta (OI) patients (Brunetti et al., 2016). OI patients treated with BPs have expected decreases in BTMs such as serum CTX and bone ALP. BTMs may therefore be useful for monitoring BP treatment that increases BMD but may have little effect on fractures or clinical status (pain, growth, functional mobility) in these patients. Interestingly, circulating SOST and OPG levels are similar between controls and OI patients, and BP treatment does not appear to change their levels. In contrast, Dkk1 and RANKL circulating levels are increased in OI patients. Dkk1 seems unaffected by BPs, but RANKL seems to increase (Brunetti et al., 2016). In 2014, excessive TGF-beta was identified as a common mechanism in OI (Grafe et al., 2014). A phase 1 trial with a TGF-antibody (fresolimumab) is currently ongoing (NCT03064074). The effects of fresolimumab on BTMs in patients with OI are currently still unknown.

X-linked hypophosphatemia

In children with X-linked hypophosphatemia (XLH), FGF-23-mediated hypophosphatemia impairs skeletal mineralization and causes rickets. Treatment consists of oral phosphate and active vitamin D. New treatment consists of burosumab, an FGF-23 monoclonal antibody. Little is known about BTMs in XLH, nor about the effects of burosumab on BTMs in these patients. Recent data from burosumab in patients with tumor-induced osteolysis demonstrated statistically significant increases from baseline levels of PINP (51%) and CTX (38%) (De Beur, 2017).

Bone turnover markers in metastatic bone disease

Multiple myeloma

In MM, skeletal complications are caused by an increased activation of osteoclasts that is not followed by reactive formation by osteoblasts (Terpos et al., 2010, 2017). Bone resorption is therefore increased in MM while bone formation seems inhibited. Of the BTMs, bone resorption markers have proven useful in the management of the disease. BTMs such as uNTX/Cr, serum CTX, and serum ICTP are increased in patients with MM, and their levels correlate with skeletal involvement of the disease, disease stage, and biomarkers of disease activity such as Beta2-microglobulin and IL6 (Terpos et al., 2003, 2010; Fonseca et al., 2000; Corso et al., 2001; Abildgaard et al., 2000). In addition, BTM levels correlate with the risk for skeletal-related events (SREs) and with overall survival (Terpos et al., 2010). In MM patients undergoing

conventional chemotherapy, bone resorption markers such as ICTP and uNTX/Cr have demonstrated prognostic significance for disease progression and survival (Terpos et al., 2010). Bone resorption markers such as uNTX/Cr seem useful to monitor the effect of antiresorptive treatment, especially bisphosphonates. Patients with persistently elevated BTM levels are at higher risk for SREs and disease progression compared with patients who respond well to BPs and have normalized bone resorption (Terpos et al., 2010). Other potentially interesting markers for diagnosis, prognosis, and/or monitoring of treatment include RANKL/OPG, Bone sialoprotein (BSP), and Dkk1.

In addition to antiresorptive therapy such as BPs and denosumab, BTMs may also be affected by immunomodulatory drugs such as thalidomide and lenalidomide in combination with steroids. From the available data, it seems that immunomodulatory drugs reduce osteoclastic function but have little to no effect on osteoblastic activity. The proteasome inhibitor bortezomib has been reported to have beneficial effects on bone formation (Mohty et al., 2014). Monotherapy in MM patients reduces Dkk1 and soluble RANKL associated with a reduction in bone resorption (TRAP5b and serum CTX) and an increase in bone formation markers (BALP and OC). However, when combined with other antimyeloma agents Bortezomib might lose its beneficial effects on bone formation.

Related to the pathophysiology of uncoupled bone turnover, with increased bone resorption and decreased bone formation, the levels of RANKL and the RANKL/OPG ratio are increased, while circulating levels of Dkk1 and SOST are increased in these patients (Terpos et al., 2017). Encouraging results from trials with RANKL, Dkk1, and SOST antibodies are slowly appearing in the literature.

Metastatic bone disease from solid tumors

Most BTMs are increased in patients with BMs from solid tumors and seem to correlate with the extent of skeletal involvement (D'Oronzo et al., 2017). However, at present BTMs are not used for routine diagnosis of BMs from solid tumors such as breast, prostate, and lung cancers predominantly because of suboptimal specificity, sensitivity, and diagnostic efficiency (D'Oronzo et al., 2017). Other biomarkers related to metastatic bone disease include tumor-derived genes, proteins, and miRNAs, some of which may indicate osteotropism of cancer cells and have prognostic possibilities. Again, at the moment none of these are routinely used in patient care (D'Oronzo et al., 2017).

BTMs have been demonstrated to be useful for the prognosis of BMs both with and without antiresorptive treatment, with increased BTMs correlating with increased risk for SREs seemingly irrespective of what antiresorptive drug is used (D'Oronzo et al., 2017). For example, elevated baseline BTMs such as high uNTX levels have demonstrated the potential to predict treatment efficacy, especially from BPs (Coleman et al., 2013). Elevated uNTX and/or BALP levels collected after 3 months of ZOL or denosumab treatment correlated with significantly reduced overall survival, increased disease progression, and worsening of BMs (Lipton et al., 2016).

Bone turnover markers for the development of bone drugs

Roughly three classes of drugs with effects on bone currently can be used for osteoporosis and/or metastatic bone disease: antiresorptive, anabolic, and dual-action. The response of BTMs as well as the relationship with disease activity and endpoints such as fracture risk or risk for SREs depends on the class of drugs, and within each class of drug it is determined by the mechanism of action of the specific drug as well as the specific pharmacokinetics and pharmacokinetic/pharmacodynamic relationships of that particular drug (Cremers and Garnero, 2006; Cremers et al., 2005; Russell et al., 2008). Another key point relevant to drug development is the translation or transfer of the relationship between BTM levels during treatment between related diseases, which might be useful when seeking regulatory approval for similar indications (Cremers and Garnero, 2006). The best example of this is the use of BTM levels during BP treatment for postmenopausal osteoporosis in seeking approval for that BP for another type of osteoporosis such as glucocorticoid-induced osteoporosis (Saag et al., 1998; Wallach et al., 2000; Lukert and Raisz, 1990). BTM levels combined with BMD response during treatment can sometimes serve as a surrogate for a true fracture-intervention study (Cremers and Garnero, 2006).

Bisphosphonates

Osteoporosis

BTMs have been very successful in dose-finding studies, with maximum suppression of BTMs being a successful target during phases 1 and 2 of drug development (Cremers and Garnero, 2006; Ravn et al., 1996; Chesnut et al., 1995; Reid et al., 2002). Phase 3 trials have subsequently revealed the relationship between BTM levels and clinical outcome (Eastell

et al., 2015; Cremers and Garnero, 2006). Simplified, antiresorptive drugs such as bisphosphonates decrease the levels of BTMs, and continued suppression of both resorption and formation markers beyond a certain degree is generally associated with antifracture efficacy (Eastell et al., 2011a; Cremers and Garnero, 2006). Too little suppression and too much fluctuation in the levels seem associated with suboptimal efficacy of BP treatment (Cremers and Garnero, 2006). It is this relationship that has been used to support the development of new dose regimens for bisphosphonates such as alendronate (from daily to weekly) and ibandronate (from daily to monthly) (Miller et al., 2005a; Schnitzer et al., 2000). This relationship between a certain level of suppression of bone turnover and antifracture efficacy is recognized by most regulatory authorities and has been used in combination with effects on BMD for approval of bisphosphonates for glucocorticoid-induced osteoporosis and osteoporosis in men (Cremers and Garnero, 2006; Saag et al., 1998; Wallach et al., 2000; Lukert and Raisz, 1990).

While generally perceived as rational, and noting that BTM targets have been defined for clinical use of BPs and drug development in general, the differences between the various BPs and the consequences for the relationships between BTMs and antifracture efficacy should be acknowledged, too. Risedronate, for example, leads, despite its higher potency, to a smaller decrease in BTMs than alendronate while having similar antifracture efficacy (Bonnick et al., 2006). It is highly likely that part of the effects of BPs are not captured by BTMs yet result in antifracture efficacy (Russell et al., 2008; Roelofs et al., 2012). Such effects may include effects on osteocytes, which may also be related to differences in the binding properties of the various BPs (Russell et al., 2008; Roelofs et al., 2012).

Last but not least, it is important to set any target for BTMs during BP therapy for the specific BTM and sometimes even the specific assay used to measure it (Vasikaran et al., 2011; Cremers et al., 2005; Greenblatt et al., 2017). There are substantial differences in the sensitivity and kinetics of the various BTMs, and therefore care should be given to extrapolating results generated with one BTM to another BTM, including during drug development (Vasikaran et al., 2011; Cremers et al., 2005; Greenblatt et al., 2017).

Metastatic bone disease

BTMs have played an essential role in defining the dose regimens of BPs used to treat metastatic bone disease (Berenson et al., 2001a, 2001b; Rosen et al., 2001; Body et al., 1995). Continued suppression of BTMs in most patients has been the basis for monthly 4 mg zoledronic acid infusions in these patients (Berenson et al., 2001a, 2001b), which made sense at a time when long-term high-dose IV BPs were generally regarded as safe provided the infusion rate was not too fast, as that is known to cause nephrotoxicity (Perazella and Markowitz, 2008). BTMs also played a role when rare complications such osteonecrosis of the jaw and subtrochanteric fractures prompted the search for alternative regimens with either smaller doses or longer dose intervals (Coleman et al., 2011). Again, continued suppression of BTMs, often measured using uNTX/Cr, has been the aim during the various decreased dosing efforts, such as q3mo treatment dosing after an initial period of monthly infusions (Hortobagyi et al., 2017).

Denosumab

BTMs have been used to determine dose and dose interval during the clinical development of denosumab for the treatment of postmenopausal osteoporosis (Bekker et al., 2004; McClung et al., 2006) as well as the treatment of metastatic bone disease (Body et al., 2006). For postmenopausal osteoporosis, short- and long-term changes in BTMs correlate with changes in BMD (Eastell et al., 2011b). BTMs also revealed rebound-increased bone turnover after stopping denosumab treatment in patients with postmenopausal osteoporosis accompanied by rapid bone loss (Tsourdi et al., 2017). Because of this rebound effect, patients at particular risk for fracture are advised to continue treatment after 5 years of denosumab treatment. Treatment is either continued with denosumab or with a BP. BTMs can be useful for monitoring the effect of such a switch in treatment. Long-term BMD outcomes during denosumab treatment can be predicted from changes in BTMs after a single dose using a semimechanistic mathematical bone cycle model that includes descriptions of denosumab pharmacokinetics and its relations with BTMs and lumbar spine BMD (Zheng et al., 2015). Treatment data for 5 and 8 years demonstrate sustained suppression of BTMs, continued increases in BMD, and persistent low-fracture incidence in patients treated with denosumab 60 mg q6mo (Papapoulos et al., 2015). BTMs in combination with BMD have been used to explore the effect of denosumab in osteoporosis other than postmenopausal such as glucocorticoid-induced osteoporosis (Dore et al., 2010; Mok et al., 2015; Sawamura et al., 2017). BTMs in combination with BMD have also demonstrated the efficacy of denosumab for the treatment and prevention of androgen-deprived and estrogen-deprived bone loss in prostate and breast cancer, respectively (Smith et al., 2009; Ellis et al., 2008). Recently, Lipton et al. reanalyzed data from phase 3 trials with antiresorptive drugs in patients with advanced cancer and BMs and concluded that relatively high levels of

BTMs (uNTX/Cr and PINP) after 3 months of antiresorptive treatment were associated with reduced overall survival and increased risk of disease progression and disease progression in bone. BTMs might therefore be useful for identifying those patients at risk for worsened clinical outcomes while on either BP or denosumab treatment (Lipton et al., 2016).

Cathepsin K inhibitors

BTMs have been extremely useful for the clinical development of cathepsin K inhibitors, despite the termination of development for most of them including odanacatib (Eastell et al., 2011c; Nagase et al., 2012; Stoch et al., 2009, 2013). Dose-finding studies were conducted based largely on BTMs, with continued suppression of BTMs in the majority of patients as a target, similar to that of other antiresorptive drugs. Interestingly, bone formation markers during cathepsin K inhibitor treatment are decreased less than they are during treatment with BPs or denosumab, suggesting continued signaling of osteoclasts to osteoblasts during treatment that results in additional bone mass increases (Costa et al., 2011). Also interesting, very low doses of odanacatib were associated with relatively small decreases in bone resorption markers but increases in bone formation markers, which in itself could perhaps also lead to renewed clinical development of low-dose cathepsin K inhibitor therapy for osteoporosis. Further phase 2 and 3 studies with strong antiresorptive doses of this compound in postmenopausal women with low bone mass revealed continued suppression of BTMs and increases in BMD. Similar to denosumab (and for that matter estrogen therapy), cessation of cathepsin K inhibitors is also characterized by a rebound effect in BTMs that is accompanied by bone loss (Eisman et al., 2011).

Odanacatib seemed to have strong antifracture efficacy in postmenopausal women with low bone mass, and its efficacy on bone loss was also investigated in other populations (Drake et al., 2017). Unfortunately, the development program was terminated before relationships between BTMs and BMD, as well as antifracture efficacy, could be established. In addition, a potential transfer of such a relationship in postmenopausal women to other osteoporosis populations such as patients with glucocorticoid-induced osteoporosis was not applied to seek approval of odanacatib for this indication based on antifracture efficacy in postmenopausal osteoporosis and its effects on BTMs and BMD in both postmenopausal women and patients with glucocorticoid-induced osteoporosis.

In a short 4-week study, odanacatib suppressed bone resorption in patients with breast cancer and BMs (Jensen et al., 2010) and might be a potentially interesting agent for the treatment of metastatic bone disease.

Overall antiresorptive treatment

Several reviews summarize the relationship between changes in BMD and antifracture efficacy during the use of various antiresorptive drugs (Eastell et al., 2003; Bjarnason et al., 2001; Greenspan et al., 1998, 2000, 2005; Iwamoto et al., 2005; Bjarnason and Christiansen, 2000; Delmas et al., 2000). Also, several reviews summarize the relationship between changes in BTMs, BMD, and antifracture efficacy during the use of various antiresorptive drugs (Vasikaran et al., 2011; Cremers and Garnero, 2006; Miller et al., 2005b). It is from these papers that a general consensus may be derived with respect to the targets of BTMs during the development of new drugs. BTMs seem useful in determining the most effective dose of antiresorptive therapy with more extensive suppression of bone resorption during a dose-ranging study, most likely resulting in more extensive gain in bone mass and perhaps more antifracture efficacy, schematically represented in Fig. 78.3 (Bonjour et al., 2014). Between various antiresorptive drugs and even between compounds of the same class, drugs decrease BTMs to different extents even when they have similar antifracture efficacy (Table 78.4; Bonjour et al., 2014). It is therefore very difficult to assess exact target levels for BTMs for the development of new antiresorptive agents. Previously assessed levels for a drug might be useful, however, for the development of alternative dose regimens as well as for studies of the same drug with the same dose regimen for a different but similar indication (such as steroid-induced osteoporosis), all in conjunction with BMD measurements.

Anabolic agents

Anabolic drugs such as intermittent PTH increase BTMs, increase BMD, and decrease fracture risk. It seems as if higher increases in bone formation markers lead to higher bone mass and thereby perhaps more antifracture efficacy (Fig. 78.3; Bonjour et al., 2014). Interestingly, various forms of PTH seem to increase BTMs to a different extent while having similar antifracture efficacy (Table 78.4; Bonjour et al., 2014). The relationship between BTMs, BMD, and antifracture efficacy is very complex for PTH, but it is used to develop new modes of administration of PTH as well as new forms of PTH such as abaloparatide (Tay et al., 2018). Given that various forms of PTH have different effects on osteoblasts, osteocytes, and osteoclasts and that these effects clearly depend on the dose regimen, one should be very careful not to overinterpret BTM

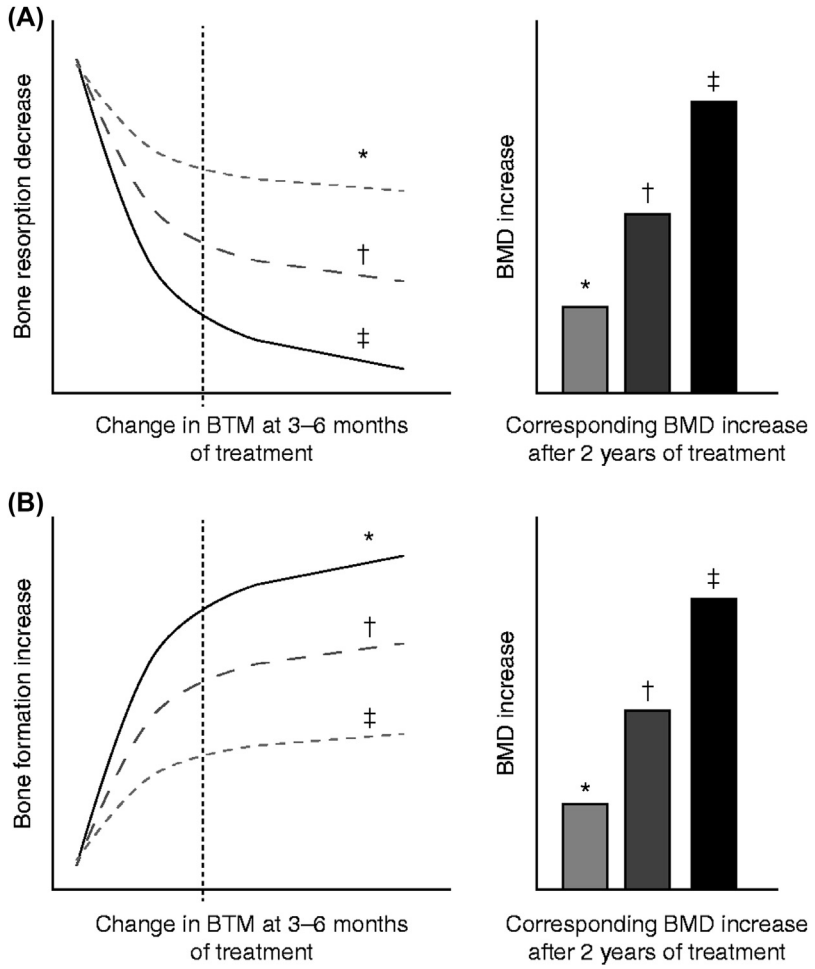

FIGURE 78.3 Schematic representation of changes in bone turnover markers (BTMs) at 3−6 months and corresponding increase in bone mineral density (BMD) during the treatment of osteoporosis. (A) Bone antiresorptive treatment (i.e., bisphosphonate); a more pronounced decrease in bone resorption marker at 3−6 months is associated with larger increases in BMD. (B) Bone formation-stimulating treatment (i.e., recombinant parathyroid hormone); a greater increase in bone formation marker is associated with a larger increase in BMD. * Mild response in changes in BTM and BMD. † Moderate response in changes in BTM and BMD. ‡ Pronounced response in changes in BTM and BMD. The diagrams show the relationship between early changes (3−6 months) in BTM and changes in BMD after 2 years of either bone resorption inhibition (A) or bone formation stimulation (B). Fig. 78.3(A) is based on quantitative data obtained by antiresorptive treatment with alendronate, documenting tertile changes at 6 months in the bone resorption marker urinary N-terminal telopeptide, and changes in BMD as assessed by dual-energy X-ray absorptiometry (DXA) in total hip, trochanter, and spine at 3 years in postmenopausal women. Fig. 78.3(B) is based on quantitative data obtained by anabolic treatment with parathyroid hormone, documenting tertile changes at 3 months in the bone formation marker N-terminal procollagen I propeptide, and the change in areal and volumetric BMD at 12 months, as assessed in the spine by DXA and quantitative computed tomography in postmenopausal women (Bonjour et al., 2014).

levels of new forms of PTH, even in conjunction with BMD measurements. BTM levels remain to be validated by bone biopsies for all novel bone agents, including bone anabolic drugs in development. Generally, intermittent PTH treatment rapidly increases bone formation followed by an increase in bone resorption marker levels, which has been repetitively confirmed by bone biopsies (Dempster et al., 2001, 2012; Rubin et al., 2011). This differential increase gives rise to a rapid gain in bone mass and has been coined the anabolic window (Rubin and Bilezikian, 2005). Besides confirming that BTMs indeed reflect increases in bone remodeling, the biopsies also demonstrate increased bone modeling, which may explain to some extent the rapid increases in bone formation markers (Dempster et al., 2018). Increases in BTMs during intermittent PTH are transient, however, with normalization of BTM levels after 12−18 months of treatment, which is also confirmed by bone biopsies (Dempster et al., 2001, 2012, 2018; Rubin et al., 2011). It is not entirely clear at the moment why normalization of levels is associated with a continued increase in BMD. Bone biopsies as well as HR-pQCT scans seem to reveal the differential effects of intermittent PTH on various bone envelopes not entirely reflected by BTMs (Nishiyama et al., 2014), which nicely illustrates that BTMs only reflect part of what is happening at the bone level.

TABLE 78.4 Changes from baseline in serum tartrate-resistant acid phosphatase (s-TRAP), serum carboxyterminal telopeptide of collagen type I (s-CTX), and serum procollagen type I N-terminal propeptide (s-PINP) in response to antiresorptive and bone-formation-stimulating treatments (Bonjour et al., 2014).

	Change from baseline (%)			
Compound	Dose and route of administration	s-TRAP	s-CTX	s-PINP
Ca + vitamin D	500–1000 mg + 10–20 μg/d (p.o.)	−20 to −25	−20 to −30	−10 to −20
Alendronate	70 mg/week (p.o.)	−30 to −40	−70 to −80	−60 to −70
Risedronate	35 mg/week (p.o.)		−50 to −60	−40 to −50
Ibandronate	150 mg/month (p.o.)			
	3 mg/3 months (i.v.)		−60 to −80	−60 to −70
Zoledronate	5 mg/year (i.v.)		−50 to −60	−50 to −60
Raloxifene	60 mg/d (p.o.)	−10 to −15	−20 to −50	−30 to −40
Denosumab	60 mg/6 months (s.c.)		−70 to −90	−60 to −70
PTH 1–34 (teriparatide)	20 μg/d (s.c.)		Up to 80	Up to 200
PTH 1–84	100 μg/d (s.c.)		10–100	90–150

Dual-action drugs such as romosozumab

Changes in BTMs during antiresorptive or anabolic therapy are fairly complex, but these changes and their apparent relationship with changes in BMD and fracture risk still seem rather straightforward compared with the transient changes during SOST-antibody treatment. During romosozumab treatment, bone formation levels increase initially and bone resorption markers decrease, with very transient dose-dependent changes and levels decreasing again after a few months of treatment (Fig. 78.2; McClung et al., 2014). In contrast, BMD perhaps surprisingly continues to increase despite the normalization of BTM levels (McClung et al., 2014). BTM levels were used to identify the seemingly most appropriate dose. However, it is presently not clear how much short-term and/or long-term changes in the BTM levels correlate with gains in bone mass or antifracture efficacy of the drug in postmenopausal women with low bone mass. The use of BTMs in conjunction with BMD might therefore also be challenging for romosozumab studies seeking approval for other indications without performing a proper phase 3 trial that includes fracture risk as an outcome. From the transient BTM levels during both romosozumab and PTH treatment, it can be appreciated that BTMs do not simply reflect bone turnover as always being a function of bone remodeling. In both cases, they probably reflect a mixture of bone modeling and remodeling, with both contributing differently during the time course of treatment. It is therefore important that BTM levels during drug development are correlated with histomorphometric data from bone biopsies in animals as well as humans.

The challenge for new drugs with new mechanisms of action

As detailed above there are numerous examples of differential use of BTMs during drug development. Results can sometimes be extrapolated to similar new drugs and similar indications, albeit that one needs to remain careful when doing so. More challenging is the use of BTMs for the development of drugs with completely new mechanisms of action. Basically, BTMs need to be revalidated completely in terms of their relationships with actual bone turnover, gain in BMD, other surrogate parameters including biomechanical properties, as well as clinical outcomes such as fracture risk.

Bone turnover markers to assess skeletal safety of new drugs

Many drugs have an unwanted effect on bone. These include NSAIDs, DMARDs, psychotropic drugs, antiepileptic drugs, vitamin K, statins, antacids, estrogens, androgens, progestins, corticosteroids, anabolic steroids, hormonal contraceptives, chemotherapeutics, targeted cancer agents, therapies that cause hypogonadism and depletion of peripheral production of sex hormones, antihypertensives, antiretrovirals, and immunosuppressants, to name a few (Goodman et al., 2007; Compston and Rosen, 2013). Effects on bone are established through various mechanisms of action and can be related to

changes in hormone levels, changes in mineral transporters in various organs, and also through direct effects on bone cells. In many cases such effects are observed after being in clinical use for a few years, and BTMs might be useful to identify the mechanism behind observed changes in bone mass or fracture risk. CTX and PINP, for example, were used to demonstrate decreased bone turnover caused by older (carbamazepine, valproic acid) as well as newer (levetiracetam) antiepileptic drugs (Hakami et al., 2016). CTX and PINP were also used to demonstrate increased bone turnover during TNF-alpha inhibitor therapy, which helps explain the loss of bone in the femoral neck that was also observed in patients on this treatment (Orsolini et al., 2016). In other cases, BTMs provide early information on potential effects of drugs on bone initially identified from routine chemistry parameters such as calcium and phosphate. NTX and osteocalcin, for example, were used to further explore the effects of the tyrosine kinase inhibitor imatinib on bone after low phosphate levels were found in a subgroup of patients treated with the drug (Berman et al., 2006).

In combination with other chemistries, BTMs could therefore be useful to assess the skeletal safety of not only established drugs but also new compounds in development. To our knowledge, this is not a routine assessment during drug development and could be a new and exciting application for these very informative biomarkers.

Chapter outline

Introduction

Bone plays an important role in the skeleton by providing both mechanical and physiological functions. At the macroscopic level, bone is described in terms of its overall size, shape, and geometry, whereas the microscopic scale captures important structural features that underpin its mechanical and physiological functions. Structurally, we differentiate the cortical compartment containing compact bone from the trabecular compartment containing cancellous bone. The cortical bone is relatively dense, with porosity ranging from 5% to 30%, and makes up approximately 80% of the total bone mass in the body (Langton and Njeh, 2004). The trabecular bone is less dense, with a porosity up to 90%, and is mostly found in the epiphysis of long bones and in vertebrae.

Bone is one of the most investigated biological materials due to its primary function of providing skeletal stability. Bone is susceptible to different local stimuli including mechanical forces and has great capabilities in adapting its mechanical properties to the changes in its environment. Nevertheless, aging or hormonal changes can make bone lose its ability to remodel appropriately, with loss of strength and increased fracture risk as a result. Due to the emergence of accurate and precise bone densitometry over the last 2 decades, bone mass has become a primary endpoint in osteoporosis diagnosis and monitoring. Strong correlations between bone mass and mechanical properties of trabecular bone have been demonstrated for large populations using power-law regressions (Carter and Hayes, 1977; Keaveny et al., 1994; Keller, 1994; McElhaney et al., 1970; Odgaard and Linde, 1991; Rice et al., 1988; Williams and Lewis, 1982). However, changes in mass can only partially explain the variation of trabecular bone strength of individuals, leaving sometimes up to 90% of the strength variation unexplained (Ciarelli et al., 1991). Thus, accurate diagnosis of bone fracture risk in a clinical environment solely based on bone densitometry is difficult. With up to 90% unexplained variation, other factors such as bone macro- and microarchitecture, bone cell distribution, bone remodeling, the distribution of microcracks or microdamage and bone matrix material properties must play important roles too. All these factors together, including bone mineral density (BMD), are often referred to as bone quality (Bouxsein, 2003; Felsenberg and Boonen, 2005; Seeman and

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00079-8

Delmas, 2006). However, the relative contribution of the different factors to define overall bone competence is still relatively poorly understood.

Macroarchitecture is often measured in terms of bone size/shape and BMD, either of the bone as a whole or in specific cortical or trabecular compartments, and can be readily assessed in vivo using a variety of imaging modalities in both animals and humans. Typical radiographic techniques used include radiography (X-ray), dual-energy X-ray absorptiometry (DXA), and quantitative computed tomography (QCT). There is also work in this area using magnetic resonance imaging (MRI) (Jara et al., 1993; Majumdar, 2002; Majumdar et al., 1998; Wehrli et al., 2001b); however, MRI is less frequently applied than radiographic techniques.

Microarchitecture is typically defined as structures measured at resolutions of 100 μm or less, and these can be found in both cortical and trabecular compartments of the bone. Measurements may include the thickness of the trabeculae, their interconnectivity, or the porosity of the cortical bone, for example. As imaging resolution increases, it is possible to move down the hierarchical scale of bone—for example, to osteocyte lacunae and lamellae. Traditionally, microarchitectural features of bone were captured using histological techniques based on stereological measurement techniques applied to physical slices in order to characterize the bone microarchitecture, and those approaches are still critical for understanding the dynamic modeling processes in bone. However, those approaches require invasive techniques and are destructive to the tested tissue. With the advent of advanced imaging, it is now possible to measure features on the submicron scale nondestructively in three dimensions (3D), albeit limited to in vitro measurements at ultrahigh resolutions due to the practical limitations of the high radiation dose and scanning times required. Synchrotron microcomputed tomography (micro-CT) provides the opportunity to have incredible insight into bone structures at the level of cells and lamellae, and while these systems are relatively rare, there are current advances toward so-called X-ray tomographic microscopes that are now approaching similar resolutions, albeit with the disadvantage of using a polychromatic X-ray source.

Using in vivo techniques while accounting for the potential harming effects of radiation and the minimization of scan time, it is possible to resolve microarchitecture down to approximately 10 μm in animals such as rats and mice, and with that, measure bone remodeling parameters using dynamic morphometry. In humans, in vivo measurements at extremities can assess structures on the order of 60 μm while keeping acquisition parameters to safe and reasonable measures. The peripheral skeleton can be examined using single-slice methods, such as peripheral QCT (pQCT), or multislice methods, such as high-resolution pQCT (HR-pQCT). On the other hand, the axial skeleton is more difficult to assess at high resolution, so QCT is often used for measures at the spine and hip and is typically limited to resolutions on the order of 200 μm, which are not enough to resolve individual trabeculae.

Overall, the options for nondestructive imaging have never been greater, and we are fortunate to have tools available that provide imaging resolutions down to the submicron level for in vitro work and well within the resolution of individual trabeculae for in vivo measures. These advances are accompanied by quantitative approaches for evaluating these rich data sets including techniques for measuring 3D structural features, numerical approaches based on the finite element (FE) method to noninvasively assess strength, and supporting tools such as 3D image registration to track bone changes over time in longitudinal studies.

From a clinical point of view, the determination of bone microarchitecture is a new opportunity to understand how bone develops and changes in disease and ultimately can provide important insight into preventing the development of fragile bones and predicting the fracture risk of patients within the context of age, disease, and treatments. While BMD remains an important feature to measure in bones, the opportunity to explore what underpins BMD is enormous, and using the vast array of imaging technologies today, we are on the cusp of making important advancements in our ability to understand the pathophysiology and progression of bone-related diseases such as osteoporosis.

In vitro microimaging

Imaging endpoints have become an important factor for success in basic research and the development of novel therapeutic strategies in biology and medicine. Biomedical imaging of biological structures has therefore received increased attention, for it is often the basis on which both qualitative (i.e., visualization) and quantitative (i.e., morphometry) image processing is performed. Especially for the assessment of microstructural tissue properties, a number of new imaging modalities have been introduced in recent years. These techniques can typically be used to image a variety of different biological materials ranging from soft to hard tissues. Whereas soft tissue imaging is actually a much larger market and is nowadays regularly used as a standard procedure to image and visualize biological structures (Badea et al., 2005; Bullitt et al., 2007; Heinzer et al., 2006; Paulus et al., 2001; Ritman, 2004), hard tissue imaging (i.e., bone) has made great progress not only with respect to qualitative imaging but also with respect to structural and functional assessment of microstructural images in

both animal and human bone (Bouxsein, 2008; Genant et al., 1999; Goldstein et al., 1993; Ito et al., 1998; Link and Majumdar, 2004; McCreadie et al., 2001; Müller, 2002; Müller and Rüegsegger, 1997; Porter et al., 2005; Wehrli, 2007).

Hierarchical imaging of bone microarchitecture

Hierarchical imaging denotes the ability to resolve anatomical features at a variety of resolutions and size scales using basically the same imaging modality and ideally covering a few orders of magnitude in resolution. This ability will allow measurements starting at the organ level (500 μm resolution) and going down to the structural level (50 μm), tissue level (5 μm), and even cell level (0.5 μm) using the same technology.

As already introduced, computed tomography (CT) is such an approach to imaging and quantifying trabecular bone in 3D, providing multiscale biological imaging capabilities with isotropic resolutions ranging from a few millimeters (clinical CT) to a few tens of micrometers (micro-CT) and further down to 100 nanometers (nano-CT) (Fig. 79.1). Early implementations of 3D micro-CT focused on the methodological aspects of the systems and required equipment that was not widely available (Feldkamp et al., 1989); recent developments have emphasized the practical aspects of microtomographic imaging (Rüegsegger et al., 1996). This and other similar types of in vitro systems, now also commercially available, can be used routinely in basic research and clinical laboratories. Also referred to as desktop or laboratory micro-CT, they provide spatial resolutions ranging from roughly 0.5−100 μm. Specimens with diameters ranging from a few millimeters to 100 mm can be measured. Micro-CT is a precise and validated technique (Balto et al., 2000; Graichen et al., 1998; Kapadia et al., 1998; Kuhn et al., 1990; Müller et al., 1998b; Uchiyama et al., 1997; Yamashita et al., 2000) and has been used extensively in the assessment of microarchitectural bone (Fig. 79.2) in the context of investigating different diseases

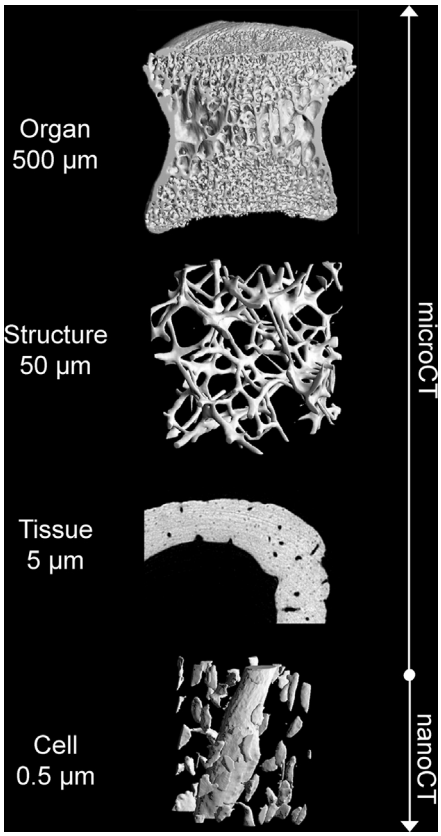

FIGURE 79.1 Schematic overview of hierarchical imaging with micro-CT and nano-CT. At the organ level, an image of a cut-through vertebral body, obtained using desktop micro-CT, demonstrates the extensive heterogeneity in the vertebra of a macaque. At the structural level, desktop micro-CT illustrates the three-dimensional trabecular microarchitecture in a human vertebral sample. At the tissue level, synchrotron radiation micro-CT of a cortical bone sample from a mouse femur illustrates vascular channels (*large holes*) and cell lacunae (*small holes*). Synchrotron radiation micro-CT at the cellular level shows osteocytic lacunae arranged around a microvessel in mouse cortical bone.

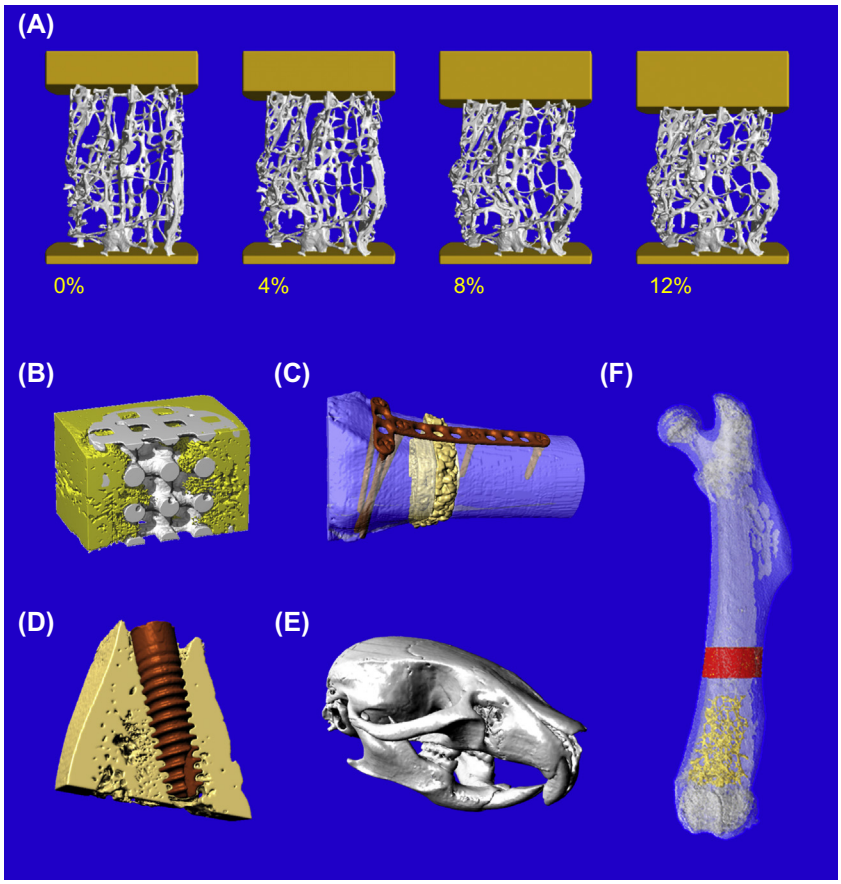

FIGURE 79.2 Typical applications of micro-CT in the imaging of bone. (A) Human spine trabecular bone structure in a two-plate compression testing experiment. (B) Three-dimensional reconstruction of scaffold and bone ingrowth in a minipig model of bone regeneration. Only part of the cylindrical scaffold is displayed to enable a view of the inside of the scaffold. (C) Performance analysis of a bone replacement material in a sheep fracture repair model. A gap was cut in the long bone and filled with bone replacement material; the fracture was fixed using a conventional T-plate. (D) Mouse femur. Typically in bone research, different compartments (full bone; cortical ring; trabecular region) are selected to compute morphometric indices. (E) Titanium screw in rat bone. (F) Mouse cranium.

and their treatment, such as osteoporosis (Alexander et al., 2001; Babij et al., 2003; Borah et al., 2002, 2004; Dempster et al., 2001; Ding and Hvid, 2000; Goulet et al., 1994; Ulrich et al., 1999; Yoshitake et al., 1999) or osteoarthritis (Badger et al., 2000; Day et al., 2001; Dedrick et al., 1993; Pettit et al., 2001); genetics and gene therapy (Bouxsein et al., 2004; Huang et al., 2005; Moutsatsos et al., 2001; Turner et al., 2000), dental research and implants (Duyck et al., 2001; Giesen and van Eijden, 2000; Peters et al., 2000; Sasaki et al., 2000), tissue engineering and biomaterials (Jones et al., 2004; Lin et al., 2003; Lutolf et al., 2003; Porter et al., 2005; Williams et al., 2005; Zeltinger et al., 2001), and the validation of other techniques aimed at investigating bone microstructure in a more clinical setting (Gluer et al., 1994; Laib and Rüegsegger, 1999; Nicholson et al., 1998).

Since the introduction of these systems, there has been an increasing demand for microtomographic technology throughout the world. With the advent of third-generation synchrotron radiation (SR) facilities, micro-CT with resolutions of 1 μm and even better became feasible (Bonse et al., 1994; Engelke et al., 1993; Salome et al., 1999). SR has several advantages over conventional X-rays, including its high brilliance, which allows higher resolutions in nanotomographic applications (Stampanoni et al., 2003) and the use of a monochromatic beam for accurate density representations (Borah et al., 2005; Nuzzo et al., 2002). The high resolution of SR micro-CT and SR nano-CT systems (systems with resolutions < 1 μm) opened a new level of magnification, which in bone research was necessary to investigate 3D properties of ultrastructural features, such as the canal network (Bousson et al., 2004; Matsumoto et al., 2007), osteocyte lacunae (Schneider et al., 2007; Fig. 79.3) and even single cells (Weiss et al., 2000) as well as direct functional outcomes such as microcracks and microfractures (Koester et al., 2008; Larrue et al., 2007; Thurner et al., 2006).

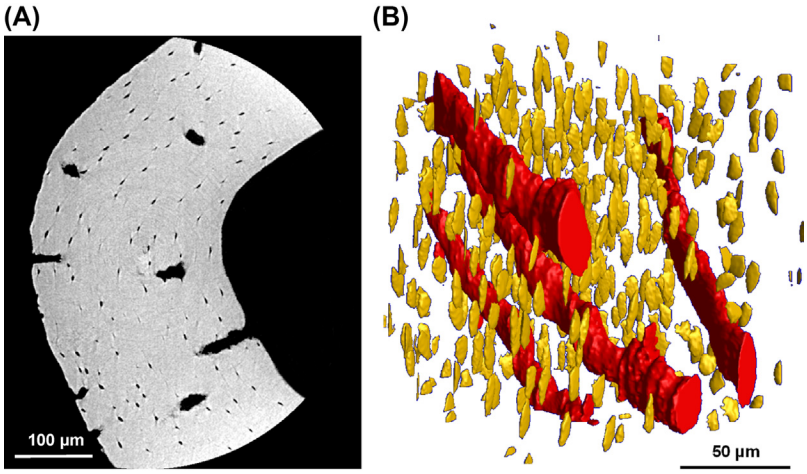

FIGURE 79.3 Ultrastructural representation of void spaces within cortical bone of a mouse femur. (A) Two-dimensional nano-CT slice of the cortical middiaphysis in transverse view showing sections through canals and osteocyte lacunae. Data were assessed at the Swiss Light Source at 700 nm nominal resolution. (B) Three-dimensional representation of the cortical subvolume visualizing the extent of the canal network (*red*) (dark gray in print version) and osteocyte lacunae (*yellow*) (light gray in print version). Volumetric information was extracted from the same data using negative imaging.

Biomechanical imaging of bone competence

Although the assessment of bone microarchitecture is important in the determination of bone quantity and quality, bone competence eventually is responsible for the mechanical and fracture behavior of bone. The gold standard to determine bone competence is mechanical testing of bone. Classical mechanical testing (Turner and Burr, 1993) provides detailed information on whole bone mechanical and bone matrix material properties but fails in revealing local failure properties. Bone failure is a time-dependent, nonlinear event including high local deformations and local fractures that build up to macroscopic failure in the final stage (Bay et al., 1999). Although some work on bone failure characteristics has been done, basic knowledge of how failure originates within both trabecular and cortical bone is still lacking. However, for estimating the risk of fractures for individual patients, an extended understanding of the failure behavior of bone is essential. For this reason, imaging techniques that allow the study of bone tissue in a nondestructive and time-lapsed fashion in situ are very important. Incorporation of such biomechanical or functional imaging methods in mechanical setups will allow better insight into bone deformation and failure characteristics on various levels of structural organization.

For this reason, a biomechanical imaging techniques have been developed and validated, allowing direct time-lapse 3D visualization and quantification of fracture initiation and progression on the microscopic level (Müller et al., 1998a; Nazarian and Müller, 2004). Additionally, novel image analysis approaches have been implemented to identify and classify individual rods and plates, to then track those elements over the time course of failure, and eventually to compute local displacements and strains from consecutive compression steps (Müller et al., 2002). In an initial study, trabecular bone specimens were compressed in steps of 0%, 1%, 2%, 4%, 8%, and 12%, and local strains were determined experimentally. The results showed that average strains were much smaller than the externally applied strain, but maximum local strain values were 5−8 times greater than the externally applied strain, providing further evidence for a bandlike, local failure behavior of trabecular bone (Fig. 79.2A). These high strains were mostly found in rodlike elements aligned with the main strain axis or platelike elements that were fenestrated. Some of these elements bend, others buckle, and some are compressed. Although internodal strains can indicate active structural elements, they cannot distinguish the different behaviors of these elements and how much energy is absorbed. They also do not correlate well with the amount of deformation in an element. Therefore, internodal strains alone cannot fully explain the failure mechanisms of trabecular bone.

Previously, histological damage labeling, micro-CT imaging, and image-based FE analysis were combined to detect regions of trabecular bone microdamage (Nagaraja et al., 2005). For the purpose of that study, bovine tibial trabecular bone cores underwent a stepwise uniaxial compression routine in which specimens were micro-CT imaged following each compression step. Regions of trabecular bone microdamage were then coregistered to estimated microstructural stresses and strains. The results indicate that the mode of trabecular failure observed by micro-CT imaging agreed well with the polarity and distribution of stresses within an individual trabecula as assessed from FE analysis. Analysis of on-axis subsections within specimens provided significant positive relationships between microdamage and estimated tissue

stress and strain. In a more localized analysis, individual microdamaged and undamaged trabeculae were extracted from specimens loaded within the elastic region and to the apparent yield point. As expected, damaged trabeculae in both groups possessed significantly higher local stresses and strains than undamaged trabeculae (Nagaraja et al., 2005).

Where micro-CT studies thus far had focused mostly on the microstructural level of analysis, SR micro-CT and nano-CT allowed for the next level of hierarchy. With this, the exploration of bone failure at the micrometer and even submicrometer level facilitates direct observation of microcracks and microfractures in a fully nondestructive and even time-lapsed fashion. To better investigate the different failure mechanisms on the micro level, a novel in situ mechanical compression device was recently developed at a synchrotron site capable of exerting both static and dynamic displacements on experimental samples (Thurner et al., 2006). To study different failure mechanisms in trabecular bone, a fatigued and a nonfatigued bovine bone sample were compared with respect to failure initiation and propagation. Where the nonfatigued sample exhibited an as-expected distinct localized failure band, the fatigued sample failed in a burstlike fashion. Moreover, microscopic cracks—microcracks and microfractures—were uncovered directly in 3D, illustrating the failure process in great detail and with true representation. Almost all of these cracks were connected to a clearly recognizable bone surface. The data also showed that the classification of microcracks and microfractures from a single two-dimensional (2D) section can sometimes be ambiguous, which is also true for the identification of diffuse and distinct microdamage. Detailed investigation of the failure mechanism in these samples illustrated that trabecular bone often fails in delamination, providing a mechanism for energy dissipation while conserving trabecular bone architecture.

The concept of hierarchical functional imaging was recently also introduced for investigating failure behavior in cortical bone (Voide et al., 2008). In that study, femoral testing in a single-legged stance configuration was performed concurrently with SR tomography to observe fracture initiation and propagation in an intact proximal mouse femur and in 3D. During femoral head compression, image-guided failure assessment showed that fracture occurred were the ratio of the bending moment relative to the cross-sectional moment of inertia was highest. In other words, bone failed at the location where the tensile stresses were the highest in the cortical bone—i.e., the superior femoral neck (Fig. 79.4A and B). Subsequently a cortical notch model was used to better investigate local postyield behavior of bone where microcracks and uncracked ligament bridging play an important role in providing additional material toughness. Uncracked ligament bridging in bone was first reported as a toughening mechanism involving 2D uncracked regions along the crack path that can bridge the crack on opening (Nalla et al., 2005). The reason for the toughening effect is that microcracking causes dilation and increases the compliance of the region surrounding the crack. In other words, uncracked ligament bridges increase resistance to fracture by sustaining part of the applied load that would otherwise contribute to crack continuation. In this study, uncracked ligament bridges were imaged for the first time in 3D at a nominal resolution of 700 nm, displaying not only the relationship of the microcrack to the canal network but also to the much smaller osteocyte lacunae (Fig. 79.4C and D). The results showed that the osteocyte lacunae did not contribute to the initiation of cracks but were important in their propagation. Many cracks actually initiated at the open surfaces of the canal network, something that was recently shown to also play an important role in human cortical bone (Koester et al., 2008). Three-dimensional visualization revealed that the uncracked ligament bridges were not 2D uncracked regions along the crack path, as reported previously (Nalla et al., 2005), but had proper 3D shapes. Their thickness varied between 1 and 3 μm. SR micro-CT also uncovered uncracked ligament bridging at two different phases. Initially, shortly after microcrack initiation, the long axes of the uncracked ligament bridges are mostly aligned parallel to the direction of crack propagation or the long axis of the crack. This can be explained by the fact that at the nanoscale, bone fails through the delamination of mineralized collagen fibrils (Thurner et al., 2007), which are the basic building blocks of bone matrix at the supramolecular level (Weiner et al., 1999). When failure progresses and the crack openings become larger, the uncracked ligament bridges rotate and eventually their long axes become oriented perpendicular to the long axis of the crack (Fig. 79.4E). New developments at synchrotron sites, which allow high-speed imaging that takes full tomographic images at microscopic resolution in only a few seconds (Di Michiel et al., 2005), will facilitate higher throughput in biomechanical imaging and therefore also allow imaging of dynamic failure behavior (Christen et al., 2012; Levchuk et al., 2018; Meier et al., 2008).

Quantitative image processing

Image processing is a large field, and to cover all aspects would be beyond the scope of this chapter. This section describes the most commonly applied procedures to extract and quantify microstructural features as they are used in the bone field. A number of guideline papers will give the reader more in-depth information on image processing, quantitative image analysis, and bone morphometry (Bouxsein et al., 2010; Dempster et al., 2013; Parfitt et al., 1987).

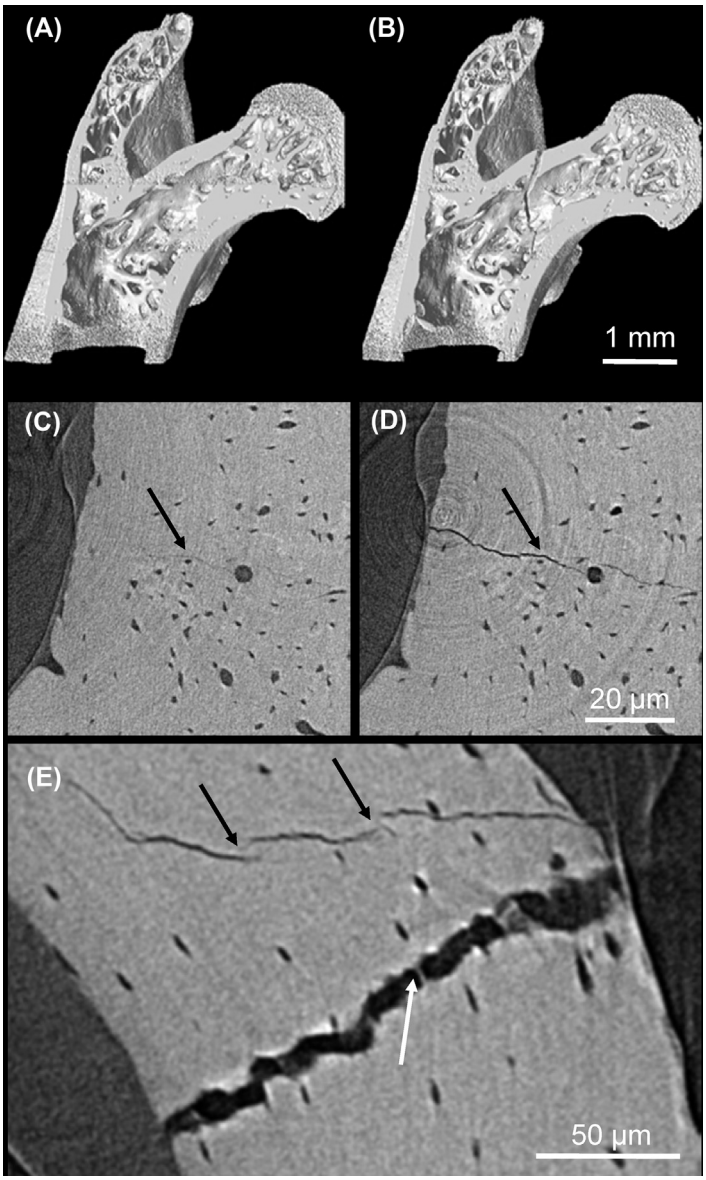

FIGURE 79.4 Hierarchical imaging of bone function with synchrotron radiation CT. Image-guided failure assessment illustrates compression and fracture at a proximal mouse femur (A) in the uncompressed femoral neck, and (B) after displacement of the femoral neck. Nominal resolution 3.5 µm for both images. (C) Reconstructed slices of mouse femoral bone from the cortical middiaphysis. Nominal resolution 700 nm; 1% apparent strain. A microcrack is faintly visible (*black arrow*). (D) At 2% apparent strain, the microcrack has propagated and is now clearly visible (*black arrow*). Nominal resolution 700 nm. (E) Cortical bone at 1% strain with a microcrack and a microfracture. Uncracked ligament bridges intersect the microcrack (*black arrows*) and span the microfracture (*white arrow*). Nominal resolution 700 nm.

Filtration and segmentation

Reconstructed image data inherently include noise that should be reduced by filtering while maintaining sharp contrast between bone and marrow (Stauber and Müller, 2008). Photon statistics, fluctuations of the CCD, and thermal fluctuations are all factors that may increase noise in final images. To reduce this noise and be better able to extract the desired features, a large set of different filtering methods have been introduced. Examples are Gauss, Hamming, Hann, Blackman, Bartlett, Welch, and Wiener filters (Gonzalez and Woods, 2002). Most filters are applied in the Fourier space, where the filters are classified as either low- or high-pass filters according their function to remove either high or low frequencies from images. High-pass filters are commonly used for feature extraction and edge enhancement, whereas low-pass filters are commonly used for noise reduction. Where high-pass filters may increase some noise, low-pass filters blur images. This trade-off can

be solved optimally using Gaussian filtration. Furthermore, the Fourier transform of the Gaussian function yields the Gaussian function again, whereby this filter can be applied in direct space, which makes this filter easily implementable and fast in computation. For these reasons, Gaussian filtration is one of the most commonly used filters for noise reduction. However, since the Gaussian filter also blurs the edges, more advanced smoothing techniques have been developed to normalize the image while preserving the edges. An example of such an edge-preserving smoothing filter is the anisotropic diffusion filter. Other filters frequently used are median, minimum, and maximum filters, which can also be applied in direct space.

The segmentation process is a critical step in bone analysis and generally involves separating an object or multiple objects from the background for subsequent quantitative analysis. An example of a typical three-phase object application is a bone with an implant, where the third phase is the background. Segmenting images is a difficult topic and has led to many publications trying to establish new methods for special purposes. The main problem is that because of beam hardening, aliasing artifact, partial volume effect, or ring artifact, the values of different materials in a single image may not be clearly distinguishable anymore. Therefore, it becomes relatively difficult to select all voxels of a certain value range and to assign it to an object. Nevertheless, the most common segmentation technique is still so-called thresholding, where all voxels above a certain value are set to white (1) and all remaining voxels are set to black (0). This procedure can also be applied to two, three, or more levels if image quality is good enough and image contrast is sufficient for the different materials to be resolved.

For structural analysis, it might in certain cases be reasonable to remove small, unconnected objects from the main object that may arise from image noise or from improper sample preparation. This is accomplished by the so-called component labeling algorithm, which first labels all components in the structure. Depending on the software, it can then be decided whether the largest, the smallest, or all components of a certain size should be kept for further evaluation.

Quantitative morphometry

A method of quantitatively describing bone architecture and changes associated with the age or stage of a disease is the calculation of morphometric indices, also referred to as quantitative bone morphometry. In the past, structural properties of trabecular bone have been investigated by the examination of 2D sections of bone biopsies. Three-dimensional morphometric parameters were then derived from 2D images using stereological methods (Parfitt et al., 1983). Highly significant correlations between 2D histology and 3D micro-CT have been found for bone volume density (BV/TV) and bone surface density (BS/TV) (Müller et al., 1998b). While measurements like BV/TV and BS/TV can be directly obtained from 2D images, a range of important parameters such as trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), and trabecular number (Tb.N) are derived indirectly assuming a fixed-structure model. Typically, an ideal plate or ideal rod model is used; however, such assumptions are critical because the type of trabecular bone architecture differs for different anatomical sites, which will lead to an unpredictable error of the indirectly derived parameters.

For these reasons, and in order to take full advantage of volumetric measurements, several new 3D image processing methods have been presented that allow for direct quantification of bone microarchitecture (Hildebrand et al., 1999; Odgaard et al., 1997). These techniques calculate actual distances in 3D space and therefore do not rely on an assumed model type and are not biased by possible deviations. In addition to the computation of direct metric parameters, nonmetric parameters can be calculated to describe the 3D nature of a bone structure. An estimation of how platelike or rodlike a bone structure is can be achieved using the structure model index (SMI) (Hildebrand and Rüegsegger, 1997b). Several studies show that the degree of anisotropy (i.e., a description of how the structural elements are oriented) together with bone volume fraction may explain a significant part of the mechanical properties of a 3D structure. Therefore, several methods, such as mean intercept length (Whitehouse, 1974), volume orientation (Odgaard et al., 1990), star volume distribution (Cruz-Orive et al., 1992), and star length distribution, have been proposed to estimate the degree of anisotropy of trabecular bone. These and other measures of architectural anisotropy are reviewed in detail elsewhere (Odgaard, 1997). An index called connectivity density (Conn.D) has been introduced to characterize the number of possible paths that connect the analyzed bone structure from one end to the other. Conn.D expresses the number of connections per cubic mm and is derived from the Euler number (Odgaard and Gundersen, 1993) as follows: $\text{Conn.D} = (1 - \text{Euler number})/\text{TV}$.

Quantitative assessment of 3D bone morphometry typically applies to porous structures as a whole and not to their individual elements. Although studies demonstrate the importance of architectural bone properties in a statistical sense, they do not explain the real physical contribution of the microarchitecture to the mechanical failure behavior of bone. A recent project aimed to calculate the structural properties of individual trabecular elements using a method called volumetric spatial decomposition (Stauber and Müller, 2006). The ability to break down the bone microarchitecture and extract individual structural elements, such as trabecular rods and plates, allows performing of local bone morphometry; i.e., it

allows determining of the shape and form of each single bone element individually. With this method it is hence possible to perform more detailed analyses of 3D structures, and it has now become possible to analyze the individual contribution of rods and plates to the competence of trabecular bone (Liu et al., 2008; Stauber et al., 2006).

Finite element analysis

Although the inclusion of architectural parameters has strongly improved the prediction of the competence of bone (Müller et al., 2004; Yang et al., 1998), they only do so in a statistical sense. They do not explain the real physical contribution of the microarchitecture to the mechanical failure behavior of bone. To understand how differences in bone microarchitecture influence bone competence, insight into load transfer through the bone architecture is needed. With the advent of fast and powerful computers, simulation techniques are becoming popular for investigating the mechanical properties of bone.

Using microstructural FE models generated directly from computer reconstructions of trabecular bone, it is now possible to perform a "virtual experiment"—i.e., to simulate a mechanical test in great detail and with high precision. Detailed FE models of trabecular bone can be created using 3D microstructural images as described before. They are often denoted as "high-resolution," "large-scale," or "microstructural" FE (micro-FE) models. After assigning appropriate material properties to the elements defining the structure, these computer models provide realistic response characteristics to simulated loading. For linear deformation conditions, comparison between biomechanical compression tests and micro-FE shows very good agreement when a homogeneous, isotropic tissue modulus is applied (Kabel et al., 1999; Ladd et al., 1998). This holds true for normal as well as osteoporotic bone (Homminga et al., 2003). These computer models allow calculation of loads at the microstructural or even tissue level (Ladd et al., 1998; van Rietbergen et al., 1995) and have been used extensively to accurately determine the mechanical properties of bone.

Later, it was shown that these micro-FE models can also accurately predict trabecular bone failure for bovine (Niebur et al., 2000) as well as human trabecular bone (Bayraktar et al., 2004); micro-FE-predicted apparent stresses and strains at failure were equal to experimentally measured values for the same bone specimens, demonstrating that the quality of micro-FE analyses has reached such accuracy that the use of such simulation techniques can be an effective way to reduce experimental errors (Van Rietbergen et al., 1998) and can be used as an alternative to destructive mechanical tests (Niebur et al., 2000). A great advantage of micro-FE analysis is that models can be analyzed multiple times under different conditions to simulate various types of loading. Furthermore, bone micro-FE models provide better insight into the relationship of structure and strength by allowing one to look inside the bone to see where strains and stresses are localizing and therefore where they may cause fracture (Borah et al., 2001).

In vivo microimaging

In parallel with the advancement of in vitro imaging modalities, the past 2 decades have seen major developments in the area of in vivo imaging. For bone, X-ray methods are particularly well suited to measure microarchitecture, and the availability of 3D methods based on CT provides opportunities to simultaneously explore changes in the composition of the bone tissue, its microarchitecture, and its macroarchitecture. While the resolution of in vivo techniques is limited by the importance of ensuring that safe X-ray dose levels are delivered (not a limitation for in vitro imaging), this drawback is offset by the exciting ability to nondestructively monitor bone at multiple time points in a living being (Waarsing et al., 2004).

The shift from study designs focused on cross-sectional analysis to longitudinal analysis has important implications for providing insight into bone adaptation. It is through time-lapse imaging that we can truly explore the dynamic nature of bone adaptation. In animal studies, the design of a longitudinal study means relatively fewer animals are needed to answer a scientific question due to the increased statistical power of the repeated measures. In contrast, cross-sectional study designs typically need larger numbers so that normal population variation does not mask the effect being studied. A longitudinal design is a powerful approach to studying an animal model of human disease, and in fact one of the challenges a scientist often faces is reining in the enthusiasm to perform longitudinal measurements too frequently and/or maximize imaging resolution, as both decisions have implications on the X-ray dose delivered to the animal and can even influence the adaptive behavior of bone if too high (Klinck et al., 2008).

In human studies, the development of high-resolution in vivo measurement techniques offers new insight into bone microarchitecture that was previously only possible using ex vivo imaging or biopsies. Both cross-sectional and longitudinal study designs can be employed, although there is a much higher proportion of cross-sectional studies (Cheung et al., 2013) despite the value of longitudinal research. Of course, a major reason for that disproportionate number of cross-sectional studies is that the time course of human research can be long, thus making those studies expensive and

time-consuming. Nevertheless, since the introduction of pQCT and HR-pQCT technologies in past decades, an increasing number of longitudinal studies have been published. This is evident in the area of fracture prediction based on microarchitecture, where there is a shift from the establishment of large cohort studies that are cross-sectional in design and focused on prevalent fractures, toward longitudinal cohort studies where incident fractures can be investigated.

In human and animal studies using in vivo techniques, common challenges must be overcome. First, if using an X-ray-based technique, it is important to minimize the X-ray dose while balancing that with maximized resolution, field of view, and frequency of follow-up exams. Second, in a living being, movement during scan acquisition is inevitable. While this can be minimized in an animal by anesthetizing it, or minimized in a human by using supporting braces, movements will inevitably occur during scanning acquisition, and depending on the magnitude of the artifact, can have a significantly negative impact on the measurement of microarchitecture (Pauchard et al., 2012). Third, it is important to measure the same region of interest in the bone at each exam. While most imaging devices have built-in software and hardware designed to maximize the repositioning of follow-up scans, it is not possible to be perfectly realigned. The problem of misalignment becomes more acute when the region of interest is small. For example, in HR-pQCT only a 1 cm length of bone is typically scanned at the wrist and ankle, and therefore small perturbations of the positioning can unduly influence the ability to track changes in bone. This problem can be mitigated using postprocessing techniques, in particular region-matching approaches based on 3D image registration to maximize reproducibility (Boyd et al., 2006; Ellouz et al., 2014), and in some cases, they are critical (and nontrivial) to employ.

In the following sections, we outline strategies and techniques for both animal and human in vivo imaging of bone microarchitecture.

In vivo animal microimaging

The primary tools for assessing microarchitecture by in vivo imaging of animals are X-ray-based due to excellent contrast for bone tissue and high resolution. Although other methods have been developed using techniques, such as micro-MRI, that avoid ionizing radiation to the animal (Majumdar, 2002; Majumdar et al., 1998; Wehrli et al., 2001a), they are challenged by lower resolution, longer imaging times, and the fundamental inability to collect an imaging signal from bone (rather than marrow and soft tissues). While micro-MRI is a promising noninvasive tool for microimaging, our focus here is on X-ray-based techniques.

The most frequently applied tool for measuring microarchitecture is micro-CT, and its extension from desktop in vitro micro-CT to in vivo systems has provided the exciting ability to study processes of bone remodeling and adaptation in research related to fracture healing (Taiani et al., 2014), mechanical loading (Schulte et al., 2013) and aging (Razi et al., 2015), hind limb unloading (Manske et al., 2015a), osteoporosis (Campbell et al., 2008), osteoarthritis (Panahifar et al., 2012), orthopedics (Li et al., 2017), bone metastases (Bondareva et al., 2009; Buie et al., 2013), bone development (Buie and Boyd, 2010), and many more.

Many of the challenges for in vivo animal assessment are the same as for in vivo human assessment. That includes issues of subject movement during image acquisition, radiation exposure, maximizing reproducibility, and quantification of microarchitecture parameters.

A fixture to support the animal is required to ensure that minimal movement occurs during the scanning protocol while at the same time providing a method to deliver anesthetic to the animal. Although manufacturers of in vivo systems provide commercially available devices, it is frequently the case that customized versions need to be developed for the specific needs of the research. Taking the scanning of a mouse vertebra as an example, it is challenging to prevent excessive movement caused by expansion of the mouse's lungs during respiration. A custom jig developed for in vivo studies of mouse vertebra (Buie et al., 2008) was designed to allow the mouse to be anesthetized with a mask, reducing exposure to the operator and minimizing the risk of a mouse awakening during setup. The mouse could be positioned on its stomach or back, the latter of which reduces motion of the vertebra. The lower limbs were held in place on opposite sides of a partition using a single orthodontic elastic band around both ankles. A latex glove finger is used to cover the body to catch feces and keep the tail contained. The small size of the fixture enabled a scan resolution of 12.5 μm, and the resolution of the whole-body device was limited to 19 μm because of the large diameter of the tube (Fig. 79.5).

Radiation considerations

A major consideration for in vivo micro-CT imaging is whether the ionizing radiation delivered during an exam is sufficient to cause damage to the bone. It has been shown that with high-resolution imaging ($\sim$10 μm) and weekly scans, a significant effect on bone microarchitecture in a mouse can be detected (Klinck et al., 2008). It is prudent to establish an

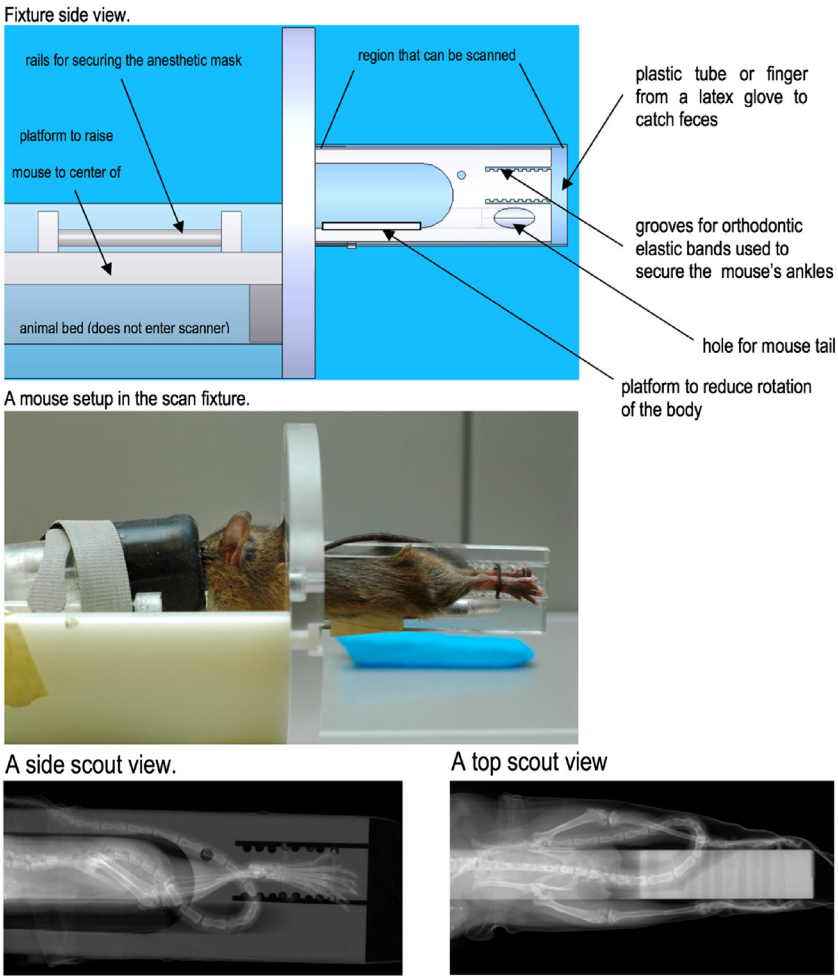

FIGURE 79.5 A custom fixture designed for in vivo mouse scans of the lumbar spine and lower extremities is shown. The left and right limbs can be aligned and scanned simultaneously.

appropriate protocol for an in vivo micro-CT study that ensures that radiation effects are avoided or minimized (Brouwers et al., 2007; Laperre et al., 2011), and this is typically considered in study design. For example, in a study with many time points, having a control group that is measured only at the start and end of the protocol would provide evidence of the effect (or lack thereof) of repeated in vivo micro-CT measurements on bone adaptation. Interestingly, although most studies seek to avoid radiation effects on bone, there are some exceptions where those effects are specifically of interest and might be applied intentionally to study effects on bone microarchitecture (Michel et al., 2015). Nevertheless, the majority of in vivo animal research is focused on understanding the processes of bone adaptation in disease models while minimizing any effects the micro-CT measurements themselves may have on bone.

Reproducibility

The challenges of measuring the same region of bone at each time point in an in vivo study is significant, and in anatomic regions where the bone varies strongly as a function of the distance along its length such as at the ends of long bones (Boyd, 2008), the effects of misalignment are exacerbated. The use of a 2D X-ray, often referred to as a scout view (Fig. 79.6), prior to image acquisition significantly improves follow-up accuracy; however, the application of other postprocessing tools can further improve reproducibility. The most common approach is to use 3D image registration to align scans so that a common region of analysis can be identified for an entire time series of data (Boyd et al., 2006). Using the standard repeated-measures approach to measure imaging reproducibility (Gluer et al., 1995), it has been shown that the use of image registration maximizes the sensitivity of in vivo micro-CT to detect bone microarchitecture changes (Nishiyama et al., 2010; Schulte et al., 2014).

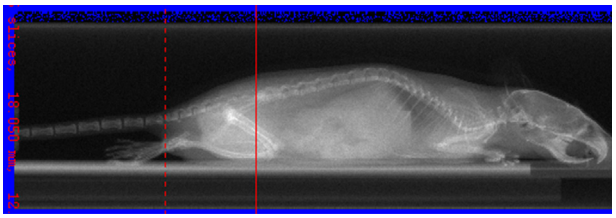

FIGURE 79.6 A two-dimensional X-ray acquired prior to the full three-dimensional scanning protocol helps assure that the same region of the skeleton is scanned at each follow-up measurement. Shown here is a scout view of a mouse body.

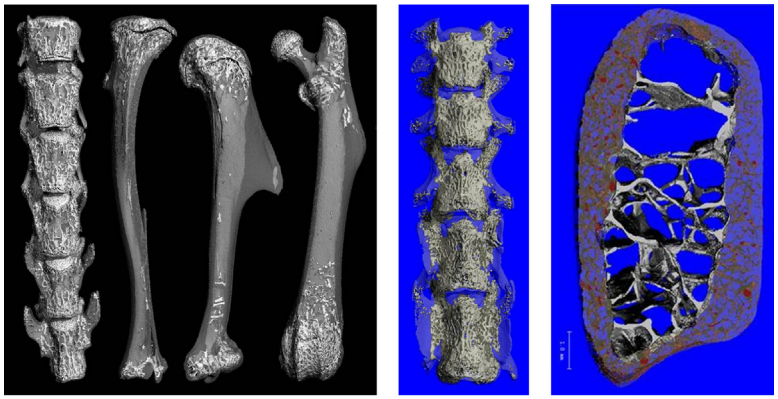

FIGURE 79.7 Automated segmentation of the cortical and trabecular compartments is shown for whole mouse bones, rat vertebra, and a human rib. The versatility of the method is important to accelerate in vivo microarchitecture studies due to the ability to efficiently segment compartments for subsequent morphological analysis.

Another important component of generating reproducible results is how bony compartments, such as the trabecular and cortical compartment, are consistently identified. The endocortical margin defining the border between the trabecular and cortical compartments is a region of particular interest in terms of adaptive remodeling and is also important for defining microarchitecture parameters related to the cortex, such as cortical porosity. Two major approaches have been developed to define the compartments (Buie et al., 2007; Zebaze et al., 2013), both based on an image analysis approach, and are designed to generate highly reproducible results (Burghardt et al., 2010). One method focuses on the gradient change between the cortical and trabecular compartments to define the border (Zebaze et al., 2013), and the other uses a series of thresholding procedures to distinguish the compartments (Buie et al., 2007). While both are used in the context of human in vivo imaging, typically only the threshold-based approach has been applied with in vivo animal studies to date (Fig. 79.7).

Altogether, image processing techniques for 3D registration as well as defining bony compartments play an important role in maximizing the reproducibility of in vivo imaging outcomes for microarchitecture and improving the sensitivity of longitudinal studies to detect subtle changes related to bone adaptation in growth, aging, disease processes, and treatment effects.

Dynamic morphometry

In time-lapse or longitudinal in vivo imaging, several images of the same object are taken over time fully noninvasively. This allows for the following of changes that occur in that object over time. To determine such changes, follow-up images need to be aligned to each other, and the differences need to be defined (Christen and Müller, 2017). Images of bone are usually aligned using rigid image registration. In that approach, an optimization algorithm is used to find the transformation that translates and rotates images onto each other until they overlap well enough such that a certain objective function is met. Once the transformation is found, it is applied to the image, and interpolation is used on the follow-up image to assign each voxel its new coordinates. In a final step, registered images are superimposed, revealing the differences between follow-up images, to visualize and quantify bone resorption and bone formation.

In cases where image resolution is high and the changes occurring over time are small, rigid image registration has been successfully used in animal experiments to align and subsequently superimpose baseline with follow-up images (Boyd et al., 2006). This approach also allows for determination of sites of bone resorption and bone formation. A total of six parameters for both bone resorption and bone formation were determined and described: bone formation rate, bone resorption rate, mineral apposition rate, mineral resorption rate, mineralizing surface, and eroded surface (Lambers et al., 2013; Razi et al., 2015; Schulte et al., 2011). It is important to note that with this approach, not only bone formation but also bone resorption, can be quantified, which is not possible with dynamic histomorphometry because there are no labels for bone resorption as these are removed when bone is resorbed.

The approach has been applied to the mouse caudal vertebra as assessed by in vivo micro-CT at a voxel size of 10.5 μm (Lambers et al., 2013; Schulte et al., 2011). Time-lapse imaging was performed at baseline and 4 weeks and then every 2 weeks for 14 weeks. Grayscale images were aligned using 3D rigid image registration based on an intensity-based least-squares objective function and B-spline interpolation. Sites of bone resorption and bone formation were quantified and visualized by overlaying segmented follow-up images. This revealed good agreement with histomorphometry and erroneously resorbed bone volume of 4.9% ± 1.8% (mean ± standard deviation) and formed bone volume of 5.3% ± 2.1% (mean ± standard deviation). In another example, the approach has been applied to mouse tibia also imaged with micro-CT at a voxel size of 10.5 μm (Razi et al., 2015). Time-lapse in vivo imaging was performed at baseline and on days 5, 10, and 15. Also in this case, grayscale images were aligned using 3D rigid image registration but based on a normalized mutual information objective function and Lanczos interpolation. Sites of bone resorption and bone formation were again determined by overlaying segmented follow-up images. This study revealed good agreement with histomorphometry and reported an error of 3.49% ± 3.42% classifying voxels into bone resorption and bone formation. Newest developments extended this approach to track bone resorption and bone formation events over time and thus study sequences of bone resorption and bone formation in the mouse tibia (Birkhold et al., 2015).

In vivo human microimaging

Advancements in the area of in vivo CT imaging of animals have largely been paralleled by advancements in human imaging. As noted for animal studies, technologies such as micro-MRI can be used to assess bone microarchitecture; however, the best contrast and resolution can be obtained using X-ray-based methods. The most common clinical tool is DXA, which is primarily used to assess areal BMD of key skeletal sites for major osteoporotic fracture (hip, spine, forearm). Although the 2D approach of DXA is not well suited to distinguish trabecular and cortical compartments, and hence bone microarchitecture, the recent introduction of the trabecular bone score appears to generate an index related to microarchitecture. There is currently significant interest in its use as an independent predictor of osteoporotic fracture, although the field is still evaluating its effectiveness in that area (Bousson et al., 2015).

The most common modalities used to measure 3D bone microarchitecture in humans in vivo include CT, pQCT, micro-CT, and HR-pQCT. Of course, MRI can also be used (Wehrli et al., 1998, 2001b), and it holds the advantage that it does not use ionizing radiation; however, resolution of the images provided is at the limit for detecting human bone microarchitecture. Furthermore, an MRI image provides geometric information but no information about the tissue material itself. This is in contrast, for example, to X-ray methods such as CT that simultaneously acquire geometric information and density information about the tissue. In general, the highest in vivo imaging resolutions by CT are achieved when measuring at peripheral skeletal sites. The smaller gantry size necessary for an extremity is better suited for allowing high-resolution images to be acquired while keeping within safe doses of ionizing radiation exposure for the patient.

Clinical computed tomography

CT is the basis of most 3D methods to acquire bone microarchitecture, although the implementation of the technology can vary widely for specific purposes, with varying gantry size, resolution, number of slices, etc. The clinical use of CT is widespread, and although the technology is constantly evolving, it generates a series of 2D axial slices ranging between 0.3 and 5 mm in thickness with an in-plane resolution on the order of 0.2−0.5 mm. The advancing of the body inside the gantry allows the acquisition of a large number of 2D slices that are the basis of the 3D volumetric analysis. The scalar data represented in the CT data set are typically expressed as Hounsfield units, which can then be calibrated to a measure of the density of the object (Kalender et al., 1987; Lang et al., 1999). Although clinical CT is highly versatile and provides a rich data set representing bone that can be used as input for FE models to assess bone strength, those models typically include a continuum-level distribution of bone mass (Cody et al., 1999, 2000) because the resolution is insufficient to capture detailed bone microarchitecture.

Peripheral quantitative computed tomography

Peripheral CT systems began with single-slice methods such as pQCT (Dambacher and Ruegsegger, 1994; Rittweger et al., 2000, 2005). The advantage of a pQCT system is that it can capture BMD of the cortical and trabecular compartments at peripheral sites and requires very low radiation doses (Hangartner et al., 1985; Fig. 79.8). Also, it is well suited to measure muscle cross-sectional areas in the lower limbs, which can provide important functional information to help understand the relationship between bone and muscle adaptation. The pQCT systems function on the same principles as whole-body QCT but are smaller, easier to site, and cheaper to operate and purchase. The resolution of these systems is on the order of 200 μm, and due to the ability to separate cortical from trabecular bone compartments, small changes in volume and mineral content can be identified (Ferretti et al., 1995). It is not well suited to measure structural features of trabecular bone microarchitecture but is able to measure moments of inertia, volume, cortical thickness, and other gross measurements. It has applications in both animal and human work and in the detection of osteoporosis (Butz et al., 1994; Takagi et al., 1995), monitoring treatment effects (Ruegsegger et al., 1995; Schneider et al., 1999), and studying growth and development in relation to physical exercise (Burt et al., 2012, 2013; Gabel et al., 2015).

High-resolution peripheral quantitative computed tomography

In contrast to pQCT, an HR-pQCT system is capable of collecting multiple slices in the same acquisition, thus providing a 3D volumetric measure of the bone microarchitecture (Müller et al., 1994). The systems are self-enclosed with lead shielding to avoid stray radiation and are relatively simple to operate for image acquisition (Cheung et al., 2013). Numerous studies have demonstrated an association of microarchitecture with major osteoporotic fracture (Boutroy et al., 2008; Burt et al., 2018; Christen et al., 2013; Nishiyama et al., 2013; Sornay-Rendu et al., 2009; Stein et al., 2010; Vico et al., 2008; Vilayphiou et al., 2010, 2011).

The first-generation system allowed the acquisition of a 9 mm thick region of interest at the tibia or radius at an isotropic resolution of 82 μm in under 3 min with an effective radiation dose of less than 3 μSv. The second-generation system captures a 10 mm thick region at 61 μm voxel size in about 2 min with an effective dose of less than 5 μSv. For all HR-pQCT systems, the extremity is supported in a cast to minimize movement during image acquisition, and similar to micro-CT, a scout view is acquired so that the scanning region is precisely located (Fig. 79.9).

Following acquisition, analysis of the data is not very different from analysis of in vivo micro-CT systems because essentially it is the same type of data, albeit collected on a human instead of an animal. However, in the first-generation systems (Boutroy et al., 2005), which could achieve in vivo nominal isotropic resolutions of 82 μm, some standard morphometric parameters such as Tb.Th, Tb.Sp, and Tb.N were determined by derivations rather than by the direct analysis approaches typically applied for micro-CT. For example, BV/TV was derived by determining the BMD of the trabecular compartment and then dividing that by a density of 1200 mg HA/ccm (the assumed density of fully mineralized trabecular tissue). Although Tb.N was measured using the standard direct approach (Hildebrand and Rüegsegger, 1997a), Tb.Th and Tb.Sp were derived from the Tb.N and BV/TV measures in the trabecular compartment (Laib et al., 1998).

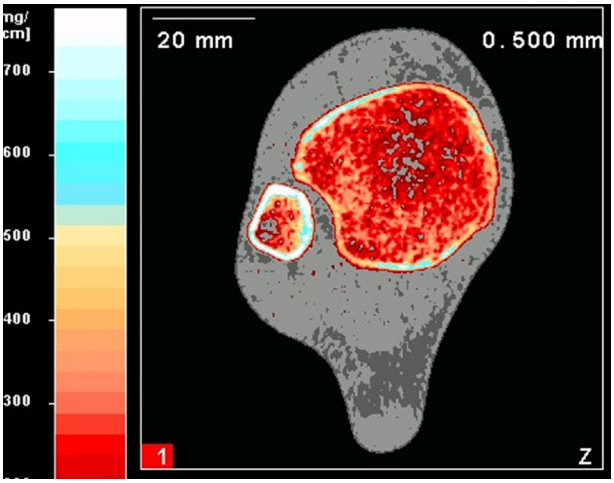

FIGURE 79.8 Sample image of the distal tibia showing variations of density of the tibia and fibula as well as the muscle and interstitial fat.

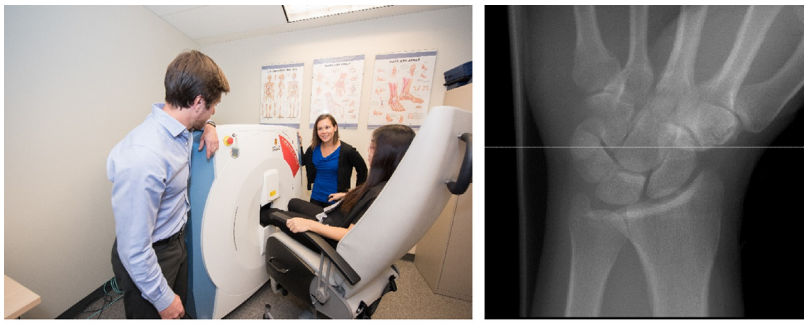

FIGURE 79.9 An HR-pQCT of the distal tibia is acquired with the leg supported in a cast to prevent movement. A scout view (right) is shown for a distal radius scan and is typically used to identify the scanning site.

Additionally, the cortical compartment was originally segmented using a relatively simple thresholding approach to determine its mask and measures of thickness and porosity, but that was later replaced by a more robust approach to identifying the cortical compartment based on a series of thresholding steps (Buie et al., 2007). Other morphological parameters such as Conn.D, SMI, and the different anisotropy measures are limited by the 82 μm voxel size. Even some standard measures, such as Tb.Th, do not appear to be accurately measured by the first-generation HR-pQCT (MacNeil and Boyd, 2007). On the other hand, advanced morphological decomposition has been validated for HR-pQCT systems (Liu et al., 2010a).

The development of the second-generation HR-pQCT system provides a higher resolution and slightly larger field of view, as previously noted. The accuracy of morphological measures by second-generation HR-pQCT is improved (Manske et al., 2015b), albeit with absolute values that are slightly altered due to the higher resolution. Therefore, significant work has attempted to establish the conversion between parameters measured on both generations so that the data generated on each system can be compared (Agarwal et al., 2016; Manske et al., 2017) and so that the field continues to move forward with improved ability to measure microarchitecture in vivo in humans.

Subject movement during scans is important to minimize, as it has a direct effect on the accuracy of microarchitecture measurements. Based on reproducibility studies, it has been shown that density measures such as total density, cortical density, and trabecular density can be measured with a precision of about 1%, whereas morphological measures such as Tb.N and cortical thickness are measured with a precision closer to 5% (MacNeil and Boyd, 2008b). Density measures are more precisely measured than morphological measures because they are less sensitive to movement artifact. Clearly, a human trabecula having a thickness of about 100 μm cannot be accurately measured if there is any small patient movement, especially given the relatively similar structure size to the imaging resolution. There are automated approaches to assessing patient movement during HR-pQCT scans (Pauchard et al., 2012) and even proposals for how the sinogram can be manipulated to "correct" for that motion (Pauchard and Boyd, 2008). However, the most frequently (and practically) used approach is to provide a subjective measure of the motion grade on a scale from 1 to 5 (lowest to highest motion artifact) and to perform a repeat scan if the subject is available for a second measurement attempt (Pialat et al., 2012).

Although the primary utilization of HR-pQCT is for the assessment of bone microarchitecture in the distal tibia and radius, there is increasing interest in learning about bone microarchitecture at other skeletal sites. For example, there is increasing interest in using HR-pQCT to understand the development and treatment of bony erosions that occur in rheumatoid arthritis (Barnabe et al., 2013), and with the larger gantry of the HR-pQCT system, the possibility to study microarchitecture in acutely injured knees (Kroker et al., 2017b).

Radiation dose

An important safety consideration for in vivo imaging is the X-ray dose delivered to the person, which is measured as effective radiation dose and reported as sieverts (Sv). This measure is a function of the amount of radiation emitted by the system, that absorbed by the body, and the sensitivity of the organs that receive radiation. The effective dose in DXA is low, with an estimated 5 μSv being reported for a total body exam (Scafoglieri et al., 2011) and less than 10 μSv for a spine or hip bone exam. An HR-pQCT system measurement at the wrist or ankle is typically less than 5 μSv, although it can be higher if a larger-than-normal region of interest is measured or for a different measurement site. For example, a scan of the knee covering about 6 cm in length results in about 50 μSv (Kroker et al., 2017b).

The X-ray dose of a pQCT system is very small, typically under 1 μSv. On the other hand, clinical exams using standard radiography and QCT can vary widely in effective X-ray dose depending on the site measured and imaging protocol used. For example, a spine X-ray with two views may result in over 400 μSv, and a QCT exam of the spine of a large patient can be as much as 10,000 μSv. These are all approximations, and the risk to the patient depends on many factors including how frequently they are scanned using X-ray methods. For reference, the average background radiation that a person in North America receives is approximately 3000 μSv, and the dose received on a transatlantic flight is roughly 60 μSv. Translating the effective dose into the risk of cancer mortality is approximated by International Commission on Radiological Protection guidelines (ICRP, 2007), which suggest 5% increased risk per Sv, which translates to approximately a 2.5×10^{-5}% increased risk of cancer per HR-pQCT.

Normative data

The 3D microarchitecture measured by HR-pQCT provides novel insight into the structure of bones, but without a reference cohort to compare those data against, it is difficult to interpret them. It is important to know the normal range of values for the morphological parameters measured by HR-pQCT as a function of sex, age, and ethnic background. In Canada, the Canadian Multicentre Osteoporosis Study (CaMos) (Tenenhouse et al., 2000) has been the basis to establish normative values of predominantly Caucasian men and women (Burt et al., 2016). Using these published data, it is possible for studies involving HR-pQCT to make conclusions about special populations, and this avoids the unnecessary and challenging task of establishing a control cohort for each study. This has been done, for example, in a recent study looking at bone microarchitecture in persons with hemophilia (Lee et al., 2015). Furthermore, while published data can be a rigorous way to share information about population variations, it can be much more practical to make those data available in a public domain, and this has been the basis of developing a web page (normative.ca) that provides an opportunity for scientists around the world to compare their patients' results with a normative population and even provide individual reports that can be shared with those patients. While the CaMos cohort provides important normative information, it is specific to the Canadian population. For this reason, other parts of the world have established normative data representing their own populations such as Hong Kong (Hung et al., 2015), the USA (Khosla et al., 2006), and Europe (Hansen et al., 2014). Furthermore, all these reference data are focused on adults, and there is a need to incorporate reference data for pediatrics as well (Gabel et al., 2017), although the challenge has been how to determine a standardized measurement site in growing children. Overall, reference data is an active and necessary area of research if HR-pQCT is ever to be used in a more clinical setting.

Fracture prediction

Microarchitectural information can provide insight into the progression of diseases or the effects of treatments; however, it is challenging to translate that knowledge into a predictor of fracture. Early attempts at linking microarchitecture to fracture prediction have focused on *prevalent* fractures. These studies are cross-sectional designs where the subjects recruited have suffered a fracture prior to study entry. While significant knowledge can be gained from these studies, their limitation is that by the time HR-pQCT scanning is performed, other factors (bedrest, changes in activity levels, etc.) may have influenced their microarchitecture. Subsequently, using *incident* fractures as a basis for study requires longitudinally following a cohort of people who have not yet suffered a fracture. Eventually, fractures will occur within the population, and from that information the linkage between fracture risk and microarchitectural features can be established and are not confounded by the same problems found in studies of prevalent fractures. The major challenge of studies with incident fractures is that larger populations must be included in the study, and it requires longitudinally monitoring the cohort—both of which result in increased costs and time.

Cross-sectional studies have identified key microarchitectural features in the radius and tibia that are most highly associated with fractures; typically these parameters include trabecular BMD, Tb.N, and total BMD (Boutroy et al., 2005; Melton et al., 2007; Sornay-Rendu et al., 2007; Vico et al., 2008). In addition to microarchitectural features, estimated bone strength from FE modeling has consistently been shown to be a good predictor of fracture (Boutroy et al., 2008; Kirmani et al., 2009; MacNeil and Boyd, 2008a; Nishiyama et al., 2013; Stein et al., 2010; Vilayphiou et al., 2010). The advantage of an FE approach to predicting fracture is that it intrinsically includes all microarchitectural features in a single outcome measure of bone strength, and based on this fact it would appear logical that bone strength would be related to fracture risk. Furthermore, it seems that despite the fact that measurements are taken at the radius and tibia, these sites are relevant to overall skeletal health (Kroker et al., 2017a; Liu et al., 2010b). Increasingly, studies with incident fractures are becoming available now that the technology has been accessible for over a decade and there has been time to follow longitudinal

cohorts. The microarchitectural features that seem most highly related to fractures are surprisingly consistent with earlier cross-sectional studies (Boutroy et al., 2016; Burt et al., 2017, 2018; Sornay-Rendu et al., 2017). Currently, the most ambitious project to date is close to completion, where groups from around the world have combined their prospective data to establish the parameters most highly associated with fracture risk (Samelson et al., 2019), and consistent with previous work, bone strength has been identified as an important outcome measure. These data, combined with the establishment of large normative databases, are paving the way for HR-pQCT to become a new and important contributor to the assessment of skeletal health and prediction of fracture in the future.

Summary

During the last 2 decades, bone microimaging based on high-resolution CT has become the method of choice for quantifying 3D bone microstructure and architecture in vitro. It is a nondestructive, noninvasive, and precise procedure allowing the measurement of trabecular and cortical bone as well as the computation of microstructural and micromechanical properties, both static and dynamic. It has demonstrated its effectiveness in evaluating many applications such as the characterization of genetic effects in different mouse models and in quantifying microarchitectural changes resulting from diseases such as osteoporosis, the effects of hormones and medications such as estrogen and bisphosphonates, and effects of bone adaptation, such as those due to mechanical loading. Recent studies have shown the great potential of time-lapse in vivo micro-CT for a better understanding of structural changes in bone geometry and bone microstructure as well as mechanical properties. These structural changes can be quantified using morphometric measures derived from the 3D data sets, and effects on bone competence can be estimated from micro-FE analyses. The ability to noninvasively track changes over time is likely to establish in vivo micro-CT as a standard methodology in the coming decade. The procedure might help improve predictions of fracture risk, clarify the pathophysiology of skeletal diseases, and define the response to therapy in both preclinical and clinical settings. We expect these findings to improve our understanding of the influence of densitometric, morphological, and also loading factors in the etiology of traumatic and spontaneous fractures of the forearm, hip, and spine as well as detection of longitudinal changes related to bone remodeling and adaptation in growth, aging, disease processes, and treatment effects.

Chapter outline

Introduction

In vivo imaging of bone in the context of osteoporosis primarily refers to radiographs for fracture assessment and dual-energy X-ray absorptiometry (DXA) and quantitative computed tomography (QCT) to quantify bone mineral density (BMD). For the clinician, radiographs and DXA are the main imaging techniques to support the diagnosis of osteoporosis, to assess the risk of osteoporotic fracture, and to monitor the effectiveness of intervention. Today about 50−100 patients with osteoporosis must be treated to prevent one fracture (Albert and Reddy, 2017), while about 50% of subjects who do fracture do not have osteoporosis as judged by DXA analysis using World Health Organization (WHO) criteria (Schuit et al., 2004; Siris et al., 2004).

Many different avenues have been pursued to improve fracture risk prediction and to better identify high-risk patients. One approach is the 3D quantification of trabecular architecture, initially imaged in samples of trabecular bone using micro-computed tomography (micro-CT). Nowadays trabecular architecture can be directly measured in vivo in the peripheral skeleton. In the spine and hip, in vivo CT- and DXA-based techniques are being explored to determine bone texture as a surrogate for bone microarchitecture because the spatial resolution achievable in the central skeleton is not adequate to separate individual trabeculae.

An exciting development is so-called opportunistic screening, which utilizes existing CT examinations obtained for various diagnostic purposes, such as routine abdominal or thorax examinations performed in every radiological department. These examinations may be used for detection of vertebral fractures and to quantify BMD either of the hip or of the spine. However, since these scans are not obtained using routine QCT protocols appropriate BMD calibration routines must be used.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00080-4

A different approach is the determination of bone strength by CT-based finite element analysis (FEA), a method originally developed to solve complex elasticity and structural analysis problems in civil and aeronautical engineering. With respect to bone strength FEA combines the distribution of BMD with the geometry of a given bone. Individual components contributing to bone strength, such as cortical thickness, moments of inertia, and other geometrical measures, can also directly be measured by CT or estimated from DXA scans. Of course, with CT cancellous (also referred to as trabecular) and cortical bone can be assessed separately.

More recently, advanced statistical methods in combination with progress in computational power have facilitated analytic approaches such as voxel-based and tensor-based morphometry methods, cortical thickness mapping, and statistical shape analysis. These approaches were originally developed to distinguish pathologic brain anatomy from the wide range of normal variations (Li et al., 2009; Toga and Thompson, 2002). Recent efforts have extended this approach to spinal radiography and CT examinations of the hip and spine, spatially heterogeneous skeletal sites with large subject-specific density and geometric variations.

Magnetic resonance imaging (MRI) has been used for imaging of trabecular architecture in the wrist and calcaneus in the past, but due to rather complicated scan protocols not routinely available on most magnetic resonance (MR) systems and long scan times, it has largely been replaced by high-resolution peripheral QCT (HR-pQCT). More recently, MRI has been used to quantify cortical water and to differentiate it into components of bound water, characterizing collagen content, and free water, characterizing cortical porosity. Another application is imaging of marrow fat content and composition, marrow perfusion, and marrow molecular diffusion (Griffith, 2017).

Another interesting development is imaging of muscle as a reflection of systemic disorders. The main application is in frailty, cachexia, and sarcopenia, but the paradigm of the bone−muscle unit has triggered expanding research into the relation of muscle properties and fractures. Of course it is of high interest whether parameters describing muscle and the distribution of muscle and adipose tissue in general can improve fracture risk prediction of BMD.

Radiography

Radiography is the most widely available, noninvasive technique of visualizing bone structure. The term osteopenia, "paucity of bone," is used to describe visually decreased bone density—or radiolucency—on radiographs. Thus, it also provides qualitative information on bone density. However, radiographs are rather insensitive to changes in BMD. In the spine, for example, it has been estimated that as much as 20%−40% of bone mass must be lost before a decrease in bone visual density can be seen in lateral spine radiographs. The decrease in density is primarily a result of a decrease in mineralized bone volume since in osteoporosis and osteopenia the amount of calcium per unit of mineralized bone volume remains constant at about 35%. Alone or in conjunction with other advanced imaging techniques, radiography is still widely used to diagnose osteoporotic fractures and to differentiate various disorders associated with osteoporosis and osteomalacia.

Changes in the axial skeleton and the ends of the long tubular bones are most prominent, since these sites have a relatively greater proportion of trabecular bone. Trabecular bone has more surface and responds more quickly than cortical bone. As bone mineral is lost, non-weight-bearing connecting trabeculae are resorbed first, leaving the remaining weight-bearing trabeculae more widely separated. Some may undergo compensatory thickening in the direction of mechanical stress. Trabecular anisotropy increases, resulting in distinct patterns on radiographs, such as the organized sequential trabecular changes along the compressive and tensile stress in the proximal femur and an appearance of vertical striation in the lumbar spine in the early stages of osteopenia caused by rarefaction of the horizontal trabeculae and a relative reinforcement of the vertical trabeculae (Fig. 80.1). At a later stage, vertebrae may appear on radiographs as a "picture frame" or as an "empty box" because of accentuation of the cortical margins surrounding the lucent trabecular center. Osteopenic vertebrae may also demonstrate increased bioconcavity of the vertebral end plates owing to protrusion of the intervertebral disk into the weakened vertebral body.

Vertebral fracture, the hallmark of osteoporosis, has a wide range of morphologic appearances, from increased concavity of the end plates, anterior wedging, to a complete destruction of the vertebral morphology in vertebral crush fractures (Fig. 80.2). Fractures can be graded by radiologists or experienced clinicians and quantified with morphometric methods to reduce the subjectivity inherent in grading (Genant et al., 1996; Wu et al., 2000). The Genant semiquantitative scoring method (Genant et al., 1993; Lentle et al., 2007) shown in Fig. 80.3 grades 0 for normal, 1 for mildly deformed (20%−25% reduction in anterior, middle, and/or posterior height, and 10%−20% reduction in the projected area of the vertebral body), 2 for moderately deformed (25%−40% reduction in height, and 20%−40% in area), and 3 for severely deformed (40% or greater reduction in height and in area). This method offers high reproducibility (Wu et al., 2000). It has been widely used to evaluate fracture end points in most epidemiological and clinical studies investigating the efficacy of osteoporotic drugs (Black et al., 2007; Boonen et al., 2011; Ettinger et al., 1999; Genant et al., 2005; Grados et al., 2004).

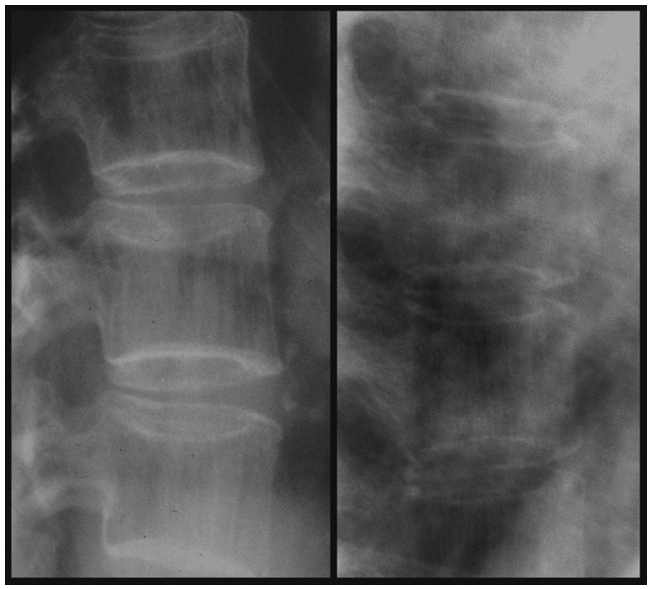

FIGURE 80.1 (Left) Increased vertical striation due to the proportionally greater loss of horizontal trabeculae and compensatory hypertrophy of the vertical trabeculae. (Right) Severe osteoporosis: the vertebrae can hardly be distinguished on the lateral lumbar spine radiograph. There are multiple end-plate and compression fractures.

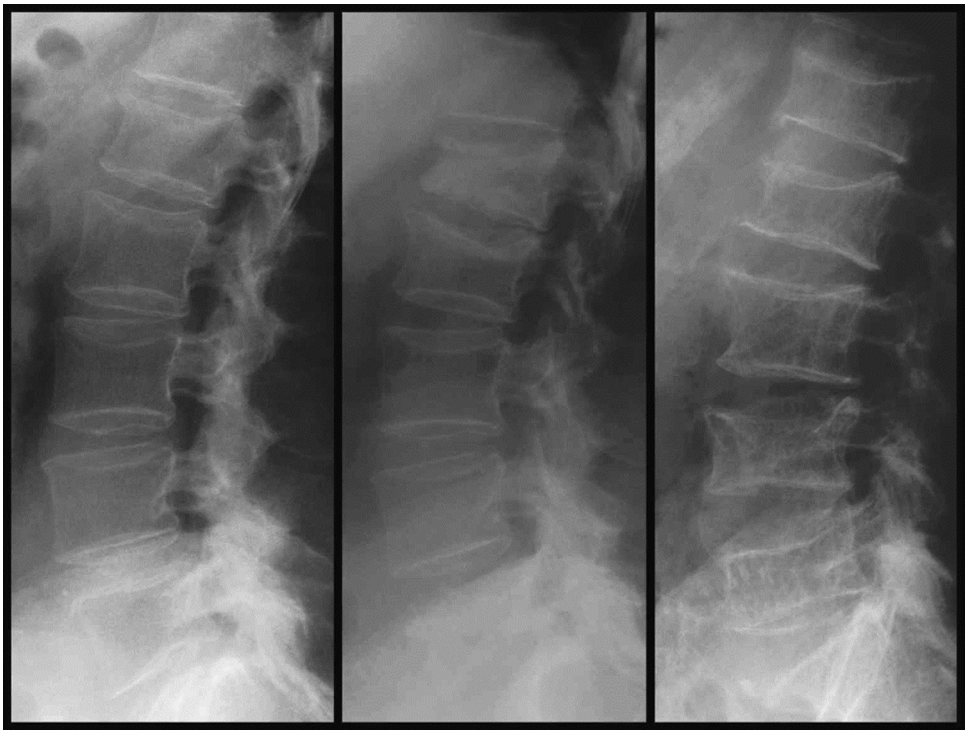

FIGURE 80.2 Multiple fractures in the thoracic spine in advanced involutional osteoporosis, including (left) end-plate, (middle) wedge, and (right) compression fractures.

Of most concern in osteoporosis are fractures of the hips, spine, and wrists. Changes in the bone cortex or spongiosa may make such injuries more likely to occur. Fractures of the vertebral bodies are a result of predominantly axial compressive loads. One reason for the decreased load-bearing capacity is the increased absorption and removal of the horizontal trabeculae or lateral support cross-ties (Mosekilde et al., 1985). The vertical trabecular bone, therefore, behaves as a column and is prone to critical buckling loads (Townsend et al., 1975). A 50% decrease in cross-sectional area (CSA)

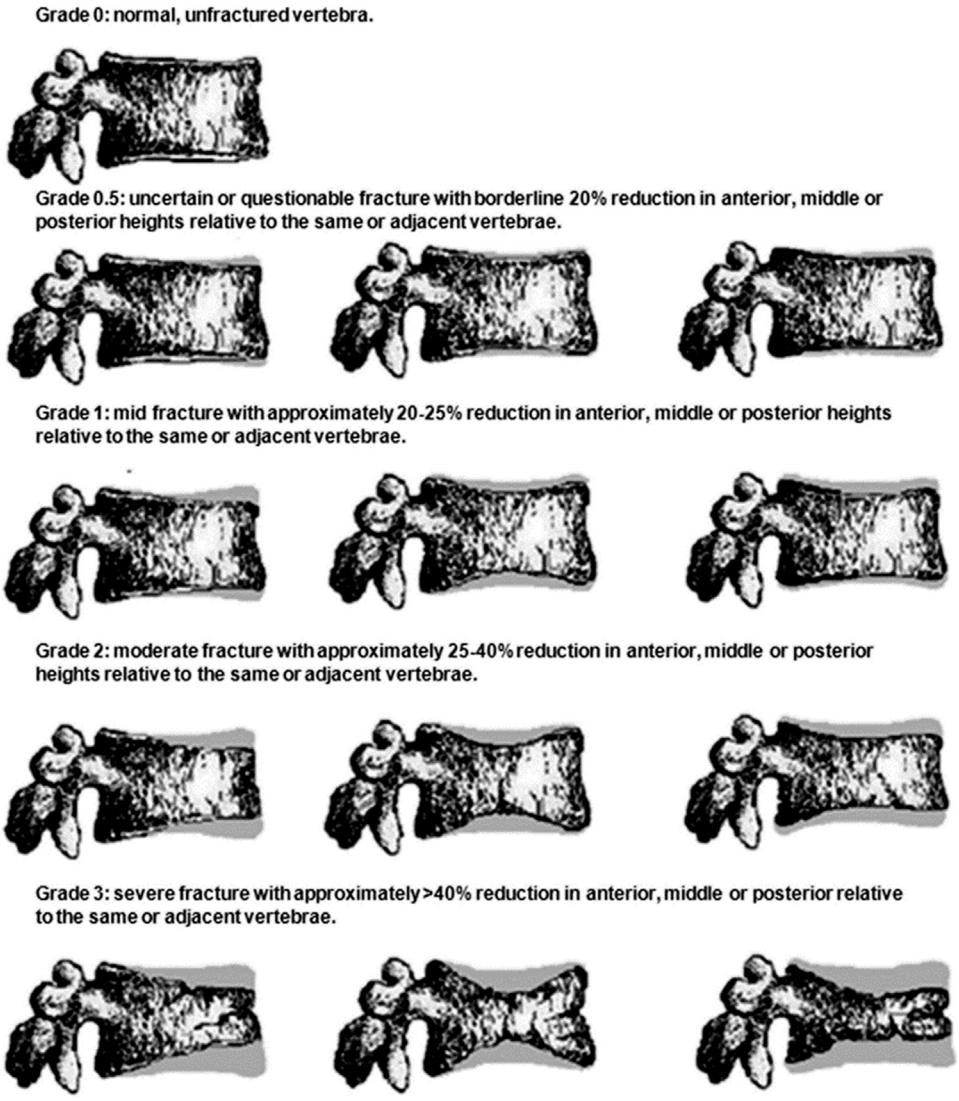

FIGURE 80.3 The Genant grading method for a semiquantitative evaluation of osteoporotic vertebral fracture grades: fracture severity from normal (grade 0) to severe deformity (grade 3). The scoring scheme illustrates reductions in the anterior height that correspond to the grade of deformity. Reductions in the middle or posterior heights or combinations thereof can be evaluated accordingly.

as a result of absorption of the horizontal trabeculae is associated with a 75% decrease in the load-bearing capacity of the vertebral body (Einhorn, 1992).

In the hip and forearm, radiographs are typically used to diagnose a fracture. Quantitative grading has not gained much attention, although in the hip the Singh index has been developed to grade differences in the trabecular pattern (Singh et al., 1973). The trabecular compartment is of interest because osteoporotic fractures of the hip and the forearm typically occur in trabecular-rich locations: at the neck and trochanter region of the hip and at the ultradistal site of the radius, whereas osteoporotic fractures are much less frequent in the shaft, where bone strength depends only on compact bone (Smith and Smith, 1976).

Standard DXA

DXA technique

DXA is the most widely used technique to determine areal BMD (aBMD) of the central (spine and hip, Fig. 80.4) and peripheral (forearm) skeleton. Further routine applications include whole-body measurements to assess aBMD and soft-

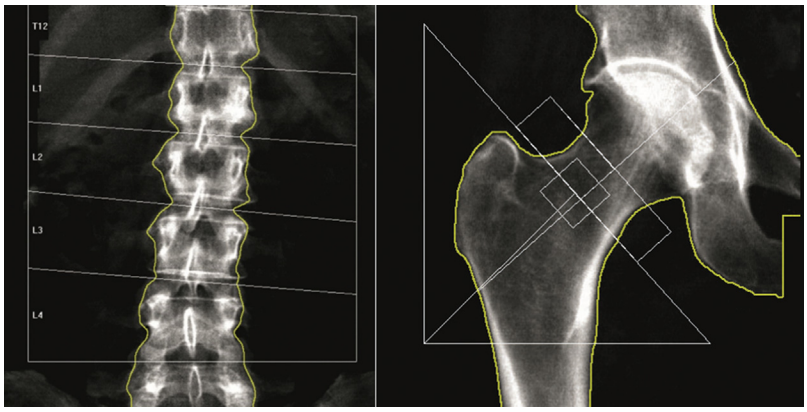

FIGURE 80.4 Dual-energy X-ray absorptiometry. (Left) Spine scan. (Right) Hip scan.

tissue composition of various body segments as well as vertebral fracture assessment (VFA) of the spine. DXA has emerged as the gold standard for the diagnosis of osteoporosis, fracture risk assessment, and monitoring of age-, disease-, and treatment-related changes in aBMD. DXA has been used in all major epidemiological studies on fracture risk and in almost all clinical trials to monitor the longitudinal effectiveness of pharmacological treatment of osteoporosis. Other reasons that made DXA a success were low precision errors; early commercialization, which provided wide accessibility to DXA equipment; ease of use; standardization across DXA manufacturers; and the availability of reference data from a large variety of different populations. The basic DXA technology has not changed significantly since 2009, and most technical reviews were published some years ago (Blake and Fogelman, 1997; Kalender et al., 2009). Recommendations on the clinical use of DXA are periodically updated by the International Society for Clinical Densitometry (ISCD) and other national and international organizations (Verdijk et al., 2009; Crabtree et al., 2014; Camacho et al., 2016).

DXA is a projection technique to determine aBMD in grams per square centimeter. aBMD is measured in a segmented area termed the region of interest (ROI). Bone mineral content (BMC) is then derived as aBMD × area. The projection approach is associated with a number of technical limitations. The bone dimension perpendicular to the projected area, i.e., the true bone volume, is not considered. This complicates, for example, longitudinal BMD monitoring in children because of bone growth (Adams et al., 2014). A larger problem in elderly subjects is degenerative and hypertrophic changes in the spine, which typically result in an overestimation of vertebral aBMD (Rand et al., 1997). In the hip, differences in the rotation of the leg relative to the scanner table have an impact on aBMD and dedicated positioning devices ensuring constant leg rotation should be used (Rosenthall, 2004; Goh et al., 1995). Frequently the acetabulum overlaps with the proximal neck; thus in DXA only a small neck box positioned either in the center of the neck or adjacent to the greater trochanter is analyzed as the neck ROI.

Experienced DXA operators achieve short-term in vivo precision errors of about 1%−1.5% in the spine and 1.5%−2% in the hip. Long-term errors are 30%−50% higher (Fan et al., 2008; Tothill and Hannan, 2007). In individual patients longitudinal changes are significant if they are larger than the least significant change defined as 2.7 × precision error. Based on in situ measurements and on simulations, accuracy errors of up to 30% have been reported (Hagiwara et al., 1994; Sabin et al., 1995; Bolotin, 2001). Accuracy errors arise from the heterogeneous distribution of adipose tissue external to bone and variations in marrow, obesity, beam hardening, scatter (Kalender et al., 2009), and potentially intake of strontium ranelate (Blake and Fogelman, 2007). Accuracy errors primarily affect the diagnosis of osteoporosis. In longitudinal measurements they are of concern if long-term precision is affected by changes in inaccuracy between measurements of a given patient. One example of such an effect is severe weight change in obese patients after bariatric surgery (Ko et al., 2016; Yu et al., 2014; Rajamanohara et al., 2011).

aBMD figures obtained from DXA scanners of different manufacturers are highly correlated, but differences in BMD calibration materials cause a bias of up to 10% in aBMD. Standardization efforts have suggested using a standardized aBMD (sBMD) to correct this bias (Genant et al., 1994; Shepherd et al., 2002), but in clinical practice the use of T scores and standardized reference data has replaced sBMD. T scores express an aBMD result in terms of standard deviations (STD) relative to aBMD of a young normal (YN) reference population:

$$\text{T score} = \frac{\text{aBMD} - \text{aBMD}_{\text{YN}}}{\text{STD}_{\text{YN}}}$$

For the hip, the use of the NHANES III reference data (Looker et al., 1997) is suggested. DXA T scores are also the basis for the operational WHO definition of osteoporosis (WHO, 1994). T scores of the hip are used in the FRAX algorithm (http://www.shef.ac.uk/FRAX) for calculation of fracture risk (Kanis et al., 2009; Lewiecki et al., 2011). There are no universal reference data for spine or forearm DXA, typically manufacturer-specific reference values are used. The use of T scores and reference data decreases the clinical impact of aBMD accuracy errors because any constant bias is eliminated. The remaining accuracy errors will increase the standard deviation of the normal population, thus lowering the T score (Blake and Fogelman, 2008). Accuracy errors of a given aBMD measurement that largely differ from those inherent in the reference population will affect the diagnosis of an individual patient. There is a vast body of literature on discordance between spine and hip T scores and on the use of gender-, ethnic-, and country-specific reference data, but a more detailed discussion is beyond the scope of this chapter.

Fracture prediction using areal bone mineral density

One of the important clinical advantages of DXA compared with other types of bone density measurements is that its ability to identify patients at risk of fracture has been assessed and proven in a large number of epidemiological studies (Johnell et al., 2005; Stone et al., 2003; Marshall et al., 1996). The Marshall meta-analysis (Marshall et al., 1996), which included women only, was based on more than 2000 osteoporotic fractures from 90,000 person-years of follow-up. Different BMD measurement sites showed similar abilities to predict fractures (relative risk [RR] 1.5; 95% confidence interval [CI] 1.4−1.6), with the exception of hip BMD predicting hip fractures (RR 2.6; CI 2.0−3.5) and spine BMD predicting vertebral fractures (RR 2.3; CI 1.9−2.8). The authors concluded that hip and spine BMD values were the best measurements for predicting hip and spine fractures, respectively. The Johnell meta-analysis (Johnell et al., 2005) included both men and women and was based on 971 hip fractures from 168,000 person-years of follow-up from 12 different fracture studies from Australia, Canada, Europe, and Japan. There was no significant difference in hip fracture risk between men and women (women: RR 2.2; CI 2.0−2.4; men: RR 2.3; CI 1.8−2.9). The RR decreased progressively with increasing age, varying from an RR of 3.7 (CI 2.6−5.2) at age 50 to an RR of 1.9 (CI 1.8−2.1) at age 85. A 2017 study showed that hip aBMD was a persistent long-term predictor of hip (relative hazard per standard deviation (RH/SD) 2.6; CI 2.2−3.0 for 0−5 years, to RH/SD 1.8; CI 1.4−2.4 for 20−25 years) and nonvertebral fracture (Black et al., 2017). Of course in clinical practice, BMD is combined with other factors for a comprehensive fracture risk assessment (Johansson et al., 2009; Krege et al., 2013; Siris et al., 2007; Robbins et al., 2005).

Monitoring osteoporosis treatment with DXA

Measurement of aBMD was part of almost all clinical trials investigating the efficacy of osteoporosis treatments. Interestingly, the relationship between gains in aBMD and reduction in fracture risk is still a topic of investigation (Cummings et al., 2002; Delmas et al., 2004; Hochberg et al., 2002). In particular for antiresorptive drugs, small aBMD increases of below 10% are associated with a 50% or even higher reduction of vertebral fractures. At the study level, the relationship appears to be robust. However, for the individual patient, aBMD seems not to be a strong predictor of effects of osteoporosis treatment on fracture risk, questioning the utility of serial BMD measurements to assess treatment efficacy (Compston, 2009). In contrast, a more recent study reported that on a patient level, the change in total hip BMD explained 35% (CI 20%−61%) of the treatment effect with denosumab in reducing new or worsening vertebral fracture risk and 87% (CI 35%−100%) in reducing nonvertebral fracture risk (Austin et al., 2012).

Vertebral fracture assessment

VFA is a special DXA analysis to detect spinal fractures from a lateral image of the spine. The main advantage of VFA compared with radiography is the much lower radiation exposure and the possibility of adding a quick VFA scan after a standard aBMD assessment. The main disadvantage is the lower spatial resolution of VFA. In the absence of scoliosis, VFA compared favorably with standard spine radiography for diagnosis of moderate and severe vertebral fractures. In women over the age of 65 years, a sensitivity of 87%−93% and a specificity of 93%−95% was reported (Schousboe and Debold, 2006), but sensitivity dropped significantly for mild vertebral fractures. Also visualization of vertebral levels T4−T7 is often poor (Rea et al., 2000). Thus VFA does not replace radiography but its integration into the workflow for diagnosis of osteoporosis would help to detect many fractures that remain unnoticed otherwise (Zeytinoglu et al., 2017). This is important as in particular moderate or severe vertebral fractures present a high risk factor for the risk of future fractures (Black et al., 1999).

Computed tomography

CT is an X-ray-based technique that generates a cross-sectional image of so-called CT values, measured in Hounsfield units (HU), i.e., a map of the X-ray absorption coefficient calibrated to water. QCT denotes the specific method to quantify BMD on CT images, which requires a second calibration from CT to BMD values (Kalender et al., 2009; Genant et al., 1982). Since the early development of QCT to measure trabecular BMD in single transverse CT slices at the lumbar midvertebral levels and the distal forearm, proponents of QCT have always claimed its superiority over DXA. A true measurement of physical density in grams per square centimeter must be better than the measurement of aBMD in grams per square centimeter. Also, trabecular and cortical bone compartments can be separately assessed by QCT.

Standard quantitative computed tomography to assess bone mineral density

aBMD of the spine and hip are strong predictors of future fracture risk but still not strong enough to predict whether an individual patient will eventually fracture. aBMD is a surrogate parameter and its assessment does not differentiate pathophysiological causes for low BMD. In addition, aBMD has limitations to characterizing bone status under treatment. Since the late 1990s, one important focus of the technical development of QCT and of advanced techniques based on QCT such as FEA was the compensation for DXA deficiencies.

Volumetric QCT of the spine and hip (Fig. 80.5) is now an established technique widely used in research studies and clinical trials and also increasingly in clinical routine with precision errors comparable to DXA (Engelke et al., 2009; Lang et al., 1997; Museyko et al., 2016). Early single-slice peripheral QCT (pQCT) of the forearm or tibia is now mostly restricted to use in children (Adams et al., 2014). Table 80.1 summarizes recommendations of the ISCD on the clinical use

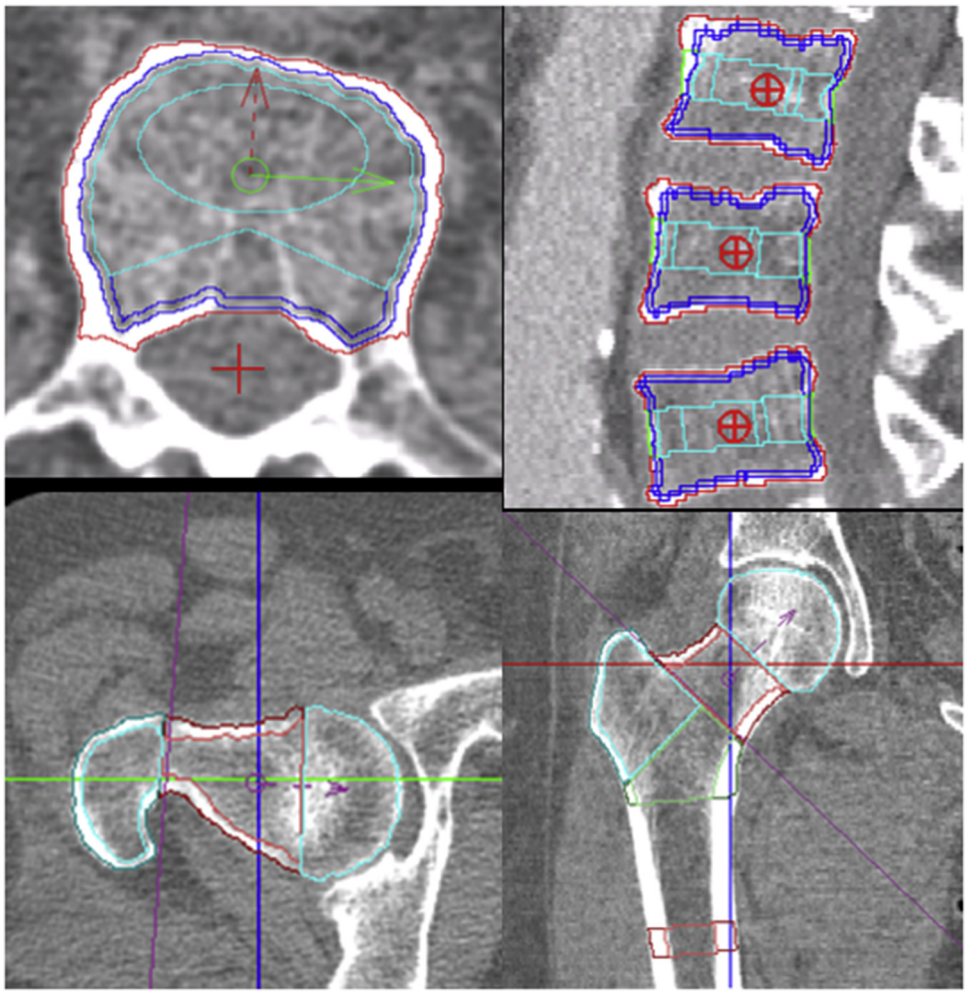

FIGURE 80.5 Advanced 3D quantitative computed tomography at spine and hip (slice thickness 1 mm, in-plane resolution 300 μm) to analyze regional bone mineral density and geometry such as cortical thickness. Left axial, right coronal multi-planar reformations of 3D data sets.

[a]*Predicts hip fracture, no position for radius fracture.*

[b]*There was insufficient evidence at the time (2007) when International Society of Clinical Densitometry positions for quantitative computed tomography of the spine were issued; however, there is now plenty of evidence that integral BMD of the spine can be used for monitoring. Note: in men, there are fewer studies and several of the positions that are supported for women are not supported for men because of missing evidence.*

of QCT of the spine and hip (Engelke et al., 2008, 2015a; Zysset et al., 2015). As can be seen from the table, QCT BMD assessments of the hip and spine cannot be used for a diagnosis of osteoporosis because the exclusive applicability of the WHO diagnostic classification to DXA is inherent to the definition. T scores define an age-independent threshold that depends on the mean BMD and standard deviation of the young normals of the DXA reference population. It is an intrinsic deficiency of the WHO definition that it cannot be adapted to other densitometric techniques, as standard deviation and age-related decline are different from those of DXA.

The only exception is CTXA (CT X-ray absorptiometry) of the hip, a technique to simulate DXA using projectional data from 3D CT images to estimate aBMD. US FDA−approved implementations of CTXA are available for QCT Pro from Mindways Software, Inc. (Austin, TX) (Cann et al., 2014), and for VirtuOst from O.N. Diagnostics (Berkeley, CA) (Weber et al., 2014). A projectional option is also available in the UCSF QCT hip software developed by Lang (Lang et al., 2012). CTXA DXA equivalent T scores (Khoo et al., 2009) and aBMD for the femoral neck have been integrated into FRAX, which calculates 10-year fracture probability (World Health Organization Collaborating Center for Metabolic Bone Diseases, 2015).

According to Table 80.1 QCT BMD assessments of the spine and hip can be used for fracture prediction. Overall evidence on fracture prediction is still limited; in many studies the number of fractures is often low, resulting in large CIs and hiding potential significance. Existing data suggest that QCT BMD measured in vivo at the hip does not predict hip fracture risk better than hip aDXA (Engelke et al., 2015a). In the spine an analysis of the prospective AGES−Reykjavik study indicated a significantly better fracture prediction using QCT BMD of the spine compared with spinal aBMD but after adjustment for aBMD, QCT BMD did not remain significant in a multivariate analysis although relative hazards were only slightly decreased by the adjustment (Wang et al., 2012). The area under the curve (AUC) value for integral BMD of 0.83 was significantly higher than for aBMD (0.67).

Compared with DXA the interpretation of longitudinal changes of trabecular and cortical BMD measured by QCT needs special attention because absolute values of trabecular BMD are much lower than those of cortical and integral BMD. As a consequence, percentage changes typically used to report age-, disease-, or treatment-related BMD changes may be rather high for trabecular BMD. For example, in the hip with mostly fatty marrow, trabecular BMD values below 20 mg/cm^3 are frequently encountered. At this level, even a small change of, for example, 5 mg/cm^3 results in a 25% change. However, the same absolute change amounts to just 5% if trabecular volumetric BMD (vBMD) is 100 mg/cm^3, a typical value for osteopenic subjects in the lumbar spine. Thus, a percentage change of trabecular vBMD has to be interpreted also in the context of the absolute value. The use of absolute vBMD or even BMC also provides additional insights into the differential actions of pharmaceutical treatment on cortical and trabecular bone. For example, in studies with denosumab (Genant et al., 2013) and cathepsin-K inhibitors (Engelke et al., 2014, 2015b) in which this analysis was used, absolute cortical vBMD increases were higher than absolute trabecular vBMD increases and more than 60% of the newly formed bone was deposited in cortical and subcortical compartments.

Components of bone quality

Apart from the straightforward assessment of BMD, QCT opens many avenues to assess components of bone quality, defined broadly as all geometric, microarchitectural, and material factors (e.g., trabecular architecture, collagen cross-linking, mineralization, microcracks, …) (Donnelly, 2011). Not all of them can be measured in vivo but specific HR-pQCT using dedicated scanners has been developed to quantify trabecular architecture. High-resolution CT (HR-CT) has also been applied to the spine to characterize trabecular architecture of the vertebrae. Three-dimensional geometry can be quantified from standard QCT images of the spine, hip, and forearm.

FEA is a computer-based simulation of the strains and stresses induced by mechanical loading of an object and is widely used in engineering. The object is described as a connected set of simply shaped elements, which are ascribed elastic properties. FEA is based on QCT acquisitions. Currently, the elastic properties of each voxel are derived from the corresponding BMD values. FEA potentially integrates density and geometry and accounts for regional variations better than the separation of a bone into subvolumes. It is primarily promoted to calculate an integral parameter of bone strength, which is easy to explain in clinical practice: if bone strength is too low for a given external load the bone will fracture. Mechanical experiments in which bones are loaded until they fracture have indeed shown that bone strength of the hip or vertebrae as determined by FEA is a better predictor of failure load than corresponding DXA or QCT measurements of BMD or content (Cody et al., 1999; Dall'Ara et al., 2012; Danielson et al., 2012; Pottecher et al., 2016). However, similar to QCT, in vivo FEA showed significantly better fracture prediction than DXA only at the spine and not at the hip (Wang et al., 2012; Imai et al., 2009).

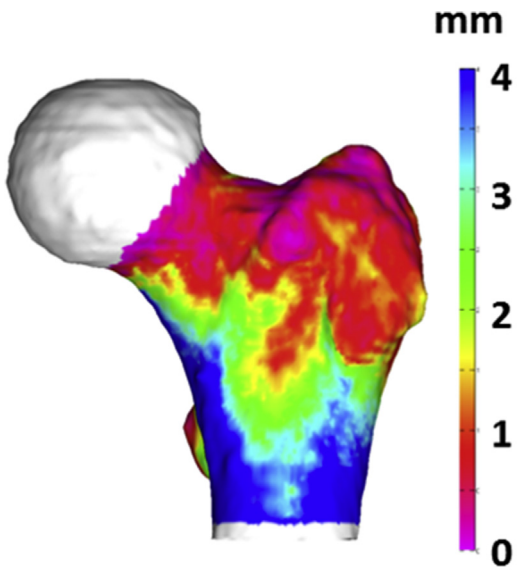

FIGURE 80.6 Cortical thickness map: proximal femur right. *Courtesy: Julio Carballido-Gamio, UCSF.*

Interestingly, at the hip, several QCT studies found a BMD-independent contribution of cortical geometry to fracture risk (Museyko et al., 2016; Bousson et al., 2011; Chappard et al., 2010; Cheng et al., 2007; Yang et al., 2014a, 2017; Borggrefe et al., 2016). These findings have triggered further research into a more comprehensive characterization of cortical and subcortical bone compartments as discussed in the next section. Although a multivariate analysis of BMD, cortical thickness, and strength has not been published as of this writing, the added effort of FEA may not be required after combining BMD and cortical geometry. At the spine, vertebral compressive strength has been estimated as a linear combination of integral BMD and CSA, two parameters that also can easily be determined from QCT alone (Bouxsein et al., 2006; Bruno et al., 2014). Of course, in clinical practice it is intriguing to use only bone strength as a single parameter, as the combination of BMD and geometry is more difficult to understand.

With FEA, the distribution under load can be calculated, which may give important insights into the fracture process and fracture load patterns (Faisal and Luo, 2017; Haider et al., 2018; Bessho et al., 2004). Methods of statistical parameter mapping can be used to compare an individual stress pattern with that of an average subject represented mathematically by a so-called atlas. This procedure eliminates residual anatomic variability so that a given spatial coordinate in one scan is mapped to the anatomically homologous coordinate in the scans comprising the atlas. Statistical tests are then usually performed on a voxel-by-voxel basis generating statistical maps to identify regions where the feature of interest is significantly related with the effect or outcome of interest. Typical features have been cortical thickness (Poole et al., 2012, 2015) and BMD (Li et al., 2009; Carballido-Gamio et al., 2013a, 2013b; Bredbenner et al., 2014).

Results are often displayed as a feature map, for example, as a colored surface of an average femur indicating the local cortical thickness variation in a group of subjects under treatment (Fig. 80.6). The interpretation is challenging and the clinical utility of these methods still has to be established (Engelke et al., 2015c), but in combination with machine learning techniques, these methods could be able to delineate feature variations in relation to specific clinical end points such as fracture (Poole et al., 2017), and to interventions such as medication or exercise regimes. These methods also allow for an integration of the various parameters that can be obtained from QCT data (Carballido-Gamio et al., 2015). One critical issue is the generation of a representative atlas, which usually requires a large number of data sets to capture the population variance.

Cortical bone

The separate assessment of cortical bone, a key feature of QCT, is important not only because of the independent contribution to strength and fracture risk (Reeve, 2017; Tang et al., 2018; Johannesdottir et al., 2011), but also to better understand age-related changes of bone geometry and density (Nicks et al., 2013; Carpenter et al., 2011) and to explore differential effects of pharmaceutical drugs used to treat osteoporotic patients (Fitzpatrick et al., 2012; Langdahl et al., 2017).

State of the art spiral CT offers almost isotropic spatial resolution of about 0.5 mm when using high-resolution acquisition and reconstruction protocols, but for standard QCT a slice thickness of 1 or 1.25 mm and medium sharp reconstruction kernels are used to limit noise or to allow for lower dose protocols. Thus, in particular in the femoral neck and the vertebral body where cortical thicknesses of 200−500 μm are frequently encountered in elderly people, the measurement of cortical parameters is impaired by partial volume artifacts, causing an overestimation of cortical thickness and an underestimation of cortical BMD (Dougherty and Newman, 1999; Newman et al., 1998). An additional difficulty is the definition of the endosteal border because of a more or less continuous transition from the cortical to the trabecular compartment characterized by increasing porosity transitioning to trabecular architecture (Zebaze et al., 2010).

Measurements of cortical thickness and BMD differ among QCT analysis programs because fundamentally different segmentation approaches are used. This is confusing for the user unfamiliar with image processing details. The software program VirtuOst simply defines a 3 (2)-mm outer shell in the hip (spine) in separating finite elelment based strength measurements in cortical and trabecular compartments, but does not report cortical BMD or thickness. The MIAF software from the University of Erlangen uses locally adaptive 50% thresholds, which theoretically is the best approach as long as the cortex is thick enough (1−3 mm for current CT equipment and scan protocols) (Prevrhal et al., 1999). The Stradwin software from the University of Cambridge implements a deconvolution algorithm reversing the blurring effects. Cortical thickness is more accurate compared with the other methods but this technique requires input of BMD of the unblurred cortex, a so-called reference BMD. This can be determined in locations with a thick cortex, largely unaffected by blurring (Treece et al., 2010). Further refinements have been reported to determine the reference BMD closer to the location of the cortical measurement (Treece and Gee, 2015; Treece et al., 2012). A hybrid approach combining deconvolution for thin cortices with 50% local thresholds for thicker cortices has been developed for MIAF (Museyko et al., 2017). Fig. 80.7 compares the standard 50% local threshold used in MIAF with the new hybrid segmentation using a deconvolution for thin cortices.

A comparison of the MIAF (Genant et al., 2013) and Stradwin softwares (Poole et al., 2015) to assess changes in cortical parameters after 3-year treatment with denosumb versus placebo suggests the use of cortical BMC for longitudinal measurements. Stradwin's deconvolution-based method resulted in higher changes in cortical thickness but lower changes in cortical BMD than MIAF's standard local 50% thresholds. However, increases in cortical BMC, which balance the overestimation of cortical thickness and the underestimation of cortical BMD, were similar and may prove more useful in longitudinal studies. Obviously, the use of BMC in cross-sectional studies is more problematic as people with larger bones by definition have higher BMC.

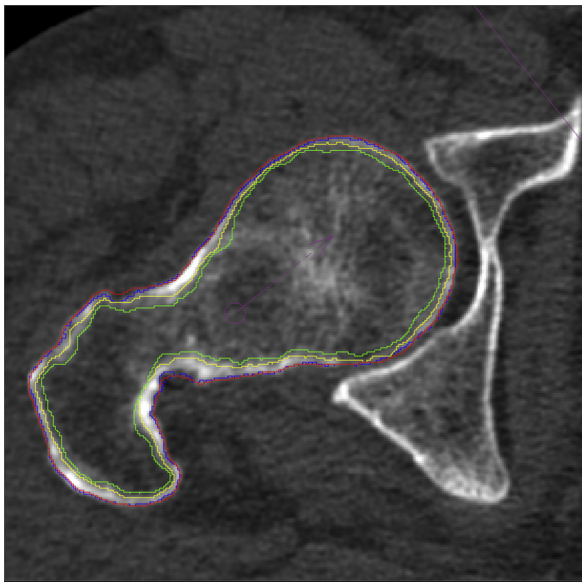

FIGURE 80.7 Effects of different cortical segmentations in the hip: periosteal (*red*, 50% local thresholds - outermost contour; *blue*, deconvolution technique - contour almost identical to 50% local threshold contour) and endosteal (*green*, 50% local thresholds - innermost contour; *yellow - between blue and green contour*, deconvolution technique) surfaces of the cortex (Engelke, 2017).

High-resolution computed tomography

The primary aim of high-resolution tomography is the assessment of trabecular structure and increasingly of cortical porosity. The accuracy of cortical thickness measurements also increases with higher spatial resolution. In the past many attempts have been reported to determine trabecular architecture with clinical whole-body CT scanners also used for standard QCT measurements. With appropriate acquisition and tomographic reconstruction protocols, an almost isotropic spatial resolution of approximately 0.5 mm can be obtained in the axial skeleton. Dedicated single-slice pQCT scanners have improved in-plane resolution by about a factor of 2−3 but use slice thicknesses of 1−2 mm. However, given typical dimensions of trabeculae (100−400 μm) and trabecular spaces (200−2000 μm) this resolution is still insufficient for an accurate determination of standard stereological parameters.

This is illustrated in Fig. 80.8, where HR-CT images were simulated from a stack of 21 sagittal grindings (thickness 5 μm) of a trabecular network from a human calcaneus. The thickness of each grinding was 5 μm and the distance between two adjacent grindings was 51 μm. A stack of binary images with isotropic voxels $(12\ \mu m)^3$ was obtained from the digitized grindings. The images of the stack were averaged along the direction indicated in Fig. 80.8. The first row of simulated images shows two radiographic-type images. The one on the left resulted from averaging half the stack and the one on the right from averaging all images of the stack. Thus a total slice thickness of 0.51 mm and of 1.02 mm was simulated, respectively. The in-plane pixel area in these radiographic type images is unchanged at $12 \times 12\ \mu m^2$. There are still artificial discontinuities in the gray value variations. They would be avoided by averaging more images. The second and third rows show simulated hrCT images with pixel sizes of 100 and 200 μm. The images were blurred with a Gaussian filter to give a more realistic impression of what can be expected in vivo.

The simulations demonstrate that in HR-CT images only the dominant structures are preserved, details of the trabecular network cannot be extracted. The textures in the CT-like and in the radiographic-like images are similar and a major deterioration of the network will be noticeable in the HR-CT images. However, a determination of parameters typically used in histomorphometry is problematic. It is evident that parameters like Tb.Th, Tb.Sp, or Tb.N change drastically and artifactually. To indicate that structural parameters measured in HR-CT and HR-MR images differ significantly from those

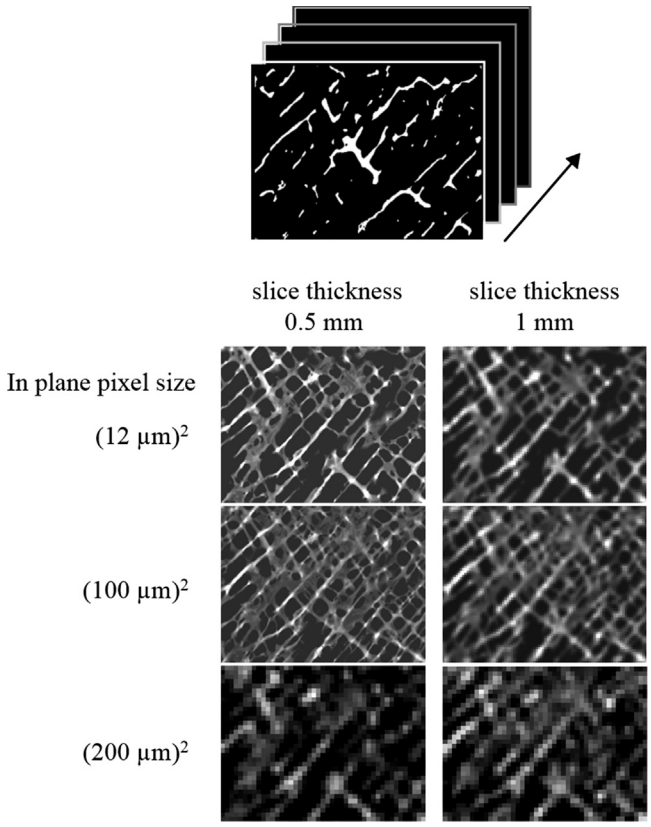

FIGURE 80.8 Effects of slice thickness and in-plane pixel size on trabecular structure. Simulation of radiographic and high-resolution computed tomography (HR-CT) images based on a stack of stained grindings. Stack of grindings (top). Simulated radiographic and hrCT images (bottom).

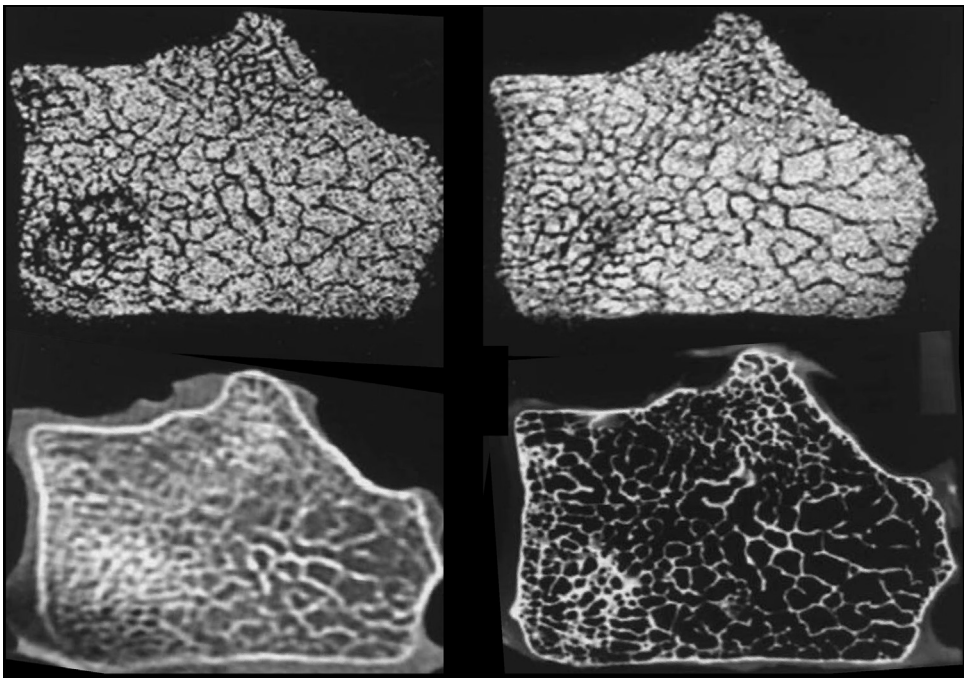

FIGURE 80.9 Comparison of trabecular structure a calcaneus specimen imaged with high-resolution magnetic resonance imaging (HR-MRI), high-resolution computed tomography (HR-CT), and microradiography. (Top) 3D HR-MRI spin echo sequence, in-plane pixel size 150 μm, slice thickness 300 μm (left) and 900 μm (right). (Bottom) Left, HR-CT plane pixel size 250 μm, slice thickness 1000; right, contact radiograph of a 1-mm-thick section cut from the calcaneus, slice of plane pixel size 5 μm (Link et al., 2003).

measured by microscopic histomorphometry of thin section it is recommended to call them apparent trabecular thickness, etc., and to use the prefix "app," such as appTb.Th, appTb.Sp, or appTb.N.

A number of cadaver and specimen studies have explored potentials and limitations of using whole-body spiral CT scanners for high-resolution imaging of trabecular structure of the calcaneus and the lumber vertebral bodies (Fig. 80.9). However, only a few in vivo studies have been published more recently (Grados et al., 2004; Graeff et al., 2013; Ito, 2005; Link and Bauer, 2002). Similar to techniques of high-resolution radiography, HR-CT of the spine and calcaneus has not been widely used in clinical practice. Potentially advanced analysis techniques using texture parameters (Milovanovic et al., 2014; Wolfram et al., 2009; Checefsky et al., 2016; Baum et al., 2010) that do not require the segmentation of individual trabeculae may stimulate further progress in this field.

HR-pQCT

For high-resolution in vivo scanning at the forearm and tibia the XtremeCT (Scanco Medical, Brüttisellen, Switzerland) has been introduced (Boutroy et al., 2005). The first version of this device provides an isotropic voxel size of 82 μm^3 resulting in a spatial resolution of about 120 μm (Burghardt et al., 2013; Fig. 80.10). The trabecular dimensions of the forearm and tibia are similar to those of the spine, but due to the much smaller cross section compared with the central body, the spatial resolution can be increased without a radiation dose penalty. In contrast, as the forearm tissue is less radiation sensitive than that of the spine, the effective dose per scan is below 10 μSv.

As suggested by Laib (Laib and Ruegsegger, 1999), histomorphometric parameters are determined from a measurement of bone volume fraction (BV/TV) and apparent trabecular number (Tb.N). BV/TV is obtained from the BMD of the trabecular compartment by assuming a density of 1200 mg/cm^3 for fully mineralized bone. Tb.N is directly measured using ridge extraction methods. A critical step in the analysis of follow-up scans is the registration of baseline and follow-up scans with an accuracy error that should be lower than 100 μm. Thus during the scans even slight motion of the forearm must be avoided, which is not an easy task given a scan time of 3 min. Motion causes artifacts in the reconstructed images.

Most information on HR-pQCT scanner technology (Burghardt et al., 2011; Nishiyama and Shane, 2013) is available for the first-generation device. The second-generation XtremeCT II provides higher spatial resolution using a voxel size of 61 μm^3 and a reduced scan time of 2 min. The higher spatial resolution allows for a direct quantification of trabecular

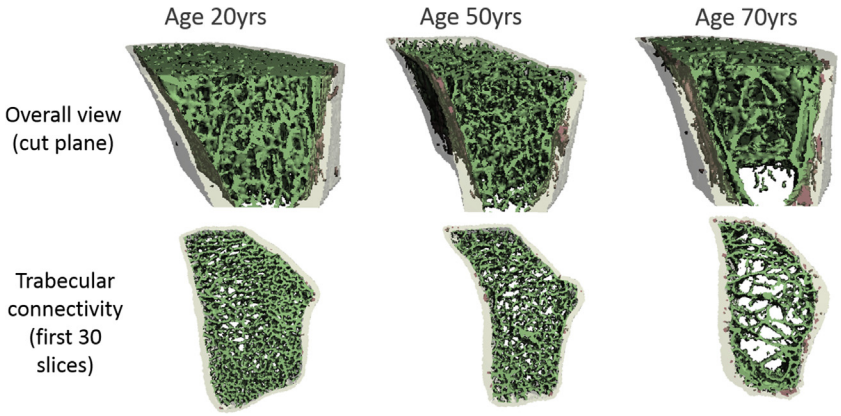

FIGURE 80.10 Characteristic age-related changes in trabecular bone of the distal radius imaged by HR-pQCT (82 × 82 × 82 μm).

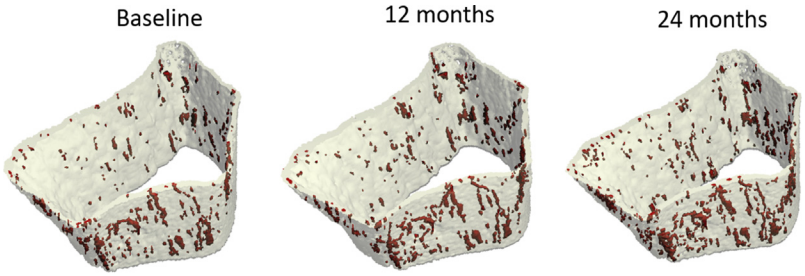

FIGURE 80.11 Cortical porosity of the distal radius imaged by high-resolution peripheral quantitative computed tomography (82 × 82 × 82 μm). A 2-year follow-up of a 58-year-old menopausal woman is shown. Notice the increase cortical porosity at the palmar side.

structure independent of trabecular BMD (Manske et al., 2015). Both XtremeCT versions apply 2D slice by slice−based area matching between baseline and follow-up scans. A full 3D registration reduces motion artifacts and improves precision but expands the time required for image processing (Ellouz et al., 2014).

The resolution of HR-pQCT is high enough to directly detect larger cortical pores (Fig. 80.11). The quantification of cortical porosity has received considerable attention as an increase in number and size of pores is largely responsible for the decrease in cortical BMD as long as mineralization is stable. Porosity (p) increases with age (Bousson et al., 2001) and is increased in diabetes type 2 (Paccou et al., 2016; Patsch et al., 2013a). However, so far it is not known whether porosity-related parameters such as the pore size distribution themselves carry clinical information not obtainable from easier to measure parameters such as cortical BMD. It has been argued that differences in bone tissue mineralization do not account for elastic properties (Zebaze et al., 2011), which are an essential input to FEA, but the combination of porosity and mineralization is reflected by cortical BMD.

Two different approaches exist to quantify cortical porosity in HR-pQCT data. With the software implemented by the manufacturer, pores are segmented directly using a threshold of 450 mg/cm^3 (Jorgenson et al., 2015). Smaller pores are missed and porosity is underestimated. The second technique is based on cortical BMD. It assumes that the density of fully mineralized bone is 1200 mg/cm^3; that within 20% of this upper limit, i.e., for voxels with cortical BMD larger than 960 mg/cm^3, cortical bone may be slightly less mineralized but that no pores exist, i.e., $p = 0$; and that for voxels with cortical BMD below 960 mg/cm^3 $p = (1 - \text{BMD}/1200) \times 100$ (Jorgenson et al., 2015). Compared with synchrotron radiation (SR)−based micro-CT measurements, the density approach overestimates porosity. However, results from the direct segmentation and the density-based technique were highly correlated with SR results ($r^2 > 0.94$) (Jorgenson et al., 2015).

HR-pQCT is predominantly used as a research tool because the number of deployed scanners is still below 100 worldwide, since the equipment is far more expensive than DXA systems. A review of clinical imaging of bone microarchitecture with HR-pQCT was published in 2014 (Nishiyama and Shane, 2013). More recent clinical in vivo studies examined differences between fractured and nonfractured subjects (Zhu et al., 2016; Sornay-Rendu et al., 2017; Macdonald et al., 2018; Sundh et al., 2017; Boutroy et al., 2016), collected normative data (Gabel et al., 2018; Alvarenga et al., 2017; Burt et al., 2014), or reported on monitoring age-related changes (Vilayphiou et al., 2016; Burt et al., 2017) or the

effects of osteoporosis drugs on cortical and trabecular bone microstructure (Lespessailles et al., 2016; Lima et al., 2018; Tsai et al., 2017). Quite a number of further studies focused on technical details or explored changes in trabecular architecture and porosity in specific diseases or differences between populations.

Opportunistic screening

In the field of osteoporosis the term "opportunistic screening" refers to the use of existing clinical CT images for the diagnosis of osteoporosis and prediction of fracture risk. If widely implemented, opportunistic screening could significantly improve the identification of patients at high risk for fracture. First ideas were published as early as 2000 (Hopper et al., 2000) and reviewed more recently (Engelke et al., 2015c; Gausden et al., 2017). The major challenges of opportunistic screening are missing a calibration phantom, lack of standardization of CT scanners with respect to BMD measurements, large variation of CT acquisition parameters affecting BMD measurements such as tube voltage and table height, and the use of contrast agents in many routine CT examinations. The simultaneous calibration typically used in QCT can be replaced by an asynchronous calibration, as modern CT scanners are rather stable over time (Pickhardt et al., 2015). DXA scanners from Lunar also use an asynchronous BMD calibration. A step further facilitating the clinical workflow is an internal calibration based on the absorption of air, of internal organs, and of the aorta. Good agreement between simultaneous and a scanner-specific internal calibration has been reported but exact details of the method were not published (Lee et al., 2017).

Many authors advocate the direct use of HU values (Gausden et al., 2017), arguing that clinical CT scanners are regularly calibrated to air and water. However, this calibration ensures only that CT values of water equivalent materials, i.e., to a first approximation of soft tissues, are comparable across scanners and are also independent of the specific tube voltage. Because X-ray mass absorption coefficients of bone and water are very different, this is not the case for bone (Kalender et al., 2009). As a consequence, HU values for trabecular and cortical bone may vary widely between different CT scanners. Any HU thresholds reported in the literature for opportunistic screening may be valid only for the specific scanner and tube voltage used for the study. They should not be generalized automatically. The same is true for correction factors that have been applied to account for elevated BMD caused by X-ray contrast (Baum et al., 2011). Here additional difficulties apply, such as the amount of contrast and the timing of the CT scan after contrast injection (Emohare et al., 2014; Pickhardt et al., 2016).

Prior to the widespread introduction of opportunistic screening into clinical routine, a thorough standardization is required. If the accuracy error of a BMD measurement is high, a secondary analysis of CT data obtained for tumor and other routine clinical diagnoses could be used to categorize fracture risk as low, medium, or high. It has been suggested that subjects with high fracture risk could be followed up with DXA or could be directly referred to counseling on appropriate intervention even without an additional DXA scan. Both scenarios are convenient and cost effective because DXA scans and associated logistics are not required. An additional benefit of the dual use of CT scans is the possibility of using a lateral scout view or a sagittal reconstruction of the spinal column to assess fractures.

DXA beyond bone mineral density

Several advanced analyses such as trabecular bone score (TBS), hip structure analysis, FEA, and 3D DXA have been introduced to obtain information from DXA scans beyond BMD. Most of these techniques are implemented in a fashion so that large data sets can be analyzed automatically. As so much DXA data are available, the techniques can be rapidly validated.

Trabecular bone score

Some of the underlying ideas for the TBS analysis were originally developed for the texture analysis of high-resolution X-ray films (Pothuaud et al., 2000, 2001). TBS is a specific texture analysis applied to DXA images. It is based on the gray level variogram. When applied to trabecular samples, TBS reflects bone microarchitecture (Hans et al., 2011; Pothuaud et al., 2008). In vivo the relation may be less obvious because of soft tissue, spinal, and transverse processes, and degenerative changes alter the texture of the pure trabecular bone. Nevertheless, a recent meta-analysis (Harvey et al., 2015) impressively demonstrated the potential of TBS. Low TBS is associated with an increase in prevalent and incident fractures partly independent of clinical risk factors and of aBMD at the lumbar spine and proximal femur. According to the ISCD positions "TBS can be used in association with FRAX and aBMD to adjust FRAX-probability of fracture in

postmenopausal women and older men" but "is not useful for monitoring bisphosphonate treatment in postmenopausal women with osteoporosis" (Silva et al., 2015).

Hip geometry, hip structure analysis, and finite element analysis

Several investigations have found that projectional measurements of parameters describing femur geometry can predict hip fractures independent of BMD. One prominent example is the hip axis length (HAL) determined from conventional radiographs or DXA. It predicts hip fracture, as a longer HAL is associated with an increase in femoral neck and trochanteric fracture risk (Faulkner et al., 1994; Glüer et al., 1994). Instead of varying with age after midadolescence, the HAL seems to be mainly influenced by genetic factors (Flicker et al., 1996), which supports other reports that differences in the HAL may partially explain racial differences in hip fractures (Cummings et al., 1994).

A more comprehensive approach to estimate geometrical and mechanical properties from DXA of the hip is hip structural or hip strength analysis (HSA), which was first applied to cross-sectional bone mineral absorption curves generated by single-photon absorptiometry at the forearm (Martin and Burr, 1984). This early work was extended to DXA data at the proximal femur to automatically estimate cross-sectional moments of inertia (CSMI) and CSAs of the neck, the trochanter, and the shaft, as well as the femoral neck shaft angle, bending moments, and HAL (Beck et al., 1990).

For HSA 1D profiles are extracted from narrow regions across the neck, the intertrochanter, and the shaft by averaging pixel values perpendicular to the profile directions (Fig. 80.12). For each pixel along the profile, aBMD is obtained from the DXA measurement, and BMC is determined using the known pixel dimensions. The BMC distribution along the profile is used to calculate p_c, the position of its center of mass. Under the assumption that the specific axis through p_c, which is perpendicular to the plane of the DXA image, is also the main bending axis, the CSMI of the cross section defined by the profile can (apart from a multiplicative constant) be accurately calculated from the DXA images by:

$$\mathrm{CSMI} = \frac{1}{\mathrm{BMD}_{\mathrm{cort}}} \sum_i \mathrm{BMC}_i [\Delta(p_c - i)]^2$$

$\mathrm{BMD}_{\mathrm{cort}}$ is the areal density of cortical bone, and a value of 1.051 g/cm^2 is assumed. Δ denotes the length of a profile pixel.

A comprehensive review of the clinical utility of HSA and of parameters describing hip geometry was published in the 2015 official positions of the ISCD (Broy et al., 2015). According to these recommendations none of the parameters should be used for fracture prediction, with the exception of HAL, which predicted hip fractures independent of BMD in multiple studies of postmenopausal women. There was also good evidence that HSA structural parameters predicted hip fracture in postmenopausal women, but not independent of BMD, questioning their clinical relevance. None of the parameters should

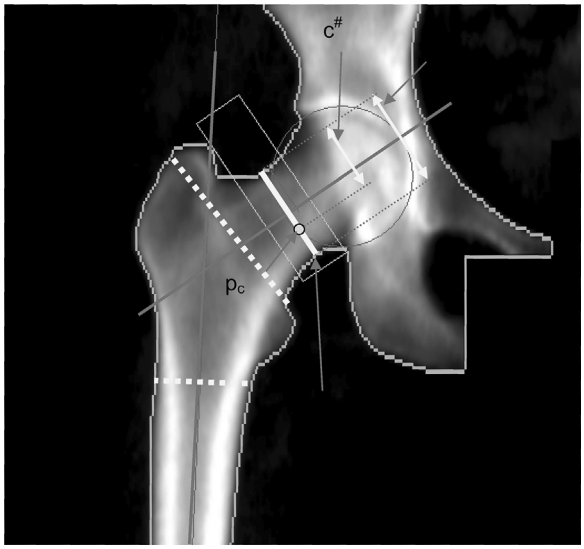

FIGURE 80.12 Hip strength analysis: p_c, center of mass of cross section; $C^{\#}$, defined by hip strength analysis (see text). In hip structure analysis, cross-sectional moment of inertia (CSMI) is estimated along the three yellow profiles; in hip strength analysis CSMI is estimated only along the solid profile (arrow).

be used for monitoring intervention, because either the expected changes were less than the least significant change of the measurement or there were no expected changes as for HAL and neck shaft angle. Thus, the main value of these parameters is their use in dedicated research studies.

A further extension of the structural analysis of DXA is its direct use for FEA. Early results showed surprisingly good agreement to strain-gauge measurements and to a 3D finite element model (Testi et al., 1999). More recent publications showed significant hip fracture discrimination of femoral strength and load-to-strength ratio determined from DXA even after adjustment for standard DXA aBMD of the neck (Naylor et al., 2013). A post hoc analysis of the Study of Osteoporotic Fractures in postmenopausal females showed a prediction of incident hip fracture by femoral strength after adjustment for age, body mass index (BMI), and DXA neck aBMD with a hazard ratio of 1.71 (Yang et al., 2014b). However, in males from the Osteoporotic Fractures in Men (MrOS) study the results were less convincing (Yang et al., 2017). In the large Manitoba registry study increased hip fracture risk was significantly associated (OR = 1.36) with lower femoral strength after adjusting for FRAX hip fracture (Yang et al., 2018). So far, fracture prediction or discrimination with FEA has not been compared between QCT and DXA data in the same study.

Three-dimensional DXA

Three-dimensional DXA is a technique to simulate a 3D data set from a projectional 2D DXA scan. Initially it was termed VXA (Ahmad et al., 2010) and based on five projections of the hip obtained with a C-arm scanner under different angles. These projections were fitted to a statistical 3D atlas of the femur generated from volumetric CT data of 100 subjects. It was shown that 95% of the individual anatomical variations from the atlas could be described by 10–20 different parameters (Whitmarsh et al., 2011), the so-called eigenvectors, suggesting that a limited number of 2D projections suffice to obtain accurate 3D geometrical and densitometric information of the femur. The result is a simulated QCT image.

Newer implementations now known as 3D DXA are based on a single projection, the standard DXA images, and can therefore also be implemented on DXA scanners without a C-arm. Nowadays, one direction of the development of 3D DXA seems to be the differentiation of cortical and trabecular compartments. A recent cross-sectional study in 157 subjects demonstrated the potential of the method: correlations between QCT and 3D DXA were 0.95 for total hip cortical density and 0.91 for total hip cortical thickness with mean absolute differences of 72 mg/cm^3 or 7.6% and 0.33 mm or 18.3% for density and thickness, respectively (Whitmarsh et al., 2011). The 3D DXA images still looked somewhat blurred (Fig. 80.13). CT scans were obtained on two different scanners, one of them using a soft tissue reconstruction kernel that would also generate a blurred cortex in the QCT images.

Magnetic resonance imaging

Hydrogen is the most abundant atom in the body. MRI imparts a very short burst of energy via the MR radio-frequency (RF) coil, which is placed near to the body part being examined. The freely mobile hydrogen atoms, mainly in the form of water or fat, take up this energy momentarily but hydrogen atoms in fat release the energy faster than hydrogen atoms in water. This differential energy release forms the basis of MRI, which essentially differentiates all tissues in the body into those composed of fat or water. MRI looks at the concentration of free hydrogen atoms and determines whether these are contained in fat or water. Trabecular and cortical bone contain very little fat or water and appear dark with no emitted signal (hypointense) on MR images. MR depicts trabecular bone as a negative image by virtue of its signal void contrasting against the strong signal generated by the marrow fat and water in the adjacent marrow tissue. Marrow fat increases with increasing age and particularly in osteoporotic bone, allowing better contrast differentiation between fatty marrow and trabecular bone than between red marrow and trabecular bone.

Trabecular structure

Bone trabecular macrostructure has been studied mainly in the distal radius and the calcaneus, as these are bone areas close to the skin surface. This close proximity to the RF coil allows a high signal-to-noise ratio (SNR) to be generated. For good contrast of bone structure imaging by MRI a minimal SNR of 10 is recommended (Chang et al., 2017). The SNR can be increased by scanning at higher field strength, using multichannel coils with individual smaller coil dimensions and using SNR-efficient pulse sequences (Chang et al., 2017). Both spin-echo (Magland et al., 2006) and gradient-echo sequences (Majumdar et al., 1995) have been used to image trabecular structure but HR-pQCT has largely replaced MRI for this purpose.

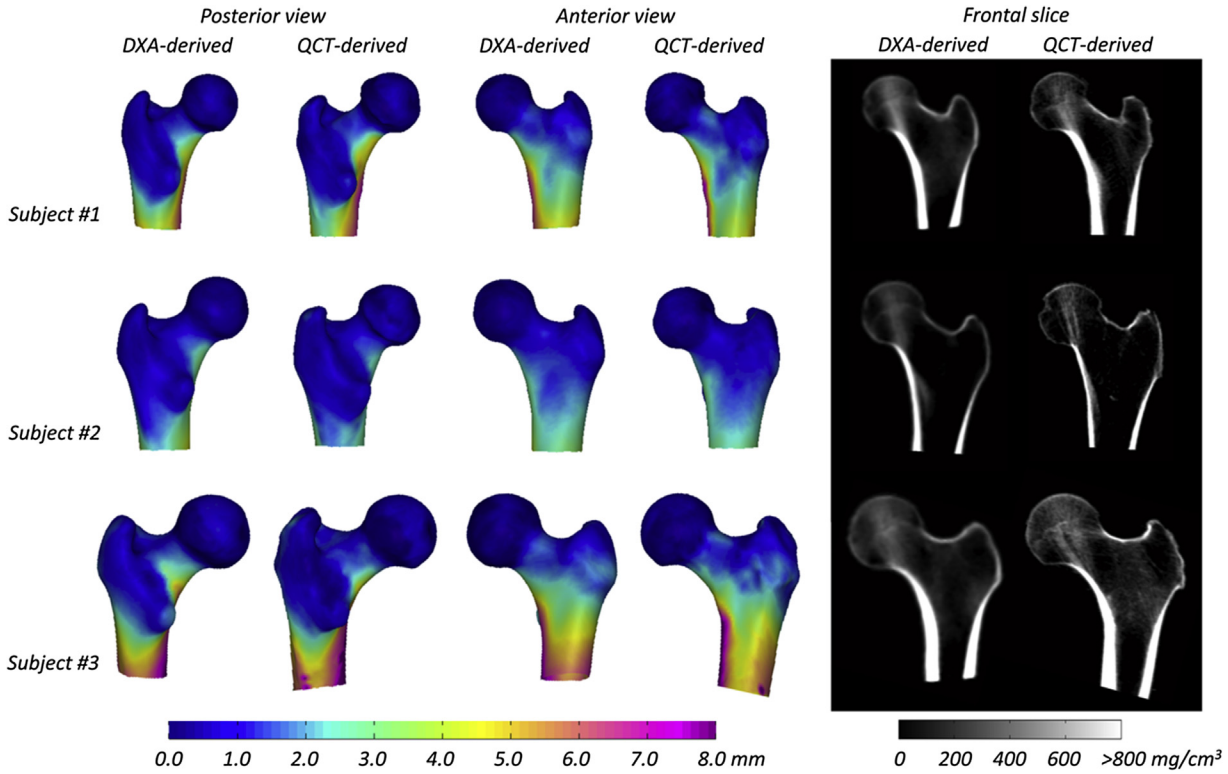

FIGURE 80.13 Comparison between dual-energy X-ray absorptiometry (*DXA*)- and quantitative computed tomography (*QCT*)-derived femoral shapes: cortical thickness distributions (left) and frontal slices showing bone density values (right). *Courtesy: Ludovic Humbert, Galgo Medical, Barcelona, Spain; Reproduced from Humbert, L., Martelli, Y., Fonolla, R., Steghofer, M., Di Gregorio, S., Malouf, J., et al. 2017. 3D-DXA: assessing the femoral shape, the trabecular macrostructure and the cortex in 3D from DXA images. IEEE Trans. Med. Imaging 36(1), 27–39; IEEE copyright line © 2017 IEEE.*

Fast 3D spin-echo approaches are less sensitive to local T2* differences between bone and bone marrow. Overestimation of trabecular size is more pronounced on gradient echo images (Boutry et al., 2004), especially when the echo time (TE) is increased, as this leads to local magnetic field inhomogeneities at the trabecular to marrow interface. These inhomogeneities lead to a signal void and hence artifactual broadening of the trabeculae. This "ballooning effect" can be used to advantage to enhance the visibility of trabecular bone structure. Gradient echo sequences provide higher signal-to-noise characteristics allowing for shorter scan times, important for in vivo imaging (Majumdar et al., 1995). Scanning at higher field strength such as at 3T and 7T allows one to reduce the voxel size and scan time and investigate more proximal sites such as the biologically relevant femoral neck.

Cortical water

An advantage of MRI over traditional imaging techniques such as DXA and CT is its specific ability to investigate cortical water content. The collagen matrix and water contribute significantly to bone strength and account for about half of the cortical bone volume. Cortical bone contains free water within cortical pores (cortical pore water; CPW), which also includes the water residing within haversian canals and the lacunar–canalicular system lacunae and collagen-bound water (CBW), which is water bound to collagen within the bone matrix. CPW has a T2 relaxation time of >1 ms, while that of CBW is 0.3–0.4 ms; thus collagen-bound water essentially emits no signal using standard MR pulse sequences. This limitation can be overcome by using ultrashort TE (UTE) sequences, with nominal TEs of less than 100 μs. Studies have mainly used the anterior tibial cortex and, to a lesser extent, the distal radius and proximal femur, as these areas possess relatively thick cortical bone. Using a water phantom, one of the earliest UTE cortical bone studies performed on a clinical 3T MRI scanner, and looking at new water content of cortical bone, showed that renal osteodystrophy patients had a 43% higher cortical bone water content than postmenopausal subjects and a 135% higher bone water content than premenopausal subjects (Techawiboonwong et al., 2008).

It is advantageous to distinguish between CPW and CBW signals as cortical bone strength increases with higher concentrations of bound water but decreases with higher concentrations of free water. With recently developed variations of the UTE technique such as antibiotic inversion recovery (Manhard et al., 2015), radial cones trajectory (Chen et al., 2016), or a suppression ratio technique (Li et al., 2016), CPW and CBW components of cortical water can be distinguished. Bound water is an indirect marker of collagen matrix content, while pore water is an indirect measure of porosity. Cortical bone specimens with more bound water tend to have higher peak and yield stress values and elastic toughness, while cortical bone specimens with a greater concentration of pore water generally tend to have higher porosity and lower peak stress, yield stress, and toughness (Manhard et al., 2015). In 40 healthy women, the mean free water concentration and bound water concentration were 5.9% and 19.6%, respectively, with cortical bone free water concentration showing a strong positive correlation ($r^2 = 0.62$) with age (Abbasi-Rad and Saligheh Rad, 2017).

Bone marrow

MRI also provides information on marrow fat content and composition, marrow perfusion, and marrow molecular diffusion (Griffith, 2017). Marrow fat content can be measured using either MR spectroscopy or fat–water separation techniques such as IDEAL imaging. MR spectroscopy provides information on marrow fat composition as well as content but can examine only a limited area of about 1 cm^3 at any one time (Fig. 80.14). Fat–water separation techniques can examine much larger areas but do not provide information on fat composition.

Lifelong studies addressing physiological changes in marrow fat content show a gradual physiological increase in percentage marrow fat content with advancing years (Duda et al., 1995; Kugel et al., 2001). As a rule of thumb vertebral body marrow fat content increases from 25% at 25 years of age to 65% at 65 years (Montazel et al., 2003; Patsch et al., 2013b; Yeung et al., 2005; Fig. 80.15). In addition, there is a distinct sex difference in marrow fat content (Kugel et al., 2001; Griffith et al., 2012). From the time of skeletal maturation to extreme old age, males show a gradual increase in lumbar vertebral marrow fat content of 7% per life decade (Kugel et al., 2001; Griffith et al., 2012). In contrast, females show a less steep increase in marrow fat of about 5% per decade up to 55 years and a dramatic increase in marrow fat content between the ages of 55 and 65 years (Kugel et al., 2001; Griffith et al., 2012), corresponding to the known reduction in bone mass that occurs at that time (Fig. 80.16).

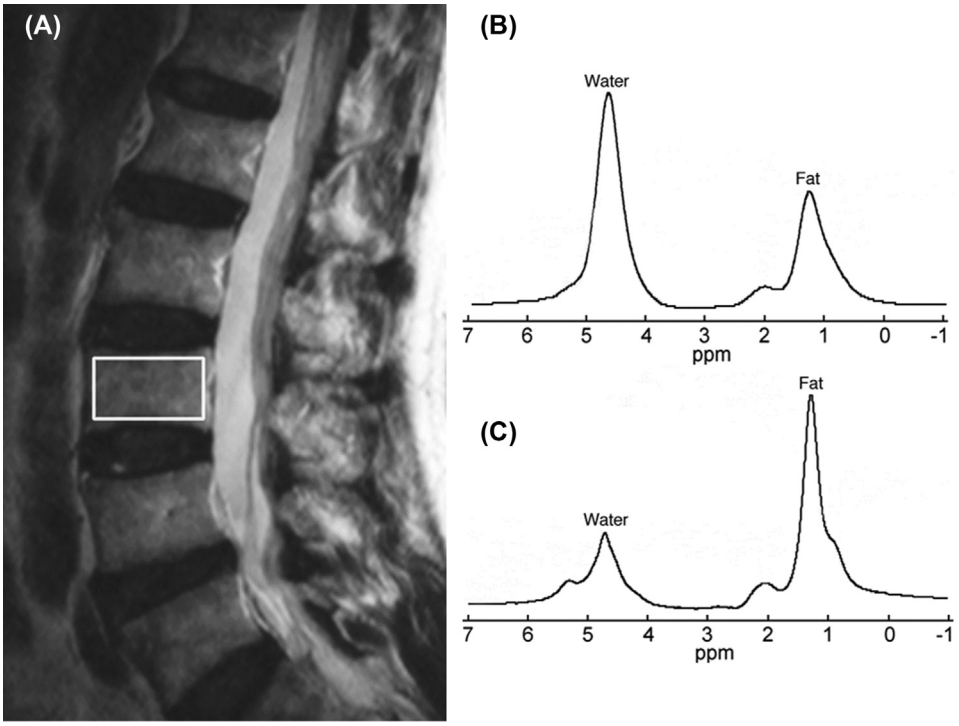

FIGURE 80.14 ^{1}H MR spectroscopy examination. (A) Sagittal T2-weighted MR image showing positioning of volume of interest (white rectangle) for proton spectroscopy of L3 vertebral body. (B) Typical ^{1}H MR spectra in a normal subject with little marrow fat and (C) an osteoporotic subject with a large amount of marrow fat.

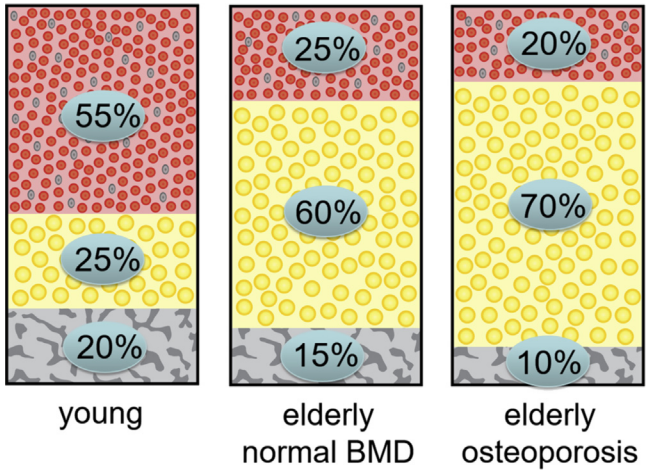

FIGURE 80.15 Distribution of trabecular bone, fatty marrow, and red marrow. For young subjects in the confined space of the bone marrow, there is about 20% trabecular bone, 25% fatty marrow, and 55% red marrow (dark gray in print version). With aging, the amount of trabecular bone and red marrow decreases, while the amount of fatty marrow increases. *BMD*, bone mineral density.

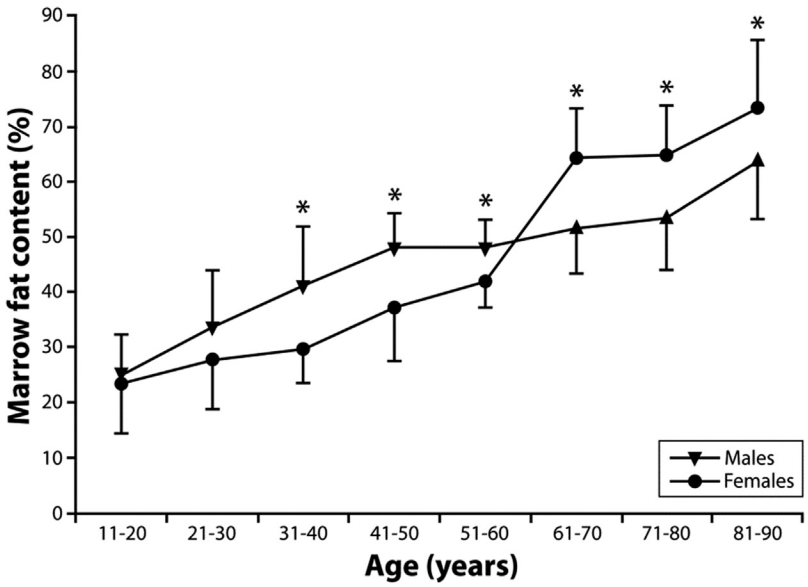

FIGURE 80.16 Marrow fat content (%) of lumbar vertebral body stratified for age and sex. Marrow fat increases slowly and steadily for males, while for females there is a dramatic increase around the time of menopause. * significant ($p < 0.05$) differences between males and females.

An increase in marrow fat is associated with a reduction in BMD. There is also an increase in marrow fat in conditions associated with reduced BMD such as anorexia nervosa, alcohol abuse, spinal cord injury, and prolonged bed rest (Schwartz, 2015). Higher prevalent marrow fat predicts future increased bone loss. Postmenopausal women with a marrow fat content above the median experienced average bone loss of 4.7% over 4 years, while those with a marrow fat content below the median experienced a bone loss of only 1.6% (Griffith et al., 2011). Increased marrow fat may also increase fracture risk. Mean vertebral marrow fat was 55% in those with a prevalent vertebral fracture compared with 45% ($p < .001$) in those without a prevalent vertebral fracture, even after adjusting for the effect of marrow fat on DXA measurements (Wehrli et al., 2000). A knowledge of the marrow fat content would also help to correct accuracy errors in DXA and in particular in single-energy QCT BMD measurements (Blake et al., 2009; Glüer and Genant, 1989), but so far is not routinely done.

MR spectroscopy also has the ability to evaluate the type as well as the quantity of fat. Young normal controls have a higher (0.127) portion of unsaturated fat in the bone marrow than postmenopausal females with osteoporosis (0.091) (Yeung et al., 2005). Vertebral insufficiency fracture patients were shown to have 1.7% lower unsaturation levels and 2.9%

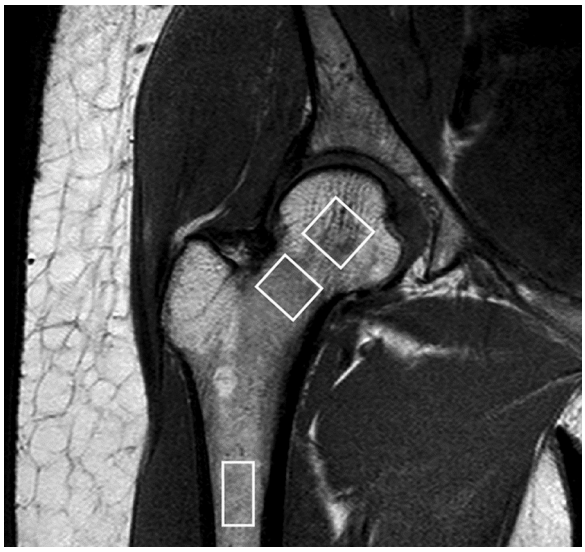

FIGURE 80.17 Dynamic contrast-enhanced MRI. Coronal oblique T1-weighted image of proximal femur showing regions of interest used to measure marrow perfusion in the femoral head, neck, and shaft.

higher vertebral marrow fat saturation levels (Patsch et al., 2013b). In the same study, diabetics had 1.3% lower unsaturation and 3.3% higher vertebral marrow fat saturation levels. Diabetics with fractures had the lowest marrow unsaturation and highest saturation. Although changing marrow fat composition was associated with diabetes and insufficiency fracture, the marrow fat content (%) per se did not change with either diabetes or fracture (Patsch et al., 2013b).

Further techniques are dynamic contrast-enhanced MRI to measure marrow perfusion (Fig. 80.17), and diffusion-weighted MRI is able to measure the apparent diffusion coefficient (ADC) of water. Bone perfusion is a critical element in bone fracture healing, including microfracture healing, which is highly relevant in osteoporosis (Griffith and Guglielmi, 2013; Griffith et al., 2013). The ADC is associated with marrow compaction (Griffith and Guglielmi, 2013; Griffith et al., 2013). It decreases with the accumulation of fat cells within the bony trabeculae, which restricts extracellular diffusion. ADC values in females age less than 50 years were significantly higher than in males (presumably reflecting reduced fat packing), while ADC values of postmenopausal females were lower than in premenopausal females (Jie et al., 2016).

Quantitative muscle imaging

The paradigm of the bone−muscle unit has steered interest in quantitative muscle assessments such as muscle volume, CT muscle density and content, and distribution of adipose tissue. Fields of application are falls, fractures, and sarcopenia, where muscle function and perhaps muscle mass are important parameters to measure. The typical anatomical location is the lower appendicular skeleton. Lean and fat mass can also be differentiated by DXA or bioelectrical impedance but these techniques do not provide a spatially resolved distribution of muscle and adipose tissue. This is the domain of CT and MRI.

At the thigh and calf, standard MR T1 sequences show excellent contrast between muscle and fat and display the inter- and intramuscular adipose tissue. Larger agglomerations of adipose tissue can be identified but the true fat content of muscle cannot be measured from T1-weighted images because the gray values do not scale in a known way with fat content (Hollingsworth et al., 2012). More quantitative MR techniques to determine fat fraction are spectroscopy and Dixon sequences (Grimm et al., 2018a, 2018b). In spectroscopy typically only a very small volume of interest ($\approx 1\ cm^3$) is analyzed, which is often not representative of the muscle−fat distribution, in particular in elderly and diseased subjects with a high muscle fat infiltration. MR Dixon sequences provide a scalable map of the fat fraction from 1% to 100%, in which a gray value of 1 corresponds to a fat fraction of 0.1% and a gray value of 1000 to a fat fraction of 100%. Intra- and extracellular lipids can be distinguished with MR spectroscopy (Velan et al., 2007) but not with Dixon sequences.

In contrast to MR, CT is faster, more widely available, and accessible and cheaper. Another advantage of CT is the possibility of quantifying muscle density, which linearly depends on the fat content of muscle. MRI and CT can both be used to measure muscle volume, but the spatial resolution of CT images is higher. Typical MR parameters are a slice

thickness of 3−5 mm and an in-plane pixel size of 0.4−0.8 mm, whereas in CT a slice thickness of 1 mm and an in-plane pixel size of 300 μm are state of the art parameters.

MR techniques have mostly been applied in sarcopenia and muscle diseases, whereas the association of muscle parameters with hip fracture risk has been investigated in some studies (Wong et al., 2014a, 2014b; Lang et al., 2008, 2010; Hahn and Won, 2016) using QCT or pQCT. In a CT study of the pelvis from Lang (Lang et al., 2008), CSA of total fat and extensor and adductor muscles, and CT attenuation of adductor muscles, remained significantly lower in fractured subjects after adjustment for age and BMI. Compared with DXA aBMD alone, fracture discrimination was improved by the inclusion of the soft tissue descriptors in a multivariate model. In the Health, Aging, and Body Composition (Health ABC) Study (Lang et al., 2010), CT attenuation of the thigh muscle predicted hip fracture with a RR of 1.4 after adjustment for aBMD. In the MrOS study, composite descriptors combining the stress strain index or bending strength of bone with muscle cross-sectional area were determined by pQCT of the lower limb. These descriptors predicted hip fracture with a hazard ratio of 1.2 after adjustment for aBMD of the spine and total hip (Wong et al., 2014a). In the EFFECT study the amount of adipose tissue of the upper thigh and the distribution of the adipose tissue in the muscles discriminated hip fracture (AUC 0.85) as well as trochanteric trabecular BMD combined with neck cortical thickness (AUC 0.84) (Mühlberg et al., 2019; Muhlberg et al., 2017).

Summary

Musculoskeletal quantitative and semiquantitative in vivo imaging has matured considerably since 2009. While radiography is the mainstay of fracture diagnosis, most attempts to improve hip fracture prediction using QCT, FEA, or trabecular bone architecture beyond the use of aBMD determined by DXA were not unduly successful. In osteoporosis, bone is lost and fracture risk increased but the remaining bone is optimally distributed so that the integral density remains the essential parameter to be determined. In the spine the projectional DXA technique often overestimates aBMD, particularly in older subjects due to degenerative change and aortic calcification, so for vertebral fracture prediction the use of QCT is better. This is important because prevalent vertebral fractures are an important risk factor for new fractures. The technique of opportunistic screening and the use of existing clinical CT scans may open new strategies for identifying patients with high fracture risk. Imaging of muscle and adipose tissue in the upper thigh and pelvis region may improve hip fracture risk prediction because they are associated with muscle function and therefore probably with falls, the component so far not considered in hip fracture prediction.

The introduction of HR-pQCT has enabled in vivo quantification of trabecular architecture and cortical parameters at the distal radius and tibia. Together with the differentiation of cortical and trabecular compartments at the spine and hip by QCT and the analysis of strength by FEA, a wealth of new quantitative parameters characterizing bone quality has been introduced that already have greatly improved the understanding of pathophysiology and the mechanisms of anti-osteoporotic medication. However, the multitude of parameters is confusing for the non-expert and these should be consolidated into those that are really independent of one another and thus provide unique information.

There are several new developments in MRI that should gain more attention in the bone field. Quantitative imaging of cortical water may be an important component to better understand bone strength. Current FEA techniques use only the BMD distribution as measured by QCT as input. The second important achievement is the possibility of marrow fat imaging, including the differentiation of red and yellow marrow. While in elderly subjects most of the bone marrow is composed of fat, at age 50, in the spine about 50% is red marrow. However, this portion decreases with advancing age. Thus in particular in QCT, changes in BMD observed beyond 5 years or associated with diabetes may be overestimated and MRI marrow measurements may offer a correction strategy. MRI remains the most important technique for muscle imaging, but in the periphery where radiation exposure is low, CT may be an alternative. Also in opportunistic screening muscle analysis of existing CT images may be an alternative.

Chapter outline

Introduction

Lineage tracing is an approach that has been widely used in developmental biology to identify the origin and fate of cells. Lineage tracing studies have been performed in numerous organisms for over a century using various methods to identify and track cells (reviewed in Stern and Fraser, 2001). Cells, or more commonly cell populations, have been identified using various vital dyes, radioactivity, genetic markers, or physical characteristics. Their fate can then be traced to later stages of development or to the adult organism. Many of these studies utilized organisms with transparent embryos to facilitate labeling and analysis. Ideal systems for tracking cells require the ability to deliberately label a specific cell or population of interest in an appropriate model system. The optimal label should be permanent, without loss of signal following cell division or change of phenotype or the ability to transfer to unlabeled neighboring cells. Finally, the labeling procedure ideally should not affect other aspects of the cell's biology.

In recent years, the ability to perform lineage tracing in animals at various stages of life has been greatly facilitated by genetic mouse models. This has enabled extensive study of various stem and progenitor populations in vivo. In addition to studying embryonic development, these models have been utilized to identify adult stem and progenitor cells. In this chapter, we provide an overview of models and reporters that can be used for lineage tracing in the skeleton and outline their use in different settings including development, postnatal growth, adulthood, and after injury. To date, lineage tracing studies in the field have primarily focused on characterizing cell fate within the osteoblast and chondrocyte lineages, so this chapter will focus primarily on these cell types.

Cre recombinase

Genetic manipulation has been utilized to direct the specific overexpression or deletion of genes. As described in previous chapters, targeted deletion of genes has often been achieved using a Cre/lox system, a genome site-specific recombination model allowing for spatial and in some cases temporal gene activation or deletion (Feil et al., 2009; Carlone, 2016). Briefly, Cre recombinase is an enzyme derived from P1 bacteriophage that catalyzes recombination between two 34−base pair loxP sequences. Depending on the orientation of the loxP sequence, Cre will catalyze excision, inversion, or translocation

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00081-6

of the sequence between the loxP sites. Spatial control of recombination is achieved by using tissue-specific promoters or other regulatory sequences to drive Cre. Temporal regulation of recombination is achieved by using a ligand-dependent Cre enzyme. CreER is a fusion protein composed of Cre and a mutated hormone binding domain of the estrogen receptor (Metzger et al., 1995). Cre activation is achieved by the binding of 4-hydroxytamoxifen (4-OHT, a metabolite of tamoxifen), which enables translocation of Cre to the nucleus. A number of modifications were made to improve ligand-independent activity and tamoxifen sensitivity, with CreERT^2 representing the optimized and most frequently used tamoxifen-inducible Cre (Feil et al., 1997). In order to activate CreER activity, mice are administered either 4-OHT or tamoxifen. Tamoxifen is most frequently used, primarily because it is cheaper, and is administered in oil either IP or orally. In order to perform lineage tracing, a Cre model must be combined with a suitable reporter gene.

Reporters

Reporters are genetic constructs that express a marker gene following activation, in this case by Cre recombination. Many lineage tracing studies have utilized a well-known reporter gene, β-galactosidase (detected as lacZ staining), ubiquitously expressed under the ROSA26 locus and controlled by a flox-Stop cassette (Fig. 81.1A; Soriano, 1999). Although useful in developmental biology, detection of lacZ activity requires a staining procedure usually performed on whole mount tissue. In tissues such as bone, penetration of the stain can give variable results. It is also possible to overstain, making it difficult to distinguish labeled cells from background signal. Use of fluorescent protein (FP) reporters has a number of benefits over staining-based approaches, including eliminating staining steps that can introduce experimental variability and enabling the isolation of live cells for further characterization. An early version utilized expression of enhanced green FP (GFP) following Cre-mediated lacZ deletion (Z/EG) (Novak et al., 2000; Lobe et al., 1999; Fig. 81.1B). There are a number of drawbacks associated with Z/EG mice including lack of ubiquitous expression of the transgene and the possibility of silencing that inhibits Cre-mediated recombination in adult cells (Long and Rossi, 2009). These phenomena were observed in postnatal life in tissues including hematopoietic cells, adult kidney, liver, testis, and other organs.

The next improvements were the generation of R26R-EYFP and R26R-CFP strains that were cloned in the ROSA26 locus to achieve ubiquitous expression (Fig. 81.1C). In this case, Cre recombination would remove a sequence between floxed sites containing a PGK promoter and neo cassette to activate the downstream FP. Indeed, these constructs were useful during developmental stages, but in adult bone samples they exhibit very weak fluorescence, particularly the cyan

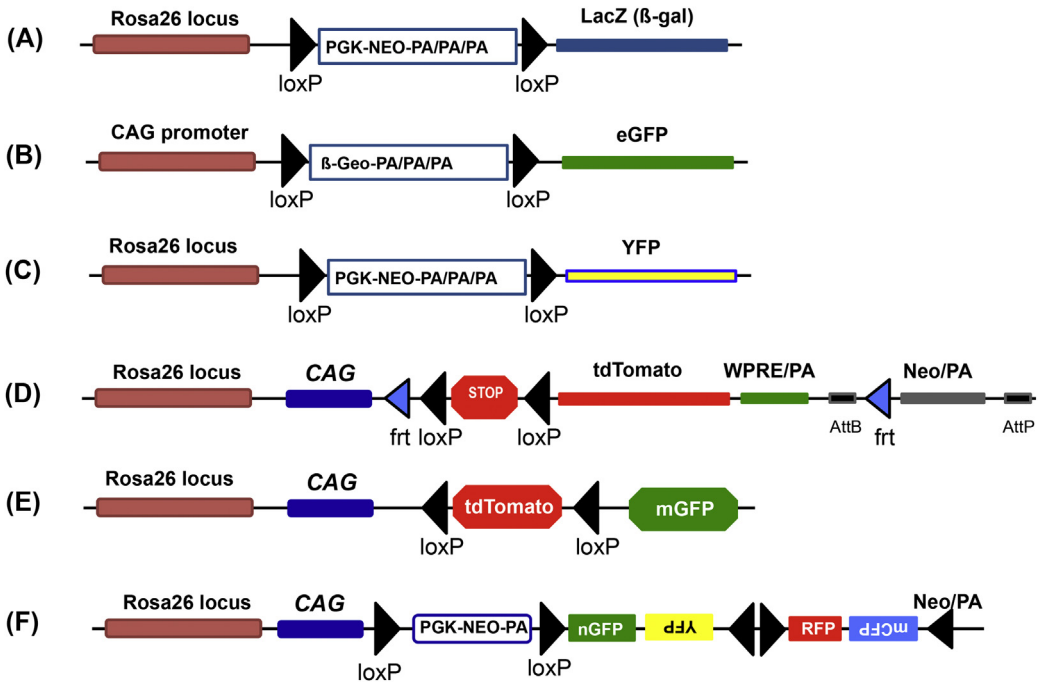

FIGURE 81.1 Reporter genes for Cre activation. (A) R26R reporter, Jackson Labs stock # 003474. (B) Z/EG reporter, stock # 004178. (C) R26R-EYFP, stock # 006148. (D) Ai9 reporter, stock # 007909. (E) mT/mG reporter, stock # 007676. (F) R26R-Confetti, stock # 017492.

FP (CFP) variant (Srinivas et al., 2001). One reporter construct allows for better temporal and spatial localization of recombination, as it contains double fluorescence markers, a membrane-targeted tdTomato and membrane-targeted GFP (Fig. 81.1D). Transgenes are expressed ubiquitously under the control of a CAG promoter cloned into the ROSA26 locus. Following Cre excision, ubiquitously expressed tdTomato is deleted and cells cease to be red and express GFP (Muzumdar et al., 2007). The minor disadvantage is that membrane-bound forms of tdTomato and GFP are harder to detect on histological sections. Madisen et al. (2010) developed a series of constructs that exhibit robust expression of various GFP forms under the control of a CAG promoter and ROSA26 locus with the addition of a woodchuck hepatitis virus post-transcriptional regulatory element that provides stability to the mRNA transcript. These constructs were termed Ai2, Ai3, Ai6, Ai9, and Ai14 (Fig. 81.1E). Strong and reliable fluorescence has been reported using numerous Cre lines. Recently, a multiplex reporter approach has been developed to assist with identification of clones (Snippert et al., 2010; Livet et al., 2007). This strategy utilized the R26R locus and CAG promoter with a neomycin resistance that is excised following recombination, and a Brainbow 2.1 construct randomly activates to generate four different outcomes (Fig. 81.1F). A GFP reporter is localized in nucleus and CFP is membrane-bound while RFP and yellow FP (YFP) are cytoplasmic. Unfortunately, the fluorescent signal generated by this reporter is weak, which makes imaging technically challenging, particularly in tissues with high autofluorescence such as bone marrow. At least one other four-color ubiquitous reporter has been published; however, it does not appear to be available from Jackson Labs (Rinkevich et al., 2011). Numerous other reporters are available for specific purposes, but for basic lineage tracing analysis, Ai3 (YFP), Ai6 (ZsGreen), and Ai9/Ai14 (tdTomato) provide a bright signal easily detected for microscopy including intravital or whole mount imaging as well as flow cytometry.

Experimental design for lineage tracing

Both temporal and spatial factors need to be considered when designing lineage tracing studies. For spatial regulation, it is necessary to identify a "marker" gene and a promoter/enhancer element that can specifically mark a homogeneous group of cells at a specific stage of cell lineage development. If we can identify a marker gene and a promoter/enhancer element specifically expressed by "stem cells" but not by their downstream progeny cells, an inducible genetic tool utilizing this particular gene would unambiguously demonstrate cell fates of these stem cells in unperturbed conditions. Conversely, if we can identify a marker gene and a promoter/enhancer element specifically expressed by "terminally differentiated cells" but not by their upstream precursor cells, an inducible genetic tool utilizing this gene would unravel the plasticity and/or transdifferentiation of such cells. In reality, no gene or promoter/enhancer element is specifically active in "stem cells" or "terminally differentiated cells"—rather, they always mark a heterogeneous group of cells at different stages, and therefore a deliberate characterization of the cell population initially labeled is essential for interpreting the result of lineage tracing experiments.

Lineage tracing with inducible Cre typically involves a pulse−chase experimental design. The "pulse" component allows for identification of cells in which recombination occurs, and it is usually completed by sacrificing animals within 12 h to 2 days after tamoxifen treatment and evaluating labeling histologically. Careful analysis of the cell population initially labeled is critical for accurate interpretation of results. Further characterization by immunostaining, flow cytometry, or cell sorting followed by gene expression or other ex vivo analyses can be performed. The "chase" component is completed days, weeks, or months following initial labeling and indicates the progeny of the initially labeled cells. CreER can exhibit "leakiness" or recombination in the absence of tamoxifen, so it is important to examine reporter expression in mice that have not received tamoxifen, at least at later time points or following injury manipulations. Control mice should be housed separately from animals receiving tamoxifen to avoid inadvertent exposure. The half-life of tamoxifen in vivo is reported to be around 16 h, although how long the Cre remains active depends on the initial dose of tamoxifen as well as various other factors including the level of CreER expression (Wilson et al., 2014). Generally, tamoxifen can remain active for 24−48 h after administration. Alternatively, 4-OH tamoxifen, which activates recombination more rapidly, can be injected to reduce the window of action, typically to 6−9 h after injection. Dosage should be determined experimentally for each system. In some cases, less efficient labeling is desirable—for example, if trying to identify clones, in which case tamoxifen dosage can be reduced. Timing of labeling will depend on the experimental question, but for studies attempting to identify tissue-resident cells contributing to injury, a washout period of at least 24 h after the last tamoxifen dose is helpful to avoid the labeling of cells that activate the promoter after injury.

Lineage tracing can also be used to determine the number and type of cells derived from a single clone in vivo. Generally this involves the use of a Brainbow-type reporter that produces multiple colors and requires labeling a relatively small number of cells initially. Statistical analysis should be performed to determine the probability of adjacent cells receiving the same label to ensure that sufficient samples are analyzed. Clonal analysis is simpler in tissues with clear

organization such as growth plate and more complicated in regions like bone marrow. Ideally, the ability for clones to expand over three dimensions should be considered, although this makes analysis more challenging technically.

Effects of tamoxifen on bone

CreER is the most common inducible system; however, it should be noted that tamoxifen or 4-OHT required to induce Cre activity has actions in the bone that should be taken into account. Tamoxifen is a selective estrogen receptor modulator, and in bone its effects mimic those of estrogen and thus promote bone formation while inhibiting resorption (Zhong et al., 2015). Trabecular bone volume is increased in male and female mice in response to a range of doses of tamoxifen, with effects reported for a cumulative dose as low as 1 mg/kg (Zhong et al., 2015; Perry et al., 2005; Sugiyama et al., 2010). The effect of tamoxifen can be dramatic, with threefold increased trabecular bone volume reported with high-dose tamoxifen (100 mg/kg daily for 4 days) 1 month after treatment of 1-, 2-, or 3-month-old animals (Zhong et al., 2015). Trabecular effects are evident in both actively growing mice around 1 month of age and more mature animals and have been noted in both inbred strains (C57Bl/6 and CBA-1) and mixed-background animals. Similar anabolic effects have been reported with administration of 4-OHT (Starnes et al., 2007). We performed a pilot experiment that clearly demonstrates the dramatic effects of tamoxifen treatment on bone during adolescent growth (Fig. 81.2). Four-week-old female αSMA-CreER mice (C57Bl/6) were given three doses of 75 mg/kg tamoxifen over 9 days, and μCT analysis was performed on femora 3 weeks after the initial dose. As expected, αSMA-CreER mice do not show any differences in bone parameters compared with wild-type littermates. In contrast, tamoxifen treatment dramatically increases trabecular bone while also altering the overall size and shape of bones. Tamoxifen-treated bones were longer, with a smaller periosteal and endosteal perimeter and increased cortical thickness. Others have reported increased cortical thickness and increased biomechanical strength when growing mice are exposed to similar doses of tamoxifen (Zhong et al., 2015; Starnes et al., 2007), and even 10-week-old animals showed growth plate changes in response to much lower doses of tamoxifen (28 days of 0.1, 1, or 10 mg/kg) (Perry et al., 2005). Notably, the effects on the growth plate are the opposite of those from 17β-estradiol, which reduces longitudinal growth (Perry et al., 2005). Interestingly, low-dose tamoxifen (1 mg/kg total given over 10 days) also increased the anabolic response to mechanical loading (Sugiyama et al., 2010). 4-OHT (1 μM) also reduced CFU-F formation when added to cultures of cells derived from a ubiquitous CreER mouse, but not with wild-type cells (McHaffie et al., 2016).

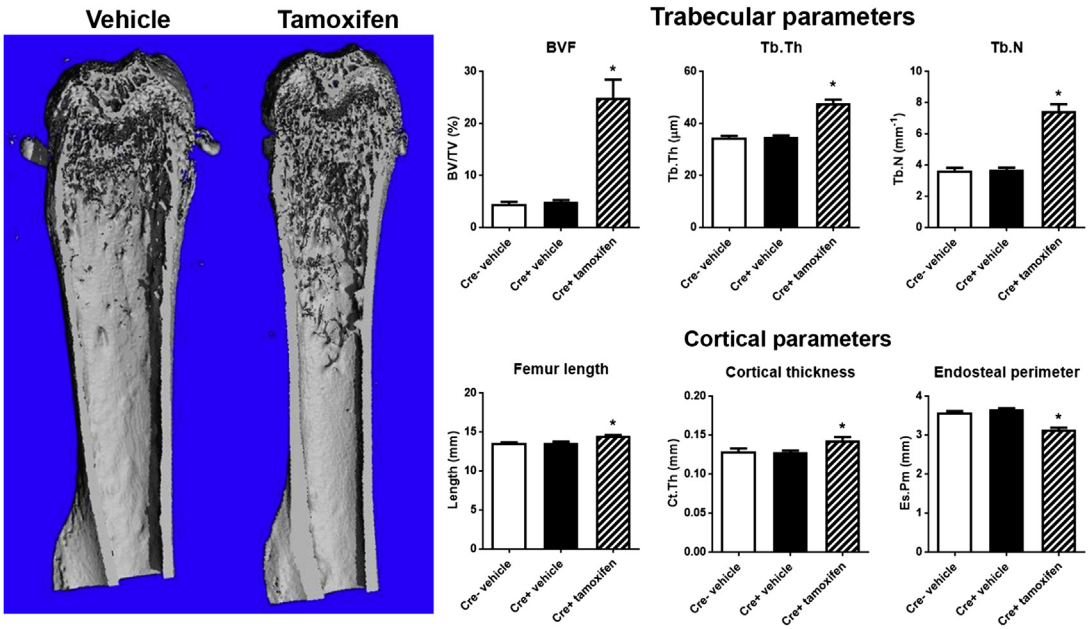

FIGURE 81.2 Tamoxifen effects on bone parameters of growing mice. Female C57Bl/6 mice, either with or without the αSMA-CreERT2 transgene, were treated with 75 mg/kg body weight of tamoxifen or vehicle on P28, P32, and P37. At 7 weeks of age, bones were collected and μCT analysis was performed on the femurs ($n = 5–7$). Reconstructions of representative bones from Cre+ mice are shown. Selected parameters representing changes in trabecular and cortical bone are depicted graphically. *$P < .05$ 1-way ANOVA with Dunnett's posttest compared with Cre+ vehicle.

While doses of tamoxifen or 4-OHT used for lineage tracing studies vary, the majority of studies using tamoxifen-inducible Cre in the bone field use one or more doses of 50−100 mg/kg, although in some studies high total cumulative doses of around 1000 mg/kg have been used (Shi et al., 2017; Worthley et al., 2015). Clearly this is not ideal and should be carefully considered in studies where inducible Cre is used to target genes in order to evaluate the bone phenotype. It may also mean that the contribution of various cell populations to osteoblasts and osteocytes, particularly in the short term, is overestimated in many studies.

Tet expression systems

The Tet-On and Tet-Off systems are widely used genetic systems that enable inducible control using the antibiotic tetracycline or more commonly its derivative doxycycline (Dox). In order to be useful for lineage tracing, Tet systems need to be coupled with Cre under the control of a tetracycline-responsive promoter element (TRE) (for example, the tetO-Cre mouse, Jackson Labs stock #006234). This therefore comprises a three-part system. In a Tet-Off system, the tetracycline-controlled transactivator protein (tTA) is expressed under control of a tissue-specific promoter, and is active under normal conditions but inactive when bound to Dox. In the Tet-On system, reverse tTA (rtTA) is expressed under control of the tissue-specific promoter, and is only able to activate the TRE (and thus Cre) when doxycycline is present. The Tet-On system is therefore more suitable for lineage tracing studies, as it allows transient activation of Cre activity without chronic antibiotic treatment. This system has not been used in many studies in the bone field but has been used to identify stem cells in calvarial sutures and mammary gland (Maruyama et al., 2016; Van Keymeulen et al., 2011; Rios et al., 2014). Dox can be administered via food, water, or intraperitoneal injection, providing flexibility in terms of dosage and timing of administration. Tet systems frequently suffer from leakiness, so untreated controls as described for CreER should always be included.

The Osx-GFP::Cre mouse that has been widely used for targeting osteoblast lineage utilizes the Tet-Off system, although both components are contained within a single construct (Rodda and McMahon, 2006). This mouse shows delayed craniofacial mineralization and small body size early in life, so its use has declined in recent years (Wang et al., 2015; Davey et al., 2012). Interestingly, these phenotypes can be avoided by Dox administration to the mothers during development. Given that other osteoprogenitor-directed Cre models do not have this phenotype, this may be due to tTA binding to DNA during development. Like tamoxifen, Dox has widespread actions that may affect bone. Dosage in different studies varies widely, although most are within the range of antibiotic activity, meaning there is potential to alter the microbiome, especially when administered orally over a long period. It is also notable that tetracyclines are contra-indicated in humans during pregnancy and childhood due to tooth discoloration and some indications of skeletal deformities (Mylonas, 2011). In mouse studies, Dox was shown to inhibit osteoclastogenesis but not alter osteoblast growth or differentiation in vitro or in vivo (Kinugawa et al., 2012). The in vivo effects of Dox on osteoclastogenesis have been demonstrated in situations of enhanced resorption but are likely negligible under normal conditions (Kinugawa et al., 2012; Fowlkes et al., 2015). Finally, members of the tetracycline family bind to bone mineral and can be used as mineralization labels for dynamic histomorphometry (Pautke et al., 2010). It is therefore plausible that the half-life of Dox activity is extended in bone tissue.

Intersectional strategies to identify cells

The aforementioned methods rely on the use of one promoter or promoter fragment to identify a specific cell type or population. In reality, most promoters are expressed in multiple cell types or at least a heterogeneous cell population. A number of strategies have been developed to address this issue by requiring that two different promoters are expressed in the same cell prior to labeling. Split Cre systems allow two parts of the Cre molecule that are not active individually to be expressed from different promoters, enabling activity only in cells where both are expressed simultaneously (Casanova et al., 2003; Wang et al., 2012). These can be combined with standard Cre reporters or any other construct containing lox sites. In the more recently developed version of this system, the split Cre-induced reporter identified more cells than in situ hybridization for both components, suggesting high efficiency (Wang et al., 2012). Alternatively, a number of reporter mouse lines are now available that require the activity of two different recombinases in order to activate the reporter (Madisen et al., 2015). Most commonly this involves a combination of Cre and Flp activity, although reporters are also available for Cre and tTA or Cre and Dre. This system would not necessarily require simultaneous expression of both recombinases, although CreER and/or FlpER could be used to enable the labeling to remain inducible. Presumably, a loss in efficiency will result from combining multiple recombinases and should be considered.

Lineage tracing during embryonic development

Embryonic development is a highly dynamic and organized process in which a simple primordial structure increases its complexity over time and differentiates into functional tissues. The reproducibility of this process makes it particularly attractive for studying cell lineage within the native environment. The basic principle here is to mark a particular group of "early" cells within undifferentiated, relatively simple primordial structures and observe how these cells produce their progeny and contribute to more differentiated cells in later stages as the tissue architecture becomes more complex. The lineage tracing technique is particularly advantageous for unraveling this important aspect and has been successfully applied to a number of major organ systems. Timing of initial labeling is particularly important in analyzing cell lineages during embryonic development, as tissue formation occurs very rapidly.

In the bone research field, a number of marker genes have been utilized to identify various stages of cells in the chondrocyte and osteoblast lineage. These genes include *SRY-Box 9* (*Sox9*), *type II collagen alpha-1* (*Col2a1*), *aggrecan* (*Acan*), and *type X collagen* for the chondrocyte lineage; and *osterix* (*Osx*), *alpha-smooth muscle actin* (αSMA), *type I collagen alpha*-1, *osteocalcin* (*Oc*), and *dentin matrix protein-1* (*Dmp1*) for the osteoblast lineage. It is important to note that essentially all "early marker" genes are also expressed in late cells of the lineage with the exception of αSMA-CreER, which is not expressed in mature osteoblasts or chondrocytes (Grcevic et al., 2012). For example, *Sox9* and *Col2a1* are expressed by more differentiated chondrocytes including proliferating and articular chondrocytes, and *Osx* is also expressed by matrix-producing osteoblasts and osteocytes. Conversely, seemingly "late marker" genes can be expressed by some cells earlier within the lineage. For example, *Dmp1* is expressed not only by osteocytes but also by matrix-producing osteoblasts and possibly some other cells within bone marrow (Matic et al., 2016). Therefore, no single set of available makers can define cells at a specific stage in bone cell lineages. One way to circumvent this limitation is to mark these early cells in the primordial stage before more differentiated cells appear in the structure. This becomes possible when recombination is induced at a specific stage of development before these marked cells move down the lineage. Several studies over the last decade have undertaken this approach using tamoxifen-inducible $CreER^{T2}$ genetic tools and successfully revealed the nature of early cells of the chondrocyte and osteoblast lineages during development. For example, Osx-CreER can mark osteoblast precursor cells in the perichondrium that have the capability to move into the nascent marrow cavity (Maes et al., 2010), whereas Sox9-CreER and Col2a1-CreER can mark osteo-chondro-progenitor cells in mesenchymal condensations that can robustly continue to produce both chondrocytes and osteoblasts (Ono et al., 2014). To better understand how available genetic tools can be utilized to unravel the dynamics of putative progenitor and precursor populations, it is important to know the sequence of embryonic bone development. Endochondral bone development of major long bones (e.g., femurs and tibias) in mice is described next as an example.

Endochondral bone development is a highly organized process in which the lineage development of chondrocytes, osteoblasts, and their precursors occurs sequentially, following highly reproducible trails. In mice, the limb bud, a primordial structure for future limb skeletal elements, is formed at embryonic day (E) 10.5. At E11.5, mesenchymal cells start to condense, establish bone anlage free of vasculature, and first express *Sox9*, a master transcription factor of chondrogenesis, and then *Col2a1*, the major collagenous extracellular matrix of the cartilage. Tamoxifen injection at these stages (e.g., E10.5−E11.5 for Sox9-CreER, and E11.5 for Col2a1-CreER) can effectively mark osteo-chondro-perichondro-progenitor cells in mesenchymal condensations, which demonstrate diverse differentiation potential by contributing to chondrocytes, perichondrial cells, and osteoblasts at later stages (Ono et al., 2014). At E12.5, condensed mesenchymal cells start to differentiate into chondrocytes and become hierarchically organized. Tamoxifen injection at this stage (E12.5) for Col2a1-CreER can mark these nascent chondrocytes and their precursors that contribute to a majority of chondrocytes and osteoblasts at later stages. By contrast, these cells contribute to perichondrial cells to a much lesser extent, indicating that perichondrial cells diverge from these nascent chondrocytes at an earlier stage. At E13.5, chondrocytes in the center of cartilage templates undergo hypertrophy, and subsequently the first osteoblast precursor cells appear in the adjacent perichondrium. These perichondrial osteoblast precursors can be effectively marked by Osx-CreER at these stages (E12.5−E13.5) (Maes et al., 2010). These cells further move into the nascent marrow space and contribute to osteoblasts and stromal cells at later stages. However, perichondrial cells marked by Osx-CreER appear to be transient precursor cells, as they do not stay in the perichondrium at later stages and eventually disappear from most marrow cavity (Maes et al., 2010; Mizoguchi et al., 2014). Earlier precursor cells for *Osx*-expressing cells should exist in the fetal perichondrium, although their identity has not been revealed. The formation of the primary ossification center and marrow cavity starts at E14.5, and hematopoiesis in bone marrow starts at E15.5. By this time, the complexity of the skeletal structure is well developed, and the diversity of the bone cell lineage has been fully established. Tamoxifen injection any time after this point (E14.5−E15.5) in the CreER lines mentioned above marks a wide spectrum of cells over the lineage, therefore making it more challenging to determine the definitive precursor−progeny relationships. For example, tamoxifen injection

of Osx-CreER after E15.5 results in marking a variety of bone cells, including perichondrial cells, osteoblasts and their precursors, and stromal cells in the marrow cavity. At later stages, these cells proliferate within the marrow space well into postnatal development but then gradually disappear in the metaphysis, while a small population remains in the metaphyseal marrow space (Ono et al., 2014; Mizoguchi et al., 2014; Liu et al., 2013). It cannot be ascertained which initially Osx-expressing cells contribute to persisting marrow stromal cells because of the heterogeneity of the cell population initially labeled by Osx-CreER. Similarly, tamoxifen injection for Sox9-CreER or Col2a1-CreER after E15.5 results in marking cells beyond chondrocytes and their precursor cells, including osteoblast precursor cells (Ono et al., 2014; Balani et al., 2017). At later stages, these cells continue to feed into osteoblasts and stromal cells for a long period well into adult and aged stages.

Below is the summary of discoveries from lineage tracing during embryonic endochondral bone development in mice so far:

1. Osteo-chondro-perichondro-progenitor cells in mesenchymal condensations
   a. *Sox9-CreER*: tamoxifen at E10.5−E11.5
   b. *Col2a1-CreER*: tamoxifen at E11.5
2. Osteo-chondro-progenitor cells in cartilage templates
   a. *Sox9-CreER* and *Col2-CreER*: tamoxifen at E12.5−E14.5
3. Osteoblast precursor cells in perichondrium
   a. *Osx-CreER*: tamoxifen at E12.5−E14.5

For the purpose of studying cell fates of the chondrocyte and osteoblast lineage using available CreER genetic tools, a tamoxifen pulse at a late stage of development between E15.5 and E18.5 is particularly challenging. Delivering a relatively high dose of tamoxifen into late pregnant dams is technically difficult because of antiestrogenic activities of tamoxifen that often induce abortion. An equal amount of progesterone can be added into the mixture to mitigate the risk for abortion (Danielian et al., 1998), but still the success rate is quite low if chased more than 3 days (∼15% in our experience, if outbred CD-1 mice are used as breeders). More acute pulse experiments require administration of 4-OH tamoxifen, but this reagent is more difficult to handle and costlier than standard tamoxifen. In addition, part of administered tamoxifen is accumulated in a pregnant dam's fat pads due to its high hydrophobicity. Therefore, if high doses of tamoxifen are given to pregnant dams, there is a chance that pups are reexposed to a new wave of tamoxifen as soon as the delivered mother starts to lactate. For these reasons, injecting an extremely low dose of tamoxifen shortly after birth to newly born pups would be a better option for studying the cell fates of bone cells after the marrow space is fully established.

Postnatal lineage tracing

There is great interest in the identity of postnatal stem cells, particularly in the context of their utility in regenerative medicine. Mice grow rapidly up to about 6 weeks of age when they reach sexual maturity, then continue to grow more slowly until about 4 months of age when they reach peak bone mass. Their growth plates narrow over this time period, but unlike those of humans, they never fully close. A number of markers used in lineage tracing identify progenitor cells in the primary spongiosa or trabecular region that are abundant during rapid growth around 1 month of age but are rare or absent in adulthood. These include *Gli1*, which identifies "metaphyseal mesenchymal progenitors" that contribute primarily to trabecular osteoblasts over a long period, *Gremlin1*, which labels a very rare population of "osteo-chondro-reticular progenitor cells," and αSMA, which labels a transient osteoprogenitor population (Shi et al., 2017; Worthley et al., 2015; Grcevic et al., 2012). Notably, *Gli1*and *Gremlin1* also label a subset of chondrocytes. In contrast, leptin receptor (LepR)-labeled cells do not appear until around 2 months of age (Zhou et al., 2014a). Unfortunately, all the lineage tracing studies of LepR+ cells utilized a noninducible Cre, making it difficult to determine whether the increasing contribution to osteoblasts as the mice age is because LepR identifies a self-renewing population or LepR is activated at a later stage in the lineage.

Mature osteoblast markers have been used to trace the fate of osteoblasts as well as estimate their life spans. Live cell imaging using Osx-CreER in calvaria showed peak labeling after 30 days followed by a gradual drop in cell number. Oc-CreER, which identifies more mature osteoblasts, shows peak labeling by 14 days followed by a drop and returning close to baseline by 60 days, suggesting that osteoblasts have a maximal life span around 60 days in young mice (Park et al., 2012). Both Oc-CreER and Dmp1-CreER, which efficiently labels the majority of osteoblasts despite being considered primarily an osteocyte marker, have been used to label and characterize bone lining cells that were previously very difficult to identify given their similarity to osteoblasts (Matic et al., 2016; Kim et al., 2012, 2017; Jang et al., 2016). This was achieved either by labeling osteoblasts, then waiting for the majority to disappear from the bone surface and leave bone

lining cells (and osteocytes within the matrix), or by genetically ablating osteoblasts. This technique has allowed unique characterization of these cells that had not been possible using other methods.

Osteoblast-to-chondrocyte transition

Lineage tracing has been used to address the hypothesis that chondrocyte-to-osteoblast or chondrocyte-to-osteoblast precursor transformation continues to occur during postnatal growth. It is technically challenging to formally prove this process because of the heterogeneity of the cell population initially labeled by so-called chondrocyte-specific transgenes such as Sox9-CreER, *Col2a1-CreER*, *Acan-CreER*, and *ColX-CreER*. In recent years, a series of studies have suggested that the chondrocyte-to-osteoblast transition is the major route providing new osteoblasts in the epiphyseal growth plates of long bones (Yang et al., 2014a, 2014b; Zhou et al., 2014b) and mandibular condylar cartilage of lower jaws (Jing et al., 2015) as well as during fracture healing (Zhou et al., 2014b; Hu et al., 2017). However, as discussed previously, these "chondrocyte-specific" constructs can simultaneously mark other closely associated cell types, especially osteoblast precursors, upon tamoxifen injection in postnatal mice. For example, one recent study shows that Sox9-CreER can mark osteoblast precursors in adult mice that can robustly respond to intermittent administration of PTH (Balani et al., 2017). Therefore, the significance of this chondrocyte-to-osteoblast transition route in providing new osteoblasts needs to be further validated using more sophisticated genetic tools. We have developed a resting chondrocyte-specific genetic tool (PTHrP-CreER) and demonstrated that PTHrP^{+} resting chondrocytes can differentiate not only proliferating and hypertrophic chondrocytes as expected, but also osteoblasts and reticular stromal cells in bone marrow (N.O., unpublished data). Although our data unambiguously show that the chondrocyte-to-osteoblast transition does occur, the extent of osteoblastogenesis to which this process contributes appears to be rather modest, at least based on our genetic model in normal bone growth.

Lineage tracing following injury

Lineage tracing has proved a valuable technique to identify cell types involved in healing processes as well as the pathological processes of inappropriate bone formation. Genetic lineage tracing has the benefit of not requiring the additional manipulations involved in transplantation studies, to either the transplanted cells or the recipient animal, that may affect growth and differentiation potential. Since these processes involve de novo tissue formation, many studies have utilized constitutive Cre models to evaluate contribution. While lineage tracing with constitutive Cre simplifies experimental design and is useful for proving lack of contribution or very limited contribution to a system, results showing contribution are more difficult to interpret, particularly if the promoter in question may be injury responsive and therefore activated in cells that were not labeled prior to injury.

Rinkevich et al. (2011) used lineage tracing to investigate the contribution of different cell types to digit tip regeneration in mice. This process involves generation of a blastema at the wound site, which was hypothesized to contain pluripotent cells prior to regeneration of multiple tissue types. Their data confirm lineage-restricted contribution to new tissues, with ectoderm-specific Cre-labeled cells contributing to the regenerated epidermis and related structures, while Prx1-Cre-labeled mesenchymal cells contributed to bone, tendon, and dermis, and endothelial cells were derived from Tie2-Cre and VE-cadherin-CreER endothelial lineages. This indicated that lineage-restricted tissue stem/progenitor cells, as opposed to pluripotent blastema cells, were responsible for regeneration.

Lineage tracing has also been utilized in fracture healing. Colnot (2009) performed an elegant series of studies using transplantation of bone grafts from a LacZ reporter mouse. The results demonstrate that matrix-forming cells were primarily derived locally, and the periosteum but not the endosteum was the source of chondrocytes, while both were capable of contributing to osteoblasts. A number of subsequent studies have identified markers of osteo-chondro-progenitors in the periosteum. Prx1-CreER identifies some osteoblasts and chondrocytes in fracture calluses, although many cells are not labeled and tamoxifen was administered after the fracture, so the role of resident Prx1+ cells in fracture remains unclear (Kawanami et al., 2009). αSMA-CreER identifies cells in the periosteum that contribute to a large proportion of osteoblasts, chondrocytes, and fibrous tissue in a fracture callus (Grcevic et al., 2012; Matthews et al., 2014). When tamoxifen is given at the time of fracture, some animals show contribution to over 90% of osteoblasts, suggesting that the vast majority of osteoprogenitors express αSMA at some point in their lineage (B.G.M. unpublished data). LepR-driven Cre (non-inducible) identifies cells that contribute to around 50% of osteoblasts and chondrocytes in a fracture callus (Zhou et al., 2014a), as does Gli1-CreER when tamoxifen is administered at 1 month of age with fractures performed at 2 months of age (Shi et al., 2017). Gremlin1-labeled cells also contribute to fracture callus, albeit for a smaller fraction of cells (28% of osteoblasts and 14% of chondrocytes) (Worthley et al., 2015). Mx1-Cre, an interferon-inducible promoter that is activated

in a number of different types of stem cells, also identifies osteoprogenitors that contribute to fracture healing, although not chondroprogenitors (Park et al., 2012). In contrast to other studies, which used long bone fractures to assess contribution to both cell types, this study used different microfracture models to assess contribution to the lineages separately, so the presence of lineage-restricted progenitors in the context of periosteal fracture healing has yet to be proven. Finally, lineage tracing has been used to evaluate the contribution of muscle to fracture healing. MyoD-Cre-labeled myogenic cells make little or no contribution to closed fractures with intact periosteum but can contribute to both osteoblasts and chondrocytes in an open fracture model (Liu et al., 2011). Another study showed contribution of muscle-derived cells to chondrocytes in an open fracture, although given the ubiquitous nature of the reporter used in the muscle graft, it is unclear whether this contribution was myogenic or a different muscle-resident cell type (Abou-Khalil et al., 2015). Many of the markers utilized in fracture studies also identify stem or progenitor populations in the bone marrow compartment involved in growth or adult turnover, but in most cases the periosteal resident populations involved in fracture healing were not characterized separately despite clear indications that these cells have different functions and differentiation capacity in vivo (Colnot, 2009). To date, we do not have any selective markers of periosteal progenitors, and it is unclear how the populations identified by different markers overlap. Further studies combining lineage tracing with other characterization are required to better understand the heterogeneity and source of progenitors contributing to fracture callus formation.

A number of recent studies have identified progenitor populations in calvarial sutures. By combining lineage tracing studies with diphtheria toxin—mediated cell ablation studies, Zhao et al. (2015) demonstrated that Gli1-CreER identifies cells in the suture that contribute to osteoblasts in the calvaria during postnatal growth and into adulthood. Ablation of these cells causes premature suture fusion and prevents bone defect healing. Axin2-rtTA also identifies cells in the suture that show some stem cell characteristics, particularly upon isolation and transplantation, although they appear to make a much smaller contribution to bone growth and adult turnover than the Gli1 lineage (Maruyama et al., 2016). They also appear to contribute to injury healing. Finally, Prx1-CreER also identifies progenitors in the suture that contribute to defect healing (Wilk et al., 2017). These cells are likely a subset of the Gli1 population but separate from Axin2-labeled cells. Ablation studies indicate that this population is not necessary for postnatal growth but is critical for the healing of a cranial defect. Together these studies indicate that at least in the cranium, the cells that respond to injury may be separate from the populations involved in normal growth and turnover. To date, there is no evidence of a similar phenomenon in long bones.

Lineage tracing in heterotopic ossification

One setting where lineage tracing has been used extensively to identify the source of progenitors is heterotopic ossification (HO), covered in a recent review (Lees-Shepard and Goldhamer, 2018). HO involves pathological formation of bony tissue in muscle or other soft connective tissues. Acquired HO can occur as a complication of severe injury or orthopedic surgery. There are also rare genetic forms of HO, most notably fibrodysplasia ossificans progressive (FOP). FOP is caused by mutations in the BMP receptor *Acvr1* that sensitize the receptor to activin A, resulting in inappropriate BMP signaling (Hatsell et al., 2015). Excessive BMP signaling is likely a common mechanism for all types of HO, and identifying the cell type that transforms into bonelike tissue has been a major focus of the field. The majority of studies evaluating cellular contribution to HO have utilized ectopic administration of BMP or the Nse-Bmp4 mouse. Recently, mice that selectively express Acvr1 mutations found in FOP or other constitutively active forms only following Cre activity have been developed and used to identify cell populations involved in pathological bone formation (Lees-Shepard et al., 2018; Dey et al., 2016). If these mutants are expressed in permissive cell populations, HO forms either spontaneously or following a muscle injury. Studies using various Cre lines have clearly ruled out the possibility that hematopoietic lineages could directly contribute to the lesions in both BMP-mediated and FOP HO (Dey et al., 2016; Kan et al., 2009). The muscle lineage was another potential candidate, based on the ability of satellite cells and myoblasts to differentiate into osteoblasts with in vitro BMP treatment. Again, lineage tracing results using both satellite cell-specific (*Pax7*) Cre and other models that target later in the muscle lineage (*MyoD, Myf5, Myf6*) showed negligible contribution of the muscle lineage to the lesions and total absence of HO when Acvr1 mutants were targeted to the muscle lineage, indicating that the in vitro differentiation capacity of these cells was not indicative of their capability in vivo, even under pathological conditions (Lees-Shepard et al., 2018; Dey et al., 2016; Kan et al., 2009; Matthews et al., 2016; Lounev et al., 2009). Endothelial cells were another candidate based on lineage tracing data using Tie2-Cre, in addition to histological studies from human FOP lesions and in vitro results suggesting that endothelial-to-mesenchymal transition was occurring during HO (Lounev et al., 2009; Medici et al., 2010). However, other markers of endothelial cells, including a different Tie2-Cre line that shows more restricted expression, failed to show contribution to HO (Lees-Shepard et al., 2018; Dey et al., 2016; Kolind et al., 2015; Wosczyna et al., 2012), and follow-up studies indicated that the population labeled by Tie2-Cre that could contribute to HO was actually a nonhematopoietic, nonendothelial interstitial population that expressed Sca1 and PDGFRα (Wosczyna

et al., 2012). Therefore, confirming what cells are targeted by Cre in the tissue of interest is vital for correctly interpreting the results. Cells identified by a number of different mesenchymal markers have been shown to contribute to HO in muscle, including perivascular markers—αSMA and *Glast*, and *Mx1* and PDGFRα—that identify interstitial cells (Lees-Shepard et al., 2018; Dey et al., 2016; Matthews et al., 2016; Kan et al., 2013). Whether these markers identify one overlapping population or different types of cells that can contribute to HO is still unclear.

Conclusions

To summarize, despite some weaknesses associated with lineage tracing approaches, a tremendous amount of knowledge has been obtained using this technique. Besides identifying different population of cells during development and postnatal differentiation and injury, lineage tracing has been critical in indicating what stage or cell population we can target for gene deletions or overexpression. It is increasingly indicating that in vitro assays are not a clear indicator of plasticity and the differentiation potential of cells in vivo. Future improvements should be directed toward developing inducible models that would avoid the use of the compounds that affect bone metabolism, and strategies that target more defined cell populations.

Chapter outline

Introduction

Rodents have proven to be useful models to study metabolic and genetic bone diseases. Bone histomorphometry is a unique technique that histologically and quantitatively assesses bone cells, growth, tissue remodeling, bone architecture, and repair. It provides critical information for understanding tissue-level mechanisms of action and plays an important role in documenting the biological effects and possible side-effects of new drug treatments. In this chapter, we introduce histomorphometric techniques that can be applied to rodent bone including in vivo labeling, sample preparation, parameter readouts, and their biological significances. We also include histomorphometric evaluation of microdamage and bone healing. Histomorphometric changes found in common rodent models of bone loss and skeletal drug effects also are reviewed.

Methodologies

In vivo labeling

One of the most important endpoints in rodent histomorphometry is the assessment of the rates of osteoblastic bone formation and bone mineralization. These measurements are made on bones harvested from animals given fluorochrome

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00082-8

labels in vivo. Fluorochromes are fluorescent, calcium-seeking substances incorporated into the mineralization front of mineralizing surfaces (MSs). Once incorporated into a specific bone site, fluorochromes persist and are not released until resorption of the fluorochrome-containing bone matrix by osteoclasts. In histological bone sections, fluorochrome labels can be visualized by excitation with UV or blue light or with light in the red−green range. Typical fluorochromes used for dynamic histomorphometry in rodents are calcein green, alizarin complexone, tetracyclines, and xylenol orange (Erben, 2003). For the calculation of the mineral apposition rate (MAR) and bone formation rate (BFR), two labels given at different time points are necessary. Due to its low toxicity and bright fluorescence, the authors generally recommend using double labeling with calcein green at a dosage of 10−20 mg/kg in young and 10 mg/kg in aged rats and mice. In most cases, two different labels do not offer any advantage unless the information contained within the individual labels is used—for example, in multiple labeling regimens (Erben et al., 1997).

In most cases, fluorochromes are given subcutaneously or intraperitoneally in mice and rats. An exception to this rule may be tetracyclines, mainly due to animal welfare considerations because the injection solutions must be slightly acidic to keep the tetracyclines in solution. Therefore, subcutaneous or intraperitoneal injection may cause transient pain that can be avoided by intravenous administration. However, intravenous injection of fluorochromes needs to be done slowly, especially with alizarin, due to their calcium-complexing nature. For details of preparation of fluorochrome injection solutions, the reader is referred to more specialized textbook chapters (Erben, 2003).

An important aspect of experimental planning is to use an appropriate time interval between individual fluorochrome labels and between the last fluorochrome label and necropsy. The reason the time interval between the last label and necropsy should be at least 1 day in mice and 2 days in rats is that the last label needs to be covered with new bone matrix to prevent elution during subsequent sample processing. The time difference between the two labels is called the interlabel time (Ir.L.t) or marker interval. To appreciate the major consequences of the Ir.L.t on dynamic histomorphometric parameters in cancellous bone of rodents, it is essential to understand the nature of label escape error and skewed sampling error. The label escape error describes the influence of the Ir.L.t on the proportion of double-labeled remodeling sites. The magnitude of the label escape error depends on the ratio between the Ir.L.t and the formation period (FP), or Ir.L.t/FP ratio. The shorter the Ir.L.t, the higher is the proportion of double-labeled remodeling sites. When the Ir.L.t is greater than the FP, remodeling units may not be double labeled, making it impossible to measure MARs and BFRs. Therefore, keeping the Ir.L.t as short as possible is important for reliable data generation. It is obvious that a limiting factor in this context is the distance between the fluorochrome labels because for accurate assessment of MAR, the double labels need to be clearly separated. Hence, in practical terms, the trade-off between label escape error and accurate measurement of MAR determines the appropriate marker intervals. There is general agreement that an Ir.L.t/FP ratio below 0.2 results in an acceptable label escape error (Frost, 1983a). Even with appropriate Ir.L.ts, label escape will occur because some sites will either begin bone formation or cease formation between the time the initial label is given and the time the second is administered. Therefore, a correction for label escape should always be made (Martin, 1989).

The skewed sampling error describes the error in the measurement of MAR introduced by an inappropriately long Ir.L.t. Osteoblastic matrix formation and MAR are more rapid during the early phase of the FP. Moreover, osteoblasts may temporarily stop their bone-forming activity, especially during the late phases of the FP (so-called OFF periods). Therefore, the longer the marker interval, the lower the measured values of MAR will be (Frost, 1983b) and the less accurate relative to actual MAR.

In conclusion, use of appropriate marker intervals is necessary to avoid large label escape and skewed sampling errors. The authors recommend the use of a marker interval of 1 day in 3−4 week-old mice, of 2−3 days in 6−12 week-old mice, of 3−5 days in mice older than 4 months, and of 5−7 days in rats older than 3 months (Erben, 2003). If the study also analyzes cortical bone, longer label intervals are needed for older mice and rats. For a more detailed description and explanation of label escape and skewed sampling errors, the reader is referred to other textbooks (Erben, 2003; Frost, 1983b).

When periosteal bone formation is measured in studies involving aged rats or mice, an Ir.L.t suitable for cancellous bone histomorphometry may result in inseparable double labels at periosteal surfaces. Periosteal MAR shows an age-dependent decline in all species including mice and rats. Therefore, periosteal MAR may be much lower than cancellous and endocortical MAR in aged rodents. This problem can be solved by introducing a second pair of fluorochrome labels with a different color and a longer Ir.L.t. For example, a calcein double label with a marker interval of 3−5 days is given for the measurement of cancellous BFRs in an aged mouse study, and an alizarin complexone double label with a marker interval of 10 days is given for the measurement of periosteal BFR. In some experimental situations, introducing a single baseline fluorochrome label for the assessment of periosteal bone formation over the whole experimental period can add useful information.

Sample preparation

An important consideration with major implications for later analytic possibilities is how to embed the bone samples. This decision depends on the planned endpoints of a study. If the endpoint is standard bone histomorphometry, the bones are usually embedded undecalcified in methylmethacrylate (MMA), because MMA embedding yields the highest quality undecalcified bone sections. Decalcification with subsequent paraffin embedding is often used for bone and bone marrow histopathology but plays only a minor role in rodent bone histomorphometry, mainly because decalcification results in complete loss of fluorochromes. As described above, fluorochromes are bound to calcium in mineralized bone matrix. Therefore, dynamic bone histomorphometry is not possible in decalcified, paraffin-embedded bone samples. If done properly, MMA embedding and histological processing result in high-quality sections of undecalcified bone, a prerequisite for any sound histomorphometric evaluation. However, the downside of standard MMA embedding is that radicals formed during the exothermic chain reaction occur during MMA polymerization. This will covalently alter all macromolecules present in the sample, resulting in almost complete loss of antigenic determinants and enzyme activities. Therefore, any reliable histochemical or immunohistochemical analysis is not possible on bone specimens embedded in standard MMA. There are two options to circumvent this. One is to use low-temperature MMA embedding methods that reduce covalent modification of biomolecules by slowing down the polymerization process and the number of radicals formed through the lowering of the polymerization temperature to about −20°C (Erben, 1997). These low-temperature MMA embedding methods are suitable for histochemistry and immunohistochemistry, and the histological section quality is not inferior to conventional MMA embedding (Erben, 1997). Because TRAPc histochemistry is necessary for the quantification of osteoclast numbers (Oc.Ns) in mice, we embed all our mouse bones using low-temperature MMA embedding. The other option is to use cryoembedding and cryosectioning of bones. Although previously considered fraught with unsurmountable technical difficulties, the latter technology has made significant progress during recent years, and it is now possible to routinely prepare high-quality frozen sections of undecalcified bone.

Fixation

To avoid autolysis of tissue and preserve optimal cellular detail, it is important that the bones are fixed immediately after necropsy. Careful cleaning of the bones from adherent muscles and tendons helps with later orientation of the blocks in the microtome. To achieve optimal fixation results, the marrow cavity should be opened in larger bones such as femora, tibiae, or larger rat vertebrae before fixation. In long bones, this is best done by transversally cutting the bone with a low-speed or small oscillating saw to isolate the different parts of the bone (distal femur, proximal tibia, and shaft) for separate analysis. There are many different fixation protocols. The most commonly used in bone histomorphometry are ethanol preservation and fixation in formalin/paraformaldehyde (PFA). We recommend fixation in 40% ethanol at 4°C for 48 h in rat bones, and 4% PFA in 0.1 M phosphate buffer at pH 7.4 and 4°C for 24 h in mice. After fixation in 40% ethanol, the specimens are transferred to 70% ethanol. After PFA fixation, the samples are washed overnight in 0.1 M phosphate buffer, pH 7.4, containing 10% (w/v) sucrose. Thereafter, they are also transferred to 70% ethanol for long-term storage.

Standard methylmethacrylate embedding

The dehydration and infiltration steps shown in Table 82.1 should be carried out at 4°C using a magnetic stirrer. Incubation times for the individual steps depend on the sample size and ages of the animals. Larger samples and samples from older animals or those treated with antiresorptives require longer durations.

For polymerization, the infiltrated bones are placed in 25 mL glass vials containing a plastic base. The bases are prepared by pouring 5 mL of freshly prepared MMA solution III (see next section) in the empty vials, capping them with an airtight plastic cap, and polymerizing the plastic at 40°C for 24 h. For optimal positioning of the blocks in the microtome, a plastic base is helpful because the sample is surrounded by plastic on all sides after polymerization. A label is added to identify the sample. The glass vials are then filled to the top with freshly prepared MMA solution III and capped airtight with a plastic cap. The vials are kept in a water bath overnight at 26°C. The next morning, the temperature is increased to 28°C. Subsequently, the temperature is increased by 0.5°C every 12 h until the final temperature of 31°C is reached. Using this protocol, polymerization usually occurs at about 29−30°C (Schenk et al., 1984).

TABLE 82.1 Dehydration and methylmethacrylate (MMA) infiltration procedure.

Step	Time (days)
70% ethanol	1–4
96% ethanol	1–4
100% propan-2-ol, repeat twice	1–4
Xylene, repeat twice	1–4
MMA solution I	2–4
MMA solution II	2–4
MMA solution III	2–4

MMA solution I: methylmethacrylate with 20% (v/v) dibutyl phthalate; MMA solution II: MMA solution I with 1% (w/v) dry benzoyl peroxide; MMA solution III: MMA solution I with 3% (w/v) dry benzoyl peroxide.

Low temperature methylmethacrylate embedding

The infiltration is done according to the regimen given in Table 82.1. However, the chemistry of MMA infiltration solutions is different to allow for low-temperature polymerization and the preservation of enzyme activities and antigenic determinants:

MMA solution I—methylmethacrylate with 35% (v/v) butyl methacrylate, 5% (v/v) methyl benzoate, and 1.2% polyethylene glycol 400
MMA solution II—MMA solution I with 0.4% (w/v) dry benzoyl peroxide
MMA solution III—MMA solution I with 0.8% (w/v) dry benzoyl peroxide

Similar to the process for the routine MMA embedding procedure, glass vials with plastic bases are used. To prepare the bases, add 600 μL of *N*,*N*-dimethyl-*p*-toluidine to 100 mL of freshly prepared MMA solution III at 4°C and stir for a few minutes. Five mL of the polymerization mixture is poured into each glass vial. Before capping each vial with an airtight plastic cap, it needs to be gassed with N_2 or CO_2 for 20–30 s to remove O_2 from the vial. Polymerization of the bases is achieved by incubating vials for at least 24 h at 4°C.

To prepare the polymerization mixture, 400 μL of *N*,*N*-dimethyl-*p*-toluidine is added to 100 mL of MMA III solution at 4°C and stirred for a few minutes. The infiltrated bones are placed on the plastic bases in the prechilled glass vials (around 0°C on ice), filled with the polymerization mixture to the top, and the vials are capped with airtight plastic caps. The vials are then transferred to a cooling unit at −23°C for 16 h. It is critical for the quality of the embedding protocol that the temperature, and thus the velocity of the polymerization, is well controlled. It is recommended that a programmable climate chamber is used for this purpose. The polymerization is initiated by gradually increasing the temperature from −23°C to −22°C over 1 h and thereafter from −22°C to −20°C over 46 h. Subsequently, the temperature is increased from −20°C to −18°C over 24 h and from −18°C to +2°C over 12 h. The polymerized blocks should be stored frozen at −20°C.

Sectioning of plastic-embedded bone specimens

Microtome sectioning

Sectioning of undecalcified plastic-embedded bone specimens can be performed on rotary or sledge microtomes. In our hands, the best section quality can be achieved on sledge microtomes with a knife angle of 40 degrees. Typical section thickness is between 3 and 7 μm. To achieve optimal section quality, the drying process should be performed in a slide press. To improve reproducibility and reduce interindividual variance, it is important to standardize the sectioning planes. Standard bone sites for cancellous bone histomorphometry are the proximal tibia and lumbar vertebrae (L1 or L2) in rats and the distal femur and L1 or L2 in mice. We use midsagittal sectioning planes for rat tibiae and vertebrae as well as for mouse distal femora. Alternatively, rat tibiae may be sectioned using a coronal sectioning plane through the cruciate

ligaments. Mouse vertebrae should be sectioned in a frontal plane to make sure that enough cancellous bone is available for histomorphometric analysis. It is also possible to use the proximal tibia in mice for cancellous bone histomorphometry. However, due to the strong curvature of the murine tibia, sectioning is more difficult than it is with the distal femur. In addition, the amount of cancellous bone is lower in the proximal tibial metaphysis than in the distal femoral metaphysis, making the distal femur the preferred long bone site in mice.

Micromilled cross sections of cortical bone

For cortical bone histomorphometry, the tibial shaft at 2−3 mm proximal to the insertion of the fibula is the standard sampling site in rats, whereas in mice the midshaft of the femur is usually used. To reduce the interindividual variance, the sampling site should be exactly defined and standardized within an experiment. The bones are embedded in standard MMA, cut perpendicular to the long axis of the bones with a water-cooled precision diamond band saw, microtome saw, or diamond-embedded wire saw into 80−200 μm-thick slices, glued to 3-aminopropyltriethoxysilane (APES)-pretreated glass slides using adhesive (e.g., Loctite 420, Henkel) and a splicer, and finally microground with a microgrinder or by hand to provide ∼20-μm-thick transverse sections. To prepare the APES-pretreated slides, immerse acetone-cleaned glass slides in APES for 5 min, rinse in distilled water, and allow them to dry.

Cryoembedding and cryosectioning

As mentioned above, it was previously thought impossible to prepare high-quality cryosections of undecalcified bone. However, with the advent of tape technology, the situation has considerably changed (Hong et al., 2012). Using this technology, it is now possible to prepare high-quality cryosections of undecalcified bones employing a standard cryotome. The advantages are immediately evident: (1) enzyme activities and antigenic determinants are optimally preserved, (2) the technology saves 4−5 weeks of time because the time-consuming plastic embedding of the specimens is not necessary, and (3) it opens up new methodological horizons beyond bone histomorphometry such as laser capture microdissection. We recently employed this technology to elucidate the cellular mechanisms by which estrogen deficiency causes bone loss (Streicher et al., 2017). Cryosections of bone also can be used for standard dynamic cancellous bone histomorphometry (Hong et al., 2012).

Immediately after harvesting, the bones are snap-frozen in liquid nitrogen using an appropriate cryoembedding medium such as TissueTek (SAKURA, Finetek, USA). Thereafter, the blocks can be stored at −80°C. Before sectioning, the blocks should be brought to −25°C for at least 2 h to make them less brittle. Sectioning at 4−8 μm-thickness can be done with a standard cryotome (e.g., Leica) equipped with a tungsten carbide knife. Before the section is taken, the block is covered with an adhesive tape (Section Lab Co. Ltd., Hiroshima, Japan). Air bubbles between the block and the tape need to be avoided. The section is collected together with the tape and mounted on a glass slide with the tape facing the slide and the bone section facing upward. It is not necessary to use any glue between the tape and glass slide. Further processing of the cryosections depends on the intended purpose. For histochemistry or immunohistochemistry, the cryosections are briefly (2 min) fixed in methanol or acetone at −20°C before incubation with primary antibodies or enzyme substrates.

Staining

Von Kossa/MacNeal's stain

The von Kossa stain with MacNeal's tetrachrome counterstain combines good cellular detail with a clear distinction between mineralized and unmineralized bone (Schenk et al., 1984). It is the standard stain for static cancellous bone histomorphometry in mice and rats. A disadvantage is that mineralized bone and calcified cartilage are uniformly stained black. Therefore, information about structural details within the mineralized bone matrix such as remodeling units or calcified cartilage remnants is lost. Before staining, the MMA is removed from the sections.

Toluidine blue stain

The toluidine blue stain at acid pH is a nuclear stain and gives very good cellular detail. It also provides a good distinction between mineralized and unmineralized bone (Baron et al., 1983). It is often used for histomorphometric measurement of cellular parameters in rats and can be used for measuring osteoid. It also is frequently used for evaluation of non-mineralized skeletal tissues, such as cartilage.

Masson–Goldner stain

Masson-Goldner, or Masson's trichrome, staining is a multicolor staining commonly used for bone to distinguish cells from surrounding connective tissue. The staining can be used on formalin-fixed material and for paraffin, frozen, or MMA embedding sections. Though there can be a slightly difference in the solution ratio, most recipes produce red keratin and muscle fibers, blue or green collagen and bone, light red or pink cytoplasm, and dark brown to black cell nuclei (Gruber, 1992).

Cement line stain

The cement line stain is a surface-staining technique for demonstration of cement lines in undecalcified sections (Erben, 1996). For this stain, the MMA is *not* removed, but the surface of the bone should be acid-etched prior to staining. Alternatively, the toluidine blue can be mixed with tetraborate and formic acid: 1% (w/v) toluidine blue O, 1% (w/v) sodium tetraborate, and 0.1% (v/v) formic acid in distilled water (filter before use, can be used several times).

Histochemical tartrate resistant acid phosphatase staining

This protocol is used for histochemical identification of osteoclasts in undecalcified sections of mouse and rat bones that have been embedded using the low-temperature MMA protocol described above. Osteoclasts will stain red and provide an easier and more accurate count for the measurement of osteoclast Oc.N and perimeter (Oc.Pm).

Staining of micromilled cross sections

Micromilled cross sections of cortical bone can be stained with toluidine blue after etching the surface with H_2O_2 (Reim et al., 2008). The plastic is not removed before staining. This stain provides a nice representation for the measurement of cortical porosity, osteoid, cellular detail, and cement lines.

Cancellous bone histomorphometry

Cancellous bone histomorphometry is an indispensable tool for the assessment of bone turnover, bone mineralization, and bone remodeling dynamics. Although structural bone parameters also are measured during routine histomorphometry procedures, high-resolution μCT technology is far superior to histomorphometry with regard to the assessment of bone structure, because the latter technology is able to assess bone architecture in three dimensions (3D) in a much larger volume and an assumption-free manner. However, it is important to consider that this is only true under the condition that bone mineralization is normal. By definition, the term "bone" comprises both mineralized and unmineralized matrix (osteoid). μCT scanners pick up only mineralized bone. Therefore, μCT-based structural parameters are associated with a large error when bone mineralization is impaired.

The primary spongiosa beneath the growth plate is normally excluded from measurement by keeping a certain distance from the growth plate. This distance depends on the longitudinal elongation rate at a specific site. In the tibial metaphysis of young rats, bone within 1 mm of the growth plate should be excluded from measurements. In rats beyond 5 months of age, this distance can be reduced to 0.5 mm. In lumbar vertebrae of rats at all ages, it is safe to exclude bone within 0.5 mm from the cranial and caudal growth plates. In mice, these values can be halved—i.e., 0.5 mm in the distal femoral metaphysis in rapidly growing mice and 0.25 mm in the vertebrae as well as distal femoral metaphysis of older mice. In addition, cancellous bone within 0.25 mm of endocortical bone surfaces should generally be excluded from measurements to avoid inclusion of endocortical bone turnover activities.

Structural parameters

All two-dimensional and 3D structural parameters are derived from the primary measurements, namely total (measuring or tissue) area, bone area, and bone surface (Table 82.2). Of note, calculation of the 3D parameters bone surface, trabecular thickness, trabecular number, and trabecular separation is based on the model assumption that the structure is isotropic (Parfitt et al., 1987). It is clear that structural bone elements are not oriented in a spatially random fashion in mouse and rat cancellous bone. Therefore, 3D histomorphometric parameters calculated on the basis of this model are always associated with some systematic error and may deviate from assumption-free assessment of the same parameters by μCT.

TABLE 82.2 Structural trabecular histomorphometric parameters.[a]

Primary parameters (abbreviation)	(Unit)
Total area (Tt.Ar; bone + bone marrow)	(mm^2)
Bone area (B.Ar)	(mm^2)
Bone surface (B.Pm)	(mm)
Two-dimensional derived parameters	
Bone area (B.Ar/T.Ar) = B.Ar/T.Ar × 100	(%)
Bone surface ratio (B.Pm/B.Ar) = B.Pm/B.Ar	(mm/mm^2)
Trabecular width (Tb.Wi) = B.Ar/B.Pm × 2000	(μm)
Trabecular number (Tb.N) = 0.5 × B.Pm/T.Ar	(no./mm)
Trabecular separation (Tb.Sp) = 1/Tb.N × 1000 − Tb.Wi	(μm)
Three-dimensional derived parameters	
Bone volume (BV/TV) = B.Ar/T.Ar × 100	(%)
Bone surface ratio (BS/BV) = B.Pm/B.Ar × 4/π	(mm^2/mm^3)[b]
Trabecular thickness (Tb.Th) = B.Ar/B.Pm × 2000 × π/4	(μm)
Tb.N = 4/π × 0.5 × B.Pm/T.Ar	(no./mm)
Tb.Sp = 1/Tb.N × 1000 − Tb.Th	(μm)

[a]*For formula explanation, interpretation, and complete histomorphometric indices lists, refer to (Dempster et al., 2013).*
[b]*The obliquity correction often is not used for measurements in rodents but is used in larger animal species. If a correction is used, the values 1.199/2.00 for trabecular number or 2000/1.199 for trabecular width and separation are recommended.*

Bone formation

Bone formation is best assessed by dynamic, fluorochrome-based bone histomorphometry (Table 82.3). These measurements represent a functional determination of matrix synthesis by an osteoblast team and its subsequent mineralization and are clearly superior to a purely morphology-based assessment of osteoblastic activity such as osteoblast perimeter/surface or osteoblast number as long as there is no mineralization deficit. Fluorochrome-based measurements are made on unstained sections, mounted in nonfluorescent media such as Fluoromount (Serva) or Eukitt's without removal of the plastic. The Ir.L.t is the time interval between the administration of the labels. The MAR is given in μm/day and is the mean distance between the labels divided by the Ir.L.t. In cases where broader diffuse labels are present, the interlabel distance should be measured from midpoint to midpoint of the labels (Frost, 1983c). Fluorochrome labels appear in the form of bands in sections, whereby the width of a band depends on the angle at which a 3D label plane has been sectioned, speed of

TABLE 82.3 Dynamic histomorphometric indices of bone formation.

Primary parameters (abbreviation)	(Unit)
Bone surface (B.Pm)	(mm)
Double-labeled surface (dLS.Pm)	(mm)
Single-labeled surface (sLS.Pm)	(mm)
Interlabel distance (Ir.L.D)	(μm)
Derived parameters	
Mineral apposition rate (MAR) = Ir.L.D/Ir.L.t	(μm/day)
Mineralizing surface (MS/BS) = (dL.Pm + 0.5 × sL.Pm)/B.Pm × 100	(%)
Bone formation rate/BS (BFR/BS) = MS/BS/100 × MAR	($μm^2$/μm/day or $μm^3/μm^2$/day)

matrix mineralization, and time the fluorochrome was present in the extracellular fluid. The mineralizing bone perimeter (M.Pm) is either defined as the double-labeled perimeter (dL.Pm) or the sum of dL.Pm and one-half the single-labeled perimeter. The latter definition is widely used in nonrodent species. Which calculation of M.Pm is most suitable for rodents is a controversial issue. The definition M.Pm = dL.Pm underestimates the "true" M.Pm, but on the other hand reduces the likelihood of errors introduced by nonspecific labeling of resting or resorptive bone surfaces, which is often a problem in mice and rats. Therefore, to be "on the safe side," many labs use the latter definition of M.Pm. BFR is the amount of mineralized bone matrix produced per unit of bone surface, tissue volume, or time. The authors recommend using surface-based BFR because it best reflects the intensity of bone formation per unit of bone perimeter/surface and is not directly influenced by differences in cancellous bone mass. This is particularly relevant in osteopenia models such as gonadectomized mice and rats in which there is substantial loss of bone volume.

The essential information about the intensity of cancellous bone formation is contained in the three parameters MAR, MS/bone surface (BS), and BFR/BS. Therefore, static histomorphometric indices of bone formation such as osteoblast perimeter/surface (Table 82.4) are dispensable when only a minimum data set is required.

Bone mineralization

Histomorphometry is indispensable for reliably assessing alterations in bone formation and mineralization. One of the key parameters that needs to be measured for the assessment of bone mineralization is osteoid width (O.Wi). Osteoid measurements are usually performed on sections stained with von Kossa/MacNeal's, toluidine blue, Goldner's trichrome, or Villanueva staining (Villanueva et al., 1994). O.Wi either can be calculated from osteoid area (O.Ar) and perimeter as shown in Table 82.4, or measured directly by a two-point distance measurement, sampling osteoid seams every 50 μm. However, compared with those of humans and higher mammals, osteoid seams are very thin in rodents with normal bone mineralization, which makes it difficult to measure reliably unless one uses very high magnification. Increases in bone formation can lead to moderate increases in osteoid perimeter (O.Pm) and O.Ar in the absence of impaired bone mineralization. The most sensitive parameter indicative of impaired bone mineralization is osteoid maturation time (Omt). Impaired bone mineralization is typically reflected in increased Omt. The calculation of mineralization lag time (osteoid thickness/Aj.Ar; with adjusted apposition rate Aj.Ar = MAR × M.Pm/O.Pm) is not useful in rodents in most cases, because the M.Pm/O.Pm ratio often is greater than 1 in mice and rats. However, there are specific cases, such as in chronic kidney disease, in which Aj.Ar is much more sensitive than Omt in detecting a defect in mineralization. Severe impairments in bone mineralization often result in complete lack of fluorochrome double labeling, making the calculation of Omt impossible. In these cases, the impaired bone mineralization is reflected in profound increases in O.Wi and O.Ar.

TABLE 82.4 Histomorphometric indices of bone formation and of bone mineralization.

Primary parameters (abbreviation)	(Unit)
Bone surface (B.Pm)	
Bone area (B.Ar)	
Osteoid surface (O.Pm)	
Osteoid area (O.Ar)	
Osteoblast surface (Ob.Pm)	
Osteoid width (O.Wi)	
Derived parameters	
O.Pm = O.Pm/B.Pm × 100	(%)
Ob.Pm = Ob.Pm/B.Pm × 100	(%)
O.Ar/B.Ar = osteoid volume (OV)/BV = O.Ar/B.Ar × 100 (%)	
O.Wi = O.Ar/O.Pm × 1000	(μm)
Osteoid maturation time (Omt) = O.Wi/MAR	(d)
Osteoid thickness (O.Th)[a] = O.Wi × π/4	(μm)

[a]*Many labs do not normalize for obliquity of section in rats, so this may only apply to large nonrodent animal models.*

Bone resorption

In contrast to the assessment of bone formation by dynamic histomorphometry, histomorphometric measurements aimed at assessing bone resorption are purely based on morphology. Histomorphometry cannot provide a functional determination of osteoclast activity. In part this is because erosion surfaces are shallow and can be difficult to detect in rodents. In other cases, such as some conditions of osteopetrosis or low bone remodeling due to pharmaceutical treatment, osteoclasts are prevalent but inactive and unable to resorb bone. To assess osteoclast activity, measurements of collagen cross-link excretion in urine or collagen cross-link serum levels are necessary.

In rats, osteoclasts can be reliably detected in toluidine blue, Goldner's trichrome, and von Kossa/MacNeal's-stained sections on the basis of their typical morphology (Fig. 82.1). In mice, a large proportion of osteoclasts are mononuclear, and Howship lacunae are often shallow, making it much more difficult to recognize osteoclasts. Therefore, histochemical tartrate-resistant acid phosphatase (TRAcP) staining is routinely used to quantify osteoclasts in mice. Another possibility is using cathepsin-K immunohistochemistry to sensitively detect osteoclasts in mice. Since TRAcP staining makes all osteoclast profiles readily visible, it is important to count only TRAcP-positive nucleated cells in contact with bone as osteoclasts. TRAcP-positive cells within bone marrow or osteoclast profiles lacking a nucleus are not included in the measurements. The most commonly used primary and derived measurements of Oc.N and bone resorption are shown in Table 82.5. Oc.Pm is defined as the contact perimeter between the osteoclast and the bone surface.

An important point to consider is that Oc.Ns expressed per tissue area (N.Oc./T.Ar) can lead to erroneous conclusions when the amount of cancellous bone differs between groups of animals. Therefore, Oc.Ns should always be expressed per mm of bone perimeter (N.Oc/B.Pm) to avoid this pitfall. Osteoclasts can normally be found only on mineralized bone surfaces. Therefore, it can be useful to express Oc.Ns per mineralized perimeter to correct for osteoid surfaces, especially when O.Pm differs between different groups of animals. The measurement of eroded perimeter (E.Pm) includes prior and currently active sites of bone resorption. This parameter is sometimes assessed in rats, although the measurement is not always reliable because the erosion cavities are shallow. The authors recommend using a certain cutoff (e.g., at least 3 μm resorption depth) to exclude very shallow lacunae and increase reproducibility of the measurement.

Bone remodeling dynamics

Although aged mice also show clear evidence of remodeling units, remodeling-based parameters are usually assessed only in rats. The most commonly used variables reflecting bone remodeling indices in rat studies are wall width (W.Wi), active FP, and activation frequency. Because the relative proportion of cancellous bone remodeling versus modeling increases with age, especially in the long bones of the appendicular skeleton (Erben, 1996), rats older than 6 months of age are used for the measurement of remodeling-based parameters in most cases. As shown in Table 82.6, measurement of W.Wi forms the basis of all remodeling-based parameters. W.Wi is the mean width of completed remodeling packages. Wall thickness (W.Th) is the corresponding 3D parameter. In rodents, W.Wi is most reliably measured using cement line-stained sections viewed under polarized light (Fig. 82.1). Similar to O.Wi, W.Wi can either be measured directly by two-point distance measurements, using evenly distributed perpendicular distance measurements between the reversal line and the bone surface per remodeling unit, or indirectly by tracing the bone surface and the reversal line of the remodeling package. It is important to exclude remodeling units with a scalloped bone surface indicative of earlier resorptive activities and units with active bone formation at the bone surface, because both would reduce the measured values for W.Wi. We recommend measuring the width of at least 15 remodeling units per sample to arrive at reliable values. However, if bone subjected to a potent antiresorptive agent is being measured, it may be difficult to find 15 units. In these cases, W.Wi changes can underestimate the impact of the pharmaceutical agent. Therefore, W.Wi is more useful when evaluating bone anabolic agents or the effects of skeletal aging.

Cortical bone histomorphometry

For the measurement of structural parameters, we use ~20-μm-thick microground sections stained with toluidine blue. Primary measurements are cross-sectional tissue area (Tt.Ar), cortical area (Ct.Ar), marrow area (Ma.Ar), cortical thickness, and number and area of intracortical pores (N.Po and Po.Ar). To be consistent and to reduce measurement variation, we recommend that only porosities >30 μm in diameter are measured. From these data, the relative values for cortical and marrow areas (Ct.Ar/Tt.Ar and Ma.Ar/Tt.Ar, %) and intracortical pore area (Po.Ar/Ct.Ar, %) can be calculated. Relative

[a]*Not often used in rodent studies.*

values often show less variability than the absolute values for Ct.Ar, Ma.Ar, and Po.Ar and can partially compensate for small variations in sampling site. Analogous to cancellous bone, μCT analysis of cortical bone is the gold standard for assessing cortical bone structure because μCT analysis is based on a whole stack of sections, not only on one or two sections as in histomorphometry.

Rats and mice do not show genuine Haversian intracortical remodeling. Therefore, changes in N.Po and Po.Ar are not indicative of changes in intracortical remodeling. Rather, increased intracortical porosity, which can occur in sex steroid-deficient aged rats, low-calcium diets, or with underloading in the vicinity of the marrow cavity, reflects increases in a primitive remodeling activity originating from endocortical bone surfaces (Reim et al., 2008) (true intracortical remodeling can occur in rats with a significant challenge, such as occurs with a low-calcium diet or fatigue loading (Bentolila et al., 1998).

The fluorochrome-based measurement of endocortical and periosteal BFR follows identical principles as in cancellous bone. These measurements are made on unstained ~20-μm-thick microground sections. Primary measurements are the endocortical and periosteal MAR and M.Pm, from which endocortical and periosteal BFR/BS can be calculated. Because of the lack of intracortical remodeling in rats and mice, intracortical BFR is usually not measured.

Osteoclasts are not found on periosteal bone surfaces at the tibial or femoral midshaft in rodents and are only rarely observed on endocortical bone surfaces in microground sections. Therefore, the only useful histomorphometric index of endocortical bone resorption is the endocortical eroded perimeter (Ec.E.Pm/B.Pm, %). Analogous to cancellous bone, a cutoff value of at least 3 μm resorption depth should be used to exclude very shallow erosions.

Histomorphometric measurement of longitudinal bone growth

In studies involving growing rats or mice, it is sometimes necessary to assess longitudinal bone elongation rate, which is measured directly, using fluorochrome labeling. Although the routine double label administered for the measurement of cancellous BFRs can also be employed to measure longitudinal bone elongation, use of a separate single label with a different color results in more reliable measurements in most cases. When using a single label, longitudinal growth rate is assessed by measuring the mean distance between the most proximal traces of the fluorochrome label and the first calcified cartilage spicules found in the growth plate, divided by the time interval between administration of the label and necropsy. This time interval must not be too long, because metaphyseal cancellous bone is resorbed toward the diaphyseal marrow cavity in a growing animal, leading to disappearance of the label.

Microdamage measurement technique

The importance of bone microcrack accumulation in vivo was first identified by Frost nearly 50 years ago (Frost, 1960). But it was not until after validation of the *en bloc* basic fuchsin staining technique (Burr and Stafford, 1990; Burr and Hooser, 1995), originally proposed by Frost, that the role and consequences of damage accumulation in bone began to be studied in earnest. It is now clear that, at least under experimental conditions, microdamage accumulation can reduce the residual strength and stiffness of bone (Burr et al., 1997, 1998a) and is also associated in animal models with reduced bone toughness (Mashiba et al., 2000, 2001; Komatsubara et al., 2003; Allen et al., 2006). It is widely considered to be one of the five "bone quality indicators" together with architecture, turnover rate, matrix/collagen properties, and mineralization.

There are now several techniques for staining tissues *en bloc* to label microdamage. The "standard" technique is still staining with basic fuchsin (Burr and Hooser, 1995), but newer fluorescent techniques have also been developed and validated (Lee et al., 1998, 2000, 2003). Recently, a contrast-enhanced micro-CT technique using $BaSO_4$ was proposed as a 3D technique for identifying regions of microdamage (Turnbull et al., 2014), although this approach does not separate microcracks from other tissue voids such as pores.

Basic fuchsin acts by simple diffusion and will appear wherever there are spaces that it can occupy—including Haversian canals, lacunae, and canaliculi as well as microcracks. Staining under load does not improve the diffusion of dye into cracks nor does it prevent the stain from entering cracks that may have closed (Burr et al., 1998b). Fluorescent techniques rely on the presence of exposed calcium along the walls of cracks. Basic fuchsin has fluorescent properties as well, and viewing basic fuchsin staining of cracks under fluorescent microscopy improves the resolution of the microcracks in bone slightly (Huja et al., 1999). Times of en bloc staining vary depending on the size of the bone, its porosity, and the patency of its canaliculi. These are not always known, but reasonable estimates can be made using values shown in Table 82.7.

Several groups have now explored the possibility of using positron emission tomography for detecting areas of damage in vivo without the need for histological techniques (Li et al., 2005; Silva et al., 2006). These techniques do not have the resolution to detect individual microcracks, but they hold promise and with future development may provide a means to identify damaged regions in living individuals.

Microcracks are best viewed in sections that are 80−150 μm thick. Microcracks stained with basic fuchsin are difficult to see in thinner sections (3−5 μm thick) because there is not sufficient depth of staining to be easily and consistently detected in such thin sections. Because sections this thin must be used for cancellous bone histomorphometry to minimize the imprecise definition of bone surfaces caused by section thickness, it may not be possible to accurately measure microcrack numerical densities on the same section as one would measure static and dynamic histomorphometric parameters (Fig. 82.2).

In addition to brightfield microscopy, confocal microscopy can be used in conjunction with staining agents (Zioupos et al., 1994; Boyce et al., 1998) and is particularly sensitive for identifying smaller cracks within diffusely stained areas (Fazzalari et al., 1998). Confocal microscopy can discriminate between patchy areas of stain that represent poorly mineralized regions of bone and areas that are stained diffusely because they are damaged (Vashishth et al., 2000).

Microdamage comes in many varieties (Boyce et al., 1998) and is a general term that describes both various microcrack morphologies as well as "diffuse damage" that consists of very tiny (<10 um; Fazzalari et al., 1998; Seref-Ferlengez et al., 2014) cracks that may never develop into a linear microcrack (Vashishth et al., 2000). Microcracks are defined by their shape (more jagged than canaliculi or vascular canals), some depth of field, and permeation of stain into the bone matrix through the crack walls. They are typically 40−80 μm "long" in cross section (or in trabecular bone) but can run 2−3 mm or more longitudinally in cortical bone (Burr and Martin, 1993). In 3D they are elliptical with an aspect ratio of 4:1 or 5:1 (Larrue et al., 2011). Diffuse damage is more difficult to quantify and is usually assessed by the stained area representative

TABLE 82.7 Times for *en bloc* staining of different samples.

Type of bone		Time per step[a]
Mouse	Femur/tibia	1 h
Rat		
	Ulna	2 h
	Proximal tibia	2 h
Dog		
	Rib (periosteum removed)	4 h
	L3 vertebra	4 h
	Femoral neck	4 h
Human

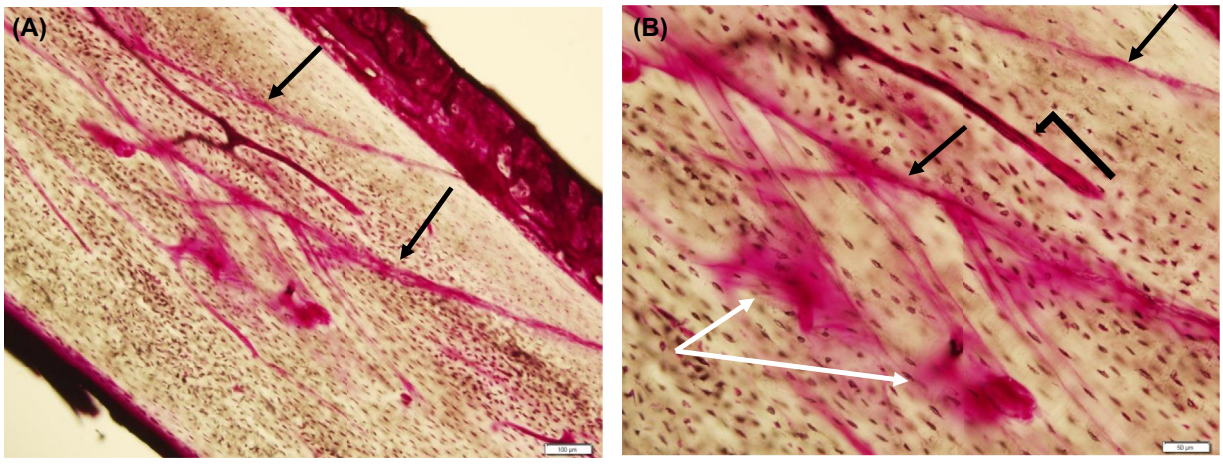

FIGURE 82.2 Bone microdamage in longitudinal section in a rat that was mechanically loaded. *Arrows* identify two linear microcracks that appear to be emanating from the periosteal surface of the bone; 100× magnification. *Black arrows* identify the linear cracks from (A). Note that the basic fuchsin stain diffuses in an irregular way into the bone matrix outside the cracks. (B) *White arrows* show areas of diffuse microdamage. In these areas, individual cracks are much smaller (10 μm) and more numerous, and require a higher magnification or confocal microscopy to identify. However, because there is a collection of damage here, the basic fuchsin stain is able to diffuse into the crack spaces and create an area of intense staining. The perpendicular arrow points to a vascular space. Note that there is no diffusion into the bone matrix as there is for the linear microcracks. This is one way to distinguish microcracks from vascular spaces, which will also be stained. 200× magnification. *Photomicrographs courtesy of Dr. Jiliang Li, Department of Biology, Indiana University—Purdue University, Indianapolis.*

TABLE 82.8 Intraclass correlation coefficients for microdamage measurement.

Variable	Intraclass correlation coefficient (brightfield)	Intraclass correlation coefficient (fluorescence)
Crack density	0.70	0.83
Crack surface density	0.82	0.90
Damage area	0.82	0.89

Crack density (Cr.Dn) = crack number/area. Crack surface density = Cr.Dn × Cr.Le, where Cr.Le = average crack length. Damage area = area of diffuse damage.
From Li, J., Miller, M.A., Hutchins, G.D., Burr, D.B. 2005. Imaging bone microdamage in vivo with positron emission tomography. Bone 37(6), 819–824.

of damage, normalized to bone area (Burr et al., 1998a). Typically, three measurement parameters are used to describe the burden of microdamage in bone: crack density (crack number (Cr.N) / bone area (B.Ar)), crack length (Cr.Le), and crack surface density (= Cr.N/B.Ar x Cr.Le). It is crack surface density that best describes the overall amount of damage in a specimen. Diffuse damage cannot be evaluated in this way because the cracks are too small and numerous to be characterized by number and length. Diffuse damage can be quantified by the area of intense stain that is different from surrounding undamaged matrix, termed the damage area, with B.Ar as the referent.

Variability in microdamage measurements occurs between laboratories and between individuals, but the intraobserver reliability of measurements is relatively good (Huja et al., 1999). Table 82.8 shows the intraclass correlation coefficients for crack density, crack surface density and damage area—all of which range between 0.70 and 0.90. Most variability occurs because of individual variation in how cracks are counted. Because of the *en bloc* staining protocol, artifactual cracks do not contribute significantly to measurement reliability. Nevertheless, particularly for bone biopsies that are taken in vivo, substantial artifacts can occur and render the biopsy unusable for damage analysis.

Intraobserver reliability is slightly better for measurements made under fluorescent light than in brightfield. Even so, averaging two to three sections per bone can reduce the number of crackless specimens and improve measurement reliability and accuracy (Martin et al., 2007).

Histomorphometry of rodent models of bone healing

Typical healing of long bones proceeds through three distinct, consecutive, but overlapping stages: inflammation, repair/callus formation, and remodeling (Einhorn and Gerstenfeld, 2015; Brighton and Hunt, 1991; Marsell and Einhorn, 2011; Ghiasi et al., 2017). The early stage is characterized by trauma-induced soft tissue damage resulting in a hematoma followed by cell infiltration and vascular invasion that result in granulation tissue formation. Bone repair proceeds through both intramembranous and endochondral ossification, which starts by depositing collagen matrix and fibrocartilage that converts granulation tissue into the soft callus. The soft callus or cartilage callus is mineralized to form a hard callus that bridges the fracture gap. Subsequently, osteoclasts remove the calcified cartilage, and osteoblasts form a woven bone bridge that eventually, through revascularization and extensive remodeling, becomes mineralized lamellar bone matrix. During the remodeling stage, the bone is restored to its original shape, structure, and mechanical strength via both modeling and remodeling processes (Einhorn, 1998; Schindeler et al., 2008a; Gerstenfeld et al., 2005), with a few exceptions (such as vertebra or with nonunion fractures).

Histomorphometry of the fracture callus is challenging but can provide unique perspectives into cellular activity and differentiation during the complex bone healing process. Histological and immunohistochemical analyses are essential in preclinical bone healing studies to clarify the biological course of healing, clarify regulating factors, and quantify the effects of pharmacological intervention. Specimens with the periosteum and callus carefully preserved are critical to allow the investigator to see the entire extent of the bridging callus. Therefore, longitudinal sections are recommended. Depending upon the study design, decalcified sections are usually prepared for histological and immunohistochemical quantitation. Undecalcified sections are prepared when mineralization status or BFR analyses are needed. For longitudinal sections, the section with the largest medial-lateral marrow cavity diameter should be obtained. If transverse sections are used, multiple serial sections at fixed increments along the long axis of the entire length of the fracture callus for each animal should be prepared. While hematoxylin and eosin staining is the basic stain for histological evaluation, Safranin-O/fast green (Hacker et al., 1997; O'Driscoll et al., 1999) or Alcian blue with hematoxylin and eosin (Kon et al., 2001; Tiyapatanaputi et al., 2004; Kratzel et al., 2008; Zhang et al., 2002) are commonly used for bone repair evaluations because

they can differentiate cartilage and soft tissues in the callus. To evaluate mineralization of the callus, von Kossa or MacNeal's tetrachrome stains can be useful on undecalcified sections. To visualize cellular details, stains such as TRAP for osteoclasts (Gruber, 1992; Schindeler et al., 2008b) and toluidine blue (Sridharan and Shankar, 2012) for osteoid, osteoblasts, and cartilage chondrocytes also are commonly used on undecalcified sections for the evaluation of bone healing. Because morphological changes during bone repair are driven by a dynamic interplay of molecular, cellular, and biomechanical processes, sampling at multiple time points is highly recommended.

Histomorphometric analyses of bone healing usually require multiple endpoints including determination of hematopoietic tissues, fibrous tissue, cartilage, hard callus area, callus composition at the healing repair site, grading of fracture union (by bridging), fracture-gap tissue type, new bone formation, cell kinetics, microstructure, and tissue vascularity. Due to the high degree of tissue heterogeneity and dynamic matrix turnover, quantitative analyses of bone repair primarily focuses on assessing the time course for cellular response, callus composition (i.e., the volume fraction of mineralized tissue), osteoblast and osteoclast activity in callus remodeling, and the structural features of mineralized bone at different healing stages. All endpoints should be normalized to per-unit T.Ar or presented as a percentage of total callus area. Time courses for the phases of the fracture healing process in rats and mice for three common models are summarized in Table 82.9.

A review of histomorphometric methods applied to the study of long bone fracture repair was published by Gerstenfeld et al. (Gerstenfeld et al., 2005). When interpreted together with other radiographic and biomechanical data, histomorphometry can provide insights into the role of cells, tissues, biological pathways, and the effects of pharmacological or mechanical intervention upon the different stages of bone repair.

Histomorphometry of bone loss rodent models

Rats and mice have been widely used to model human skeletal physiology and disease states including processes leading to bone loss and the efficacy of possible therapeutic interventions. The ovariectomized (OVX) rat model is the most common animal model in osteoporosis research (Wronski et al., 1989a; Kalu, 1991; Lelovas et al., 2008; Kimmel, 1996; Jee and Yao, 2001). OVX-induced bone loss in rats mimics several key features to those observed in postmenopausal women. These similarities include increased rate of bone turnover with resorption exceeding formation, an initial rapid bone loss followed by a steady slower phase of bone loss, and greater loss of cancellous than cortical bone. The rat 4–5 day estrus or menstrual

TABLE 82.9 Time course of repair in common rodent bone healing models.

Models (reference)	Granulation formation phase	Early bone repair phase	Late bone repair phase	Peak 2nd bone remodeling phase[a]
Closed fracture[b] (Brighton and Hunt, 1991; Hacker et al., 1997; Tiyapatanaputi et al., 2004; Turner et al., 2001; Alkhiary et al., 2005)	~3–5 days of hematoma, inflammation cells, granulation tissue	5–16 days of fibrous, angiogenic cells, osteoblasts, osteoid, chondroclasts, fibrocartilage, or soft callus	10–28 days of cartilage tissue, osteoblast, osteoclast, hard callus, and mineralized or woven bone formation	21–35 days of actively remodeling hard tissue and woven bone by osteoclast to lamellar and anatomically shape bone
Stabilized osteotomy[c] (Zhang et al., 2002; Minkwitz et al., 2015; Cao et al., 2002; Komatsubara et al., 2005; Li et al., 1999)	3–5 days of hematoma, inflammation cells, granulation tissue	3–16 days of fibrous, angiogenic cells, osteoblasts, osteoid, chondroclasts, fibrocartilages, or soft callus	7–28 days of cartilage tissue, osteoblast, osteoclast, hard callus, and mineralized or woven bone formation	14–42 of actively remodeling hard tissue and woven bone by osteoclast to lamellar and anatomically shape bone
Femoral cortical defect (Komatsu et al., 2009; Tanaka et al., 2005; Monfoulet et al., 2010)	1–3 days of hematoma, inflammation cells, granulation tissue	3–11 days of intramembranous ossification healing with osteoid, intramarrow woven bone	7–18 days of bone marrow trabecular woven bone converting to cortical bone, resolving granulation tissue	14–21 days of marrow trabecular converting to lamellar and compact cortex

[b] *Data are for both rat and mouse models.*
[c] *Healing time also depends on osteotomy gap size.*

cycle makes this skeleton sensitive to the loss of estrogen (Butcher et al., 1974; Miller et al., 1986). Following OVX in the rat, cancellous osteoclast surface increases quickly within a week from baseline. Osteoclast surface continues to increase and peaks at threefold to fourfold the levels of age-matched sham controls after 4−5 weeks. It then declines but maintains a slight increase over sham-operated animals for a long time (Dempster et al., 1995; Sims et al., 1996). Bone formation indices such as osteoblast surface, MS/BS, MAR, BFR/BS, and BFR/TV are increased about onefold to twofold following OVX but with a time delay relative to bone resorption, representing the coupling of bone resorption and formation and the reversal phase (Wronski et al., 1989a, 1989b; Turner et al., 1993). Significantly increased osteoblast surface can be detected by 7−10 days post-OVX, while increases in MS/BS, MAR, BFR/BS, and BFR/TV usually do not reach statistical significance until 2−3 weeks post-OVX, typically peaking by 5−6 weeks. Bone formation gradually declines to become only slightly higher than age-matched sham controls by 3 months post-OVX (Wronski et al., 1988a, 1989b). Although it is a technical challenge to accurately quantify the bone remodeling cycle in rats, mainly because the eroded surface is shallow and difficult to clearly identify morphometrically, a few studies have indicated that similar to humans, the cancellous bone remodeling period is shorter after OVX than in age-matched intact females (Mori et al., 1990; Ma et al., 1994, 1995a, 1995b, 2003; Chen et al., 1995; Erben et al., 2002). A detectable trabecular bone loss by histomorphometry of the proximal tibia can be seen by 2 weeks, reaches ∼50% bone loss by 30−60 days, and slows to a steady state by ∼90 days after OVX (Wronski et al., 1988a, 1989a). For example, bone volume fraction (bone volume/total volume) in the proximal tibia of a 6-month-old rat is about 17% and declines to 4% in 2 months and 3% in 5 months following ovariectomy (OVX) (Ma et al., 2008). Bone loss in lumbar vertebral cancellous bone is ∼1−3 weeks slower than in the proximal tibial metaphysis, probably due to a relatively slower bone remodeling rate (Wronski et al., 1989b). Morphometric analyses show that OVX-induced bone loss in rats is related to decreased trabecular number and connectivity parameters, and greater trabecular separation, but not related to decreased trabecular width (Ma et al., 2002, 2011; Shen et al., 1993).

Studies also show that not all cancellous bone sites lose bone after OVX in rats. For example, estrogen depletion does not induce cancellous bone loss in the calvaria, epiphysis, distal tibia, or caudal vertebrae in rats, even though bone turnover is increased after OVX in all these sites (Jee and Yao, 2001; Ma et al., 1994; Li et al., 1996a). One common feature for these sites is the presence of yellow marrow, while red marrow tends to dominate at skeletal sites with pronounced cancellous bone loss in the OVX rat, such as the proximal tibia, distal femur, and lumbar vertebra.

The low level of intracortical remodeling in rat long bones makes them unsuitable for modeling estrogen-deficiency effects on human cortical bone. However, studies show that increased endocortical bone turnover and eroded surface are seen in the tibial and femoral shafts of OVX rats (Jee et al., 1990). Periosteal bone formation is increased, which may be partly a mechanical compensation for the loss of endocortical bone and partly due to the mechanical stimulation of body weight gain after OVX (Ma et al., 2002; Wronski et al., 1987). Body weight has been observed to increase by 10%−14% within 4−6 weeks of OVX. The combination of endocortical bone loss and periosteal growth increases total T.Ar, enlarges the bone marrow cavity, thins the cortex, and modestly decreases the cortical area 8−10 weeks after OVX (Ma et al., 1995a, 1997, 2017). Ovariectomy combined with a low-calcium diet or disuse accelerates cortical bone loss (Bagi et al., 1993; Zhang et al., 2016; Keune et al., 2015; Shen et al., 1995, 1997). Although it may not be informative to study cortical remodeling in rats for agents that suppress bone remodeling, rat cortical bone does respond well to bone anabolic agents such as parathyroid hormone analogues (PTH) or parathyroid hormone receptor protein (PTHrp), as described later in this chapter.

Because of its clinical significance, a few histomorphometric studies have attempted to study age-related or OVX-associated femoral neck changes in the rat (Bagi et al., 1995, 1996; Li et al., 1997; Yamamoto et al., 1995). Compared with humans, the rat femoral neck has a much higher cortical-to-trabecular bone ratio (Bagi et al., 1997). OVX induces cellular responses in the femoral neck similar to those observed at other bone sites. Bone resorption and formation changes can be detected as early as 4 weeks post-OVX, while microstructural changes such as enlarged marrow cavity, thinner cortex, and loss of marrow trabecular bone can be detected 6−8 weeks post-OVX. One advantage of the rat femoral neck is the ability to analyze both cortical and cancellous bone parameters from the same histological section.

Mice are another useful small animal model for skeletal research, commonly used for genetic profiling, heritability studies, or evaluating the efficacy of antibodies. Genetically modified mice have powerful advantages in being able to provide insights into how genes regulate the skeletal phenotype, understanding the interaction between important biological pathways, and allowing evaluation of potential therapeutic targets and pharmacologic agents. The magnitudes and rates of cancellous bone loss, cellular activation, and dynamic bone remodeling in response to OVX or mechanical stimulation vary between mouse strains and skeletal sites, and in general are less pronounced and less consistent than in rats (Iwaniec et al., 2006; Bouxsein et al., 2005). As pointed out earlier in the chapter, when evaluating cancellous bone changes, lumbar vertebrae and the distal femur are the preferred sites for histomorphometry in mice rather than the proximal tibia, which has very little cancellous bone. The percentage of cancellous bone area in C57/B6J female mice is

reported to be only 4% in the proximal tibial metaphysis versus 7%−12% in the distal femur and 14%−24% in lumbar vertebrae (Iwaniec et al., 2006; Bouxsein et al., 2005; Amblard et al., 2003).

Orchidectomy (ORX) of aged male rats models closely models conditions in adult men suffering from androgen withdrawal. Because both androgen and estrogen levels are decreased (Erben et al., 2000), some differences in skeletal histomorphometry are observed between ORX and OVX rats. Similar to OVX in female rats, ORX rats show increased bone turnover with bone resorption exceeding bone formation leading to bone loss on both cancellous and endocortical surfaces (Erben et al., 2000; Erben, 2001; Ke et al., 2001; Turner et al., 1990; Vanderschueren et al., 1992). However, different from OVX, periosteal apposition in ORX rats is rapidly suppressed with no periosteal bone growth. This may result from the combination of androgen receptor deactivation, muscle weakening, and loss of body weight following ORX (Ke et al., 2001; Turner et al., 1990). Because both androgen and estrogen levels are closely related to peak bone mass, studies of young growing and aged male ORX rats differ with regard to time and rate of cortical bone changes. The loss of androgen in young rats mainly reduces age-dependent bone growth (i.e., failure to gain bone), whereas later loss of androgen during adulthood leads to a net loss in bone balance causing osteoclast-induced bone loss.

Many rodent models have been developed to study disuse-induced bone loss. Rodent models of reduced weight-bearing include reversible and nonreversible underloading. Hind limb suspension (HS) is the most commonly used reversible underloading model (Morey-Holton and Globus, 1998). Skeletal effects in this model are compartment specific and mimic many of the physiological changes associated with prolonged bed rest or space flight. Histomorphometry of the unloaded proximal tibia, midtibia, or femoral shaft show a 60%−70% decline in cancellous osteoblast surface and BFR and a 70%−90% decline in cortical periosteal BFR within 1−2 weeks of HS in both growing and adult rats (Shen et al., 1997; Bloomfield et al., 2002; Matsumoto et al., 1998; Barou et al., 1999). Trabecular Oc.N in this model may be increased (Kodama et al., 1997) or may not change (Barou et al., 1999). Trabecular area and width are decreased, whereas trabecular number may be increased transiently from early rapid perforation of trabeculae. However, trabecular number later is decreased. Most studies show no cortical bone loss or at least reduced age-related cortical gain in growing rats, likely due to depression of periosteal bone formation caused by reduced loading. Another hind limb immobilization model is the rat unilateral bandage immobilization bone loss model (Ma et al., 1995b; Li et al., 1990; Ijiri et al., 1995). A comprehensive review of this model was published by Jee and Ma (Jee and Ma, 1999). Mice also are commonly used for HS studies because of cost advantages and possibly greater tolerance by mice than rats for the procedures (Milstead et al., 2004; Lloyd et al., 2014).

Glucocorticoid-induced osteoporosis is the most common secondary osteoporosis in patients (Canalis and Delany, 2002; Dempster, 1989). Although rats do not consistently lose bone with excess glucocorticoid treatment (Li et al., 1996b), mice have demonstrated a loss of cancellous bone with treatment. An early prolongation of osteoclast life span and later promotion of osteoblast and osteocyte apoptosis in mice treated with prednisolone have been reported by Weinstein et al. (Jia et al., 2006; Weinstein et al., 1998). Histomorphometric analyses show remarkably reduced osteoblast surface, BFR, and bone turnover rates with 30%−40% cancellous bone loss. A significant decrease in Oc.Ns after a 2−4 week period is thought to be due to a later suppression of osteoclastogenesis with glucocorticoids in mice (Weinstein et al., 1998; Yao et al., 2008).

Histomorphometry of pharmacological efficacy in rodents

Bone histomorphometry has played a critical role in helping understand pharmacological effects on the coupling of bone resorption−formation at the multicellular unit (BMU) level. In OVX rats, studies showed that raloxifene, a selective estrogen receptor modulator, prevents cancellous bone loss by maintaining the osteoclast surface and activation frequency at sham control levels. Bone formation indices of MS/BS, MAR, and BFR/BS are either preserved at sham control levels or reduced to levels between those of OVX and sham controls. The bone histomorphometric profiles of raloxifene in OVX rats are similar to what has been seen with estrogen treatment (Turner et al., 1993; Ma et al., 2003, 2005; Evans et al., 1994; Wronski et al., 1988b). Vitamin D analogs, which are frequently the first-line supplement for preventing bone loss in postmenopausal women, have shown a biphasic effect in animal studies. At low or nonhypercalcemic doses, bone effects of vitamin D and analogs reduce bone resorption and prevent bone loss with subtle suppression or no change in bone formation indices (Erben et al., 1998; Takeda et al., 2013). At high doses, vitamin D analogs do stimulate new trabecular bone formation, but the doses are usually not clinically relevant due to hypercalcemia (Erben et al., 1997; Li et al., 2003).

The mechanism of action of bisphosphonates is to suppress osteoclast function and bone remodeling (Fleisch, 1998). In contrast to the remarkable ability of bisphosphonates to decrease circulation of bone resorption biomarkers, most OVX rat bone histomorphometry studies show that bisphosphonates slightly decrease, do not change, or even increase osteoclast surface (Erben et al., 2002; Balena et al., 1993); however eroded surface is significantly reduced (Ma et al., 2003). These

findings indicate that the primary effect of bisphosphonates is to decrease osteoclast activity rather than numbers. As powerful bone-resorption inhibitors, bisphosphonates markedly reduce bone-formation indices and activation frequency due to the bone resorption−formation coupling mechanism in rats and humans (Balena et al., 1993). In rodents, there is a reduction in bone formation on modeling (periosteal and endocortical) surfaces that is independent of coupling (Iwata et al., 2006). Although to a lesser degree than seen in human studies, bone formation activity in bisphosphonate-treated animals can also be severely suppressed to the degree that no double label is detected. For specimens without double labels, three methods have been used to calculate MAR: assign a zero, impute a value of 0.1−0.3 μm/day, or treat as a missing value. Bone formation rate is calculated accordingly (Recker et al., 2011). As a single label indicates that MAR is not zero (i.e., there is formation, at some rate, albeit too slow to measure), the recommended approach is to impute an MAR of 0.1 um/day in rodents (0.3 um/day in larger animal models and humans), which allows for maintenance of an adequate sample size to allow robust statistical analysis. Although there is debate about whether the artificial imputation of MAR is scientifically correct, for rodent studies, double labels should be detected in all control rats to confirm that the in vivo fluorochrome label schedules are appropriate.

Despite a significant increase in BMD in humans treated with antiresorptive agents, bone histomorphometry analyses show that antiresorptives including bisphosphonates reduce bone turnover to prevent further bone loss in animal models without substantially restoring architecture or volumetric bone mass. However, bisphosphonates are able to improve bone strength in rodent models by preventing bone deterioration and preserving the trabecular microstructure.

The bone anabolic efficacy of human PTH, either the amino terminal fragment teriparatide (PTH 1−34) or the full length hormone PTH1-84, has been well studied in rats. PTH was shown to restore lost bone in OVX (Ma et al., 2005, 2011; Shen et al., 1993), ORX (Martin-Fernandez et al., 2014), and disuse (Ma et al., 1995b) rat models. Histomorphometric analyses illustrate a fundamentally different mechanism of action of PTH from that of antiresorptive agents. In contrast to the antiresorptive agents' decrease in bone turnover, PTH stimulates osteoblastic activity and increases bone remodeling with a net positive bone balance to volumetrically gain new bone. Daily treatment with PTH increases osteoblast surface, single- and double-labeled surfaces, MAR, BFR, and activation frequency (Ma et al., 2003, 2011). Osteoclast surface is usually increased with time but to a lesser extent than osteoblast surface. As a result, more bone is formed than is resorbed in each BMU, as evidenced by increased mean wall thickness. Trabecular area can be increased beyond that of baseline, intact, or sham control levels depending on duration of treatment and dose (Sato et al., 1998). PTH improves trabecular microstructure mainly by thickening trabeculae with a smaller effect on trabecular number (Ma et al., 2011; Shen et al., 1993). Although the rat is not a good model for cortical bone remodeling, studies do show that PTH increases cortical bone area, thickens the cortex, and stimulates periosteal bone formation (Ma et al., 1995b, 2011; Fig. 82.3).

Abaloparatide is a newly approved human PTHrP (1−34) analog that also works through the PTH1 receptor. Abaloparatide increased bone mass and bone formation without significantly increasing osteoclast surface after 12 months of treatment in OVX rats (Varela et al., 2017). A head-to-head study comparing dose-adjusted exposures of abaloparatide with PTH at earlier time points would be informative to assess whether there are different bone histomorphometry profiles between these anabolic agents in the OVX rat skeleton.

The sclerostin−antibody (Scl-ab) is emerging as a new therapy for osteoporosis. Time course studies in OVX rats show that Scl-ab increases bone mass by a combination of early stimulation of bone formation while gradually reducing bone

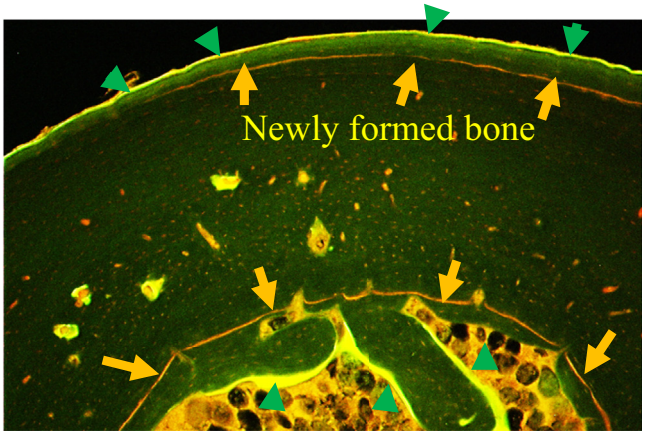

FIGURE 82.3 hPTH stimulates new periosteal and endocortical bone formation in the OVX rat. Bone formed between the xylenol orange label (*arrows*, given at day 1 of treatment) and calcein label (*arrowheads*, given at day 47 posttreatment) was formed during the experimental period.

resorption. Scl-ab rapidly stimulates bone formation activity as reflected in increased serum bone formation biomarkers and histomorphometric parameters of osteoblast surface and BFR. Different from PTH, which stimulates bone formation through both increased remodeling and modeling with daily treatment, Scl-ab−stimulated bone formation is modeling dominated; bone formation initially increases but then quickly declines. Osteoclast surface is gradually and slightly but significantly decreased (Ma et al., 2017; Stolina et al., 2014; Ominsky et al., 2014). Scl-ab histomorphometry in OVX rats parallels what has been observed in humans (McClung et al., 2014; Roux et al., 2017).

Conclusion

With proper study design, a carefully considered in vivo bone double-labeling schedule, and meticulous specimen preparation and staining, histomorphometry can provide unique information on tissue-level qualitative and quantitative changes in bone cellular activity as well as on bone structure, growth, remodeling, and repair. Together with other methods such as measurement of circulating biomarkers, bone imaging, and biomechanical testing, bone histomorphometry is an essential research tool for the comprehensive evaluation of skeletal adaptation and response to hormonal deficiency, pharmaceutical treatments, and other experimental challenges.

Chapter outline

Introduction

Despite advances in biomedical science and healthcare, skeletal fragility and its associated fractures remain as leading causes of disability and increased burden of care among the elderly population. Rodent models of skeletal fragility provide useful insights into bone biology and biomechanics that may assist in the development of interventions to prevent fractures. In particular, the application of various mechanical testing methods has allowed assessment of the functional outcomes (e.g., strengths, failure modes, and/or material properties) resulting from genetic, pharmacologic, and/or environmental interventions in rodents, thereby allowing for inferences about their potential effects on skeletal fracture incidents in humans. Accordingly, as the field continues to utilize rodent models to develop novel therapeutic interventions for skeletal fragility, functional assessment of skeleton by mechanical testing will continue to be among the key preclinical pharmacological assessments.

Mechanical testing methods for rodent skeleton have been adapted from the American Society for Testing and Materials standards that have tested the mechanical properties of steel, concrete, glass, and other common materials used for structures that need to pass rigorous safety criteria. However, unlike these materials, which are generally homogeneous, elastic, and isotropic, bone is an orthotropic and heterogeneous material that is a mixture of minerals and organic and inorganic matrix. Rodent bones in particular present additional challenges due to their diminutive sizes compared with larger mammalian bones. Despite these challenges, several studies have successfully assessed the functional alterations in rodent bones with wide-ranging mechanical testing techniques, such as whole-bone three-point bending to failure, fracture toughness, and microindention/nanoindentation. For a scientist who has a limited background in the mechanics of materials, these various testing methods can be overwhelming and perplexing. In this chapter, we will review the mechanical testing methods that have been implemented on rodent skeleton to better equip scientists with the knowledge to select appropriate testing methods and properly interpret their results. We will broadly categorize these testing methods from a whole-bone to a nanoscale assessment of mechanical properties (Fig. 83.1).

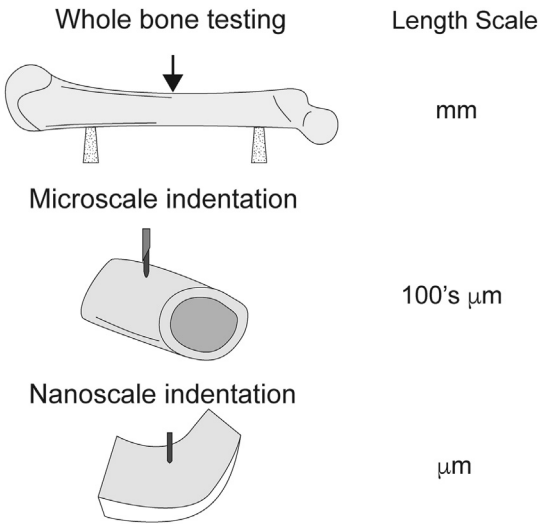

FIGURE 83.1 Common biomechanical assessment techniques of bone at different length scales in rodent models.

Whole-bone mechanical testing

Assessing the strength of a rodent bone using whole-bone mechanical testing has become a standard measure of functional outcomes in response to pharmacological therapies or genetic alterations. These testing methods are used to assess long bone or vertebral body stiffness, strength, and energy-absorbing capability, and can be combined with theoretical approaches to estimate the material (or tissue-level) properties of bone. Depending on scientific questions and observed phenotypes, investigators should select appropriate testing methods to assess functional outcomes in rodent bones.

Specimen preparation

Prior to biomechanical testing, investigators need to ensure that specimens are harvested and stored in appropriate conditions to minimize introducing environmental variables that can influence rodent bone biomechanical properties. For example, dry bone is more brittle than wet bone, which translates to increased Young's modulus and decreased toughness (Evans and Lebow, 1951). Also, use of fixatives such as ethanol, formalin, or glutaraldehyde for specimen preservation can alter mechanical properties such as modulus or strength compared with those of fresh bones (Linde and Sorensen, 1993; Unger et al., 2010). While a single or repeated freeze−thaw cycles do not alter the biomechanical properties of bone (Panjabi et al., 1985; Borchers et al., 1995; Kang et al., 1997), one study suggests potential alterations in cortical bone compositional properties following multiple freeze−thaw cycles that may influence tissue-level mechanical properties (McElderry et al., 2011). Finally, the temperature at which the tests are conducted can influence the mechanical properties of bone, where testing at a room temperature (23−25°C) slightly increases modulus (2%−4%) of bone compared with testing at a physiologically relevant temperature (37°C) (Bonfield and Li, 1968; Smith and Walmsley, 1959). However, maintaining 37°C using water baths during mechanical testing is a technical challenge to many investigators. Thus, the generally accepted specimen harvest and storage procedure is to clear soft tissues from rodent bones, wrap in saline soaked gauze, and store in a −20°C freezer until mechanical testing at a room temperature.

Standard three-point and four-point bending to failure

Bending tests are used to assess diaphyseal cortical bone biomechanical properties. The tests are performed with the bones placed on two supports at the ends and loaded at a constant rate at the center until failure. The difference between three- and four-point bending is the number of loading points applied at the center of bone; the three-point bending test applies load at a single point that generates maximum moment at the center of bone, whereas four-point applies load at two points that generate constant maximum moment between two loading points (Fig. 83.2). Since the moment is maximum at the center load point, a three-point bending test predisposes the bone to fracture at the loading point. In contrast, in four-point bending the constant moment between two loading points allows the bone to fracture at the weakest point testing the loading region. While both three- and four-point bending tests have been used previously to assess rodent bone strengths,

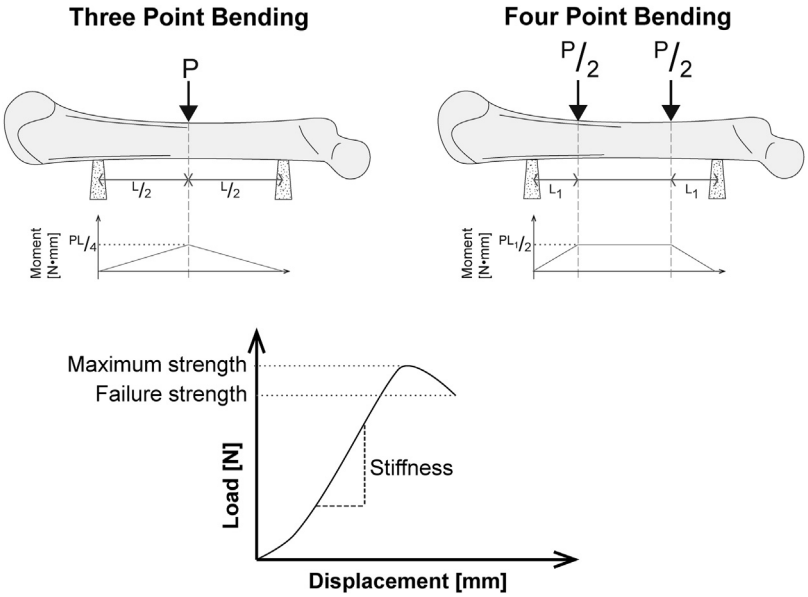

FIGURE 83.2 Experimental setup for three and four point bending, moment diagram along the bone, and typical load-displacement curve where maximum/failure strengths and stiffness can obtained. These strengths and stiffness outcomes can be converted to bending moments and bending stiffness. *P*, applied load; *L*, bottom support span length; L_1, distance between the loading point and support.

the choice between these two depends on the size of rodents and availability of fixtures, as finding four support and loading points on some small mouse bones is more challenging than it is on an older and bigger mouse or a rat bone.

The outcomes from a standard three- or four-point bending test are derived from the load−displacement curve and include stiffness (slope of linear portion), maximum strength, failure strength, and work to failure (area under the curve) (Table 83.1). These outcomes can be converted to bending stiffness and bending strengths by multiplying by the span length used. In addition, estimated cortical bone material properties (elastic modulus) can also be calculated according to beam theory, adjusting the cortical bone stiffness by the appropriate moment of inertia, which is often calculated from microcomputed tomography (micro-CT) scans (Jepsen et al., 2015). Depending on rodent models, span length can vary from 6 to 8 mm for a mouse femur to 13−20 mm for a rat femur. While these span lengths do not satisfy the assumption in beam theory that the aspect ratio of "span length:width" needs to be higher than 16:1 to calculate tissue-level properties (stress, modulus, etc.), estimated cortical bone material properties nonetheless provide some insights about whether the alterations in the whole-bone mechanical properties are due to structural or material changes. Commonly used loading rates are from 0.01 to 5 mm/s. The slower the loading rate (i.e., quasistatic), the better the test will be at capturing the postyield behavior of bone.

TABLE 83.1 Whole-bone outcomes and their respective tissue-level outcomes from mechanical tests.

	Whole-bone outcomes	Tissue-level outcomes
Three-point bending	M = max moment [N•mm] K = bending stiffness [N•mm^2] Work to failure [N•mm]	Ultimate stress [N/mm^2] = M•c/I Elastic modulus [N/mm^2] = FL^3/(48dI) Toughness = "not recommended"[a]
Torsion	T = max torque [N•mm] S = torsional stiffness [N•mm/rad] Work to failure [N•mm]	Ultimate sheer stress [N/mm^2] = T•R/J Elastic shear modulus [N/mm^2] = SL/J Toughness = "not recommended"[a]
Compression	F = max load [N] K = compressive stiffness [N/mm]	Ultimate stress [N/mm^2] = F/A Elastic modulus [N/mm^2] = stress/strain

A, cross-sectional area; *c*, maximum distance between the centroid and outermost cortical bone; *d*, displacement; *F*, applied load; *I*, area moment of inertia; *J*, polar moment of inertia; *L*, span/gage length; *R*, maximum cortical bone radius.
[a]*Because toughness involves both linear and nonlinear behavior, applying linear beam theory approximation is not recommended.*

Torsion to failure

While both bending and torsion tests predict strength and stiffness of cortical bone, the differences in functional implications as well as technical challenges occasionally lead to choosing torsional tests for rodent bone. For example, in mouse models of fracture healing, bulky and weak callus at the center of the bone presents a significant challenge for traditional three-point and even four-point bending tests, which need to apply loads at a region where the callus is formed. Thus, investigators opt for the torsional test, which applies constant torque throughout the whole bone to assess callus strength and stiffness (Gerstenfeld et al., 2009). Similar to the four-point bending test, the torsion test applies constant torque through the whole bone, allowing the bone to fail at the weakest point.

Prior to torsional testing, both ends of bone are embedded in polymethyl methacrylate at a fixed gage length. The bone is then tested under constant radial displacement (radian) until failure. Similar to bending tests, the torsion test generates a torque versus radian curve, which can then be used to calculate maximum torque, torsional stiffness (slope), and work to maximum/failure torque (Table 83.1).

Compression testing

Compression testing is used to assess whole vertebral mechanical properties in rodents. In general when testing rat vertebrae, the vertebral posterior elements are removed and endplates are cut to ensure parallel surfaces for compression testing (Glatt et al., 2004). Due to its smaller size, cutting endplates and posterior elements is generally not performed in a mouse vertebra (Tommasini et al., 2005). The main outcomes of the compression test include compressive stiffness and strength, which reflect both cortical and trabecular bone mechanical properties (Table 83.1). By performing both bending and compressive tests at these two different skeletal sites, investigators can assess mechanical properties in both the appendicular and the axial skeleton and determine whether the environmental, genetic, or pharmacological perturbations have site-specific responses.

Summaries of whole-bone outcomes and their respective tissue-level outcomes for the bending and compressive tests are in Table 83.1. As noted earlier, investigators should cautiously select appropriate whole-bone testing methods to assess functional outcomes in rodent bones based on their observed phenotypes, skeletal sites of interest, and scientific inquiries.

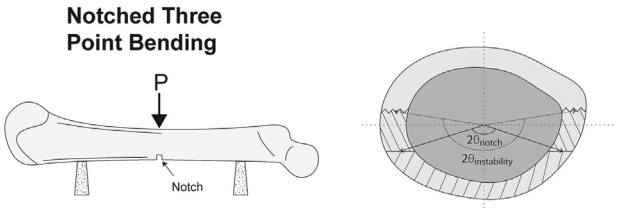
Whole-bone testing in preclinical drug development

While the testing methods described above are applicable to all investigations in musculoskeletal research, they are particularly important in the development of new therapeutic agents. In particular, it is critical to demonstrate that any new therapeutic agent maintains or increases bone strength in rodent models and maintains or increases "bone quality." While bone quality is ill defined, in this context one can interpret this to mean that the intervention maintains the normally observed relationship between bone mass and bone biomechanical outcomes. For example, there is generally a strong association between femoral bone mass and femoral failure load (or moment) from three-point bending tests. A new therapeutic agent should maintain this relationship, or perhaps improve bone failure load for a given bone mass as has been shown for all approved osteoporosis therapies in the past 2 decades (Kostenuik, 2013).

Fracture toughness testing

While not used as commonly as the aforementioned whole-bone mechanical tests, fracture toughness tests can be used to estimate tissue-level mechanical properties of rodent bone that reflect different mechanical behavior than whole-bone bending, torsion, and compression tests. Indeed, fracture toughness tests reflect the ability of the bone material to resist the initiation and growth of a crack. Similar to the three-point bending test, bones undergoing a fracture toughness test are loaded at the center (Fig. 83.3). However, by artificially creating a notch (usually by low-speed saw or razor blade) in the middle and loading at a significantly lower rate (0.001 mm/s), investigators can determine the bone's resistance to crack growth (fracture toughness).

Fracture toughness in rodent bones can be calculated using crack-initiation, maximum load, or instability methods, which are based on different crack angles from scanning electron microscopy (SEM) images or loads from a load–displacement curve. While the initial notched crack angle can be obtained from micro-CT images, it is best to use SEM to obtain both the notched and instability crack angles (for a detailed description, see review by Ritchie et al., 2008).



$$K_c = F_b \frac{P_c S R_o}{\pi (R_o^4 - R_i^4)} \sqrt{\pi R_m \theta_c}$$

FIGURE 83.3 Experimental setup for fracture toughness testing. P_c, maximum or failure loads; S, span length; R_o and R_i, mean outer and inner radii of the femoral cortex; R_m, average of R_o and R_i; q_c, notched or instability crack angles; F_b, geometry factor.

The majority of whole-bone bending and fracture toughness tests use rodent femurs due to their predominantly straight and hollow cylindrical cross-sectional properties. Several excellent tutorial and review articles have also been published describing these mechanical testing techniques in detail (Jepsen et al., 2015; Turner and Burr, 1993; Ritchie et al., 2008).

Finite element analysis

Unlike the previously mentioned destructive tests that "fracture" bones to assess biomechanical properties, finite element analysis (FEA) uses computational approaches to predict bone mechanical properties in a nondestructive manner (Spatz et al., 2013). In particular, high-resolution micro-CT images of rodent bone can be converted to an FEA model with appropriate software. After creating the FEA model, investigators conduct a virtual mechanical test to estimate bone biomechanical properties, thereby leaving the bone available for other evaluations, such as histology, immunohistochemistry, or dynamic histomorphometry. FEA may be particularly useful for assessing mechanical properties of trabecular bone in rodents, as the specimens are too small to experimentally test isolated trabecular bone. Another application is predicting strain distribution along the whole bone during in vivo mechanical loading of mouse tibia, allowing investigators to interrogate the relationships between high-strain regions and biological responses (Moustafa et al., 2012). Altogether, FEA provides avenues to uniquely integrate mechanical and biological events in rodent bones. However, despite these advantages, FEA is not free from challenges and limitations. For example, images generated from micro-CT can contain five million voxels or more, and performing voxel-based FEA can require large computational resources. Furthermore, the assumptions applied to FEA, such as boundary conditions and isotropic and linear elastic material properties, can misrepresent bone's physiological mechanical properties. These limitations are now being addressed by new computational algorithms to incorporate anisotropic and nonlinear material behaviors as well as experimental validations (Dos Santos et al., 2017; Imai, 2015). For example, in a mouse vertebra, predicted vertebral strength from FEA was well correlated with experimentally tested compressive strength and was able to assess the effects of pharmacological treatments or genetic background (Nyman et al., 2015).

Microscale and nanoscale bone material assessment

The advancement of material testing techniques has translated to allow for the assessment of bone mechanical properties at a smaller scale, such as on the order of microns, by applying a force using micrometer/nanometer sized tips. Complementing the assessment of mechanical properties at a whole-bone scale, these smaller-scale testing methods can potentially examine alterations in the material properties of an individual trabecular, perilacunar regions of osteocytes, or collagen/mineral components of bone. While multiple indentation tests have been applied to bones, we will focus on the techniques that have been applied to rodent bones.

Cyclic reference point indentation

The reference point indentation (RPI) technique was first introduced as a tool to evaluate tissue-level mechanical properties in ex vivo bone specimens (Hansma et al., 2009; Randall et al., 2009) and was subsequently applied to assess in vivo tissue mechanical properties in humans (Diez-Perez et al., 2010). Since then, two RPI devices have been introduced, OsteoProbe and BioDent. OsteoProbe administers a single impact force and records the distance that the probe subsequently descends into the bone to calculate a "bone material strength index." In comparison, BioDent performs cyclic indentations and then

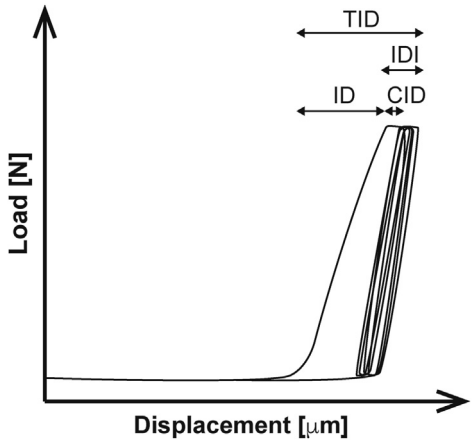


FIGURE 83.4 Load-displacement curve from cRPI test. *IDI,* indentation distance increase; *ID*, indentation distance; *TID*, total indentation distance; *CID*, creep indentation distance.

computes several outcome variables including total indentation distance, indentation distance increase, and creep indentation distance as well as loading and unloading slopes (Fig. 83.4; Allen et al., 2015; Karim et al., 2018). The indentation tip has a 2.5 um radius, and measurements can be taken at multiple locations a minimum of 500 um apart. RPI outcomes from rodent bone testing are weakly correlated or not correlated to traditional whole-bone mechanical properties and stress-intensity fracture toughness (Carriero et al., 2014; Gallant et al., 2013; Krege et al., 2016). These results indicate that cyclic RPI (cRPI) reflects mechanical properties distinct from those captured by whole-bone mechanical testing. Notably, indentation distances are increased in mouse models of diabetes (Rubin et al., 2016; Devlin et al., 2014). Also, the total indentation distance is decreased in the caudal site, but not in the cranial site, after mechanical loading of mouse tibia (Bergstrom et al., 2017). Investigations into the factors that influence cRPI and correlations with other mechanical testing variables are ongoing. However, RPI's ability to assess mechanical properties in vivo provides unique opportunities for longitudinal assessment of the material behavior of rodent bones. Investigators still need to be cognizant that in vivo cRPI measurements can be highly variable, which will affect the sample size. In a recent in vivo reproducibility study, within-animal coefficients of variation of cRPI outcomes varied from 13% to 33% in 16-week-old C57Bl/6 mice (Srisuwananukorn et al., 2015).

Nanoindentation

Nanoindentation has been used for decades to characterize the intrinsic mechanical properties of different types of materials including bone (Rho et al., 1997). Similar to other indentation methods, nanoindentation applies a static force on a rodent bone, using a diamond tip typically 100 nm in radius. The smaller tip size allows greater spatial resolution than that of the RPI method. Outcomes include measures of elastic modulus and hardness obtained from the force−displacement curve and indentation area. While this high spatial resolution technique can be used to determine local tissue-level alterations, such as the effects of tissue age on rat cortical bone (Donnelly et al., 2010), nanoindentation cannot be used in vivo due to the requirement of extensive sample preparation, including dehydration and surface polishing, prior to testing. The technique nonetheless can assess unique tissue-level mechanical properties, such as the effects of age or osteopontin deficiency, on mouse tibial cortical bone (Miller et al., 2007; Thurner et al., 2010).

Summary and discussion

Significant advancements in material science and engineering technologies now allow scientists to examine rodent bone mechanical properties from nanometer to whole-bone levels (Fig. 83.1). Which mechanical testing method(s) to choose will depend on the scientific questions asked. For example, one can design a study to determine variations in mechanical properties within a single cortex, which would require the use of nanoindentation, and integrate with whole-bone scale mechanical assessment in rodents (Kim et al., 2012). Also, an investigator may see a phenotype where mouse intact bone is unusually short, which can present significant technical challenges to performing three- or four-point bending tests. Whole-bone mechanical properties in these bones can alternatively be assessed by torsion test to failure (Liu et al., 2016). Finally,

specific cancellous and cortical bone mechanical properties from a single rodent bone can be predicted by FEA (Yang et al., 2014), where assessing such compartment-specific alterations is a significant challenge using conventional experimental approaches.

As musculoskeletal scientists continue to use rodent models to gain insight into skeletal fragility and fracture healing, appropriately assessing and interpreting the functional outcomes of genetic, pharmacologic, and environmental interventions is a crucial first step in the development of new therapies to reduce the burden of musculoskeletal diseases.

Chapter outline

Introduction

As a tissue unique to vertebrates, bone fulfills a number of essential physiological functions viewed as classical functions of this tissue. It acts as a scaffold for muscle and the other organs and hence allows locomotion. Bone is also an important reservoir for several minerals including calcium, phosphate, and magnesium. Finally, bone cells are involved in the maintenance of the hematopoietic stem cell niche and therefore in the production of lymphocytes, erythrocytes, and platelets. These functions of bone are regulated by specific hormonal and neuronal input on bone cells. This topic has been extensively covered in other chapters.

Bone modeling and remodeling, the biological mechanisms by which bone grows, maintains its integrity, and repairs fractures, involve the coordinated bone-resorbing action of osteoclasts and the bone-forming action of osteoblasts. The nature of the cell biological processes involved strongly suggests that bone remodeling is an energy-consuming function. Furthermore, the energetic cost of this physiological process is necessarily proportional to the considerable area covered by bone in the body. The hypothesis that bone remodeling is tightly linked to energy metabolism is best illustrated by the observation that anorexia nervosa, a state of low energy intake, is associated with osteoporosis in humans (Legroux-Gerot et al., 2005; Misra and Klibanski, 2011). Accordingly, several hormones and neuropeptides implicated in the control of energy metabolism, such as insulin, adiponectin, leptin, NPY, orexins, and Agrp, do influence bone mass accrual (Fulzele et al., 2010; Ducy et al., 2000; Cornish et al., 2002; Kajimura et al., 2013; Horsnell and Baldock, 2016; Wei et al., 2014a; Kim et al., 2015). As a matter of fact, the regulation of bone mass by leptin and other hormones implicated in the control of energy metabolism was a reason to consider the hypothesis that, in a classical feedback loop, bone may be implicated in the control of energy metabolism. Moreover, that bone and other organs regulating energy metabolism are not adjacent to each other implied that if bone should have such a function, it must be through endocrinal means. This hypothesis was verified

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00084-1

by the demonstration that osteocalcin is a hormone influencing pancreatic β cell proliferation, insulin secretion, insulin sensitivity, and muscle function during exercise. More recently, lipocalin-2 (LCN2) was identified as a second bone-specific hormone involved in the control of appetite and glucose metabolism. Hence, bone is a bona fide endocrine organ that influences energy metabolism through the production of at least two hormones. This chapter will review in detail the mechanisms of action and regulation of osteocalcin and LCN2.

Osteocalcin: a bone-derived hormone regulating glucose metabolism

Osteocalcin is a short protein, 46 amino acids long in the mouse and 49 amino acids long in humans, that is produced and secreted specifically by osteoblasts. Inactivation of the two genes encoding osteocalcin (*Bglap1* and *Bglap2*) has profound metabolic consequences in mice fed a normal chow diet (Lee et al., 2007). Most strikingly, osteocalcin-deficient mice ($Ocn^{-/-}$) are characterized by increased adiposity, low circulating levels of insulin, reduced peripheral insulin sensitivity, and decreased glucose tolerance. They also display liver steatosis and signs of inflammation in the liver and white adipose tissue. In addition, the absence of osteocalcin causes a marked reduction in global energy expenditure, which likely contributes to the increased fat mass of these animals. Intermittent injections of recombinant osteocalcin in lean or obese mice or rats resulted in phenotypes opposite to the ones observed in $Ocn^{-/-}$ mice—i.e., they increased energy expenditure,

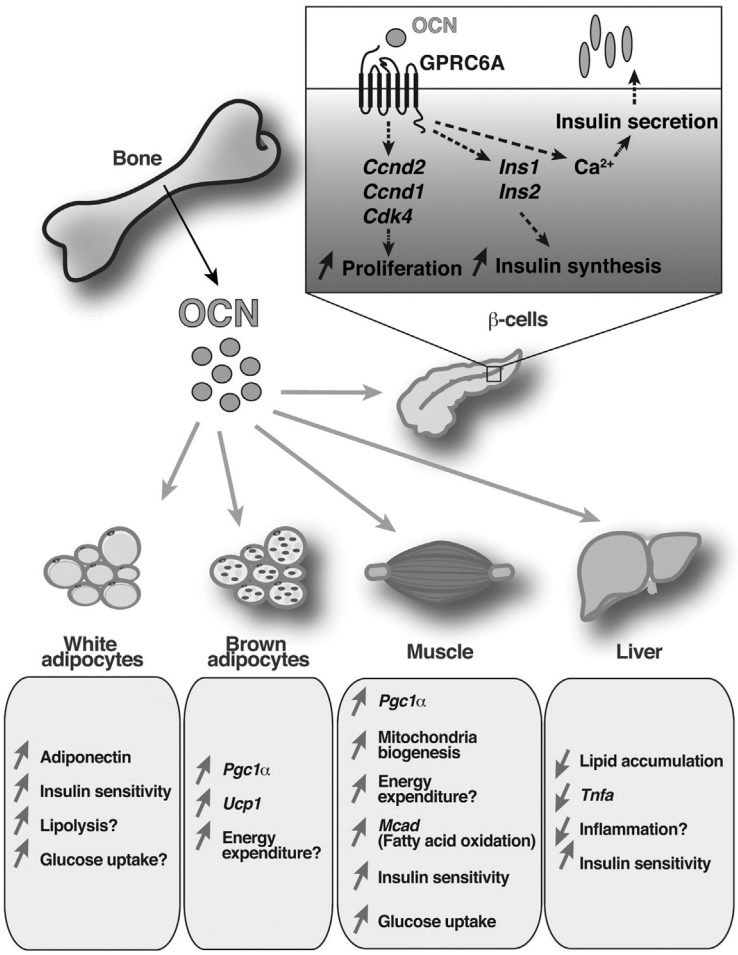

FIGURE 84.1 Endocrinal functions of osteocalcin. Once released in the circulation, undercarboxylated bioactive osteocalcin affects glucose metabolism mainly in two ways. First, osteocalcin directly affects β cell function by binding to the receptor GPRC6A and increasing its capacity to proliferate as well as to synthetize and secrete insulin. Second, osteocalcin improves insulin sensitivity and energy expenditure through multiple mechanisms. Osteocalcin stimulates energy expenditure by increasing mitochondrial biogenesis in the muscle and by regulating the expression of genes implicated in energy consumption in brown adipose tissue and skeletal muscle. Osteocalcin also affects insulin sensitivity, possibly by increasing adiponectin expression in white fat and decreasing lipid accumulation and inflammation in steatotic liver. The direct impact of osteocalcin as an insulin-sensitizing hormone is speculative and remains to be established.

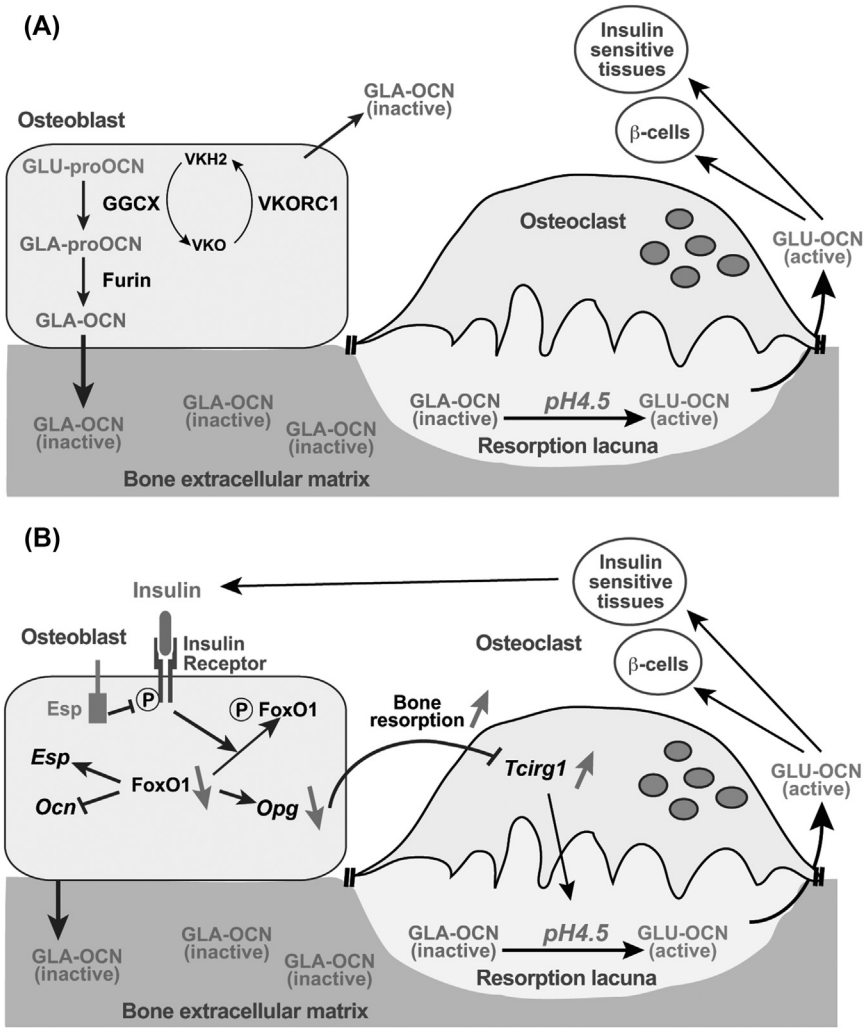

FIGURE 84.2 Regulation of osteocalcin activity. (A) Once γ-carboxylated, processed by the proprotein convertase furin, and secreted by osteoblasts, osteocalcin is stored in the bone extracellular matrix in an inactive form. To fulfill its beneficial effect on glucose metabolism, osteocalcin has to be activated—i.e., decarboxylated. This is accomplished through osteoclastic bone resorption that generates the acid pH necessary for osteocalcin decarboxylation. (B) Insulin signaling in osteoblasts affects osteocalcin activity by increasing bone resorption through osteoprotegerin (*Opg*) downregulation. Since osteocalcin stimulates insulin secretion, a feed-forward loop exists between osteocalcin and insulin activity. Esp, a tyrosine phosphatase, negatively regulates insulin receptor signaling and decreases osteocalcin activity.

reduced fat mass, improved insulin sensitivity, and prevented liver steatosis (Ferron et al., 2008, 2012; Huang et al., 2017; Gupte et al., 2014). Similarly, mouse models in which the circulating level of the active form of osteocalcin is increased—e.g., $Esp^{-/-}$ or osteoblast-specific knockout of *Ggcx* (see also sections "Regulation of the endocrine function of osteocalcin by gamma-carboxylation" and "Osteocalcin decarboxylation and activation during bone resorption" and Fig. 84.2)—are characterized by increased insulin secretion, increased β cell proliferation, improved insulin sensitivity, increased energy expenditure, and reduced fat mass (Lee et al., 2007; Ferron et al., 2015). These results indicated what has become a hallmark of osteocalcin biology—it is necessary and sufficient to favor the physiological processes it regulates (Oury et al., 2013a; Mera et al., 2016a; Khrimian et al., 2017).

The acute effect of osteocalcin on insulin secretion appears to be mediated by calcium (Ca^{2+}) signaling in β cells (Hinoi et al., 2008; Fig. 84.1). A receptor to which osteocalcin binds in pancreatic β cells, G-protein-coupled receptor family C group 6 member A (GPRC6A), which acts through G-protein α-subunit (Gsα) and cAMP response element-binding protein, mediates osteocalcin regulation of cell proliferation, insulin expression, and insulin secretion. This receptor is also expressed in myofibers and regulates the functions of osteocalcin myofibers during exercise (Mera et al., 2016a; see section "Osteocalcin regulation of skeletal muscle energy metabolism during exercise"). Remarkably, in white adipocytes,

osteocalcin stimulates the expression of adiponectin, a hormone that regulates bone mass accrual in animals fed a normal diet, but this action appears to be independent of GPRC6A not expressed in adipocytes (Kajimura et al., 2013). In addition, osteocalcin suppresses lipolysis, directly promotes glucose uptake, and can suppress the secretion of proinflammatory cytokines in white adipocytes (Lee et al., 2007; Hill et al., 2014; Fig. 84.1). Osteocalcin also promotes mitochondria biogenesis in the muscle when injected in obese mice (Ferron et al., 2012) and stimulates the expression of genes involved in thermogenesis (*Pgc1α* and *Ucp1*) in brown adipocytes in vivo and ex vivo (Ferron et al., 2008). Altogether, these observations suggest that the protective effect of this hormone on obesity and insulin resistance could be at least partially caused by its capacity to enhance energy expenditure in muscle and brown adipose tissue.

Several cell-based assays provided evidence that osteocalcin also stimulates insulin secretion in rat and human islets ex vivo (Sabek et al., 2015; Gao et al., 2016a, 2016b; Kover et al., 2015). Likewise, genetic studies further support an impact of osteocalcin polymorphisms in glucose and energy metabolism in humans (Korostishevsky et al., 2012; Das et al., 2010). Finally, two meta-analyses demonstrated respectively that circulating levels of total osteocalcin are higher in subjects with normal glucose tolerance than in patients with type 2 diabetes (Kunutsor et al., 2015), and that osteocalcin serum level is an independent risk factor for the development of type 2 diabetes (Liu et al., 2015).

GPRC6A osteocalcin receptor in β cells

As alluded to previously, and like most known peptide hormones, osteocalcin mediates its functions through the binding of at least one specific receptor, GPRC6A (Fig. 84.1). This G-protein-coupled receptor shares some sequence identity with calcium-sensing receptors involved in calcium homeostasis through the regulation of parathyroid hormone release. Based on ex vivo experiments, GPRC6A was proposed to be a cation-sensing receptor, and more recently a receptor for amino acids, steroids, and osteocalcin (Pi and Quarles, 2012; Wei et al., 2014b). *Gprc6a*$^{-/-}$ mice phenocopied osteocalcin-deficient animals with regard to their defects in insulin secretion and glucose tolerance (Pi et al., 2008). Moreover, inactivation of *Gprc6a*, specifically in the pancreas, resulted in reduced β cell proliferation and decreased insulin secretion in response to glucose (Wei et al., 2014b; Pi et al., 2016). Two pieces of genetic evidence demonstrate that in vivo, osteocalcin is the ligand of GPRC6A that accounts for the regulation of insulin secretion by this receptor. First, whereas single heterozygous *Gprc6a*$^{+/-}$ or *Ocn* $^{+/-}$ mice have normal pancreatic β cell proliferation and insulin secretion, compound heterozygous (*Gprc6a*$^{+/-}$;*Ocn*$^{+/-}$) mice have the same defect in insulin secretion and glucose homeostasis as that of *Ocn*$^{-/-}$ and *Gprc6a*$^{-/-}$ mice (Wei et al., 2014b). Second, osteocalcin capacity to induce insulin secretion is abrogated in *Gprc6a*$^{-/-}$ islets (Wei et al., 2014b; Pi et al., 2016). Additional genetic experiments in mice demonstrated that GPRC6A also acts as an osteocalcin receptor in Leydig cells, where osteocalcin-dependent signaling promotes testosterone synthesis (Oury et al., 2011; De Toni et al., 2014).

Many lines of evidence suggest that GPRC6A's function as an osteocalcin receptor is conserved in humans. First, human osteocalcin can bind and activate human GPRC6A receptor as was reported for the mouse proteins (De Toni et al., 2016a). Second and more directly, a mutation in the human *GPRC6A* gene that disrupts GPRC6A trafficking to the plasma membrane is associated with insulin resistance and testicular failure in humans, two phenotypes caused by osteocalcin deficiency in mice (Oury et al., 2013b). Third, polymorphisms in the human *GPRC6A* gene were also shown to be associated with insulin resistance and testicular failure (De Toni et al., 2016b; Di Nisio et al., 2017).

Regulation of the endocrine function of osteocalcin by gamma-carboxylation

Before it is secreted by the osteoblast, osteocalcin is γ-carboxylated on three glutamic acid residues (Glus) that are converted to γ-carboxyglutamic acid (Gla). This posttranslational modification that occurs in the endoplasmic reticulum of the osteoblast is accomplished by γ-glutamyl carboxylase (GGCX), an enzyme requiring reduced vitamin K as a cofactor (Fig. 84.2A). For each carboxylation reaction, one molecule of reduced vitamin K is oxidized to vitamin K epoxide by GGCX. A second enzyme, called vitamin K oxidoreductase, is responsible for reducing vitamin K epoxide, allowing the recycling of vitamin K and further γ-carboxylation reactions (Lacombe et al., 2018). The presence of Gla residues in osteocalcin allows its binding with high affinity to hydroxyapatite, the mineral component of bone, explaining why the majority of carboxylated osteocalcin (Gla-Ocn) accumulates in the bone extracellular matrix, where it is the most abundant noncollagenous protein (Fig. 84.2A). Yet in the circulation, osteocalcin exists in two forms, carboxylated and undercarboxylated. In vitro and in vivo studies in mice have established that γ-carboxylation of osteocalcin, particularly on its first Glu residue (Glu13 in mice and Glu17 in human), inhibits osteocalcin endocrine action on energy metabolism and that undercarboxylated osteocalcin is the bioactive form of this hormone for all known functions (Ferron et al., 2008; Zhou et al., 2013). For instance, inactivation of GGCX in osteoblasts results in increased circulating levels of undercarboxylated

osteocalcin and improved glucose tolerance in mice (Ferron et al., 2015). A cross-sectional study in postmenopausal obese women also demonstrated that the level of osteocalcin carboxylation on its Glu17 residue positively correlates with insulin resistance and low-grade inflammation (Bonneau et al., 2017), suggesting that γ-carboxylation of osteocalcin negatively regulates the function of this hormone in humans as it does in rodents.

Osteocalcin decarboxylation and activation during bone resorption

If osteocalcin is γ-carboxylated prior to its secretion by osteoblasts, how does it get converted to undercarboxylated and bioactive before reaching the general circulation? It turns out that decarboxylation of osteocalcin is a nonenzymatic process that occurs outside the osteoblast in the osteoclastic resorption lacunae (Fig. 84.2B). Indeed, it is the low pH (∼4.5) generated by the osteoclasts in the resorption lacunae that decarboxylates at least one of the Gla residues present in osteocalcin (Ferron et al., 2010), thus allowing the release of bioactive osteocalcin (Glu13-Ocn). This explains why mice with increased bone resorption also display increased circulating levels of bioactive osteocalcin and improved glucose tolerance and insulin sensitivity, while mice lacking osteoclasts have reduced levels of bioactive osteocalcin and decreased glucose tolerance (Lacombe et al., 2013). Interestingly, bone resorption couples insulin and osteocalcin in a feed-forward endocrine loop controlling glucose metabolism. Indeed, insulin signaling in osteoblasts, through a signaling pathway involving the inhibition of the transcription factor FOXO1, reduced the expression of *osteoprotegerin*, a negative regulator of bone resorption (Ferron et al., 2010; Rached et al., 2010); this has the consequence of increasing osteoclastic activity and thereby the release of bioactive osteocalcin (Fig. 84.2B).

Regulation of osteocalcin by the proprotein convertase furin

Like many other peptide hormones, osteocalcin is first synthesized as a prohormone, proosteocalcin (pro-Ocn). Yet until recently, the biological importance of pro-Ocn maturation in regulating osteocalcin and the identity of the endopeptidase responsible for pro-Ocn cleavage in osteoblasts were unknown. Based on biochemical and genetic arguments, the proprotein convertase furin was recently identified as the endopeptidase responsible for pro-Ocn processing in osteoblasts (Al Rifai et al., 2017). Proteolysis of pro-Ocn is critical for the activation of this hormone, since inactivation of furin in osteoblasts in mice results in decreased circulating levels of active osteocalcin, impaired glucose tolerance, and reduced energy expenditure. At the mechanistic level, it appears that retention of the propeptide in osteocalcin reduces its ability to be decarboxylated during the process of bone resorption. Of note, *furin* deletion in osteoblasts also reduces appetite, a function not regulated by osteocalcin. This observation suggests that osteoblasts must secrete other hormones that regulate different aspects of energy metabolism such as, for instance, appetite (see section "Are there additional osteocalcin- or lipocalin-2-independent endocrine functions of bone?").

A role for osteocalcin in adaptation to exercise

A question raised by the beneficial influence of osteocalcin on glucose homeostasis is whether there is any difference between osteocalcin and insulin endocrine actions. Considering the significant role of skeletal muscle in the maintenance of whole-body glucose homeostasis, it became important to determine whether osteocalcin influences any aspect of energy metabolism in skeletal muscle. One experimental approach to address this question was to determine whether osteocalcin exerts any function in muscle during exercise, a physiological situation characterized by an increase in glucose uptake in skeletal muscle and a simultaneous decrease in circulating insulin levels. That circulating levels of bioactive osteocalcin triple in mice and also increase in humans after a single bout of endurance exercise were additional reasons to test this hypothesis (Mera et al., 2016a).

Osteocalcin regulation of skeletal muscle energy metabolism during exercise

A common feature of all known osteocalcin functions is that they decline quite early during adult life (Lee et al., 2007; Oury et al., 2011, 2013a). The identification of a receptor for osteocalcin in testis and β cell, the G-protein coupled receptor GPRC6A (see section "GPRC6A osteocalcin receptor in β cells"), provided the necessary tool to study the role, if any, of osteocalcin signaling in skeletal muscle aside from its functions in other organs. Analysis of 3-month-old $Ocn^{-/-}$ mice and mice lacking GPRC6A only in skeletal muscle ($Gprc6a^{Mck-/-}$) revealed that when forced to run on a treadmill at a constant speed until exhausted, $Ocn^{-/-}$ and $Gprc6a^{Mck-/-}$ mice run 20%−30% less than control littermates (Mera et al., 2016a). Further investigation of this phenotype reveals that osteocalcin regulates the uptake and catabolism of glucose and

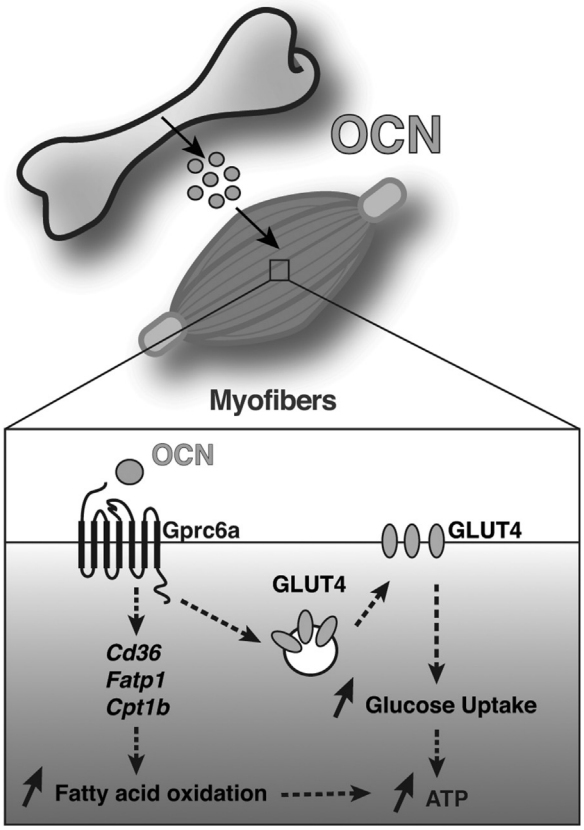

FIGURE 84.3 Mechanism of action of osteocalcin in skeletal muscle during exercise. During exercise, bioactive osteocalcin is released by osteoblasts and binds to the receptor GPRC6A in myofibers where it promotes the uptake and utilization of nutrients. First, osteocalcin favors the expression of fatty acid transporters and stimulates β-oxidation. Second, osteocalcin favors translocation of the glucose transporter GLUT4 to the plasma membrane. This in turn allows the increase in glucose uptake and catabolism.

fatty acids (FAs) in muscle during exercise (Fig. 84.3). The uptake and utilization of these nutrients by contracting myofibers is absolutely essential for adaptation to exercise. Consequently, the regulation of nutrient catabolism in skeletal muscle by osteocalcin certainly explains, at least in part, the decreased performance during exercise observed in $Ocn^{-/-}$ and $Gprc6a^{Mck-/-}$ mice. Hence, in that respect osteocalcin differs from insulin, an anabolic hormone.

Osteocalcin supports muscle function during exercise through an additional mechanism—it stimulates the production and release of interleukin-6 (IL-6), one of the first myokines ever identified (Pedersen and Febbraio, 2008; Steensberg et al., 2000). IL-6 circulating levels increase after exercise in humans and rodents in a manner proportional to the length of exercise and the degree of muscle involvement (Febbraio et al., 2004; Febbraio and Pedersen, 2002; Nielsen et al., 2007). Additionally, IL-6 is expressed in cultured myotubes and myofibers, and skeletal muscle is the major source of circulating IL-6 during exercise (Keller et al., 2001; Steenbergen et al., 2002). During exercise, IL-6 acts in an autocrine, paracrine and endocrine manner to promote skeletal muscle nutrient utilization, glucose production in the liver, and lipolysis in white adipose tissue (Pedersen and Febbraio, 2008). Considering experimental observations showing that IL-6 also signals in bone cells (Tamura et al., 1993), the regulation of IL-6 by osteocalcin during exercise raised another fundamental question: Could IL-6 signal back to bone to modulate the release of bioactive osteocalcin?

The next aspect in this work was to determine whether osteocalcin regulates skeletal muscle function and adaptation to exercise, a physiological process severely affected during early aging. Supporting this premise is the fact that circulating levels of bioactive osteocalcin decline early in adult life in mice, monkeys, and humans of both genders. This reduction in circulating bioactive osteocalcin occurs at the same time that the ability to perform exercise declines, at least in mice (Mera et al., 2016a). These observations were an incentive to test whether administration of exogenous osteocalcin to wild-type (WT) mice might increase their endurance during exercise. A single injection of exogenous osteocalcin immediately before exercise or a chronic delivery of this hormone for 1 month not only improved the exercise capacity of young mice but also restored aerobic endurance in older mice to a level similar to those seen in young adult mice (Mera et al., 2016a).

Moreover, chronic delivery of osteocalcin also favors a gain in muscle mass in older mice (Mera et al., 2016b). These experiments demonstrate that osteocalcin signaling in myofibers is necessary and sufficient to increase muscle function during exercise, highlighting the therapeutic potential of osteocalcin to reverse the age-induced decline in exercise capacity and muscle mass observed in humans.

Modulating adaptation to exercise through bone and skeletal muscle cross talk

Interestingly, after a single bout of exercise, blood markers of bone resorption and bioactive osteocalcin increase in WT mice but not IL-6-deficient mice ($Il6^{-/-}$) (Mera et al., 2016a). Recombinant IL-6 increases the expression of *Rankl*, a cytokine essential to osteoclast differentiation, and decreases *osteoprotegerin*, a decoy receptor for RANKL and an inhibitor of bone resorption (Teitelbaum and Ross, 2003) in cultured calvaria osteoblasts (Mera et al., 2016a). These results suggest that in vivo, IL-6 acts during exercise, when its circulating levels increase in the cells of osteoblast lineage to increase *Rankl* expression, bone resorption, and the production of bioactive osteocalcin (see also Fig. 84.2). Extensive genetic and molecular studies will be needed to fully understand the regulation of bioactive osteocalcin by IL-6 during exercise.

Altogether, analyses of $Ocn^{-/-}$, $Gprc6a^{Mck-/-}$, and $Il6^{-/-}$ mice revealed the existence of a feed-forward loop between bone (via osteocalcin) and muscle (via IL-6) promoting adaptation to exercise through at least three different synergistic mechanisms (Fig. 84.4): (1) osteocalcin promotes nutrient uptake and catabolism in myofibers; (2) osteocalcin signaling in myofibers increases the expression and secretion of IL-6, which in turn might allow the generation of extramuscular glucose and FAs (Febbraio et al., 2004; van Hall et al., 2003); and (3) IL-6 increases the production of bioactive osteocalcin. This model does not exclude the possibility that osteocalcin and IL-6 might have additional functions to modulate adaptation to exercise. Similarly, other molecules made by bone cells or skeletal muscle cells could contribute to this cross talk.

IL-6 and osteocalcin regulate similar aspects of skeletal muscle metabolism during exercise—e.g., the increase in glucose and FA catabolism. Experiments studying the effect of exogenous osteocalcin on glucose and FA utilization in WT and $Il6^{-/-}$-cultured myotubes showed that osteocalcin can induce these functions independently of IL-6 signaling in myofibers (Mera et al., 2016a). Whether osteocalcin and IL-6 might have synergistic functions in order to increase glucose and FA uptake and utilization in skeletal muscle during exercise remains to be established.

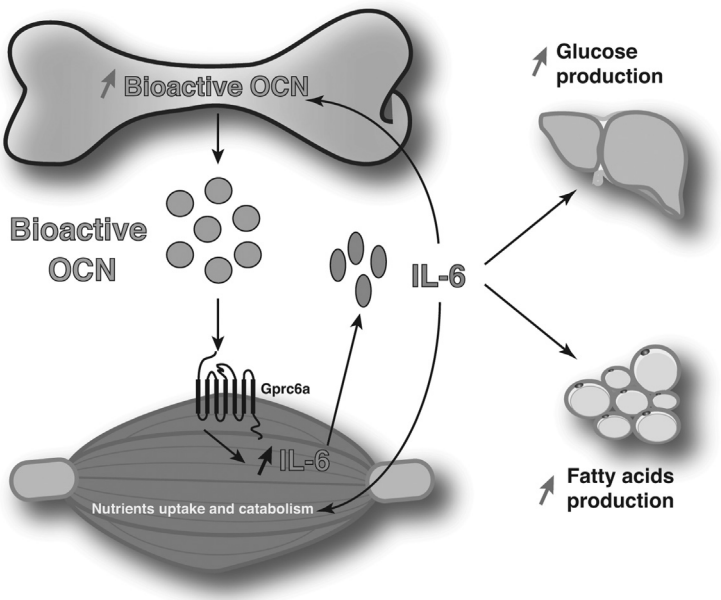

FIGURE 84.4 Cross talk between bone via osteocalcin, and skeletal muscle via IL-6, promotes adaptation to exercise. Circulating levels of bioactive osteocalcin increase during exercise. Osteocalcin signals in myofibers through GPRC6A, where it induces the expression of *Il6* and increased circulating levels of this myokine. IL-6 signals back to skeletal muscle, where it favors glucose and fatty acid (FA) utilization. IL-6 also stimulates FA production in white adipose tissue and glucose production in the liver. Furthermore, IL-6 signals to bone to increase the production of bioactive osteocalcin.

Bone as a regulator of appetite: the anorexigenic function of osteoblast-derived lipocalin-2

Taken at face value, the discovery of osteocalcin regulation of glucose metabolism established a new concept—i.e., that bone is an endocrine organ affecting energy metabolism. It also raised a fascinating question: Do additional bone-derived hormones exist and contribute to the regulation of energy metabolism? To address this question, osteoblasts were conditionally ablated in mice. As expected, a 50% decrease in osteoblast numbers decreased osteocalcin circulating levels and impacted glucose metabolism. However, and more intriguingly, another metabolic function was affected—appetite. Reduced osteoblast numbers increased food intake, a function not regulated by osteocalcin (Al Rifai et al., 2017; Yoshikawa et al., 2011). These findings implied that appetite is one more metabolic function regulated by osteoblasts, most probably mediated by at least one additional osteoblast-derived hormone.

The identification of this hormone was achieved by taking advantage of another mouse model of bone-related improved energy metabolism, the mice lacking *Foxo1* in osteoblasts (Rached et al., 2010). FOXO1 is a transcription factor regulating osteoblast function and energy metabolism at least through its ability to regulate osteocalcin activity (Ferron et al., 2010; Rached et al., 2010), raising the prospect that additional hormones involved in energy metabolism may be downstream targets of FOXO1. Comparative gene expression analysis pointed to an increase in the expression of the gene encoding LCN2 in $Foxo1^{-/-}$ osteoblasts, and therefore higher LCN2 serum levels were observed in the same mice. LCN2, also known as neutrophil gelatinase-associated lipocalin, is a secreted glycoprotein previously thought to be an adipocyte-derived hormone (Yan et al., 2007). However, expression profiling showed that *Lcn2* is expressed at least 10-fold higher in bone than in white adipose tissue or any other organ. Analysis of mice lacking *Lcn2* specifically in osteoblasts ($Lcn2^{osb-/-}$ mice) showed that inactivation of *Lcn2* in osteoblasts increases food intake (Mosialou et al., 2017). As a consequence, $Lcn2^{osb-/-}$ mice exhibit increased adiposity and body weight as well as decreased glucose tolerance and insulin sensitivity. Interestingly, the increase in food intake precedes changes in blood glucose levels and body weight and partly contributes to the development of impaired glucose metabolism. Normalization of food intake by pair-feeding $Lcn2^{osb-/-}$ to their WT littermates restores body weight, fat mass and insulin sensitivity. Finally, chronic administration of exogenous LCN2 in lean and obese mice suppresses food intake, fat mass, and body weight gain and improves glucose homeostasis (Mosialou et al., 2017), providing further evidence that LCN2 regulates energy metabolism.

Suggesting a physiological role of LCN2 in the regulation of food intake, osteoblastic expression and circulating levels of LCN2 increase threefold 3 h postprandially in mice. Interestingly, this increase in serum levels correlates with a suppression of food intake. Following its rise in the serum, LCN2 crosses the blood—brain barrier and accumulates mainly in the hypothalamus where it activates neurons in the paraventricular nucleus (PVN), as indicated by *c-Fos* induction and electrophysiological recordings. The PVN is involved in feeding regulation partly due to the actions of the well-established melanocortin 4 receptor (MC4R) anorexigenic pathway. Indeed, mice and humans with MC4R defects exhibit hyperphagia and early onset obesity, increased fat mass, decreased energy expenditure, and hyperinsulinemia (Tao, 2010). A series of molecular and biochemical studies showed that LCN2 activates the MC4R pathway, promotes cAMP production, and induces MC4R target genes through direct binding to MC4R, establishing a central role for MC4R in mediating the LCN2 anorexigenic response (Fig. 84.5). The LCN2/MC4R interaction may be extended to humans, since some obese subjects carrying mutations in MC4R had elevated LCN2 plasma levels compared with those of weight-matched people without mutations. This observation implies increased ligand levels in the case of desensitization or inactivation of the cognate G-protein-coupled receptor in an attempt to overcome resistance and reestablish homeostasis.

Altogether, these observations add the control of food intake to the endocrinal properties of bone. The regulation of appetite by osteoblasts also provides a feedback mechanism to the well-established central control of bone mass, consisting mainly of hypothalamic pathways regulating feeding, such as leptin, the Agrp neuronal circuit, orexins, NPY, Neuromedin U, and the MC4R pathway, further reinforcing the powerful cross talk between bone and the brain.

Are there additional osteocalcin- or lipocalin-2-independent endocrine functions of bone?

The identification of the anorexigenic function of LCN2 widens the range of bone metabolic functions and supports the hypothesis that more than one osteoblast-derived signal contributes to bone endocrinal function. Besides food intake, other osteocalcin-independent effects on fat mass and energy expenditure were observed in mice with partial osteoblast ablation. Gonadal fat was decreased and energy expenditure increased, which was the opposite of what would be expected with osteocalcin deficiency. This observation was confirmed by a subsequent study in mice harboring a β-catenin deletion in early

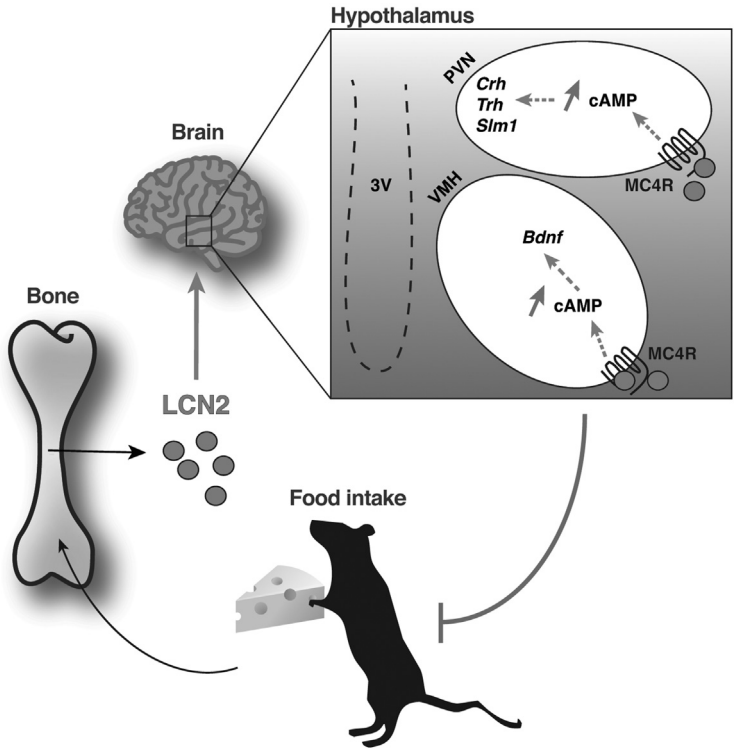

FIGURE 84.5 Regulation of food intake by lipocalin-2. Following feeding, lipocalin-2 is released by osteoblasts and accumulates in the hypothalamus where it binds the melanocortin 4 receptor (MC4R) in the paraventricular (PVN) and ventromedial (VMH) neurons of the hypothalamus. Activation of MC4R by lipocalin-2 induces cAMP and the expression of *Crh, Trh, Sim1*, and *Bdnf*, suppressing food intake.

lineage osteoblasts that led to an osteocalcin-independent increase in food intake and energy expenditure, and decreased fat mass (Yao et al., 2017). LCN2 cannot explain these effects, since one would expect to observe increase fat mass in its absence. This suggests an additional factor counteracting the effects of osteocalcin and LCN2 on adiposity. Intriguingly, the inactivation of the proprotein convertase furin in osteoblasts resulted in reduced food intake without affecting the circulating levels of LCN2. Moreover, LCN2 does not appear to be processed by furin in vitro and in vivo, suggesting that furin in osteoblasts influences appetite through an LCN2-independent mechanism (Al Rifai et al., 2017). In line with these finding, bone cells including osteocytes were proposed to act as a "gravitostat" to regulate appetite in response to body weight changes through a yet to be identified factor that is neither osteocalcin nor LCN2 (Jansson et al., 2018).

Regulation of body adiposity by the skeleton may also require osteocytes. Partial osteocyte deletion in mice led to significant fat and body weight loss through a yet to be identified cooperation with the hypothalamic nuclei regulating energy balance (Sato et al., 2013). Similarly, constitutive and inducible deletion of *Gsα* in osteocytes, which is associated with an increase in the circulating level of the osteocyte-secreted factor sclerostin, led to the expected decrease in bone mass, but also to a significant decrease in adiposity due to induction of beige adipogenesis by sclerostin (Fulzele et al., 2017). In contrast to these findings, another group reported that sclerostin-deficient mice ($Sost^{-/-}$) exhibit a reduction in adipose tissue accumulation associated with increased insulin sensitivity, while sclerostin overproduction results in the opposite metabolic phenotype due to adipocyte hypertrophy (Kim et al., 2017). Hence, the exact role of sclerostin in fat metabolism remains to be determined.

In general, glucose metabolism does not appear to be altered by genetic manipulations in osteocytes, suggesting that compared with those of osteoblasts, osteocyte functions may be limited to the regulation of fat metabolism. Additional bone-derived hormones and bone metabolic functions may yet be identified, and their exploration may shed new light on the endocrine-regulating properties of bone.

Concluding remarks

Bone has recently emerged as an endocrine organ. This was unexpected because of both the nature of bone and the increasingly broad spectrum of its functions. A more complete understanding of all the roles and the regulation of bone-

derived hormones needs to be achieved before osteocalcin- or LCN2-based therapies for metabolic disorders can be developed for humans. Nonetheless, wherever future research on bone endocrine function will take us, it is clear that these findings have significantly broadened the definition of what is bone physiology.

Principles of Bone Biology

FOURTH EDITION

Volume 2

Edited by John P. Bilezikian, T. John Martin, Thomas L. Clemens and Clifford J. Rosen

Preface from the first edition (1996): "The world of modern science is undergoing a number of spectacular events that are redefining our understanding of ourselves. As with any revolution, we should take stock of where we have been, where we are, and where we are going. Our special world of bone biology is participating in and taking advantage of the larger global revolution in modern science… we assembled experts from all over the world and asked them to focus on the current state of knowledge and the prospects for new knowledge in their area of expertise. To this end, Principles of Bone Biology was conceived." - John P. Bilezikian, Lawrence G. Raisz, Gideon A. Rodan

Praise for the previous edition: "Students, teachers, and practitioners will benefit from reading it, and investigators will use it as a reference work; it will certainly be consulted frequently."—The New England Journal of Medicine

For over two decades, "Big Gray" has been the go-to repository of knowledge in the disciplines related to bone and mineral metabolism. The fourth edition is a must-have for students new to the field; young investigators at the graduate or postgraduate level beginning their research careers; established scientists who need to keep up with the changing nature of the field, looking to enrich their own research programs, or who are changing their career direction; clinicians who want ready access to up-to-date relevant basic science.

This new edition builds on the successful formula from previous editions, taking the reader from the basic elements of fundamental research to the most sophisticated concepts in therapeutics. ***Principles of Bone Biology, Fourth Edition*** provides the most comprehensive, authoritative reference on the study of bone biology and related diseases. Bone research continues to generate enormous attention, due to the broad public health implications of osteoporosis and related bone disorders. This classic, fully updated, two volume reference is designed for anyone involved in the study of bone biology.

Key Features:

- Provides a "one-stop" shopping paradise. Anything you want to find about bone biology is here and written by the world's experts
- ***THE*** essential resource for anyone involved in the study of the skeleton and metabolic bone diseases
- Covers everything from the basic scientific concepts to the underlying principles of therapeutics and management
- Allows readers to easily search and locate information quickly in the online format

Volumes include:

- Basic Principles
- Molecular Mechanisms of Metabolic Bone Disease
- Pharmacological Mechanisms of Therapeutics
- Methods in Bone Research
