Chapter outline

Introduction

Parathyroid hormone (PTH) maintains serum Ca homeostasis by direct actions on the kidney and on bone. A fall in serum Ca enhances the activity of the Ca-sensing receptor of parathyroid glands, which immediately increases the secretion of PTH into the circulation. The rise in PTH enhances tubular reabsorption of Ca and the synthesis of 1,25-dihydroxyvitamin D3 in the kidney, which in turn stimulates intestinal Ca absorption. PTH also enhances the release of Ca from bone by increasing osteoclastic bone resorption. The cumulative impact is a rise in serum Ca which then lowers the secretion of PTH, leading to reduced tubular Ca reabsorption, Ca absorption from the gut, and osteoclastic bone resorption.

In adults, bone resorption only takes place at sites of bone remodeling (Parfitt, 1996). This process is carried out by anatomically discrete teams of osteoclasts and osteoblasts, which along with an associated capillary are called basic multicellular units (BMUs). PTH drives the assembly and maintenance of BMUs. Remodeling replaces old or damaged bone with new. In the ilium of postmenopausal women, BMUs remodel 18% of the trabecular bone surface per year and 34% of the endocortical surface. BMUs arise within Haversian canals and tunnel through the cortex to remodel 6% of the cortical bone volume per year (Parfitt, 2002). Trabecular and endocortical surfaces undergo remodeling in laboratory rodents, but in these small mammals the Haversian system is absent (Piemontese et al., 2017). PTH may also stimulate osteocytes to degrade their surrounding lacunar bone (Baud and Boivin, 1978; Tazawa et al., 2004). The high demand for Ca during lactation may be met by PTHrP-stimulated osteocytic osteolysis in rodents (Kovacs, 2017), but the role of this phenomenon in day-to-day Ca homeostasis has not been established. In contrast to the role of PTH in Ca homeostasis, daily injections of exogenous PTH (aka intermittent administration) increase bone mass. This latter feature of PTH function has been employed for the therapy of osteoporosis (Hodsman et al., 2005). This chapter focuses on the cellular mechanisms underlying the diverse effects of PTH on bone.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00032-4

The regulation of bone remodeling by parathyroid hormone

Osteoclasts initiate bone remodeling by adhering to the bone surface and forming a tightly sealed pocket into which they pump HCl and secrete lysosomes that dissolve the hydroxyapatite and degrade the collagenous and other proteinaceous components of the matrix. The degraded proteins are packaged into endosomes, transcytosed to the apical surface, and released into the extracellular space (Salo et al., 1997). Bone formation is temporally and spatially linked to this resorptive activity within the BMU in a process called coupling, which ensures that sufficient bone matrix is made to replace the one removed by osteoclasts (Sims and Martin, 2014). Mesenchymal precursors of the osteoblast lineage are recruited to the previously resorbed surface where they intermingle with some of the osteoclasts to form a "reversal-resorption" surface (Lassen et al., 2017). The mesenchymal cells deposit a thin layer of glycosaminoglycan-containing matrix that marks the limit of bone resorption. These mesenchymal cells and/or other recruited progenitors differentiate into osteoblasts and elaborate a matrix consisting of type I collagen, a variety of noncollagenous proteins, and growth factors. The matrix is then calcified. During matrix deposition, some osteoblasts differentiate into osteocytes. Osteocytes are embedded into the matrix and form connections with each other and with the bone surface. Osteoblasts eventually cease matrix production and become the very thin lining cells that cover the quiescent surface of bone.

The dependence of bone formation on bone resorption is the "sine qua non" feature of remodeling. If coupling is defective, the thickness and connectivity of trabecular bone declines. Cortical bone becomes thinner because of endosteal bone loss and more porous because the Haversian canals become wider. If excessive matrix is deposited during coupling, trabecular bone mass increases, and cortical bone becomes thicker.

In addition to remodeling, bone also undergoes modeling. As opposed to bone remodeling, bone modeling is a process carried out by osteoclasts and osteoblasts that operate independently of each other. The purpose of modeling is to sculpt the skeleton during growth and adapt it to the prevailing mechanical strains at different sites.

The function of the BMU can be measured using histologic approaches that quantify the rate of resorption and formation (Dempster et al., 2013) (see Box 32.1). The life span of BMUs in humans is 6–9 months, but the life span of osteoclasts is 1 week or so, and the life span of osteoblasts is a few months (Manolagas, 2000). All osteoclasts and the majority of osteoblasts die by apoptosis (Jilka et al., 2007, 2008). Thus, the function of the BMU requires a continuous supply of new osteoclasts and osteoblasts derived from local or circulating progenitors and the timely death of these cells (Manolagas, 2000). Recent advances in the genetic manipulation of mice has permitted more rigorous examination of the origination and fate of cells of the osteoblast lineage (Ono and Kronenberg, 2015). The important role of the timely death of osteoblasts and perhaps osteoblast progenitors by apoptosis has been illustrated by the increased trabecular bone in mice with osteoblast lineage cells lacking Bax and Bak, two proteins critical for apoptosis (Jilka et al., 2014).

BOX 32.1 Histologic measurements of bone modeling and remodeling.

Term	Description
Mineralizing surface	Bone surface undergoing mineralization as visualized by fluorochromes labeling.
Mineral apposition rate	Distance between fluorochromes labels divided by the labeling interval.
Bone formation rate	Product of mineralizing surface and mineral apposition rate.
Activation frequency	Probability that a remodeling event will be initiated on the bone surface.
Cement line	Thin line of toluidine blue staining that marks the boundary between resorption and formation in remodeled bone, or new bone formation in modeled bone.
Wall width	Amount of bone formed during remodeling by a team of osteoblasts. Measured by the average distance between scalloped cement lines and quiescent bone surface.
Eroded surface	Osteoclast surface plus the reversal-osteoclast surface.
Erosion depth	Average depth of active resorption lacunae.

The generation and Maintenance of basic multicellular units Is governed by parathyroid hormone

Bone turnover is primarily influenced by circulating levels of PTH. In hypoparathyroidism, bone remodeling and the number of BMUs is severely reduced (Rubin et al., 2008; Clarke, 2014; Langdahl et al., 1996). The length of the resorption and formation period of each BMU is prolonged, and the resorption depth and the wall thickness is reduced, as is osteoid width, mineral apposition rate, and bone formation rate (see Box 32.1). Nevertheless, cancellous bone volume is increased due to increased trabecular thickness, likely due to reduced erosion depth combined with a reduced proportion of the surface undergoing remodeling. In mice, deletion of the PTH gene has similar effects (Miao et al., 2004).

Hyperparathyroidism increases bone remodeling. In mild primary hyperparathyroidism there is a 50% increase in the activation frequency of the BMUs and increased formation and resorption surfaces (Christiansen et al., 1992; Dempster et al., 1999; Parisien et al., 2001). In cortical bone, increased remodeling is seen at both the endocortical and intracortical surfaces. The result of the increased intracortical remodeling is larger Haversian canals accounting for increased cortical porosity, and "trabecularization" of the endocortical surface (Vu et al., 2013; Stein et al., 2013). Periosteal surfaces are usually unaffected. In severe primary hyperparathyroidism, bone remodeling is dramatically increased. This is manifested by skeletal deformities, pathological fractures, subperiosteal bone erosion, "brown tumors," and peritrabecular bone marrow fibrosis, also called osteitis fibrosa.

Parathyroid hormone regulates factors that govern the assembly and maintenance of basic multicellular units

Osteoclast differentiation and life span

Under normal physiologic conditions, PTH drives the development of osteoclasts. Osteoclastogenesis requires extravasation of monocytic progenitors from capillaries near the bone targeted for renewal or from locally produced progenitors in the bone marrow. Osteoclast differentiation requires macrophage-colony stimulating factor (M-CSF) which stimulates the replication of these progenitors, and receptor activator of NF-kB ligand (RANKL) which promotes differentiation into multinucleated bone resorptive cells (Boyle et al., 2003). Mice lacking either of these two cytokines are osteopetrotic and practically devoid of osteoclasts. RANKL also maintains the viability of osteoclasts. Administration of osteoprotegerin (OPG), a soluble receptor antagonist of RANKL, causes a decline in osteoclast number coincident with the appearance of apoptotic fragments of osteoclasts as early as 6h after administration (Lacey et al., 2000). OPG also reduces osteoblast number and bone formation rate, directly demonstrating the coupling of bone formation to bone resorption (Jilka et al., 2010; Piemontese et al., 2017).

RANKL is produced by many cell types including cells of the osteoblast lineage, T and B lymphocytes, synovial fibroblasts, adipocytes, and hypertrophic chondrocytes (O'Brien et al., 2013). PTH stimulates the production of RANKL by osteoblastic cells (Rodan and Martin, 1981; Lee and Lorenzo, 1999; Yasuda et al., 1998; Fu et al., 2002; McSheehy and Chambers, 1986). These effects are mediated by activation of a distal enhancer located 76 kb from the transcriptional start site of the RANKL gene (Galli et al., 2008; Fu et al., 2006). The osteopetrotic phenotype of mice lacking a functional RANKL gene can be rescued by a 220-Kb transgene containing the RANKL gene and its upstream regulatory domains (Onal et al., 2015). Targeted deletion of RANKL in osteoblasts/osteocytes using DMP1-Cre, or in osteocytes using Sost-Cre, causes a reduction in osteoclast number and an increase in trabecular bone mass (Xiong et al., 2011, 2014, 2015; Nakashima et al., 2011). These changes are apparent as early as 5 weeks of age, indicating that osteocytes represent the main source of RANKL when skeletal growth and modeling begins to slow, and osteoclasts are needed only for remodeling. In contrast, global deletion of RANKL causes osteopetrosis that is evident from birth (Kong et al., 1999). Thus, other cell types produce the RANKL required for the formation of osteoclasts needed for skeletal development, for example resorption of calcified cartilage in the growth plate (Gebhard et al., 2008).

Conditional deletion of RANKL in osteoblasts/osteocytes with DMP1-Cre attenuates the increase in osteoclast number and the bone loss caused by dietary Ca deficiency in adult mice (Xiong et al., 2014). Osteocytes vastly outnumber osteoblasts, making the former cell type the most likely source of RANKL. Moreover, mice lacking PTHR1 in osteoblast/osteocyte fail to exhibit the increase in RANKL and the loss of bone caused by chronic elevation of PTH (Saini et al., 2013). These findings show that the stimulatory effects of chronic elevation of PTH on osteoclast number and bone remodeling are primarily mediated by direct actions of the hormone on RANKL production by osteocytes. Consistent with this contention, expression of a constitutively active PTHR1 mutant in osteocytes (using the DMP1 promoter) increases RANKL and bone remodeling (O'Brien et al., 2008; Ben-Awadh et al., 2014). RANKL is initially expressed as a

transmembrane protein on the cell surface. Following cleavage by extracellular endopeptidases, it is released in soluble form (sRANKL). Mice expressing endopeptidase[HYPHEN]resistant RANKL exhibit normal bone development. However, osteoclasts are reduced and trabecular bone is increased in adult mice, indicating that sRANKL contributes to physiological bone remodeling (Xiong et al., 2018). The circulating levels of sRANKL increase in patients with mild primary hyperparathyroidism and correlate with the level of circulating markers of bone resorption and the rate of femoral bone loss (Nakchbandi et al., 2008). However, the level of circulating sRANKL is too low to be biologically relevant, indicating that local production of the cytokine is responsible for the induction and maintenance of BMUs.

PTH exerts a negative effect on the production of OPG (Fu et al., 2002; Onyia et al., 2000). Since bone mass is severely reduced and osteoclast number is dramatically increased in OPG null mice (Bucay et al., 1998), this cytokine must play a fundamental role in the regulation of osteoclast differentiation and survival in physiological circumstances. In parathyroidectomized patients, bone exhibits a decrease in the ratio of RANKL to OPG transcripts (Stilgren et al., 2004), demonstrating that PTH increases the RANKL/OPG ratio. Surprisingly, however, little is known about the underlying genetic regulatory mechanism or the cellular source(s) of OPG.

PTH affects several other factors with proosteoclastogenic properties. The expression of monocyte chemoattractant protein 1 (MCP-1), a cytokine that promotes osteoclast multinucleation, is strongly induced by PTH in cultured osteoblastic cells (Li et al., 2007). Mice with global deletion of MCP-1 have normal bone mass and osteoclast number, but infusion of PTH fails to cause the expected cortical or trabecular bone loss (Siddiqui et al., 2017). PTH also stimulates the production of IL-11 (Walker et al., 2012), which stimulates osteoclastogenesis in ex-vivo cultures of bone marrow cells (Girasole et al., 1994), by stimulating RANKL synthesis (Horwood et al., 1998; Palmqvist et al., 2002). Moreover, global deletion of the IL-11R reduces osteoclast number (Sims et al., 2005). In vitro and in vivo studies show that PTH also stimulates the synthesis of IL-6, which can increase osteoclast number by promoting the replication of monocytic progenitors (Greenfield et al., 1996; Walker et al., 2012; O'Brien et al., 2005). However, mice lacking IL-6 have normal bone (Fattori et al., 1994; Sims et al., 2005); and studies with these mice show that IL-6 is dispensable for the increased RANKL, osteoclast number, and bone loss caused by secondary hyperparathyroidism (O'Brien et al., 2005).

Matrix metalloproteinase 13 (MMP-13) is involved in collagen turnover in many tissues including bone (Stickens et al., 2004). PTH stimulates the synthesis of MMP-13 in osteoblastic cells (Winchester et al., 2000). Moreover, PTH-induced osteoclastogenesis in calvaria is attenuated in mice bearing a mutation that causes resistance of type I collagen to MMP-13 (Zhao et al., 1999). Unexpectedly, MMP-13 may also act as a cytokine, as indicated by the finding that formation of multinucleated osteoclasts is dramatically accelerated in vitro by a catalytically inactive mutant of MMP-13 (Fu et al., 2016).

T cells bear PTH receptors, and conditional deletion of PTHR1 in these cells. Using Lck-Cre has no effect on bone mass or osteoclast number (Tawfeek et al., 2010). Infusion of PTH, however, increases T cell production of tumor necrosis factor (TNF), which may potentiate RANKL synthesis. Moreover, TNF stimulates proinflammatory T helper cells (Th17 cells) to produce IL-17A, which may also stimulate RANKL expression (Li et al., 2015). Work with an IL-17A neutralizing antibody indicates that an IL17-/RANKL cascade contributes to the bone effects of hyperparathyroidism (Li et al., 2015).

Osteoblast differentiation and the coupling of bone formation to bone resorption

Osteoblasts originate from multipotential progenitors in the bone marrow, many of which are associated with the vasculature (Bianco et al., 2013). The commitment of these progenitors to the osteoblast lineage and their development into matrix synthesizing cells, is orchestrated by locally produced growth factors like insulin-like growth factor-I (IGF-1), bone morphogenetic proteins (BMPs), transforming growth factor-β (TGFβ), and wingless-related integration site (Wnt) ligands. Osteoblastogenesis critically depends on a variety of transcription regulators including β-catenin, runt related transcription factor 2 (Runx2), and Osterix 1(Osx1). Wnt ligands bind to frizzled (FZD)\lipoprotein related protein 5 (LRP5) or FZD\LRP6 co-receptor complexes to increase proosteogenic β-catenin mediated transcription (Baron and Kneissel, 2013). Wnt signaling is suppressed by sclerostin, which is produced exclusively by osteocytes, as well as by Dkk1 and both block activation of the Wnt receptors LRP5/6. Sost null mice exhibit high bone mass, illustrating the critical role of sclerostin as a brake on bone formation under physiologic circumstances.

Release of proosteoblastogenic factors from osteoclasts, or from the bone matrix during resorption, contribute to the temporal and spatial linkage of bone formation to bone resorption within the BMU (Fuller et al., 2008; Sims and Martin, 2014). Matrix-derived TGFβ (Tang et al., 2009) and IGF-1 (Crane and Cao, 2014) are released during bone resorption and recruit osteoblast progenitors to sites of bone remodeling (Tang et al., 2009; Xian et al., 2012). Osteoclasts themselves also secrete a variety of proosteogenic factors (Sims, 2016). Among these, sphingosine-1-phosphate (S1P) (Lotinun et al., 2013; Sartawi et al., 2017; Keller et al., 2014), and leukemia inhibitory factor LIF (Koide et al., 2017) have received attention.

Importantly, osteoclast-derived LIF may suppress the expression of sclerostin by osteocytes, thus removing a brake on Wnt signaling in the microenvironment of the BMU (Koide et al., 2017). Consistent with this evidence, deletion of gp130, a subunit of the LIF receptor, in osteoblasts/osteocytes reduces osteoblast number and bone mass without altering osteoclast number, consistent with diminished coupling (Johnson et al., 2014).

Osteoclast-independent factors also contribute to coupling. In a study comparing infused RANKL and infused PTH on trabecular bone remodeling in mice (Jilka et al., 2010), both treatments increased osteoclast and osteoblast number and bone formation rate. However, osteogenic indices and bone mass were lower in RANKL-treated mice compared with PTH-treated mice. The increase in osteoblasts in mice infused with RANKL provides functional evidence for the osteoclast-derived proosteogenic signals mentioned above. However, these signals are evidently insufficient for full replacement of the previously resorbed matrix. PTH-stimulated Wnt signaling may play an additive role. This Wnt signaling is independent of osteoclasts since OPG did not affect PTH-stimulated expression of several established Wnt target genes.

PTH stimulates proosteoblastogenic Wnt signaling via several mechanisms. One is suppression of the constitutive synthesis of the Wnt signaling inhibitor sclerostin (Bellido et al., 2005; Keller and Kneissel, 2005). Indeed, the level of circulating sclerostin is decreased or increased in hyperparathyroidism and hypoparathyroidism, respectively (Costa et al., 2011; van Lierop et al., 2010). PTH also suppresses the expression of the Wnt antagonist Dkk1; and mice overexpressing Dkk1 have low bone mass (Guo et al., 2010). Importantly, continuous elevation of PTH does not increase bone formation or cause peritrabecular fibrosis in Dkk-overexpressing mice, presumably because PTH cannot reduce the Dkk transgene in this model. Mice expressing a constitutively active PTHR1 in osteoblasts and osteocytes, on the other hand, have increased bone mass and high remodeling. These changes are associated with suppression of sclerostin and increased Wnt signaling, which were attenuated by deletion of LRP5 (O'Brien et al., 2008). Finally, in vitro evidence indicates that PTH may stimulate Wnt signaling directly by inducing the association of PTH1R with LRP6, and thereby increasing β-catenin (Wan et al., 2008).

Despite increased Wnt signaling and production of other growth factors, bone mass decreases in hyperparathyroidism. This is probably due to excessive genesis and prolongation of the life span of osteoclasts secondary to increased RANKL and other PTH-regulated cytokines. Osteoblast apoptosis is unaffected in hyperparathyroidism (Bellido et al., 2003), but high levels of PTH have a negative impact on osteoblastogenesis. Indeed, the peritrabecular fibroblasts that characterize severe hyperparathyroidism likely represent osteoblastic cells arrested at a late stage of differentiation. Thus, experiments in mice receiving PTH demonstrate rapid development of these cells, and cessation of PTH administration results in their conversion to bone-forming osteoblasts (Lotinun et al., 2005). Excessive levels of PDGFa may be responsible (Lowry et al., 2008). Another cause of arrested osteoblast differentiation may be accelerated proteasomal degradation of essential transcription factors like Runx2 (Bellido et al., 2003).

The elucidation of the cellular mechanisms responsible for PTH-regulated BMU function helps explain the "hungry bone" syndrome that can be seen after parathyroidectomy (Mallette, 1994). In these patients, because of the rapid decline in PTH, RANKL levels fall, leading to premature osteoclast death, thereby reducing Ca release from bone. However, serum Ca continues to be deposited into bone by osteoblasts already assembled in the BMUs that had been generated prior to surgery and by. New osteoblasts generated upon release of progenitors from the direct or indirect inhibitory effects of PTH.

The bone anabolic effects of intermittent parathyroid hormone

Stimulation of anabolic remodeling and modeling

In contrast to hyperparathyroidism, intermittent (usually daily) injections of PTH (iPTH) increase bone mass in animals and humans. Modified amino terminal versions of hPTH(1−34) (Forteo) and hPTHrP(1−36) (Abaloparatide) increase BMD and reduce the incidence of fractures (Jiang et al., 2003; Hodsman et al., 2005; Miller et al., 2016; Doyle et al., 2018; Finkelstein et al., 2003; Orwoll et al., 2003). Anabolism is confined to trabecular, endocortical, and periosteal surfaces. In contrast, iPTH tends to increase cortical porosity (Zebaze et al., 2017; Moreira et al., 2017; Sato et al., 2004; Burr et al., 2001; Doyle et al., 2018; Fox et al., 2007a). The magnitude of the increase in bone mass declines with time with modest if any benefit after 2 years of treatment (Finkelstein et al., 2009; Dempster et al., 2018a).

Injection of a therapeutic dose of 20 μg of hPTH(1−34) increases levels of this peptide to ∼150 pg/mL after 30 min, which is 2- to 10-fold higher than the normal circulating level of 15−65 pg/mL of endogenous PTH. The exogenous peptide has a half-life of ∼1 h (Satterwhite et al., 2010). The magnitude of the change in circulating PTH required for anabolism is far beyond the ∼20%−30% variation that occurs in a diurnal manner (El Hajj et al., 1997). In rodents the

minimum effective interval between bouts of PTH administration is 6 h, with smaller intervals resulting in the histologic changes and bone loss characteristic of hyperparathyroidism. Thus, both a substantial rise and rapid decline in the level of PTH are required for the anabolic effect of the hormone.

Intermittent PTH increases bone remodeling secondary to a transient increase of RANKL. However, the increase in osteoblast number is much higher and occurs rapidly (Jilka et al., 1999; Iida-Klein et al., 2002; Bellido et al., 2003; Lindsay et al., 2006; Ma et al., 2006). Administration of fluorochromes to identify sites of bone formation prior to and following daily PTH injections in postmenopausal women have allowed for more detailed investigation of the cellular events involved. (Lindsay et al., 2006). As illustrated in Fig. 32.1, the location of each label with respect to the shape of the underlying cement lines was used to distinguish new bone made during remodeling, new bone made by overflow of osteoblasts outside the boundaries of the BMU, and new bone made by modeling. Intermittent iPTH clearly elevated remodeling on cancellous, endocortical, and intracortical surfaces after 1 month of therapy (Lindsay et al., 2006). More importantly, iPTH induced overflow labeling and modeling, both of which were rare or absent at baseline. These responses occurred in trabecular and endosteal bone but not in Haversian canals. Increased modeling was reported in another study, based on similar labeling criteria (Ma et al., 2006). iPTH also stimulated modeling-based bone formation on the periosteal surface in about half of the subjects. Increased remodeling, overfill, and modeling were also observed after 6 months of treatment, but after 24 months, overfill- and modeling-based bone formation had practically ceased (Lindsay et al., 2007;

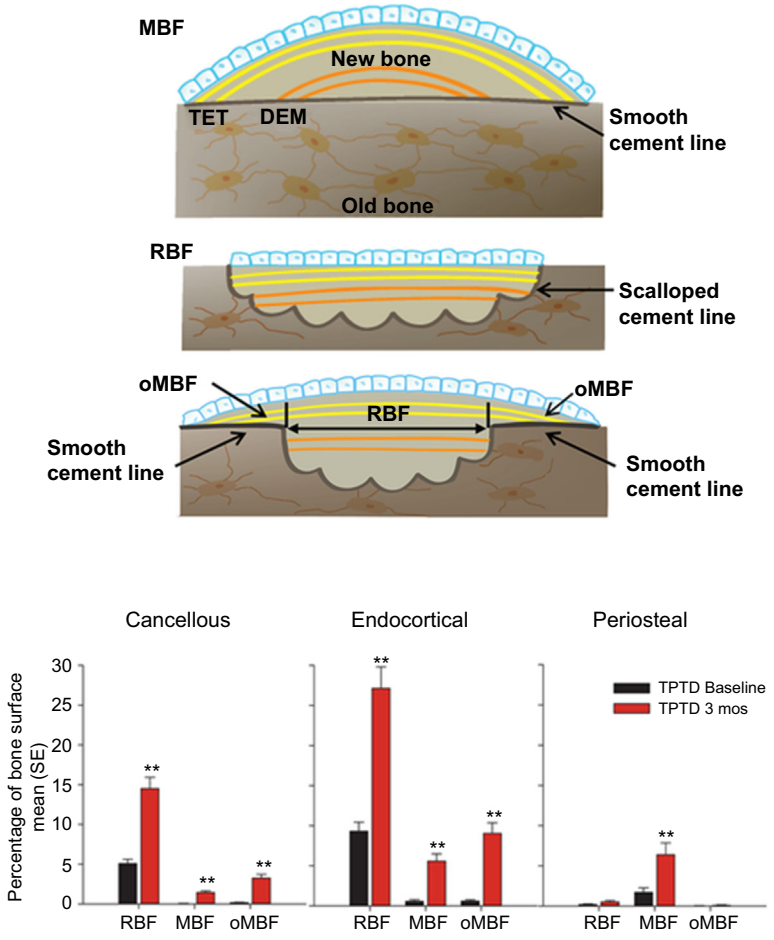

FIGURE 32.1 Cellular basis of the effect of anabolic effect of iPTH. Top. Illustration of modeling-based bone formation (MBF) marked by fluorochrome labeling overlying smooth cement lines; remodeling-based bone formation (RBF) marked by labeling on top of scalloped cement lines that mark the extent of previous osteoclastic bone resorption; and overflow-modeling-based bone formation (oMBF) taking place on smooth cement lines adjacent to scalloped cement lines. Bottom: Effect of 3 months of iPTH on different types of bone formation on cancellous, endocortical, and periosteal surface measured in the same patient using quadrupole fluorochrome labeling. Note absence of MBF and oMBF in cancellous and endocortical bone at baseline. *Reproduced from Dempster, D.W., Zhou, H., Recker, R.R., Brown, J.P., Recknor, C.P., Lewiecki, E.M., Miller, P.D., Rao, S.D., Kendler, D.L., Lindsay, R., Krege, J.H., Alam, J., Taylor, K.A., Melby, T.E., Ruff, V.A. 2018a. Remodeling- and modeling-based bone formation with teriparatide versus denosumab: a longitudinal analysis from baseline to 3 Months in the AVA study. J. Bone Miner. Res. 33, 298–306, with permission.*

Dempster et al., 2018a, 2018b). This coincides with the decline in the stimulatory effect of iPTH on BMD. Moreover, after 24 months, the magnitude of remodeling-based bone formation on cancellous and endocortical surfaces declined two- to threefold from its level at 6 months (Dempster et al., 2018b).

The increased Haversian remodeling in response to intermittent PTH is associated with increased porosity (Dempster et al., 2016; Cohen et al., 2013; Lindsay et al., 2006; Cosman et al., 2016; Ma et al., 2014). This effect is also evident following administration of PTH for 4 months to hypoparathyroid patients (Sikjaer et al., 2012). Increased porosity may be partly due to the formation of new BMUs—i.e., an increase in intracortical remodeling space. Moreover, iPTH fails to arrest ovariectomy-induced development of cortical porosity in non-human primates (Fox et al., 2007b). At a higher dose, iPTH increases cortical porosity even further in this model; yet the anabolic effect in trabecular bone is still present.

Mechanisms underlying overfill of resorption cavities in response to injections of parathyroid hormone

Improved coupling of bone formation to bone resorption at sites of remodeling, resulting from increased osteoblast number within each BMU, most likely accounts for the overfilling of resorption cavities with iPTH. In mice, the anabolic effect of iPTH is attenuated by conditional deletion of the PTHR1 in multipotent osteoblast progenitors (Balani et al., 2017), osteoblasts and osteocytes (Saini et al., 2013; Delgado-Calle et al., 2017) and in T cells (Bedi et al., 2012), suggesting that several interdependent mechanisms are responsible.

Early studies indicated that iPTH increases the number of osteoblast progenitors in the bone marrow (Nishida et al., 1994). Lineage tracing studies in mice have elucidated the underlying mechanisms. In this work the authors utilize mice bearing a floxed gene encoding a fluorescent protein, as well as a transgene consisting of a tamoxifen-inducible Sox9 promoter (known to be expressed in early multipotent mesenchymal cells) driving Cre recombinase (Balani et al., 2017). Administration of tamoxifen for 1 week caused appearance of fluorescence-labeled Sox9+ progenitors within the bone marrow. These progenitors were the source of osteoblasts needed for remodeling, because fluorescent osteoblasts and osteocytes were evident for several months after tamoxifen injection. Intermittent PTH increased the number of fluorescent Sox9+ progenitors as well as the number of fluorescent osteoblasts and osteocytes. FACS analysis of the Sox9+ cells showed that iPTH did not stimulate their replication. This finding is consistent with earlier nucleotide labeling studies (Dobnig and Turner, 1995; Jilka et al., 2009) and evidence that PTH modulates the expression of cell cycle-regulating proteins in cultured osteoblastic cells, resulting in their exit from the cell cycle (summarized in Jilka, 2007). Instead, iPTH increased the number of osteoblast progenitors by attenuating their apoptosis. Moreover, deletion of PTHR1 in Sox9+ cells abrogated the increase in progenitors, as well as the anabolic effect, suggesting that this response depends on direct actions of the hormone on Sox9+ progenitors and/or their progeny. Cessation of iPTH caused the expected loss of anabolism, but interestingly also resulted in an increase in adipocytes that were descended from labeled Sox9+ progenitors.

Besides osteoblast progenitors, intermittent PTH reduces the number of apoptotic osteoblasts in trabecular bone (Jilka et al., 1999; Bellido et al., 2003). PTH-induced survival signaling depends on CREB- and Runx2-mediated transcription, increased expression of the antiapoptotic genes like Bcl-2, and phosphorylation and thereby inactivation of the antiapoptotic protein Bad. The duration of PTH-stimulated antiapoptotic signals is about 6 h in vitro. This is probably because of a separate effect of PTH on stimulating Smurf1-mediated proteosomal proteolysis of the Runx2 required for suppression of apoptosis. This may be the reason that osteoblast apoptosis is unaffected in hyperparathyroidism.

Intermittent PTH modulates the synthesis of autocrine/paracrine factors that accelerate osteoblast differentiation. LRP6 but not LRP5 (Iwaniec et al., 2007) is required for iPTH anabolism, consistent with direct activation of LPR6 by the hormone (Wan et al., 2008). Following injection of PTH, the expression of the Wnt signaling inhibitor sclerostin in osteocytes is transiently suppressed, coinciding with the rise and fall in the circulating level of the injected hormone (Bellido et al., 2005; Keller and Kneissel, 2005). A critical role of the decrease in sclerostin in the effects of iPTH has been suggested by the attenuation of the anabolic effect of iPTH in mice with global deletion of sclerostin (Robling et al., 2011). Moreover, PTH-induced bone formation is attenuated by increasing the dosage of the Sost gene (Kramer et al., 2010). Mice over-expressing sclerostin under the control of the DMP-1 promoter, however, still respond to iPTH (Delgado-Calle et al., 2017). This seeming discrepancy could be explained by the fact that, in the latter studies, sclerostin was overexpressed in both osteocytes and osteoblasts; as opposed to normal mice in which sclerostin is expressed only in osteocytes. Intermittent PTH-stimulated production of Wnt10b by T cells may also contribute to Wnt signaling and bone

anabolism (Bedi et al., 2012; Terauchi et al., 2009), but for reasons that are unclear, this mechanism is only relevant to trabecular bone.

Of the many proosteogenic cytokines and growth factors stimulated by PTH, IGF-1 (Bikle et al., 2002; Miyakoshi et al., 2001), FGF2 (Hurley et al., 2006), or ephrinB2 (Tonna et al., 2014) are required for the full anabolic response to iPTH. However, it is unclear whether the IGF-I- and FGF2-dependent anabolism by iPTH reflects increased release from the bone matrix or locally increased biosynthetic actions of the hormone. IGF-I increases glucose uptake and oxidative phosphorylation during osteoblast differentiation, which is critical for the development of the high biosynthetic and secretory capacity of these cells (Esen et al., 2015). Deletion of gp130 — the common co-receptor for IL-6 type cytokines - in osteoblasts/osteocytes attenuates the anabolic effect of iPTH (Standal et al., 2014). This might be explained by a dependence on osteoclast-derived LIF, which can suppress sclerostin as discussed above. Notch signaling normally suppresses osteoblast differentiation, and PTH antagonizes this pathway (Zanotti and Canalis, 2017). Accordingly, mice with conditional deletion of the Notch ligand Jagged 1 in mesenchymal stem cells exhibit increased femoral cancellous bone mass. Moreover, iPTH increases trabecular bone in these mice, perhaps because of loss of Jagged1-dependent limits on osteoblast differentiation (Lawal et al., 2017).

Stimulation of bone modeling by osteoblasts in response to injections of parathyroid hormone

In adults, the periosteum contains a reservoir of osteoblast progenitors that facilitate fracture repair and the slow deposition of periosteal bone that occurs via modeling. Lineage tracing studies in growing mice using tamoxifen-inducible DMP1-Cre transgene showed that some periosteal cells are former osteoblasts (Kim et al., 2012). More important, iPTH reactivated these marked lining cells to resume their matrix-synthesizing function.

Trabecular bone surfaces have lining cells descended from osteoblasts (Kim et al., 2012). Previous morphologic studies had suggested that iPTH rapidly converts these cells into osteoblasts (Leaffer et al., 1995; Dobnig and Turner, 1995), but this has not yet been confirmed using the lineage tracing approach. Nevertheless, administration of an antisclerostin antibody did reactivate trabecular lining cells marked with either DMP1-Cre or OCN-Cre on trabecular and periosteal surfaces (Kim et al., 2012). This anabolic response was short lived, probably because most of the reactivated postmitotic osteoblasts were incorporated into the bone matrix as osteocytes or died; only a minority returned to their former life as lining cells. Thus, the constitutive production of sclerostin by osteocytes may serve an antiproosteoblastogenic role on most skeletal surfaces by suppressing Wnt signaling that would otherwise be induced by locally produced Wnt ligands. Sequestration of sclerostin by the antibody unleashes Wnt signaling throughout the skeleton. Similarly, lining cells may be reactivated by periodic suppression of sclerostin by iPTH.

Unresolved issues

Why does iPTH fail to overfill of BMUs and to reactivate lining cells in Haversian canals? There may be an inhibitory effect of the capillary, since anabolism in Haversian canals has the potential to closing the canal and blocking cortical circulation. Fundamental differences in BMU and lining cell characteristics in Haversian surfaces versus other sites is also possible.

Why does PTH-stimulated BMU overfill and PTH-stimulated modeling wane with time? It is possible that activation of negative feedback pathways on osteoblastogenesis and on reactivation of lining cells is responsible. The new BMUs generated during the later stages of therapy may also have excessive bone resorption. Given the complexity of the cellular response and the absence of anabolism at sites of intracortical remodeling, as reviewed herein, studies of changes in circulating markers of osteoclast and osteoblast function are not very informative (Seeman and Martin, 2015).

Chapter 33

Calcitonin peptides

Dorit Naot*, **David S. Musson and Jillian Cornish**
Department of Medicine, University of Auckland, Auckland, New Zealand

Chapter outline

Introduction

The peptide hormone calcitonin was discovered as the active component in extracts from the thyroid gland that acutely lowered the concentration of circulating calcium (Copp et al., 1962; Copp and Cheney, 1962). Over the years, several peptides with structural similarity to calcitonin have been discovered and became recognized as the "calcitonin family," which includes the calcitonin gene-related peptides (αCGRP and βCGRP), amylin, adrenomedullin, and adrenomedullin 2. The peptides of the calcitonin family signal through related receptors; calcitonin itself binds to the calcitonin receptor, a seven-transmembrane domain G-protein coupled receptor (GPCR), while all other family members require receptor heterodimers that include a GPCR and receptor-activity-modifying protein (RAMP). The calcitonin family peptides have been investigated extensively; in addition to studies of the biochemistry, pharmacology, and physiological activities of the peptides, a large body of literature describes the development of these peptides, their analogues and their antagonists for clinical use. This chapter provides a general introduction to the calcitonin family and summarizes the current knowledge of the skeletal activities of calcitonin, CGRP, and amylin.

Calcitonin-family gene and peptide structure

Calcitonin and αCGRP are generated by alternative splicing of mRNA transcribed from the *CALCA* gene, which in humans is located on the short arm of chromosome 11. The *CALCA* gene contains six exons: exons I–IV are included in the mRNA for the precursor of calcitonin, preprocalcitonin, whereas preproCGRP is encoded by exons I–III and V–IV (Fig. 33.1A). The alternative splicing of *CALCA* mRNA is tissue specific—calcitonin mRNA is produced mainly in parafollicular

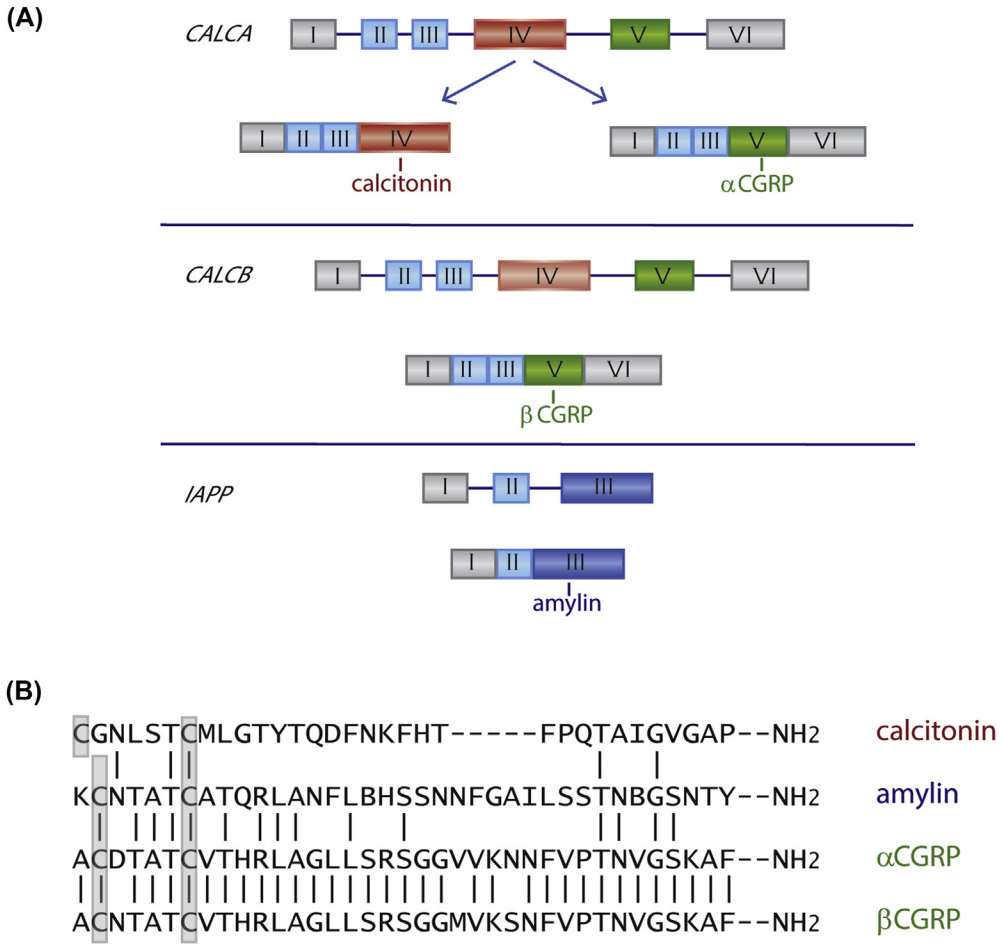

FIGURE 33.1 Genes, mRNA, and peptides of four members of the human calcitonin family: calcitonin, αCGRP, βCGRP, and amylin. (A) The *CALCA* primary transcript is processed through alternative splicing. Calcitonin mRNA contains exons I, II, III, and IV, whereas αCGRP mRNA contains exons I, II, III, V, and VI. Each mRNA is translated into a precursor protein that undergoes proteolytic cleavage to produce the mature peptides. Exon IV encodes the mature calcitonin peptide and exon V encodes the mature αCGRP. βCGRP is the only mature peptide encoded by *CALCB*. The *IAPP* gene contains only three exons, with exon III encoding the mature amylin peptide. (B) Amino acid sequences of the human peptides. All four peptides are amidated at the C terminal. The cysteine residues connected by a disulfide bond in each peptide are shaded, and identical amino acids are indicated by vertical lines.

cells of the thyroid, whereas in the nervous system, αCGRP mRNA is the predominant form (Breimer et al., 1988). In nonmammalian species—birds, fish and reptiles—calcitonin is derived from the ultimobranchial body. Salmon calcitonin (sCT), which shares only 50% sequence identity with the human peptide, has a much higher biological potency in humans than human calcitonin itself (Niall et al., 1969). A second CGRP peptide, βCGRP, which in humans differs from αCGRP by three amino acids, is encoded by *CALCB*, a separate gene located on the short arm of chromosome 11. Human amylin (also called island amyloid polypeptide) is encoded by *IAPP*, a gene that includes three exons and is located on the short arm of chromosome 12. Like calcitonin and CGRP, amylin is synthesized as a prepropeptide, which is processed by proteolytic cleavage to the mature amylin peptide. Amylin is produced mainly in β islet cells of the pancreas but has also been detected in the gastrointestinal tract as well as lung and neuronal tissues. The amino acid sequences of the mature calcitonin, αCGRP, βCGRP, and amylin in humans are presented in Fig. 33.1B. Mature calcitonin is a 32 amino-acid peptide, whereas CGRPs and amylin contain 37 amino acids. All the calcitonin family peptides have an amino acid ring structure at the N terminal created by a disulfide bond between cysteine residues at positions 2 and 7 in CGRP and amylin, and positions 1 and 7 in calcitonin, and all are amidated at the C terminal. These structural elements are shared by the additional members of the calcitonin family, adrenomedullin and adrenomedullin 2, which are not discussed further in this chapter.

Extraskeletal actions of calcitonin-family peptides

Calcitonin

Calcitonin was initially identified as a hormone that induces hypocalcemia through a rapid and potent inhibition of bone resorption by osteoclasts. The great majority of studies of calcitonin have focused on its skeletal activity and its effect on

calcium homeostasis. The scientific literature includes a large number of clinical studies of the skeletal effects of sCT, as sCT has been in wide clinical use for a number of years, mainly for patients with Paget's bone disease and osteoporosis (Chesnut 3rd et al., 2008; Henriksen et al., 2016). Although recent studies (discussed later in the chapter) indicate that calcitonin regulates bone formation during development, the physiological role of calcitonin has not yet been clearly established, and it has been suggested that calcitonin might not have a major role in mammals under normal physiological conditions (Davey and Findlay, 2013). Calcium metabolism and bone mineral density (BMD) are unaffected in patients with medullary thyroid carcinoma, who have long-term excess of endogenous calcitonin levels, or who have undergone thyroidectomy and have undetectable circulating calcitonin (Hurley et al., 1987; Wuster et al., 1992). The current understanding is that the main significance of calcitonin appears to be the conservation of body calcium stores in situations of calcium stress, including rapid growth, pregnancy, and lactation.

Outside the skeleton, calcitonin transiently enhances calcium excretion through the inhibition of tubular calcium resorption. In addition, calcitonin was found to increase the urinary excretion rate of sodium, potassium, phosphorus, chloride, and magnesium (Findlay and Sexton, 2004). Calcitonin is also involved in the regulation of vitamin D processing, enhancing the 1-hydroxylation of 25-hydroxyvitamin D in the proximal straight tubule of the kidney. Another target tissue of calcitonin is the central nervous system. Calcitonin receptors are highly expressed in the central nervous system, and calcitonin administration has been shown to affect the pituitary and the hypothalamus. In rats, intracerebral injection of calcitonin reduced food and water intake and changed the pattern of secretion of growth hormone. In humans, high concentrations of sCT reduced the circulating levels of hormones including LH, FSH, and testosterone. Calcitonin has an analgesic effect on chronic bone pain and pain associated with osteoporotic fracture (Silverman and Azria, 2002).

Calcitonin gene-related peptide

CGRP is mainly expressed in the central and peripheral nervous systems. It is stored in large, dense-core vesicles within sensory nerve terminals and is commonly colocalized with substance P. The circulating levels of CGRP are low, and it is suggested that the major effects of CGRP are exerted locally. CGRP is recognized as a potent microvascular vasodilator, and its physiological activity is largely dependent on its release from perivascular nerves (Russell et al., 2014). Interestingly, injections of CGRP antagonists to healthy individuals have no significant effects on blood pressure, suggesting that CGRP has no major role in the control of physiological systemic blood pressure. CGRP-containing nerve fibers are also present in the heart vasculature, where CGRP release produces both positive inotropic and positive chronotropic effects and is thought to play a cardioprotective role (Russell et al., 2014).

CGRP also affects energy metabolism. In skeletal muscle, CGRP inhibits glycogen synthesis and stimulates glycogenolysis, while in the liver it increases gluconeogenesis and glucose output (Lima et al., 2017). A number of animal studies have found that CGRP administration reduces food intake, with CGRP inducing anorexia through activation of the cAMP/protein kinase A pathway. Mice deficient of αCGRP were protected from obesity induced by a high-fat diet. In comparison with wild-type controls, the αCGRP knockout mice had higher metabolic rate, increased energy expenditure, and raised body temperature (Russell et al., 2014).

CGRP is involved in neuronal regulation of the immune system. It has been shown to mediate a host of immune regulatory responses, and in different experimental systems CGRP was found to have either proinflammatory or antiinflammatory effects. CGRP promotes neurogenic inflammation, and its release from nerve terminals causes local vasodilation, edema formation, increased blood flow, and recruitment of inflammatory cells. On the other hand, in murine dendritic cells, CGRP inhibited TLR-stimulated production of the inflammatory mediators tumor necrosis factor (TNFα) and C−C motif chemokine ligand 4 (CCL4), an effect that was dependent on the cAMP/protein kinase A signaling pathway (Harzenetter et al., 2007).

A large number of investigations of CGRP in recent years have focused on its involvement in the pathophysiology of migraines (Iyengar et al., 2017). Raised levels of CGRP are observed both peripherally and centrally in migraine patients. CGRP is released from trigeminal afferent nerve fibers during a migraine attack, causing vasodilatation and neurogenic inflammation. The maintenance of a sensitized, hyperresponsive neuronal state is considered a central underlying mechanism in migraine. CGRP facilitates nociceptive transmission and contributes to the development and maintenance of a sensitized state in peripheral sensory neurons as well as neurons within the central nervous system. Four monoclonal antibodies are currently in development for migraine prevention, three against CGRP itself and one against the CGRP receptor. Results from phase III trials suggest comparable efficacy, safety, and tolerability of all four antibodies (Paemeleire & MaassenVanDenBrink, 2018).

Amylin

Amylin was purified from pancreatic deposits of patients with type 2 diabetes and from human insulinoma and was found to be predominantly expressed in β cells of the islets of Langerhans in the pancreas (Cooper et al., 1987; Westermark et al., 1987). In these cells, amylin is stored in secretory granules together with insulin, and it is cosecreted with insulin in response to changes in circulating glucose levels; hyperglycemia stimulates amylin secretion, whereas hypoglycemia inhibits it. Human amylin monomers are soluble, but aggregate to form pancreatic amyloid in patients with type 2 diabetes as well as spontaneously in vitro, in a concentration-dependent manner (Konarkowska et al., 2006). The role of amylin aggregates in the development of β-cell lesions in type 2 diabetes is not entirely clear, although there is evidence that they contribute to the progressive failure and eventually to the death of islet β-cells (Lorenzo et al., 1994; Zhang et al., 2016).

The main physiological role of amylin is the regulation of energy homeostasis (Hay et al., 2015). Eating leads to a rapid increase in circulating levels of amylin, which produces satiation signals and thus controls ingested meal size. Administration of exogenous amylin into animals reduces eating within minutes, an effect that could be reproduced by amylin analogues and blocked by amylin antagonists. Mechanisms involved in the activity of amylin as a satiety signal include delayed gastric emptying, which leads to satiation and prevents further food intake, and central signaling of amylin in specific areas of the brain stem. In addition to the short-term effect on satiety, amylin is also one of a group of hormones secreted in proportion to body adiposity, and is considered an adiposity signal that has a long-term effect to reduce eating by enhancing satiety. In obese rats, basal plasma levels of amylin were higher in comparison with lean controls, and peripheral or central administration of amylin led to decreased body weight as well as fat gain. In addition to short- and long-term effects on food intake, central administration of amylin increases energy expenditure (Hay et al., 2015).

In recent years, studies have demonstrated the importance of interactions between amylin and leptin, an adipokine secreted predominantly from white fat tissue, in the control of energy homeostasis (Levin and Lutz, 2017; Lutz, 2012). Similar to amylin and insulin, leptin provides negative, catabolic feedback to the brain when body adiposity is increased. Circulating leptin levels are generally elevated in obesity, and obese individuals can become leptin-resistant. Amylin was shown to act as an endogenous leptin sensitizer, and cross talk between leptin and amylin was suggested by the observation that leptin-deficient mice have reduced expression of amylin in the hypothalamus, which could be normalized by exogenous leptin (Li et al., 2015). Moreover, infusion of the amylin antagonist AC187 acutely reduced the anorectic effect of leptin.

The synthetic analogue of human amylin, pramlintide, is currently in clinical use for diabetes as an adjunctive therapy to mealtime insulin (Qiao et al., 2017; Singh-Franco et al., 2007). Multiple clinical studies in patients with type 1 and type 2 diabetes have shown that pramlintide in combination with insulin improved overall glycemic control in comparison with insulin alone, possibly by providing a more physiologically balanced therapeutic approach. Pramlintide was found to reduce body weight in patients with insulin-treated diabetes, suggesting a potential use as an antiobesity agent (Hay et al., 2015; Qiao et al., 2017; Singh-Franco et al., 2007). Clinical studies of pramlintide for weight reduction in obese subjects have so far produced promising results (Boyle et al., 2017).

Receptors for calcitonin-family peptides

Calcitonin receptor (CTR) belongs to the type II seven-transmembrane GPCRs and was cloned initially from porcine (Lin et al., 1991) and subsequently from rat, human, and other species. In most species, calcitonin receptor RNA is alternatively spliced, resulting in the expression of several isoforms (Gorn et al., 1995; Sexton et al., 1993). The various isoforms differ from each other structurally, as well as in their tissue distribution, affinity for ligands and the downstream signaling pathways activated by these ligands. The second GPCR that binds calcitonin-family ligands is calcitonin receptor-like receptor (CRLR), which was identified as a protein that shares about 55% amino acid sequence homology with CTR (Chang et al., 1993; Njuki et al., 1993). In contrast to CTR, CRLR itself is not transported to the cell membrane, and in order to form a functional receptor it requires the coexpression of one of three of the receptor activity-modifying proteins (RAMP1—RAMP3) (McLatchie et al., 1998). These single-transmembrane domain proteins interact with the seven-transmembrane domain GPCRs, and regulate their activity through a number of mechanisms: (1) RAMPs modify the binding specificities of the GPCRs to their ligands. (2) Receptor trafficking—RAMPs act as chaperones, directing CRLR to the cell membrane. (3) Receptor desensitization—following ligand binding, the complexes of CTR-RAMP are internalized by the cell. The RAMPs appear to determine whether the complex will be directed to degradative pathways or recycled back to the cell surface (Bomberger et al., 2005; Klein et al., 2016). (4) Signaling—studies of amylin receptors (AMY1-3) found that downstream signaling pathways of intracellular calcium production depend on the specific interacting RAMP (Morfis et al., 2008). A recent study of the pharmacology of CRLR-RAMP receptor complex demonstrated that the receptors display both ligand- and RAMP-dependent signaling bias among the downstream Gα subunit activation (Weston et al., 2016).

TABLE 33.1 Receptors for the calcitonin-family peptides

Receptor name	Subunits		Ligands
	GPCR	RAMP	
CTR	CTR	-	Calcitonin
AMY_1	CTR	RAMP1	Amylin, CGRP
AMY_2	CTR	RAMP2	Amylin
AMY_3	CTR	RAMP3	Amylin
CGRP	CRLR	RAMP1	CGRP
AM_1	CRLR	RAMP2	Adrenomedullin
AM_2	CRLR	RAMP3	Adrenomedullin, Adrenomedullin2

GPCR; G-protein coupled receptor, RAMP; receptor activity-modifying protein,

It has been well-established that specific combinations of CTR and CRLR with RAMPs produce the receptors for all peptides of the calcitonin family. Thus, while calcitonin is the ligand of CTR, heterodimerization of the CTR with either of the three RAMPs produces receptors with high affinity for amylin, the combination of CRLR with RAMP1 creates a CGRP receptor, and CRLR with either RAMP2 or RAMP3 acts as an adrenomedullin receptor (Lerner, 2006; Poyner et al., 2002) (Table 33.1). Pharmacological studies have shown that each of the receptor combinations typically binds one or two of the calcitonin-family peptides with high affinity, while other members of the family can bind to the same receptor dimer with lower affinities (Bower and Hay, 2016). The cross-reactivity of members of the calcitonin family with the various receptor combinations presents a challenge when interpreting experimental results, as deficiency in one specific component can be masked by interactions of the remaining members of the peptide and receptor families.

Peptide access to the bone microenvironment

The access of calcitonin and amylin to the bone environment is mainly through the circulation. Amylin is secreted from the islets of Langerhans of the pancreas and can be found in the circulation at 5 pmol/L in fasting state, rising to 15−25 pmol/L following a meal (Hay et al., 2015). Amylin secretion is pulsatile, with peaks occurring at about 5-min intervals (Juhl et al., 2000). Increased levels of circulating amylin are found in individuals with obesity or hypertension. In early stages of type 2 diabetes, along with the development of insulin resistance, circulating levels of insulin and amylin are high, whereas at later stages the secretion of both amylin and insulin becomes deficient (Zhang et al., 2016). Calcitonin, secreted predominantly from the C cells of the thyroid, circulates at low concentrations of about 3 pmol/L (Findlay and Sexton, 2004). The release of calcitonin is stimulated by a fall in blood calcium and inhibited by elevated calcium levels. Circulating levels of CT are increased in some pathological states, for example, in patients with medullary thyroid carcinoma.

Different studies determined the concentration of CGRP in circulation within the range of 1−40 pmol/L (Born et al., 1991; Schifter, 1991). Circulating concentrations are increased by sex hormone replacement therapy in postmenopausal women (Spinetti et al., 1997). However, local nerve terminals are the most important source of CGRP in the bone environment, and in certain situations local concentrations are likely to be much higher than those found in the circulation. Sensory nerve fibers containing CGRP are widely distributed in bone and bone marrow, with the richest innervation found at the epiphysis and periosteum (Bjurholm, 1991; Hill and Elde, 1991; Irie et al., 2002). Immuno-staining of CGRP-containing nerve fibers in bone tissue demonstrated changes in distribution during bone development and regeneration (Irie et al., 2002). When bone defects are created surgically, the development of CGRP-containing nerves is noted several days later, often in association with new blood vessels (Aoki et al., 1994), suggesting a role in callus formation and bone healing. Similar responses are seen following fractures (Hukkanen et al., 1993).

Effects on osteoclasts

The osteoclast has been recognized as a main target cell for calcitonin, central to its activity in lowering circulating calcium levels. Following the discovery of other members of the calcitonin family, their activities in osteoclasts have also been studied in detail. Mature osteoclasts express CTR, CRLR, and RAMP1-3 and are therefore a potential target for direct activity by all peptides of the calcitonin family.

Calcitonin

Bone-resorbing osteoclasts become polarized and form specialized structures that attach to the bone surface: the ruffled border, where protons and proteases are secreted to demineralize and degrade the bone matrix; and the surrounding sealing zone, produced by a dense ring of actin-rich podosomes. These structure are highly dynamic and allow continuous resorption while the osteoclast is moving along the bone surface. Early studies have shown that mature osteoclasts express high-affinity calcitonin receptors, and that calcitonin binding causes the immediate arrest of bone resorption (Chambers et al., 1984; Chambers and Magnus, 1982). Within 1 min of binding, calcitonin causes arrest of cell motility, which is then followed by the disruption of the podosomes and ruffled border and detachment of the osteoclast from the bone surface. Interestingly, the effects of calcitonin on osteoclast motility and attachment are mediated via two different signaling pathways: arrest of motility is cAMP-dependent, whereas retraction and disruption of the ruffled border and sealing zone are mediated through intracellular calcium signaling (Zaidi et al., 2002) (Fig. 33.2). Detachment of the sealing zone is mediated through the phosphorylation and changes in the intracellular distribution of Src and by the tyrosine kinase Pyk2, which is highly expressed in osteoclasts and localized mainly in the sealing zone (Shyu et al., 2007; Zhang et al., 2002). In addition to the key effects on mature osteoclast motility and attachment, the antiresorptive activity of calcitonin appears to be mediated by inhibition of early stages of osteoclast differentiation. In murine bone marrow cultures, calcitonin decreased the number of tartrate-resistant acid phosphatase (TRAP)-positive multinucleated cells and reduced the ratio of TRAP-positive multinucleated to mono- and binucleated cells, indicating an inhibitory effect on the fusion of osteoclast precursors (Cornish et al., 2001). Similar results were found in cultures of mouse spleen cells and in bone marrow macrophages induced to differentiate into osteoclasts, where sCT inhibited the formation of TRAP-positive multinucleated cells and the number of resorption pits formed on bone slices (Granholm et al., 2007). The inhibitory effect was reproduced by activation of protein kinase A and cAMP. The presence of a large number of TRAP-positive mono nucleated cells suggested that expression of early osteoclastogenesis markers was not disrupted, but further differentiation and cell fusion were inhibited.

The effect of calcitonin on osteoclast activity is transient, and within 48 h of continuous or repetitive calcitonin treatment the inhibitory effect is lost (Wener et al., 1972). This desensitization of osteoclasts was named the "escape phenomenon," and further investigations have shown that the cells become unresponsive due to a ligand-induced internalization of the calcitonin receptor as well as inhibition of receptor synthesis (Takahashi et al., 1995; Wada et al., 1996). More recent studies examined whether the escape phenomenon is unique to calcitonin or shared by other members of the calcitonin family. Initially, amylin was shown to produce a transient inhibitory effect on bone resorption in neonatal mouse calvaria, and subsequently all members of the calcitonin family were found to downregulate the expression of CTR mRNA and therefore to induce desensitization of osteoclasts to further treatment (Granholm et al., 2011).

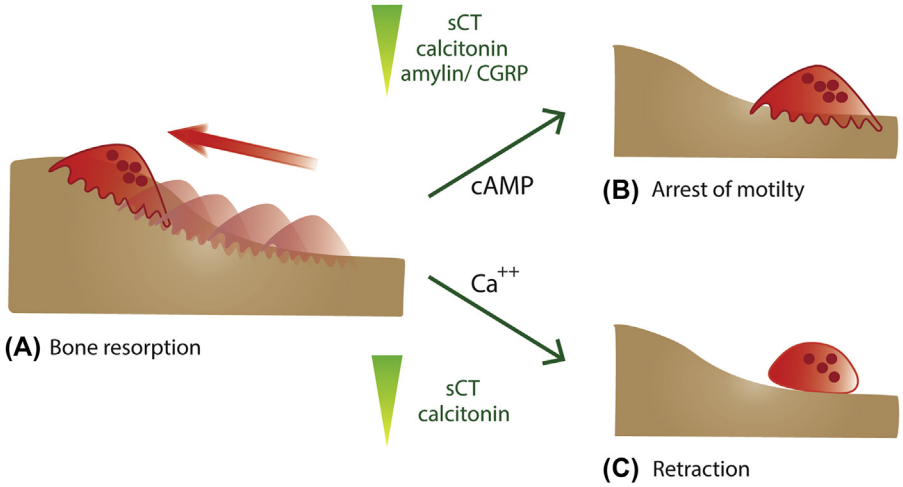

FIGURE 33.2 Inhibition of osteoclast activity by calcitonin-family peptides. (A) Actively resorbing osteoclasts attach to the bone surface through a ruffled border and a surrounding sealing zone, two highly dynamic structures that allow continuous resorption while the osteoclast is moving along the bone surface. (B) Calcitonin, CGRP. and amylin arrest the movement of osteoclast along the bone surface through a cAMP-dependent mechanism. (C) Calcitonin induces the retraction of osteoclasts from the bone surface, an effect that is mediated through intracellular calcium signaling and is not shared by the other members of the calcitonin family. This additional mechanism used by calcitonin may explain its greater potency in inhibiting osteoclast activity in comparison with the other peptides. The peptides are listed in order of potency, which is also indicated by the triangle color gradient. sCT, salmon calcitonin; CGRP, calcitonin gene-related peptide.

Interestingly, CGRP and adrenomedullin, which signal through CRLR-RAMP dimers and not through CTR, were also shown to downregulate the expression of CTR. In contrast to CTR, CRLR is not internalized following the binding of its ligands to the receptor dimers, and its levels remain unchanged.

Calcitonin gene-related peptide

Shortly after the discovery of CGRP, its injection into rats and rabbits was found to produce a calcitonin-like effect, lowering circulating calcium concentrations (Tippins et al., 1984). In rabbits, CGRP was approximately equipotent with calcitonin, whereas concentrations of two to three orders of magnitude higher than those of calcitonin were required to produce hypocalcemia in rats. A number of groups used calvariae organ cultures to study the effect of CGRP in greater detail. In this experimental system, the release of ^{45}Ca from prelabeled neonatal mouse or rat calvariae is used as a quantitative measure of bone resorption. Yamamoto et al. (Yamamoto et al., 1986) have shown that human CGRP produces a comparable level of inhibition of both basal and parathyroid hormone-stimulated resorption, but the half-maximal concentration of CGRP was 500-fold higher than that of human calcitonin. Similar studies in bone organ cultures have confirmed the antiresorptive activity of CGRP, which blocked the stimulation of bone resorption produced by different osteolytic factors (D'Souza et al., 1986; Roos et al., 1986). In cell cultures of neonatal rat osteoclasts, both αCGRP and βCGRP were found to directly inhibit bone resorption, although their potency was three orders of magnitude lower than that of human calcitonin (Zaidi et al., 1987a,b).

Further characterization of CGRP activity in osteoclasts found that it inhibits cell motility but not cell retraction. The inhibition of cell motility is mediated by increase in cAMP levels and could be blocked by the inhibitory analog CGRP(8-37), whereas CGRP had no effect on intracellular calcium levels (Alam et al., 1993a,b; Alam et al., 1991). cAMP production was also demonstrated in osteoclast-like multinucleated cells formed in cocultures of mouse osteoblasts and bone marrow cells in the presence of calcitriol (Tamura et al., 1992). It appears that the consistent lower potency of CGRP in inhibiting bone resorption, compared with calcitonin, results from its selective activation of cAMP and the downstream inhibition of motility and its lack of effect on intracellular calcium, which is linked to the downstream inhibitory effect on cell retraction (Fig. 33.2).

In addition to its activity on mature osteoclasts, evidence suggests that CGRP also affects osteoclast precursors. Specific binding of CGRP to mouse bone marrow cells and macrophages has been demonstrated, and CGRP was found to inhibit the development of osteoclasts in macrophage-osteoblast cocultures (Mullins et al., 1993; Owan and Ibaraki, 1994). In cultures of mouse bone marrow, CGRP inhibited the formation of TRAP-positive mononuclear cells as well as the subsequent fusion of these cells to form multinucleated osteoclasts (Cornish et al., 2001). Studies of the effect of CGRP on the differentiation and activity of osteoclasts in mouse bone marrow cultures found that a 100-fold higher concentration of CGRP is required for an inhibitory effect on differentiation than is required to inhibit pit formation, suggesting that the main effect of CGRP is in inhibiting osteoclast activity rather than formation (Wang et al., 2010).

In recent years, new aspects of CGRP as an inhibitor of bone resorption have come into focus. With the recognition that CGRP is released locally from sensory nerves that innervate the skeleton, a putative protective role for CGRP in the process of particle-induced osteolysis has been suggested. One of the common complications of joint arthroplasty is the formation of wear particles that induce inflammation and the release of cytokines that activate local bone resorption and can lead to aseptic loosening and eventually to early implant failure. The observation that CGRP nerve fibers are present adjacent to sites of periprosthetic osteolysis led to the hypothesis that CGRP acts locally to inhibit osteolysis. Ultra-high-molecular-weight polyethylene (UHMWPE) particles are common prosthetic wear debris and were studied in vitro in primary human osteoblasts and in the human osteosarcoma cell line MG-63 (Kauther et al., 2011; Xu et al., 2010). UHMWPE particles induced RANKL expression and inhibited the expression of OPG, while CGRP reduced UHMWPE-induced RANKL expression, suggesting an indirect inhibition of particle-induced bone resorption. CGRP was also shown to inhibit the secretion of osteolysis-associated proinflammatory cytokines and therefore could have additional beneficial effects on prevention of prosthesis loosening (Jablonski et al., 2015).

Amylin

Injection of amylin into laboratory animals strongly induced hypocalcemia with a potency that was either equal to or lower than that of human calcitonin (Datta et al., 1989; Wimalawansa, 1997; Zaidi et al., 1990). Amylin inhibits bone resorption by mature osteoclasts as determined by the reduced number of resorptive pits per TRAP-positive multinucleated cell in bone marrow cells cultured on bone slices (Cornish et al., 2001). Like CGRP, amylin inhibits the motility of mature osteoclasts in a cAMP-dependent mechanism but has no effect on cell retraction (Fig. 33.2). In organ cultures of neonatal

mouse calvariae, where bone resorption was stimulated by 1,25(OH)2D3, amylin increased cAMP levels and reduced both basal and PTH-stimulated resorption (Cornish et al., 1998b; Pietschmann et al., 1993). Fragments of amylin tested in this experimental system had no effect, and an intact amylin molecule was required in order to inhibit bone resorption. This is in contrast to the osteoblast activity of amylin tested in vitro, where a peptide fragment of the eight amino acids of the N-terminal (amylin(1-8)) acts as an agonist, and the fragment amylin(8-37) acts as an antagonist (Cornish et al., 1998a,b). Amylin was also shown to inhibit bone resorption in organ cultures of fetal mouse long bones, where its potency was similar to that of CGRP but 60-fold less than that of human calcitonin (Tamura et al., 1992). In addition to inhibiting the activity of osteoclasts, amylin has been shown to inhibit their differentiation. In mouse bone marrow cultures that were stimulated to generate osteoclasts by 1,25(OH)2D3, amylin inhibited the formation of TRAP-positive mono- and bi-nuclear cells as well as the fusion of these cells and the formation of multinucleated osteoclast-like cells (Cornish et al., 2001). Amylin inhibition of osteoclast differentiation was mediated via ERK1/2 signaling, and the expression of a negative dominant form of ERK1/2 blocked amylin's inhibitory effect (Dacquin et al., 2004). Amylin had no effect on bone marrow cell proliferation, and in the presence of amylin osteoclasts were smaller and contained fewer nuclei. Results from in vitro studies of amylin should be interpreted in light of its marked propensity to adhere to the surfaces of laboratory plasticware (Young et al., 1992), suggesting that the actual concentrations of amylin in all in vitro experiments may be one to two orders of magnitude less than the amount added to the media. Thus, both osteoclast and calvariae studies imply that amylin may regulate bone resorption at physiological concentrations.

Effects on osteoblasts

Calcitonin

A large number of studies have shown that calcitonin receptor is not expressed in osteoblasts, strongly indicating that calcitonin cannot affect these cells directly (Naot and Cornish, 2008). Consistent with this observation, calcitonin had no effect on the proliferation of osteoblasts in vitro, and when injected locally over the calvaria of adult mice, indices of bone formation were not different from those of vehicle-injected control mice (Cornish et al., 1995, 2000). However, a small number of studies found evidence for calcitonin activity in osteoblasts. These studies have shown that calcitonin stimulates the proliferation of primary osteoblasts and osteoblastic cell lines in vitro and increases bone matrix synthesis ex vivo in an organ culture system (Farley et al., 1988; Villa et al., 2003). An earlier study, using subcutaneously implanted demineralized bone matrix in rats, found that administration of calcitonin soon after the implantation stimulated osteoblast proliferation and bone formation, whereas administration of calcitonin after the initiation of bone formation had the reverse, inhibitory effect (Weiss et al., 1981). One possible explanation for the observed activity of calcitonin in osteoblasts in these experiments is that the effects were in fact indirect, mediated via osteoclasts, in a mechanism that has been discovered more recently and will be discussed in detail below (Keller et al., 2014). In addition, given the cross-reactivity of members of the calcitonin family and their receptors, a low-affinity interaction of calcitonin with receptors other than CTR might have contributed to the observed activity.

Calcitonin gene-related peptide

The activity of CGRP in osteoblasts is likely to be mediated by the high-affinity receptor complex CRLR-RAMP1, as genes encoding for these two receptor components are highly expressed in osteoblasts (Naot and Cornish, 2008). Early studies demonstrated binding of CGRP to cells of rat calvaria, and increased cAMP levels in the UMR-106 rat osteosarcoma cell line following CGRP treatment, while the cells were not responsive to calcitonin (Michelangeli et al., 1986). Subsequent studies in bone cell cultures obtained by sequential digestion of neonatal chicken, rat, and mouse calvariae again demonstrated a cAMP response to CGRP with no response to calcitonin (Michelangeli et al., 1989). Several other intracellular signaling pathways are activated by CGRP in osteoblast-like cells. In UMR-106 cells, CGRP stimulated Na+/H+ exchange and induced a transient twofold increase in intracellular calcium concentrations by mobilization of calcium from intracellular stores (Gupta and Schwiening, 1994; Kawase et al., 1995). Detailed analysis of the changes in intracellular calcium in the human osteosarcoma cell line MG-63 found a two-phase response to CGRP: a rapid transient calcium discharge from intracellular stores in a cAMP-independent mechanism followed by a secondary sustained calcium influx into the cell in a cAMP-dependent manner (Burns et al., 2004). In the osteosarcoma cell line OHS-4, CGRP increased intracellular calcium concentrations but had no detectable effect on cAMP, suggesting that in these cells

the initial cAMP-independent stage predominates (Drissi et al., 1999). CGRP was also shown to stimulate potassium efflux, inducing membrane hyperpolarization that results in rapid changes in cell morphology in UMR-106 cells (Kawase and Burns, 1998). Structure−function studies of CGRP in preosteoblast KS-4 cells found that cAMP response was greatly reduced with truncation of either the C-terminal amino acids or the disulfide bridge at the N-terminal (Thiebaud et al., 1991).

Studying the effect of CGRP on osteoblast proliferation, Cornish et al. (Cornish et al., 1995) showed a small increase in proliferation in primary rat osteoblast-like cells in response to CGRP, although the potency of CGRP was much lower than that of amylin. CGRP also stimulated proliferation in primary cultures of human osteoblast-like cells, and neither CGRP(8-37) nor amylin (8-37) inhibited this effect (Villa et al., 2000).

CGRP can activate the differentiation of precursor cells into osteoblasts. This has been demonstrated in bone marrow stromal cells derived from either healthy or ovariectomized (OVX) rats, where CGRP induced the formation of mineralizing osteoblasts in vitro (Liang et al., 2015). The effect of CGRP on bone marrow stromal cell differentiation was mediated via the Wnt/β-catenin pathway, and could be inhibited by either CGRP(8-37) or the Wnt pathway antagonist secreted frizzled-related protein (Zhou et al., 2016). The Wnt/β-catenin pathway was also found to mediate the activity of CGRP as a survival factor in human osteoblast-like primary cultures, where CGRP inhibited the apoptosis induced by serum depravation or dexamethasone (Mrak et al., 2010). Another pathway that may be involved in mediating the effect of CGRP in osteoblasts is the BMP-signaling pathway. BMP2 expression was induced by CGRP in MG-63 osteosarcoma cells and contributed to the activity of CGRP to promote osteogenic differentiation, while the proliferative effect of CGRP in these cells appeared to be BMP-independent (Tian et al., 2013).

The positive effect of CGRP on osteoblasts and its potential to enhance bone formation have been studied in the context of orthopedic implants and tissue engineering. In a recent study, Zhang et al. (Zhang et al., 2016) investigated the mechanisms underlying the effect of implants containing biodegradable magnesium to improve fracture healing. Using a fracture repair model in rats, they have shown that implant-derived magnesium increases neuronal CGRP in both the peripheral cortex of the femur and the ipsilateral dorsal root ganglia. CGRP released from sensory neurons was shown to induce local osteogenic differentiation of periosteum-derived stem cells and accelerate healing (Zhang et al., 2016). In other studies, CGRP was added to bone graft substitutes and scaffold materials, and its potential to promote local bone formation and healing was tested. Bio-Oss is a scaffold material prepared by removal of the organic component form bovine bone, and is used as bone graft that allows osteogenic cell migration (Li et al., 2017). CGRP loaded onto Bio-Oss surface was shown to enhance proliferation and differentiation of primary osteoblasts in vitro. CGRP was also shown to promote proliferation and osteogenic differentiation of rabbit adipose-derived stem cells cultured within calcium alginate gel, and a potential use of these constructs in tissue engineering has been suggested (Huang et al., 2015).

While early studies investigated the potential general role of CGRP in regulation of bone remodeling and found that it promotes osteoblast differentiation and only weakly induces proliferation, in later years the focus has shifted, and the activity of CGRP in osteoblasts is mainly studied in the context of bone healing. Thus, the role of CGRP released from nerve endings at sites of fracture or bone lesions, as well as the potential of CGRP as a bone anabolic factor added to bone scaffold materials, are areas of research that are likely to generate important novel findings in the near future.

Amylin

Shortly after its discovery, amylin was shown to stimulate cAMP production in a preosteoblastic cell line, in primary fetal rat osteoblasts and primary human osteoblasts (Tamura et al., 1992; Cornish et al., 1995; Millet and Vignery, 1997; Villa et al., 1997). These studies have shown that amylin stimulated the proliferation of primary osteoblasts from rats and humans at concentrations as low as 10 pmol/L. In rat primary osteoblastic cells, the mitogenic effect of amylin was mediated via the phosphorylation of ERK1/2, most likely through activation of Gi proteins, and was blocked by the specific inhibitor of this pathway, PD-98059 (Cornish et al., 2004). It is not clear which receptor mediates the activity of amylin in osteoblasts, as the three receptors $AMY_{1\text{-}3}$ include CTR, which is not expressed in these cells. It is possible that amylin affects osteoblasts through interaction with one of the other receptors for the calcitonin-family peptides. Surprisingly, the proliferative effect of amylin in osteoblasts required the presence of IGF1 receptor, despite the fact there was no direct binding of amylin to IGF1 receptor, nor was there a paracrine effect of osteoblast-derived IGF1. Stimulation of osteoblast proliferation in vitro was also produced by the N-terminal octapeptide fragment amylin(1-8), although its half-maximal effective concentration was 10-fold higher than that of the intact peptide (Cornish et al., 1998a,b).

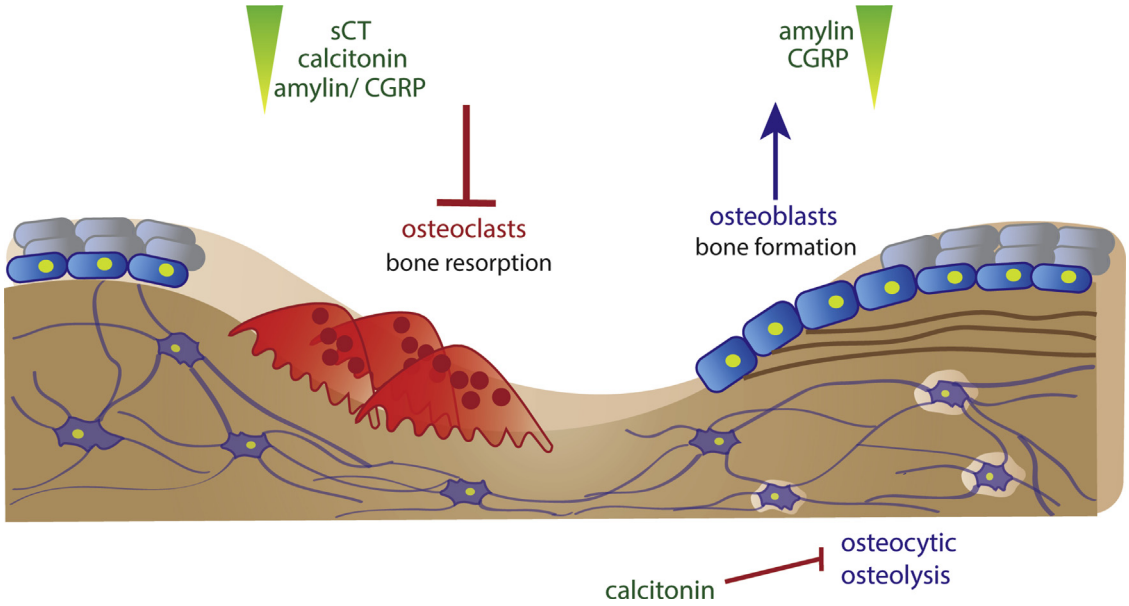

FIGURE 33.3 The effects of calcitonin-family peptides on bone cells. In vitro studies have established an overall positive effect of the calcitonin-family peptides in bone. Calcitonin, CGRP, and amylin are inhibitory to osteoclasts, and CGRP and amylin also promote osteoblast formation and activity. The osteocyte appears to be a target cell for calcitonin, as studies in genetically modified mice suggested a protective role for calcitonin in osteocytic osteolysis. The peptides are listed in order of potency, which is also indicated by the color gradient. sCT, salmon calcitonin; CGRP, calcitonin gene-related peptide.

The activities of calcitonin, CGRP and amylin in bone cells, as determined by in vitro studies, are summarized in Fig. 33.3.

Effects of local and systemic peptide administration into laboratory animals

Skeletal effects

OVX rats that were given daily subcutaneous injections of CGRP for 28 days had decreased bone resorption and a modest reduction in postovariectomy bone loss from 60% to 46% (Valentijn et al., 1997). In contrast, injection of CGRP over the calvariae of adult mice detected no significant effects on either bone resorption or formation (Cornish et al., 1995; Cornish and Reid, 1999). A different approach to determining the effect of CGRP on bone mass was used by Hill et al. (Hill et al., 1991). Reasoning that most of the CGRP that gains access to bone does so via sensory nerves, they studied the effect of sensory denervation using capsaicin treatment in rats. This intervention produced no change in cortical or medullary area, or periosteal apposition rate in tibiae, but the osteoclast surface in the mandible was decreased. In a more recent study, Offley et al. showed that capsaicin treatment destroyed the unmyelinated sensory axons containing CGRP, and the reduced CGRP signaling was associated with a decrease in bone mass (Offley et al., 2005).

Local injection of amylin over the calvariae of adult mice produced a substantial decrease in bone resorption, an increase in bone formation, and in mineralized bone area after only five daily injections (Cornish et al., 1995). Systemic administration of amylin to adult mice over 4 weeks produced a 70% increase in total bone volume in the proximal tibia (Fig. 33.4) as well as increased cortical width, tibial growth plate width, and tibial length along with increased body weight and fat mass (Cornish et al., 1998a,b). Structure–function studies identified amylin(1-8) as potentially retaining the beneficial effects in bone but devoid of amylin's activity on energy and carbohydrate metabolism. Thus, administration of amylin(1-8) by local injection over the calvariae of female mice produced a positive effect on bone formation, which was greater than that of an equimolar dose of hPTH-(1–34). Daily systemic administration of amylin (1-8) to sexually mature male mice for 4 weeks produced a near twofold increase in histomorphometric indices of osteoblast activity and resulted in increased bone strength as determined by three-point bending (Cornish et al., 2000). In contrast, amylin(1-8) administration to OVX rats had no effect on parameters of bone formation (Ellegaard et al., 2010). In rats, systemic administration of amylin for 18 days increased trabecular bone volume of the proximal tibia by 25%, although there were no changes in histomorphometric indices of formation or resorption (Romero et al., 1995). In a study of OVX rats, systemic administration of amylin increased bone formation and inhibited bone resorption as determined by analysis of the bone

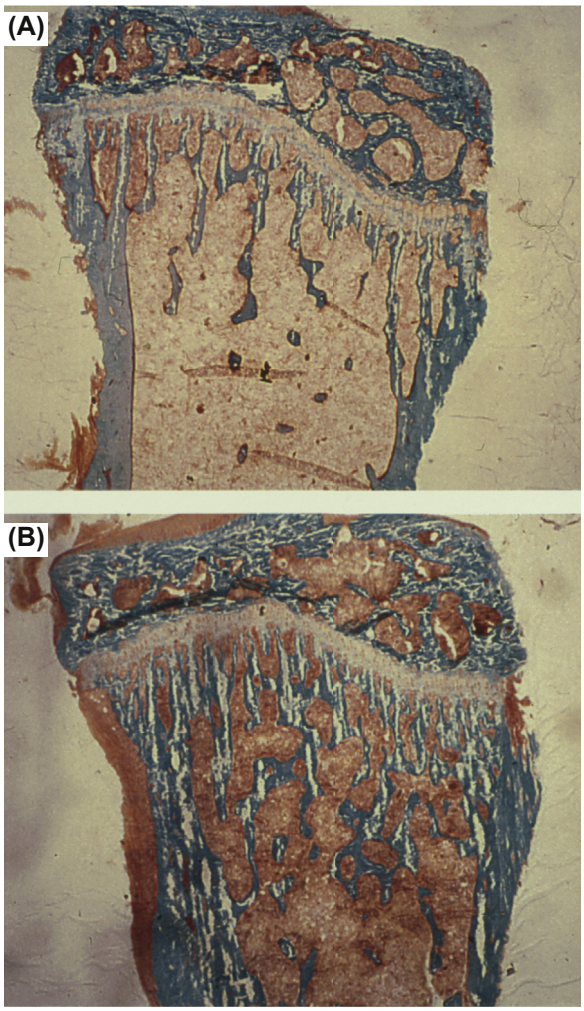

FIGURE 33.4 Increases bone volume induced by systemic administration of amylin. Photomicrographs of proximal tibiae of mice treated systemically with (A) vehicle or (B) amylin (10 μg/day) for 4 weeks. Trabecular bone volume is increased by 70% in amylin-treated animals. *Reprinted from Cornish et al., 1998a, with permission.*

turnover markers: plasma osteocalcin and urinary deoxypyridinoline. Distal metaphyseal and total femoral bone densities were higher in the OVX animals treated with amylin in comparison with untreated controls (Horcajada-Molteni et al., 2000). Interestingly, amylin infusion has also produced osteogenic effects in diabetic rat models, although its efficacy varied depending on the model (Gutierrez-Rojas et al., 2013).

In summary, the great majority of studies found that amylin administration increases bone formation and inhibits bone resorption, producing an overall positive skeletal effects. The investigations of amylin(1-8) produced less consistent results, with increased bone formation seen in a local and systemic administration models but no protective effect found against OVX-induced bone loss. In light of the recent findings regarding the mechanisms of action of calcitonin in bone, as discussed below (Keller et al., 2014), it is possible that the increase in bone formation measured in the animal models results from indirect activity of amylin through cells other than osteoblasts.

Effects on calcium metabolism

The most apparent effect of the injection of amylin or CGRP to laboratory animal is the induction of hypocalcemia. In fasted rats that were given a single intravenous bolus injections of amylin or CGRP, the decrease in total plasma calcium concentration was similar for both peptides (Young et al., 1993). Although the hypocalcemic effect is largely attributable to inhibition of osteoclastic bone resorption, amylin, like calcitonin, may have a direct calciuretic effect on the kidney. Rat amylin bound to receptors in porcine kidney with an affinity comparable to that of porcine calcitonin itself, and induced

cAMP production (Sexton et al., 1994). In rat renal tubular membranes, CGRP and amylin stimulated cAMP production with comparable half-maximal concentrations, and the effects of both peptides were blocked by CGRP(8-37) (Osajima et al., 1995). Consistent with these findings, amylin infusion doubled urinary calcium excretion in dogs (Miles et al., 1994). However, the increased urinary loss of calcium accounted for less than 10% of the fall in serum calcium, suggesting that reduced osteoclastic resorption was the principal contributor to the hypocalcemic effect. These changes were accompanied by a doubling of PTH levels, whereas circulating calcitonin concentrations remained unchanged.

The skeletal effects of calcitonin, calcitonin gene-related peptide, and amylin: lessons from genetically modified mice

Calcitonin and calcitonin gene-related peptide

In one of the early studies that examined the skeletal effects of the calcitonin-family peptides in genetically modified mice, CGRP was introduced under the osteocalcin promoter, directing its overexpression specifically to the osteoblast lineage (Ballica et al., 1999). The transgenic mice had increased bone formation rate, as well as higher trabecular bone density and volume in comparison with wild-type (WT) littermate controls, suggesting a positive effect of CGRP in osteoblasts. Later studies used mostly knockout mice to investigate the skeletal effects of the calcitonin family peptides. Mice deficient of the *Calca* gene, missing both calcitonin and αCGRP, were the first knockout model created (Hoff et al., 2002). Based on previous in vitro and in vivo studies of calcitonin activity in bone, the *Calca*-KO mice were expected to display an osteoporotic phenotype due to accelerated bone resorption in the absence of calcitonin. However, the mice had no changes in osteoclast number or bone resorption markers in comparison with WT controls, and surprisingly, had higher bone volume and trabecular number with decreased trabecular spacing. Double calcein-labeling showed the high bone volume was a result of a significant increase in bone formation (Hoff et al., 2002). *Calca*-KO mice were less sensitive to ovariectomy; while WT mice lost about one-third of their bone mass over 2 months after ovariectomy, the *Calca*-KO mice had no change in bone mass. Overall, the unexpected skeletal phenotype of the *Calca*-KO mice suggested that calcitonin or αCGRP inhibited bone formation. A second knockout mouse model, which was only deficient of αCGRP, was generated in order to differentiate between the contributions of the deficiency in calcitonin and that of αCGRP to the increased bone formation seen in the *Calca*-KO mice (Schinke et al., 2004). αCGRP-KO mice had normal levels of circulating calcitonin and unlike the *Calca*-KO, had reduced bone formation rate and developed osteopenia. This phenotype was consistent with the earlier study that demonstrated increased bone formation in mice over-expressing αCGRP (Ballica et al., 1999). A subsequent long-term study of the bone phenotype of the knockout animals showed that the osteopenia displayed by the αCGRP-KO mice was also evident at 6, 12, and 18 months of age (Huebner et al., 2006). In the *Calca*-KO mice the bone phenotype developed with age, and at 12 and 18 months, along with the increased bone formation, there was evidence for increased bone resorption. The high bone turnover resulted in a substantial increase of trabecular structures that lead to trabecularization of cortical bone, and in addition, 20% of the *Calca*-deficient mice had hyperostotic lesions. A number of common potential secondary mechanisms that cause increased bone resorption have been investigated and excluded, as the *Calca*-KO mice had normal histologic appearance of several organs and the absence of hyperparathyroidism and hypogonadism (Huebner et al., 2006). The analyses of the two mice strains, *Calca*-KO and αCGRP-KO, are confounded by the presence of an intact *Calcb* gene that encodes for βCGRP. However, a study of the bone phenotype of *Calcb* -KO mice found no differences between these mice and control WT mice, suggesting that βCGRP does not play an important role in the regulation of bone remodeling (Huebner et al., 2008).

Taken together, the studies of genetically modified mice strains imply that in vivo, αCGRP is a physiological inducer of bone formation, whereas calcitonin inhibits osteoblast activity and bone formation, at least in young animals. Our current understanding of the physiological activity of calcitonin in bone is still incomplete, and a clear understanding of the unusual histological appearance of cortical trabecularization and hyperostotic lesions in the older *Calca*-KO mice is still missing. It is possible that some unanswered questions could be resolved by examining the bone phenotype of mice deficient of calcitonin only, with functional αCGRP. However, this animal model has not yet been described.

Amylin

The phenotype of amylin-deficient mice was described by Dacquin et al (Dacquin et al., 2004). The mice had normal food intake, body weight, and glucose metabolism. At the age of 24 weeks, amylin-deficient mice had a typical osteoporotic phenotype, showing decreased bone density of long bones, low bone mass, and a 50% decrease in trabecular bone volume.

The number of osteoblasts as well as the bone formation rate, assessed by double calcein injection, were similar between amylin-deficient mice and WT controls, suggesting that the osteoporotic phenotype was not a result of a defect in bone formation. In contrast, the amylin-deficient mice had an increased number of osteoclasts and an increase in degradation products of collagen in the urine, suggestive of accelerated bone resorption. Further studies of amylin-deficient mice demonstrated that the bone-effects were sex-dependent. Amylin-deficient males showed increased trabecular thickness at 4 and 6 weeks of age and increased femoral length at 26 weeks, whereas female mice were no different than the wild type (Davey et al., 2006). The role of CTR in mediating the bone-effects of amylin was investigated in a compound hemizygous mouse model: CTR (*Calcr* +/−) and amylin (*Iapp* +/−) (Dacquin et al., 2004). These mice displayed a combination of abnormalities identified in each of the individual hemizygous knockout, leading the authors to conclude that CTR is unlikely to be mediating amylin bone effects.

Calcitonin receptor

The contribution of CTR to skeletal physiology has been studied in three different strains of genetically modified mice. Since global deletion of CTR was embryonic lethal, the skeletal phenotype was initially studied in hemizygote CTR-KO mice (*Calcr*+/-), whose level of expression of CTR in osteoclasts was half that found in the WT mice, providing a model for the study of CTR haploinsufficiency (Dacquin et al., 2004). *Calcr* +/- mice had high bone mass due to increased bone formation, whereas no changes were identified in measures of bone resorption. These observations were consistent with the phenotype of the *Calca*-KO mice, providing further evidence for a physiological role of calcitonin as an inhibitor of bone formation, and indicating its activity is mediated via CTR. A second viable animal model was generated by incomplete deletion of the CTR gene, leaving a low residual level of expression (Davey et al., 2008). In this animal model only male mice had a small increase in bone formation rate, indicating that CTR plays a minor role in the physiological regulation of bone and calcium homeostasis in the basal state. More recently, employing a modified technique to knockout the expression of CTR, viable mice with global deletion of *Calcr* have been generated (Keller et al., 2014). The *Calcr*-KO mice had high bone mass due to increased bone formation, a phenotype that was then reproduced in mice that had the gene deletion restricted to the osteoclast lineage. The study further investigated the underlying mechanisms of the activity of calcitonin, signaling via CTR, to inhibit bone formation. The loss of CTR in osteoclasts has been shown to increase the levels of SPINSTER2, an exporter protein required for the secretion of sphingosine-1-phosphate (S1P), a potent inducer of bone formation. Therefore, the study suggests that calcitonin inhibits bone formation indirectly, through interaction with the osteoclast-expressed CTR (Keller et al., 2014).

Taken together, while pharmacological studies found that calcitonin inhibits of bone resorption, studies of genetically modified animals determined that calcitonin's physiological role is to inhibit bone formation. A similar discrepancy was identified in studies of the effect of PTH in bone; as PTH is a physiological stimulator of bone resorption that stimulates bone formation in pharmacological use (Martin and Sims, 2015).

The role of calcitonin and calcitonin receptor in situations of calcium stress

The roles of calcitonin and calcitonin receptor in situations of calcium stress were investigated in the genetically modified mice models. When hypercalcemia was induced in *Calcr*-KO mice by $1,25(OH)_2D_3$, the peak levels of total serum calcium were significantly higher in the KO mice in comparison with the WT controls, suggesting that in these conditions CTR is important for calcium homeostasis (Davey et al., 2008). The underlying mechanism for calcitonin activity appears to be the inhibition of osteoclast activity, as a similar impaired response to hypercalcemia was later identified in a mouse model in which CTR was specifically missing in osteoclasts (Turner et al., 2011). A physiological condition of calcium stress is also present during lactation, as the maternal skeleton rapidly demineralizes in order to supply calcium to the milk. In the *Calca*-KO model, deficient in both calcitonin and CGRP, spine BMC dropped during lactation by over 50%, whereas in the WT controls the drop was only of 23.6% (Woodrow et al., 2006). After weaning, spine BMC was slower to return to baseline values in the *Calca*-KO in comparison with WT mice. Injection of sCT normalized the bone parameters, whereas CGRP was without effect, indicating that calcitonin is the peptide that plays an important role in calcium balance and preservation of the maternal skeleton during lactation and its recovery after weaning (Woodrow et al., 2006). Another mechanism that mobilizes calcium from skeletal stores during lactation is osteolytic osteolysis. Interestingly, osteocytes have been shown to express a number of genes in common with osteoclasts and to resorb bone locally. Histomorphometric analysis of the femurs at the end of lactation found that osteocyte lacunar area in *Calcr*-KO mice were larger than in WT, suggesting a role for calcitonin in inhibition of osteocytic osteolysis and protection of the maternal skeleton during lactation (Clarke et al., 2015).

Calcitonin, calcitonin gene-related peptide, and amylin—relevance to human bone physiology

The roles of the three peptides—calcitonin, CGRP, and amylin—in human physiology and pathophysiology have been studied extensively. The current understating is that calcitonin plays an important role in situations of calcium stress, regulating calcium homeostasis mainly through skeletal effects and perhaps through activity in the kidney during rapid growth, pathological hypercalcemia, pregnancy, and lactation. In contrast, the main physiological effects of CGRP and amylin appear not to be related directly to bone, with CGRP being a most potent microvascular vasodilator and contributing to pain especially in migraine, while amylin appears to be primarily important for energy homeostasis, inducing satiety, and increasing energy expenditure. Nevertheless, the peptides are likely to play at least a secondary role in bone metabolism.

It has been hypothesized that amylin secretion following a meal directs the absorbed calcium and protein from the meal into new bone synthesis by increasing bone growth at a time when the substrates are available (MacIntyre, 1989; Zaidi et al., 1993). Amylin may also contribute to the relationship between body mass and bone density. Body mass, and particularly fat mass, is the principal determinant of bone density in women (Reid et al., 1992a,b). A number of factors contribute to the fat−bone relationship; including the effect of weight on skeletal load bearing and adipocyte production of estrogen and adipokines (Naot and Cornish, 2014; Reid, 2002). In addition, the increased circulating levels of amylin and insulin in obesity are likely to have positive effects in bone and thus contribute to the fat mass−bone mass relationship. In fact, insulin levels were found to directly relate to bone density in normal postmenopausal women, and because amylin is cosecreted with insulin, it would seem likely that a similar relationship for this peptide exists (Reid et al., 1993). Pramlintide is a synthetic analog of amylin that is currently approved for the treatment of type 1 and type 2 diabetes, and might be in wider use in the future due to its effect on fat reduction. However, so far the effect of pramlintide on bone metabolism in humans has not been studied extensively. In a study of 23 patients with type 1 diabetes, 12 months of pramlintide treatment had no significant effects on markers on bone turnover or BMD (Chandran, 2017). As in vitro and animal studies determined an overall positive effect of amylin in bone, it would be of great interest to assess the impact of pramlintide treatment on long-term bone health and fracture risk.

Because CGRP access to bone is mainly via sensory innervation, the current understanding is that the bone activity of CGRP is predominantly localized. Evidence suggests that CGRP plays a role in the local bone response to different stimuli, including exercise, injury and the presence of metal implants. Given that monoclonal antibodies against CGRP are likely to be approved for clinical use for migraine prevention in the near future, it will be important to monitor the effects of their long-term use on bone physiology and healing.

Chapter 34

Regulation of bone remodeling by central and peripheral nervous signals

Patricia Ducy

Department of Pathology & Cell Biology, Columbia University, College of Physicians & Surgeons, New York, NY, United States

Chapter outline

Introduction

Hints of a connection between the nervous system and the regulation of bone mass have long been present in the literature. For instance, osteoporosis is a known complication of spinal cord injury and experimental models of sensory or sympathetic denervation have shown that these two neuronal systems could be involved in bone development and remodeling (Chenu, 2004; Jiang et al., 2006). Likewise, major depression is associated with low bone mass and increased incidence of osteoporotic fractures, as is the use of several types of central nervous system-active drugs such as anticonvulsants and opioids (Kinjo et al., 2005). These examples all point at a regulation of bone mass by the nervous system—i.e., at signals efferent from the brain (or nerves) to bone cells. This might explain why most of the earlier studies have focused on peripherally produced neuromediators (Chenu, 2002; Spencer et al., 2007). More recently, however, afferent signals that influence the brain's control of bone mass have been identified, and a comprehensive understanding of their central mode of action has emerged. Overall, the identification of these pathways illustrates the investigative power of mouse genetics and can be viewed as an archetype of the current effort of integrative biology. More importantly, this rapidly evolving field of bone neurobiology has shed light on perplexing clinical observations and may therefore become critical in developing novel concepts in drug development.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00034-8

Afferent signals regulating bone remodeling via the central nervous system

At the present time there are two signals known, in vivo, to affect bone mass via a central nervous system (CNS) relay. Remarkably, they both originate from adipocytes, suggesting a preferential relationship between the regulation of energy metabolism and bone homeostasis. One signal is leptin, a 16 kDa peptide hormone that was originally identified by positional cloning of the mutation present in *ob/ob* mice, a natural mutant presenting morbid obesity and sterility (Zhang et al., 1994). The other one is adiponectin, a secreted molecule previously known for its insulin-sensitizing ability in animals fed a high-fat diet (Maeda et al., 2002; Kadowaki and Yamauchi, 2005). Subsequent analysis of their respective central mode of action has identified a significant overlap in their ability to influence bone remodeling.

Negative regulation of bone remodeling by leptin

Mice harboring an inactivating mutation in the leptin-encoding gene (*ob/ob* mice) or in the gene encoding Lepr, its only known receptor (*db/db* mice), are obese and hypogonadic (Zhang et al., 1994; Tartaglia et al., 1995; Ahima, 2004). Given the negative effect of sex steroid hormone depletion on bone mass, they should therefore exhibit a low-bone-mass phenotype. Instead, these two mutant strains display a high-bone-mass phenotype when analyzed by histomorphometry, which given this mice obesity, allows the most objective evaluation of bone parameters as its results do not need to be adjusted for differences of lean/fat mass (Ducy et al., 2000; Baldock et al., 2005). This increased bone mass, which appears limited to cancellous bone, is also observed in genetically engineered *Lepr* knockout rats (Vaira et al., 2012; Solomon et al., 2014) and in transgenic lipodystrophic mice (b-ZIP mice) (Ducy et al., 2000). The latter observation is consistent with the advanced bone age observed in patients with lipodystrophy, a condition associated with a severe deficiency in serum leptin (Westvik, 1996; Elefteriou et al., 2004). Conversely, expression of a leptin transgene and intracerebroventricular infusion (ICV) of leptin can correct the high-bone-mass phenotype of respectively lipodystrophic and *ob/ob* mice, and mice expressing a gain-of-function of the leptin receptor (*l/l* mice) have decreased bone mass (Elefteriou et al., 2004; Shi et al., 2008).

The high-bone-mass phenotype of leptin-signaling deficient mice is due to an increase in bone formation rate that is already present in fat-restricted 1-month-old *ob/ob* mice and heterozygote *ob/+* mice, which are not obese, indicating that it is the absence of leptin not an increase in fat mass that is responsible for this phenotype (Ducy et al., 2000). Consistent with their hypogonadism, *ob/ob* and *db/db* mice have an increase in bone resorption (Ducy et al., 2000). It is, however, milder than their innate and permanent sex steroid depletion would have predicted, because by itself leptin deficiency has a negative effect on bone resorption through its action on the sympathetic tone (see below).

Studies using peripheral injections of pharmacological doses of leptin (over 40 μg/day; i.e., 700-fold the amount used in ICV studies) (Steppan et al., 2000; Cornish et al., 2002; Turner et al., 2013) have reported a beneficial effect on bone mass accrual, and proposed that leptin could act directly on osteoblasts. However, several arguments argue against a direct action on bone cells. First, gene expression in bone tissue or isolated osteoblasts as well as lineage-tracing studies using a Leptin receptor reporter transgene (*Lepr-YFP*) have failed to detect it in osteoblasts (Ducy et al., 2000; Ding et al., 2012). Second, osteoblasts derived from *db/db* mice proliferate and differentiate normally when cultured ex vivo (Ducy et al., 2000). Third, neither transgenic expression of leptin in osteoblasts nor the conditional inactivation of *Lepr* specifically in osteoblasts causes a bone phenotype in mice (Takeda et al., 2002; Shi et al., 2008). In contrast, inactivating *Lepr* in neurons induces the same high-bone-mass phenotype than the one observed in *db/db* mice (Shi et al., 2008; Yadav et al., 2009). The positive effect on bone mass observed upon leptin injections at high doses could in fact be explained by the well-known leptin resistance that centrally occurs when its serum concentration becomes too high, for example due to obesity (Könner and Brüning, 2012; Motyl and Rosen, 2012; Mark, 2013). Since leptin centrally affects bone mass accrual at a lower threshold than it affects body weight, the effect of leptin on bone remodeling is likely to be more quickly impacted by a leptin-resistance mechanism (Elefteriou et al., 2004; Shi et al., 2008). Hence, supraphysiological doses of this hormone injected peripherally could still cause weight loss, as some of the above mentioned studies reported, while already eliciting a central leptin resistance that will cause a gain of bone mass similar to the one observed in the absence of leptin signaling.

Dual action of adiponectin on bone remodeling

Analysis of mice deficient in adiponectin has identified both central and peripheral effects of this hormone on bone mass accrual. Young adult *Adiponectin−/−* mice display a high-bone-mass phenotype that is due to an increase in the number of osteoblasts and bone formation rate (Kajimura et al., 2013). Genetic and in vitro studies attributed this effect to adiponectin's ability to regulate proliferation and apoptosis of osteoblasts in a FoxO1-dependent manner via PI3 kinase activation.

This early high-bone-mass phenotype, however, cannot be observed in older mice that, instead, show a decreased bone mass characterized by a lesser number and proliferation ability of osteoblasts and an increase in bone resorption parameters (Kajimura et al., 2013; Wu et al., 2014). This phenotype is consistent with the observation that injection of an adiponectin-expressing adenovirus increases bone mass by suppressing osteoclastogenesis while activating osteoblastogenesis (Oshima et al., 2005).

The observations mentioned above indicate that the adipocyte secretes two hormones exerting opposite influences on the same physiological functions in adult mice. The fact that b-ZIP lipodystrophic mice have a high-bone-mass phenotype despite lacking both these hormones (Ducy et al., 2000), however, suggests that lack of leptin is dominant over the absence of adiponectin.

Central and efferent regulators of bone remodeling

Leptin's action on bone remodeling is mediated by brain serotonin signaling and the sympathetic nervous system

Leptin's action on appetite and reproduction depends on its binding to a specific receptor expressed by brain neurons (Ahima and Flier, 2000; Ahima, 2004). In agreement with this central mode of action, ICV infusion of low doses of leptin in *ob/ob* mice, at a rate that does not result in any detectable leak of leptin in the general circulation, corrects their high-bone-mass phenotype (Ducy et al., 2000). This rescue is complete and occurs even at minimal doses that do not influence body weight (Elefteriou et al., 2004). Likewise, low doses of leptin administered by ICV infusion in wild-type animals induce a potent antiosteogenic effect resulting in severe bone loss within 1 month (Ducy et al., 2000).

Chemical lesioning experiments identified the ventromedial hypothalamus (VMH) as the relay of the leptin antiosteogenic effect in the brain (Takeda et al., 2002). Yet deletion of the leptin receptor in these same neurons does not cause a bone phenotype (Balthasar et al., 2004; Yadav et al., 2009). This apparent contradiction is explained by the fact that leptin uses a serotonin relay to act on the VMH neurons of the hypothalamus (Yadav et al., 2009; Ducy and Karsenty, 2010; Oury and Karsenty, 2011). Indeed, leptin signals to neurons of the dorsal and median raphe nuclei in the brain stem to blunt the production of brain serotonin that itself is a positive regulator of bone mass accrual (Yadav et al., 2009) (Fig. 34.1). In support of this mechanism, *Tph2*-deficient mice, which lack brain serotonin, show a low-bone-mass phenotype mirroring the one observed in *ob/ob* mice, and normalizing the brain content of the *ob/ob* mice by inactivating one allele of *Tph2* corrects their bone phenotype (Yadav et al., 2009). Conversely, inactivation of *LepR* in the *Tph2*-expressing neurons of the brain stem causes a bone phenotype similar to the one presented by *db/db* mice (Yadav et al., 2009). The negative influence of a deficit in brain serotonin signaling on bone mass explains the bone loss observed upon chronic use of selective serotonin reuptake inhibitors (SSRIs) as well as in a mouse model of Alzheimer's disease (Dengler-Crish et al., 2016; Ortuno et al., 2016).

Consistent with the lesioning experiments that identified the VMH nuclei as mediating leptin antiosteogenic action, dextran anterograde and retrograde neuron tracing studies showed that serotonergic neurons project from the brain stem to the VMH nuclei (Yadav et al., 2009). Serotonin then signals to VMH neurons via the Htr2c receptor to regulate CREB phosphorylation on Ser133 via Ca^{2+} as a second messenger and a CaMKKβ/CaMKIV cascade (Oury et al., 2010). This osteogenic pathway was demonstrated in vivo as mice with an inactivation of *Creb* in VMH neurons (*Creb* $_{VHM}$*−/−*) or heterozygous compound for *Creb* and *Htr2c* (*Creb* $_{VHM}$*−/−*; *Htr2c+/−)* or for *Creb* and *CaMKIV* (*Creb* $_{VHM}$*+/−*; *CaMKIV* $_{VHM}$ *+/−)* in VMH neurons all show a low-bone-mass phenotype characterized by decreased bone formation and increased bone resorption (Oury et al., 2010). Thus, leptin negatively regulates bone mass by inhibiting brain stem serotonergic neurons, which normally signal to VMH neurons via an Htr2c → CaMKKβ → CaMKIV → CREB cascade to increased bone formation and decrease bone resorption (Fig. 34.1).

A recurrent feature of the mouse models mentioned above is an increase in sympathetic tone, as evidenced by high *Ucp1* expression in brown adipose tissue and urinary levels of epinephrine (Oury et al., 2010). In contrast, *ob/ob* mice are known to exhibit low sympathetic activity (Bray and York, 1998) that, when corrected by treatment with an adrenergic agonist, leads to a dramatic decrease in bone mass (Takeda et al., 2002). The role of the sympathetic nervous system (SNS) as an antiosteogenic activity is supported by the observation that mice deficient in dopamine β-hydroxylase (DBH), an enzyme necessary to produce norepinephrine and epinephrine (the catecholamine ligands produced by the SNS), have a high-bone-mass phenotype (Takeda et al., 2002). Also consistent with this notion is the existence of a high-bone-mass phenotype associated with both an increase in bone formation and a decrease in bone resorption in mice deficient globally or only in osteoblasts for the β2 adrenergic receptor, the main adrenergic receptor expressed in these cells (Takeda et al., 2002; Kajimura et al., 2011). Importantly, the bone phenotype observed in Adrβ2-deficient mice cannot be rescued by

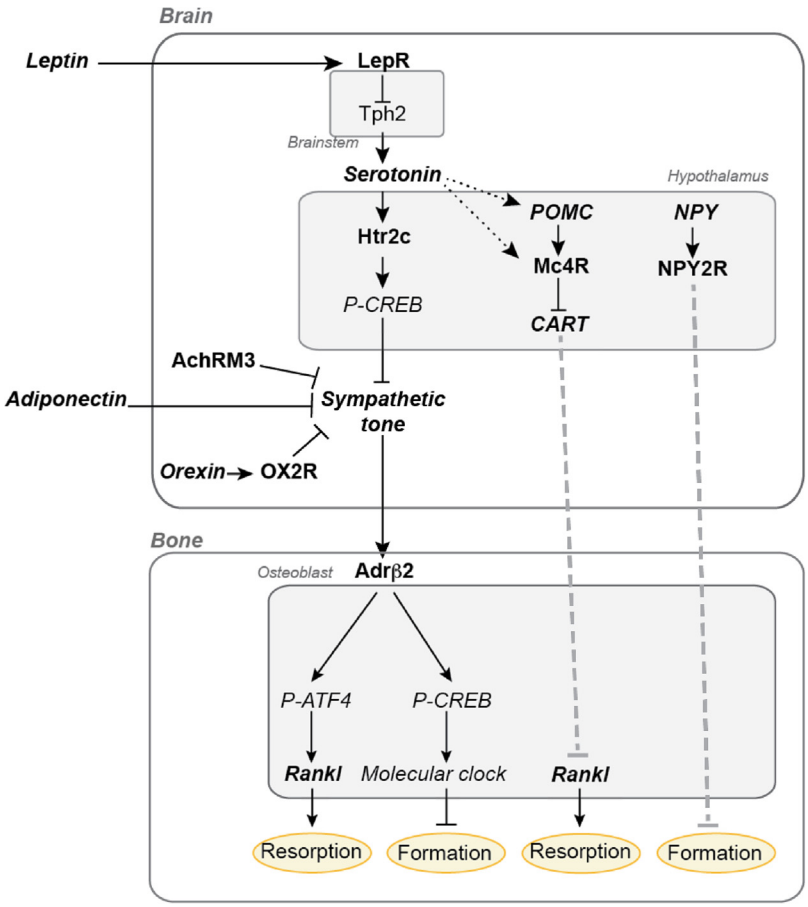

FIGURE 34.1 Central regulation of bone remodeling in mice. Secreted molecules are shown in bold Italics, receptors are shown in bold letters and intracellular effectors are shown in italics. *Black dotted lines* indicate regulation that are most likely to exist but have not yet been demonstrated formally. *Dashed gray lines* indicate mode of actions that have not yet been identified.

leptin ICV infusion demonstrating that the sympathetic nervous system, via Adrβ2 mediates leptin regulation of bone mass (Takeda et al., 2002; Elefteriou et al., 2005). Pharmacologic experiments have confirmed the genetic demonstration of an effect of the SNS on bone mass. Treatment of ovariectomized mice or rats with low doses of propranolol, a nonselective β-blocker, inhibits bone loss and preserves mechanical properties (Takeda et al., 2002; Bonnet et al., 2008; Khajuria et al., 2013). Similar improvements have been observed in a rat model of hypertension associated with bone fragility using low doses of butoxamine, a selective Adrβ2 antagonist (Arai et al., 2013).

At the molecular level, sympathetic signaling acts in osteoblasts through a dual mechanism (Fig. 34.1). It impairs osteoblast proliferation through phosphorylation of CREB, the molecular clock, type D cyclins, and *AP-1* gene expression (Fu et al., 2005; Kajimura et al., 2011). It also promotes *Rankl* expression in osteoblast progenitor cells following protein kinase A phosphorylation of ATF4, a cell-specific CREB-related transcription factor essential (Yang et al., 2004; Elefteriou et al., 2005; Kajimura et al., 2011).

Counterregulation of sympathetic nervous system control of bone remodeling by the parasympathetic nervous system and adiponectin

The low-bone-mass phenotype observed in aged adiponectin-deficient mice, which is due to the conjunction of a decrease in bone formation and an increase in bone resorption parameters is caused by an increase in sympathetic activity. Indeed, infusing adiponectin centrally or removing one allele of *Dbh* from *Adiponectin−/−* mice normalizes *Ucp1* expression in brown fat, norepinephrine content in the brain and urinary epinephrine elimination. and triggers an increase in bone mass secondary to an increase in osteoblast numbers and bone formation rate (Kajimura et al., 2013; Wu et al., 2014). The regulation of SNS output by adiponectin is mediated by its activity on the neurons of the locus coeruleus (LC), the site of *Dbh* expression in the brain stem. Indeed, *Adiponectin−/−* mice lacking only in neurons of the LC one allele of *FoxO1,* which encodes an intracellular effector of adiponectin signaling, have normal sympathetic activity as measured by *Ucp1*

expression in brown fat and a significant increase in bone mass, osteoblast number, and bone formation rate while osteoclast number, *Rankl* expression, and serum CTx levels are decreased compared with *Adiponectin−/−* mice (Kajimura et al., 2013).

Signaling through the muscarinic receptor 3 (AchRM3) is another mechanism counteracting the SNS control of bone remodeling. Muscarinic receptors (AchRM1-4) bind acetylcholine, the main neurotransmitter used by the PNS. While inactivation of *AchRM1*, *AchRM2*, or *AchRM4* does not significantly affect bone mass, mice lacking AchRM3 either globally or only in neurons have a low-bone-mass phenotype associated with increased bone resorption and decreased bone formation (Shi et al., 2010). This phenotype can be attributed to the negative action of the SNS, since it is associated with elevated levels of epinephrine in the urine and is corrected when catecholamine signaling is normalized through coinactivation of one allele of *Adrβ2* (*AchRM3−/−; Adrβ2+/−* mice) (Shi et al., 2010). *AchRM3* being expressed in the noradrenergic neurons of the LC but not in the VMH of the hypothalamus or in sympathetic chain ganglia (Shi et al., 2010) suggests a direct effect on central sympathetic output similar to the one described for adiponectin signaling (Fig. 34.1). Whether these two effectors indeed mechanistically overlap still needs to be defined.

Other regulators of sympathetic nervous system control of bone remodeling

NeuromedinU

NeuromedinU (NMU) is a neuropeptide produced by nerve cells in the small intestine and in the brain (Brighton et al., 2004). It is generally assumed that NMU regulates various aspects of physiology including appetite, stress response, and SNS activation (Brighton et al., 2004). NMU-deficient mice present a high-bone-mass phenotype associated with an increase in bone formation similar to the one displayed by *ob/ob* mice (Sato et al., 2007). This phenotype is not cell autonomous, as NMU-deficient osteoblasts in culture are indistinguishable from wild-type osteoblasts and treatment of wild-type osteoblasts with NMU do not affect their proliferation or differentiation. In contrast, ICV infusion of NMU in wild-type, NMU−/− and *ob/ob* mice decreases bone formation and bone volume (Sato et al., 2007). However, ICV infusion of leptin in NMU−/− mice cannot decrease bone mass, indicating that NMU is a mediator for leptin's action on bone formation (Sato et al., 2007). Accordingly, NMU affects the leptin-dependent negative regulation of bone formation by the molecular clock and it was thus proposed that the high-bone-mass phenotype of the NMU−/− mice is caused by their resistance to the antiosteogenic activity of the SNS (Sato et al., 2007). Yet the basis of this mechanism of action still remains incompletely understood.

Endocannabinoid signaling

Endocannabinoids are lipid mediators that regulate analgesia, energy balance, and appetite by binding to the G protein-coupled receptors CB1 and CB2. CB1 is predominantly expressed in the brain and peripheral neurons, where it is responsible for the psychotropic action of cannabinoids, but it is also expressed in peripheral tissues including immune cells as well as the reproductive system, gastrointestinal tract, and lungs (Di Marzo et al., 2004). Global and conditional inactivation of *CB1* in noradrenergic and adrenergic neurons of the central and peripheral nervous system up-regulates bone formation and bone mass while decreasing bone resorption in adult male mice (Idris et al., 2005; Tam et al., 2006; Deis et al., 2018). Although skeletal levels of norepinephrine are not changed in the conditional knockout mice, expression of *Adrβ2* is increased (Deis et al., 2018). Whether this increase explains their bone phenotype and the molecular basis of this observation remain to be defined. In contrast, *CB2* is not expressed in the brain but is mainly expressed by immune cells (Di Marzo et al., 2004). It is also expressed at lower levels in osteoblasts and osteoclasts and CB2-deficient mice have a low-bone-mass phenotype most likely of peripheral origin (Ofek et al., 2006).

Orexin signaling

Orexins are neuropeptides expressed in the lateral hypothalamus, stimulating multiple behaviors including wakefulness and feeding by binding to two receptors OX1R and OX2R. In the absence of orexin, mice develop a low-bone-mass phenotype caused by a decrease in bone formation (Wei et al., 2014). Analysis of mice lacking the orexin receptors identified an underlying complexity to this phenotype (Wei et al., 2014). Indeed, inactivation of OX1R is associated with increased bone formation and bone mass while bone resorption and *Rankl* expression are decreased. This phenotype appears to be caused by a peripheral effect involving signaling in osteoblasts by Ghrelin, a peptide predominantly expressed in stomach that binds to receptors expressed in osteoblasts to regulate their differentiation and function (Delhanty et al., 2014; Ma et al., 2015). In contrast, absence of OX2R is associated with decreased bone formation and

bone mass, and this phenotype is centrally mediated since it can be reproduced by ICV injection of an OX2R-selective antagonist (Wei et al., 2014). Orexin's central effect could be achieved through modulation of the sympathetic tone, since *Ucp1* expression in brown adipose tissue is increased in OX2R−/− mice (Wei et al., 2014), and the densest extrahypothalamic projection of orexin-positive neurons extends to the noradrenergic LC (Peyron et al., 1998) (Fig. 34.1). Such a mechanism, however, stills needs to be formally demonstrated.

Regulation of bone resorption by melanocortin receptor 4 and cocaine- and amphetamine-regulated transcript

In addition to the SNS-related pathway mentioned above, the absence of brain serotonin causes a sharp increase in the expression of the melanocortin receptor 4 gene (*Mc4R*) (Yadav et al., 2009). Melanocortins, a family of peptides produced by posttranslational processing of proopiomelanocortin (POMC), regulate food intake and energy expenditure via binding to two melanocortin receptors expressed in the central nervous system (Mc3R and Mc4R). While these receptors show a widespread presence in the rodent brain (Mountjoy et al., 1994; Kishi et al., 2003), POMC has a limited distribution, being described in only two neuronal populations: one in the arcuate nucleus of the hypothalamus (ARC) and the other in the nucleus of the tractus solitarius (NTS) of the brain stem (Palkovits et al., 1987; Bronstein et al., 1992). The POMC neurons of the ARC are known to be responsive to leptin and MC4R has thus been implicated in leptin's control of appetite (Cheung et al., 1997; Cone, 1999). It was first reported that patients lacking Mc4R have high bone mineral density (BMD) and advanced bone age (Farooqi et al., 2000). Subsequently, *Mc4r−/−* mice were shown to have an increase in bone mass caused by an isolated decrease in osteoclast number and function consistent with decreased *Rankl* expression (Elefteriou et al., 2005). The same decrease in bone resorption activity was also noted in MC4R-deficient patients (Ahn et al., 2006).

This high-bone-mass/low-resorption phenotype has been explained by an increase in CART signaling. CART is a neuropeptide encoded by a gene expressed in hypothalamic neurons among other parts of the nervous system and in peripheral organs such as the pancreas and the adrenal glands but not in bone cells (Couceyro et al., 1997; Elias et al., 1998; Wierup et al., 2004; Elefteriou et al., 2005). That *Cart* expression is virtually undetectable in hypothalamic neurons of *ob/ob* mice suggested that it is positively regulated by leptin and could therefore act as a mediator of its functions (Douglass et al., 1995; Kristensen et al., 1998). Yet Cart-deficient mice do not present a body weight or reproduction phenotype (Asnicar et al., 2001). Instead they display a late-onset low-bone-mass phenotype (Elefteriou et al., 2005). Osteoblast numbers and bone formation rates are normal in these mice, but the osteoclast surface and number are nearly doubled, leading to a significant increase in urinary Dpd elimination. Given the absence of *Cart* central expression in *ob/ob* mice, this negative regulation of bone resorption by CART explains, at least in part, the increase in bone resorption observed in these mice.

The action of CART on bone resorption is peripheral, as ICV infusion of recombinant CART in *Cart−/−* mice does not correct their low-bone-mass phenotype while transgenic mice harboring a twofold increase in CART circulating level display high bone mass due to an isolated decrease in osteoclast number. Moreover, this same transgene can rescue the low-bone-mass phenotype of the *Cart−/−* mice (Singh et al., 2008). The *Cart−/−* phenotype is not bone cells autonomous as Cart-deficient bone marrow macrophages differentiate normally into osteoclasts and Cart-deficient bone marrow stromal cells can normally support osteoclastogenesis in coculture experiments (Elefteriou et al., 2005). *Rankl* expression is increased in *Cart−/−* bones, suggesting that Cart regulates bone resorption by ultimately modulating Rankl signaling (Elefteriou et al., 2005; Ahn et al., 2006). In the absence of any identified CART receptor, however, one can only speculate whether this factor acts directly on osteoblasts or uses one or several relays to signal to bone cells.

Mc4r inactivation in mice causes an increase in hypothalamic *Cart* expression, and serum CART levels are significantly elevated in patients heterozygous for inactivating mutations of Mc4R (Elefteriou et al., 2005; Ahn et al., 2006). Moreover, inactivation of one or two copies of the *Cart* gene in Mc4r-deficient mice normalizes their bone resorption parameters, *Rankl* expression, and thereby their bone mass (Ahn et al., 2006). Thus, in addition to the SNS pathway, leptin also controls bone resorption via an MC4R/CART pathway (Fig. 34.1). Although likely, whether this regulation also occurs via a brain serotonin relay remains to be genetically confirmed.

Y receptor signaling

The Y signaling system is complex, consisting of at least five receptors (NPY1R, NPY2R, NPY4R, NPY5R, and NPY6R in mouse) with different binding profiles and sites of expression in the central nervous system and the periphery as well as multiple endogenous ligands: neuropeptide Y (NPY), peptide YY (PYY), and pancreatic polypeptide (PP) (Lin et al., 2004). NPY is widely expressed in the central and peripheral nervous system, and NPY fibers project from the ARC nuclei,

which are known to participate in the control of appetite (Hokfelt et al., 1998). The related family members PYY and PP are produced in the small intestine and colon or in the pancreas, respectively (Hazelwood, 1993), where they affect gut motility in addition to pancreatic and gall bladder secretion. PYY is also expressed in a subset of brain stem neurons (Glavas et al., 2008). PYY and PP can signal to specific Y receptors in the hypothalamus and the brain stem to further influence pancreatic and gastric secretion. NPY and PYY have identical affinity for all known Y receptors, and PP binds preferentially to the Y4 receptor (Larhammar 1996).

While *PP−/−* mice do not show a bone phenotype, both PYY-deficient and NPY-deficient mice show an increase in bone mass (Wortley et al., 2007; Baldock et al., 2009; Wong et al., 2012), suggesting that the latter two peptides are negative regulators of bone remodeling. Evidence from overexpressing mice and studies of genetically engineered models suggests that only NPY may exert such activity via central signaling (in addition to direct effects on bone cells) (Matic et al., 2012; Wong et al., 2012) (Fig. 34.1). Indeed, overexpression of NPY in the hypothalamus decreases bone mass by inhibiting bone formation, and this activity can, even if partly, normalize bone mass in the *NPY−/−* mice (Baldock et al., 2005; Baldock et al., 2009). This central activity is most likely mediated by the NPY2R receptor, as its hypothalamus-specific depletion causes an increase in cancellous bone volume by increasing bone formation (Baldock et al., 2002; Baldock et al., 2006; Shi et al., 2010), while the peripheral activity of NPY depends on NPY1R (Baldock et al., 2007). An opposite role has been recently proposed for the Y6 receptor, which is expressed in brain but not in bone and whose global inactivation is associated with reduced bone mass, decreased bone formation, and increased osteoclast number (Khor et al., 2016). This central role, however, awaits to be confirmed via brain-specific inactivation experiments.

Brain-derived neurotrophic factor

Brain-derived neurotrophic factor (BDNF) is a member of the nerve growth factor family of proteins that binds to the tyrosine kinase receptor type B (Trkb). It is expressed in the CNS as well as the peripheral nervous system and is known to affect memory, cognition, and behavior including feeding. Specific inactivation of *Bdnf* in the brain of mice causes a high-bone-mass phenotype associated with decreased osteoclast number, at least in females (Camerino et al., 2012). These mice do not show changes in sympathetic activity or serotonin levels suggesting another, yet unidentified, mode of action.

Interleukin-1

IL-1 is a polypeptide product that mediates several components of acute-phase response to infection and injury. Its main sites of expression are the peripheral immune system and bone cells as well as glia and neuron cells in the CNS (Lorenzo et al., 1990; Dinarello, 1997). When injected subcutaneously, IL-1 is a potent stimulator of bone resorption, and IL-1R-deficient mice do not lose bone after ovariectomy (Sabatini et al., 1988; Lorenzo et al., 1998). Targeted overexpression in the CNS of mice of human IL-1Ra, a natural IL-1 receptor antagonist, results in a low-bone-mass phenotype caused by a doubling of osteoclast numbers (Bajayo et al., 2005). However, the cellular and molecular bases of this central activity are still unknown.

Evidence of central/neuronal regulations of bone mass in human

While genetic engineering in mice has been a powerful tool in identifying many central and neuron-related factors controlling bone remodeling, human genetic evidence confirming these findings is still limited. One possible explanation for this paucity of data stems from the fact that most of the factors identified have major roles regulating other key functions in the body such as feeding, energy metabolism, reproduction, ad behavior, and it is therefore difficult to assess effects on bone mass independently of these other consequences in patients. For example, correcting for body weight or body mass index (BMI) may weaken correlations, since they could be inherent to the trait analyzed and therefore legitimately associated with it but also may simply reflect lifestyle differences. Another issue could come from the exclusion (or absence of exclusion) of patients using medications (yet) considered unrelated to bone health but that are designed to address other activities of these pleiotropic factors. Given these limitations, as much as a positive genetic evidence can be considered a validation of the findings made in rodents, an absence of evidence should be interpreted cautiously.

In addition to the limitations mentioned above, association studies based on the quantification of these factors' blood levels or on therapeutic interventions related to their role in other diseases can be biased by the technical difficulty to accurately extrapolate neuron-produced levels of neuromediators from blood to bone and by the specificity (or lack thereof), dose, effect, and side effects of the drugs evaluated. In that respect, their conclusions should be taken with even more reservation than genetic associations.

Leptin

An association with increased circulating levels of leptin and incidence of osteoporosis has been reported in patients harboring specific alleles at two polymorphism sites of the leptin receptor gene (rs1137100 and rs1137101, both G variants) (Ye and Lu, 2013). Although these variants were not associated with obesity in this particular population, suggesting that they do not cause a receptor loss-of-function, their impact on leptin signaling has not been elucidated, and these data should therefore be interpreted carefully. In contrast, a patient harboring a known obesity-inducing inactivating mutation of the leptin gene was shown to display high bone mass, more definitely indicating that leptin fulfills a role in humans similar to the one it plays in rodents (Elefteriou et al., 2004). Other, although indirect, evidence of such a role is the advanced bone age and presence of osteosclerotic lesions in lipodystrophic patients, whose serum leptin levels are extremely low due to the absence of adipocytes (Westvik, 1996; Elefteriou et al., 2004).

Multiple studies have also assessed a correlation between leptin serum levels and bone mass. However, especially in the case of leptin, one must be cautious when reporting the results of clinical studies including obese participants since their blood leptin levels are expected to be high, but they may be experiencing central leptin resistance. The mere fact that obese individuals are overweight despite high levels of serum leptin most likely demonstrates such a leptin loss-of-function effect. In this case, finding a positive association of leptin levels with BMD would be an expected outcome. In contrast, when leptin levels are moderately elevated and body weight remains within the normal range, negative correlations between serum leptin levels and bone mass have been observed. For instance, an early study noted an inverse association between serum leptin levels adjusted for fat mass and BMD in a group of 221 Japanese men (Sato et al., 2001). Likewise, in a large cohort of young men (the Gothenburg Osteoporosis and Obesity Determinants cohort), leptin was found to be a negative independent predictor of areal BMD at several measured sites, and of cortical bone size at both non−weight-loaded bones (radius) and weight-loaded bones (tibia) (Lorentzon et al., 2006). Importantly, this study was performed on a primarily healthy population with normal body mass indexes sparing the need to adjust BMD readings for differences in lean and fat mass. In another population of healthy subjects without difference on body weight or body mass index, serum levels of leptin were significantly associated with reduced total body, hip, femoral neck, femoral shaft, and total femur BMD (Wu et al., 2009). Other cross-sectional studies have failed to show such a negative association between serum leptin levels and areal BMD (Goulding and Taylor, 1998; Martini et al., 2001; Thomas et al., 2001; Papadopoulou et al., 2004). Most likely, some of the differences between these and other studies can be attributed to the way data are evaluated and are presented, either adjusted or unadjusted for body weight. For instance, in a large North American population-based study including a high representation of the elderly, non-Hispanic blacks, and Mexican Americans, BMD increases with increasing leptin concentration in men. However, after adjustment for BMI and other bone-related factors, an inverse association emerged, being most evident in men younger than 60 years (Ruhl and Everhart, 2002). Similarly, in a few recent studies in men, leptin was inversely correlated to aBMD, an association that became apparent only after adjustment of aBMD for body weight (Sato et al., 2001; Morberg et al., 2003). Lastly, in a small population of middle-age (non-pre-menopausal) Japanese subjects, significant negative correlations were observed between cortical bone thickness and both blood leptin levels and sympathetic activity, as assessed by quantification of heart rate variability, while a positive correlation existed between leptin levels and sympathetic activity (Kuriyama et al., 2017).

Adrenergic signaling

Multiple nongenomic evidence indicates that the SNS function on bone mass is conserved in humans. For instance, patients with reflex sympathetic dystrophy, a disease characterized by localized high sympathetic activity, develop a severe and localized osteoporosis that can be treated by β-blockers (Kurvers, 1998). Likewise, short sleep, which causes an increase in SNS activity, is associated with bone loss; pheochromocytomas, which cause an increase in catecholamine levels, are associated with an increase in bone resorption that can be normalized by adrenalectomy; and sympathetic activity, quantified by microneurography, was found inversely associated with bone volume, trabecular thickness, and bone strength at the distal radius in women (Farr et al., 2012; Veldhuis-Vlug et al., 2012; Kuriyama et al., 2017). Genetic evidence, however, has not been conclusive. While the risk of osteoporosis at the femoral neck was associated with a polymorphism in the *ADRβ2* gene (rs1042713, AG and GG genotypes) in a medium-sized population of postmenopausal Korean women, no correlation could be found with BMD and fracture risk in case-control and meta-analysis studies of populations of European origin (Lee et al., 2014; Veldhuis-Vlug et al., 2015). Additional studies are needed that analyze polymorphisms at this locus in different populations but also in genes encoding other adrenergic receptors, as in humans those may contribute to the effect of the SNS on osteoblasts.

From a pharmacological standpoint, beneficial effects of β-blocker administration on BMD and/or fracture risk in women have been reported by multiple epidemiologic studies. In postmenopausal women (Geelong Osteoporosis Study), higher BMD at the total hip and ultradistal forearm as well as a decreased fracture risk and serum CTx levels were associated with β-blocker use (Pasco et al. 2004, 2005). Likewise, in a large cohort of elderly men (Concord Health and Aging in Men Project, CHAMP), age-related loss of BMD was found attenuated by the use of β-blockers (Bleicher et al., 2013). Analysis of the Dubbo Osteoporosis Epidemiology Study (DOES) cohort also showed that both men and women using β-blockers had higher BMD at the femoral neck and spine as well as lower fracture risk than those not treated (Yang et al., 2011) Case-control studies also showed that the use of β-blockers decreases the odds ratio for facture and was associated with a higher BMD at the spine, femoral neck, and proximal femur (Schlienger et al., 2004; Bonnet et al., 2007). Two prospective case-control studies respectively in elderly and severely burned patients showed that BMD was significantly improved in β-blocker users (Turker et al., 2006; Herndon et al., 2012). More generally, meta-analyses have identified an association between use of β-blockers (but not α-blockers) and a statistically significant protection against all fractures, with protection against hip fractures being stronger (Wiens et al., 2006; Yang et al., 2012).

A few studies also reported less conclusive evidence of a beneficial effect of β-blockers on bone mass in human patients. For instance, in US women enrolled in the Study of Osteoporotic Fractures, total hip BMD was greater among β-blocker users, but adjustment for body weight or other parameters eliminated the difference. Nevertheless, there was a protective effect of β-blockers against hip fracture (hazard ratio for hip fracture associated with β-blocker use was 0.76 [95% CI 0.58−0.99]) (Reid et al., 2005). Analysis of a large cohort of Medicare beneficiaries treated with antihypertensive agents also did not observe a protective effect of β-blockers on the incidence of bone fractures identified based on diagnosis and procedure codes, but in the absence of radiographs and BMD data (Solomon et al., 2011). The discrepancy between the results of these and the studies cited above could have many origins. One of them could relate to the absence of specificity of the β-blocker used, a parameter that is usually not taken into account. As a matter of fact, many studies have been performed on populations using β-blockers following a diagnosis of hypertension and therefore most likely to be treated with β_1-blockers, which are cardioselective. Although a lower risk of fracture was associated with usage of this class of drugs in the Korean Health Insurance Review and Assessment Service database (Song et al., 2012), their biological effect on bone cells is not clear, since studies in mice have suggested that the Adrβ1 receptor could counteract the effect of Adrβ2 on bone remodeling (Elefteriou et al., 2005; Pierroz et al., 2012). Perhaps even more critical, the length of treatment and dose of β-blockers could be other significant factors of variability within and between studies. At least in ovariectomized rats the best preventive effect against bone loss was obtained with the lowest dose of propranolol, the highest dose being ineffective, while the opposite was observed for cardiac hemodynamic functions (Bonnet et al., 2006). Given that most patients analyzed in studies using β-blockers were prescribed these drugs to treat hypertension, it is thus possible that a significant proportion of them may be taking doses inappropriate to achieve a positive effect on bone mass.

Brain serotonin and neuromedinU

Variants of human *TPH2* linked to serotonin deficiency have been reported as associated with a spectrum of neuropsychiatric disorders such as major depression or bipolar disorder, and these conditions are also associated with bone loss and/or increased risk of fractures (Misra et al., 2004; McKinney et al., 2009; Hsu et al., 2016). Although this observation is suggestive of a link between these variants and bone health, specific studies are needed to confirm this hypothesis. Another indication that brain serotonin plays a role in the control of bone mass in human stems from the bone loss observed in patients chronically using SSRIs (Wu et al., 2009; Haney et al., 2010; Rizzoli et al., 2012; Zhou et al., 2018). This same effect can be reproduced in rodents, and molecular studies have shown that it is mediated by a decrease of brain serotonin signaling leading to increased sympathetic output (Warden et al., 2005; Bonnet et al., 2007; Warden et al., 2008; Ortuno et al., 2016). Accordingly, it could be prevented by cotreatment with a β-blocker (Ortuno et al., 2016). This latter observation also awaits confirmation by clinical studies.

In contrast, the contribution of NeuromedinU to the central regulation of bone mass has already been assessed in humans. Analysis of a large population of European children (IDEFICS cohort) has associated variants of the *NMU* gene with bone strength (C variant of both rs6827359 and rs12500837 as well as homozygosity of the C variant of rs9999653) (Gianfagna et al., 2013). Interestingly, this study also reported a synergistic effect between NMU and ADRB2 variants (*NMU* rs6827359, CC variant and *ADRB2* rs1042713, GG variant), confirming the functional link observed in mouse models (Sato et al., 2007).

Melanocortin receptor 4 and cocaine- and amphetamine-regulated transcript

As mentioned above, inactivating mutations in one allele of MC4R are linked to advanced bone age, assessed by radiography of the wrist, in children and a high-bone-mass phenotype in adults (Farooqi et al., 2000). This phenotype is associated with an increase in circulating CART levels and a decrease in the resorption biomarker CTx (Ahn et al., 2006). In addition, a polymorphism in the CART gene (rs2239670, AG variant) was found associated with a higher BMD at the lumbar spine (Chun et al., 2015) in Korean postmenopausal women while a significant association between another one (rs7379701, TC and CC variants) and forearm BMD was reported in Caucasian postmenopausal women (Guerardel et al., 2006).

Neuropeptide Y, brain-derived neurotrophic factor, and cannabinoid receptor 2

A small longitudinal substudy of early postmenopausal women (Kuopio Osteoporosis Risk Factor and Prevention population) has shown that a gain-of-function polymorphism in the *NPY* gene (rs16139, variant C) associates with a better maintenance of femoral neck BMD after 5 years (Heikkinen et al., 2004, Ding et al., 2005) and analysis of a population of Afro-Caribbean men (Tobago Bone Health Study) has identified two single nucleotide polymorphisms (SNPs) in the *NPY* gene associated with higher total-hip BMD (rs16135 and rs16123, G variants) (Goodrich et al., 2009). However, the other variant of the latter polymorphism (rs16123, CC variant), along with another NPY SNP (rs17149106, GG variant), was associated with increased odds ratio for osteoporosis at the lumbar spine (although there was no significant difference in BMD) in postmenopausal Korean women (Chun et al., 2015). This discrepancy may reflect sex-based differences, a trend that was also observed in mouse models (Baldock et al., 2009). Lastly, in this same population of women, the combination of two polymorphisms in the *NPY2R* gene (TT variants of both rs2880415 and rs6857715) was also associated with a higher rate of osteoporosis at the lumber spine (Chun et al., 2015). Altogether, these results support an involvement of NPY signaling in the regulation of bone mass in human.

While the analysis of four SNPs in human *CB1* did not find a statistically significant correlation with bone health, in a small population of postmenopausal women, several *CB2* SNPs, alone or in combination, show a significant increase in the odds ratio for osteoporosis (Karsak et al., 2005). These results are consistent with an involvement of at least the *CB2* locus in human osteoporosis.

Lastly, two studies have shown a link between BDNF and bone mass. A genome-wide search for phospho-SNP associated with BMD at the hip and spine identified a BDNF variant (rs6265, V66M) in both Caucasian and Chinese populations (Deng et al., 2013). This variant, which impairs the phosphorylation of BDNF by the CHEK2 kinase at amino-acid T62, also associates with multiple mental disorders (Gratacos et al., 2007; Deng et al., 2013). In addition, an integrative analysis that combined four genome-wide association study datasets identified two *BDNF* SNPs (rs7124442, 3′UTR variant and rs11030119, intron variant) with spine BMD and osteoporotic fractures (Guo et al., 2016).

Conclusions and perspective

Since the identification of leptin's central regulation of bone remodeling in mice, the past 2 decades have seen a large number of studies revealing the complexity and potential biomedical importance of the neuronal control of bone mass. The pleiotropic nature of these pathways as well as the technical difficulty in measuring central or even peripheral neuromediator levels or activity in patients have somewhat hampered their validation in human physiology, but many elements have also emerged that confirm findings made using animal models. Whether some or most of these regulations take place in humans, they represent potential targets for designing new diagnostic and therapeutic tools that should be further explored to predict or treat bone health disorders.

Chapter outline

Estrogens and estrogen receptors

Osteoporosis, characterized by loss of bone mass and microarchitecture, is an enormous and growing public health concern worldwide. Indeed, one in three women and one in five men will suffer an osteoporotic fracture in their lifetime (Melton 3rd et al., 1998; Kanis et al., 2000). Moreover, this burden in women exceeds the incidence of breast cancer, stroke, and myocardial infarction combined in a given year (Cauley et al., 2008). Although aging is the greatest risk factor for osteoporotic bone loss, estrogen deficiency in women and men is an important determinant for bone loss later in life (Riggs et al., 2002). Interestingly, although menopause is the major life event leading to the reduction in gonadal function in women, increasing evidence demonstrates that gradually declining levels of biologically available estrogens in men also lead to age-related bone loss (Khosla et al., 2008). Therefore, the understanding of how estrogens modulate bone physiology is critical not only from a scientific perspective, but also from a clinical perspective due to the widespread prevalence of osteoporosis.

The general importance of estrogen in the regulation of bone physiology was first recognized by the studies of Fuller Albright in the 1940s, who demonstrated that estrogen deficiency, through either ovariectomy (OVX) or following menopause, caused bone loss that could be effectively reversed through the administration of estradiol (Albright, 1940). Following this seminal discovery, investigators hypothesized that a protein, or receptor, must exist which can bind estrogens and mediate their effects on cellular and/or tissue physiology. The first evidence for an "estrogen receptor" (ER) came from experiments conducted by Gorski and Jensen in the 1960s, where they showed that rat uterus protein extract homogenate bound labeled-17β-estradiol (Gorski et al., 1968; Jensen et al., 1968; Shyamala and Gorski, 1969).

The molecular evidence for a direct effect of estrogens on bone did not occur for another 20 years, when a number of investigators demonstrated that bone was indeed an estrogen-responsive tissue (Chow et al., 1992; Ernst et al., 1989; Spelsberg et al., 1999; Tobias and Chambers, 1991; Tobias et al., 1991; Turner et al., 1993). Two distinct ERs are now recognized as mediating the effects of estrogen. ERα (*ESR1*) was cloned in the 1980s (Greene et al., 1986; Walter et al., 1985), and ERβ (*ESR2*) was cloned about a decade later (Kraus et al., 1995; Mosselman et al., 1996; Onoe et al., 1997). Both receptors share a structural homology with each other as well as with all members of the nuclear hormone superfamily of receptors (Mangelsdorf et al., 1995): (1) a central DNA binding (DBD) and hinge domain exists that mediates the interaction with specific DNA sequence elements and dimerization, (2) a C-terminal ligand binding domain (LBD), which also contains a transcriptional activation function (AF2) that allows specific ligands to bind causing a conformational change in the 12 α-helices necessary for activation of the ERs, and (3) a variable N-terminal domain with a secondary activation function (AF1). The simplified domain structure of human ERα and ERβ, with percent homologies, is shown in

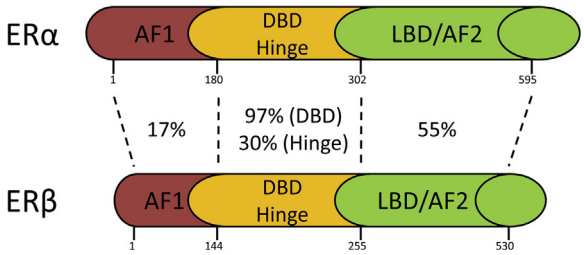

FIGURE 35.1 Structure and amino acid identity between human ERα and ERβ.

Fig. 35.1. ERα is expressed in cells of the osteoblastic (Eriksen et al., 1988; Ikegami et al., 1993) and osteoclastic (Oursler et al., 1991, 1994) lineages. ERβ is also often also coexpressed in these same lineages (Braidman et al., 2001; Vidal et al., 1999; Windahl et al., 2000; Arts et al., 1997; Monroe et al., 2003a).

Since estrogens are steroid molecules and largely hydrophobic, they can easily diffuse into cells from the circulation, where they encounter and bind to the ERs. This complex can directly regulate the transcription of genes under the control of estrogen response elements, called primary response genes, which typically occurs within 30–60 min of estrogen binding. These proteins then can modulate the transcription of further downstream genes (24–48 h later), in a process termed the "cascade model" of steroid hormone action (Landers and Spelsberg, 1992). ERs typically function as dimers, with both homodimers and heterodimers observed in osteoblastic cells. Although ERα and ERβ can regulate some of the same genes, their patterns of expression have been shown to be largely unique in bone cells (Monroe et al., 2003a, 2005). There is also considerable evidence that nongenomic ER pathways exist that are mediated by membrane-bound ERs and activate kinase cascades to elicit very rapid (within minutes) cellular effects (Razandi et al., 1999). These functions have been extensively reviewed (Levin, 2002; Saczko et al., 2017; Kelly and Levin, 2001) and thus will not be discussed in further detail here.

Estrogen receptor mouse models

As described above, the effects of estrogen on bone physiology are largely mediated through two related yet distinct soluble proteins belonging to the nuclear receptor superfamily of transcription factors, termed ERα and ERβ (Mangelsdorf et al., 1995; Monroe et al., 2003b; Almeida et al., 2017). Although more information exists on the role of ERα in bone physiology compared with ERβ, our understanding of the full effects of ERα on bone during growth and aging is far from complete. The first studies conducted on understanding the role of ERα in bone physiology were performed by Sims and colleagues, who examined mice harboring a global deletion (e.g., in all tissues) of ERα (Sims et al., 2002). They found in both males and females that global ERα deletion triggered a complex phenotype, including a decrease in bone turnover, decreased cortical thickness, and an increase in trabecular bone mass. However, the effects were confounded by high circulating estrogen levels in female mice and high testosterone levels in both sexes. Because ER expression has been shown to exhibit a compartment-specific expression pattern (with ERα expression in both cortical and trabecular sites, whereas ERβ expression is only evident in trabecular sites) (Onoe et al., 1997; Bord et al., 2001), these data suggest that high estrogen levels activate ERβ in trabecular bone, leading to a compensatory response at trabecular sites. On the contrary, global deletion of ERβ did not affect circulated steroid levels in either males or females and largely had no effect on bone in males. In females, trabecular bone, periosteal, and endosteal circumference were increased (Windahl et al., 1999, 2000; Sims et al., 2002). Even with the confounding steroid levels in the ERα global knockout mouse models, these studies demonstrated that loss of ERα decreased cortical thickness, that ERβ could compensate for loss of ERα in trabecular bone, and in the setting of intact ERα signaling, ERβ seemed to antagonize ERα action in bone.

Although the data garnered from these global ER knockout mouse models provided some insights into ER function in bone physiology, it was necessary to characterize the functions of these receptors in the various cell types responsible for bone remodeling (i.e., osteoblasts, osteoclasts, osteocytes). Therefore, more conclusive data on the functions of ERs in bone came from utilizing the Cre/LoxP system to achieve cell-specific deletion of ERs. In these systems, a crucial exon in either ERα or ERβ is flanked by loxP recombination sites and crossed into a "driver" mouse model whereby a tissue-specific promoter drives expression of Cre recombinase, thereby triggering a recombination event in which the gene is effectively knocked out in a cell-specific manner. Recently, this system has been used to demonstrate that an important target cell for ERα action is the osteoclast. ERα deletion in the early myeloid lineage using the LysM-Cre model (Martin-Millan et al., 2010) and in the more differentiated osteoclast lineage cells using the Ctsk-Cre model

(Nakamura et al., 2007) led to reduced trabecular bone mass due to increased osteoclast number and bone resorption in female mice. These data suggest that ERα is crucial for the control of osteoclast number and resorption in female mice.

The Cre/LoxP system has also been utilized to examine the role of ERα and ERβ in osteoblasts, using osteoblast lineage-specific Cre mouse drivers. Using Cre drivers that are active in early mesenchymal progenitor cells (Prx1-Cre) (Logan et al., 2002) or in osteoprogenitors (Osx-Cre) (Rodda and McMahon, 2006) to delete ERα resulted in impaired Wnt signaling and impaired optimal cortical bone mass acquisition that was ligand independent (Almeida et al., 2013). No trabecular phenotype was observed in either model. Surprisingly, deletion of ERα using the Col1a1-Cre driver, which is active in fully differentiated osteoblasts, elicited no bone phenotype in either sex up to 26 weeks of age (Almeida et al., 2013). In contrast with these findings, deletion of ERα using an osteocalcin-Cre (Ocn-Cre) model, which also is active in differentiated osteoblasts (although possibly somewhat more mature than the Col1a1 promoter), led to deficits in bone mass at both trabecular and cortical sites in female mice (Maatta et al., 2013; Melville et al., 2014). There was also a deficit in trabecular bone in males, although this phenotype was not apparent until ~6 months of age (whereas the phenotype in females was evident by 3 months of age).

Since the osteocyte has recently been identified as an important controller of bone metabolism (Bonewald, 2017), studies have been conducted in which ERα was conditionally deleted in osteocytes using the osteocyte-dominant Dmp1 promoter-driven Cre (Dmp1-Cre) (Kalajzic et al., 2004). This promoter may slightly overlap with the Ocn-Cre and has yielded somewhat inconsistent results. Windahl and colleagues (Windahl et al., 2013) reported that only male mice exhibited a lowered trabecular bone mass, whereas Kondoh and colleagues (Kondoh et al., 2014) reported the same phenotype but in only female mice. The two studies were consistent in that no cortical phenotype was observed in either sex. Although the true nature of ERα function in osteocytes cannot be cleanly gleaned from these studies, it is clear that ERα signaling is somehow important in late osteoblasts/osteocytes. Future studies will need to be designed to address these discrepant findings.

Studies examining the role of cell-specific deletion of ERβ have begun to shed insight into this molecule as well. Deletion of ERβ in osteoprogenitor (Prx1-Cre) or osteoblasts (Col1a1-Cre) elicited opposite effects to that of ERα deletion, which is an increase in trabecular bone mass with no effect on cortical bone mass in female mice (Nicks et al., 2016). In experiments examining the effects of ERβ deletion using bone marrow stromal cells, an increase in the ratio of colony-forming unit (CFU)-osteoblasts to CFU-fibroblasts was observed, suggesting an increased differentiation capacity of ERβ-negative progenitor cells. Consistent with this, ERβ has been shown to antagonize ERα in other systems (Hall and McDonnell, 1999); it is likely that ERβ plays a similar antagonistic role in bone.

The understanding of how ERα and ERβ function in bone physiology is now becoming more complete and Table 35.1 summarizes the current published knowledge from multiple laboratories concerning the phenotypes of the ER conditional-deletion mouse models. Although certainly discrepancies exist, a general consensus is becoming evident: ERα deletion in osteoclasts leads to reduced trabecular bone but not cortical bone in female (but not male) mice, ERα deletion in later osteoblastic lineages generally leads to reduction in both trabecular and cortical bone mass (although this appears to be somewhat sex-specific in some cases), and that ERβ deletion in osteoblastic lineages leads to increased trabecular bone mass in female mice. However, these data were all collected in mice where the conditional deletion was present from conception onwards and therefore may involve developmental effects of the deletion that may persist into adulthood. In order to understand the specific roles of the receptors in a cell-specific manner in adulthood without the confounding effects of developmental deletion, inducible mouse models in which the deletion can be induced later in life are necessary to further understand and clarify the role of both ERα and ERβ in the adult skeleton.

Estrogens—from a clinical perspective

Over 70 years ago, Fuller Albright demonstrated that estrogen deficiency, achieved through either OVX or menopause, caused a rapid bone loss that estrogen replacement could mitigate (Albright, 1940). This also occurs in men, as it was shown that following the removal of the testes, men also experienced a similar loss of bone (Stepan et al., 1989). Since the major sex steroid in males is testosterone, this at the time led to the generalization that estrogen regulates bone mass in women, and testosterone regulates bone mass in men. This, however, proved to be an oversimplification, and as we will discuss shortly, estrogens prove to be the major sex steroid regulating bone physiology in both sexes. In this section, we will review our understanding of how estrogen regulates bone metabolism in humans in both sexes.

The first crack in the notion that testosterone is the dominant regulator of bone mass in men was the identification of a 28-year old male with homozygous null mutations in the ERα gene (Smith et al., 1994). This man exhibited osteopenia with unfused epiphyses and had a spine bone mineral density (BMD) of 2 standard deviations below the average for normal 15 year-old males. This was followed by two independent reports describing a two males with a complete

deficiency in the aromatase enzyme, the molecule responsible for the conversion of testosterone to estrogens (Carani et al., 1997; Bilezikian et al., 1998). Interestingly, these males exhibited a virtually indistinguishable bone phenotype for the original ERα-deficient man. These reports demonstrated that estrogens indeed had an important role in both epiphyseal closure and the attainment of peak bone mass that occurs in the late puberty of males. The original ERα-deficient male (Smith et al., 1994) was reanalyzed later in life and a reduction was found in the bone parameters of both trabecular and cortical compartments (Smith et al., 2008), demonstrating that his osteopenia tracked into later life. While the typical forms of osteoporosis, such as in hypogonadal men or estrogen-deficient women, exhibit increased bone turnover (with indices of resorption and formation both increasing), this male had a reduction in both resorption and formation indices. These "experiments of nature" logically lead to an interesting insight into molecular mechanism—that a loss of estrogen (e.g., the ligand) leads to reduced bone mass in a fundamentally different manner than the loss of the receptor. This notion is supported by the presence of many estrogen-independent effects that have been observed in numerous other tissues (Ciana et al., 2003). Interestingly, cultured primary bone cells from the ERα-deficient male exhibited an increase in the ERβ protein, suggesting a compensatory response (Smith et al., 2008). However, when this data is considered in context with the high circulating estrogen levels present in this individual, it suggests that the ERβ pathway cannot adequately compensate for ERα in the regulation of global bone mass. Whether this is due to the loss of ERα itself, the compensatory increase in ERβ protein, changes in transcriptional coregulatory dynamics, or all of the above, is unclear and would warrant further investigation.

In women, a number of observational studies have also substantiated the original observation made by Fuller Albright and further confirm the essential and key role of estrogens in the regulation of bone physiology. The decline in serum estrogens that occurs throughout menopause is tightly associated with an increased in the bone resorption parameter N-telopeptide of type I collagen (Sowers et al., 2013). Since androgen production, albeit at a low level, still continues in the ovaries following menopause, androgen levels are unchanged and argue against their role in estrogen deficiency-mediated bone loss (Handelsman et al., 2016). The radical idea that estrogen regulates BMD in both women and men has been documented in other human observational studies, where serum estradiol levels appear to be more closely correlated to BMD and turnover indices than androgen levels (Khosla et al., 1998).

A number of human interventional studies from various groups have also concluded that estrogen is indeed the dominant sex steroid that regulates bone physiology. The Women's Health Initiative study, which investigated the effects of estrogen/progesterone (vs. placebo) in a large cohort of postmenopausal women, demonstrated that steroid treatment increased BMD at multiple sites and reduced the risk of hip fracture by one-third (Cauley et al., 2003). Another key study compared the effects of estrogen and testosterone treatment in older men (mean age 68 years) where endogenous sex steroid production was pharmacologically eliminated, and exogenously treated with either sex steroid alone or in combination using patches for 3 weeks (Falahati-Nini et al., 2000). Increases in bone resorption indices were prevented by treatment with steroids as well as by the estrogen-replaced group alone. Importantly, the testosterone-replaced group, in which aromatization to estrogens in inhibited, was ineffective in altering bone resorption makers. Using a statistical model, the investigators estimated that 70% of the effect was due to estrogen alone. This notion was confirmed by a similar study that found that testosterone replacement in hypogonadal men (±an aromatase inhibitor) was ineffective in altering serum turnover markers and that estrogen was indeed the major sex steroid involved in the regulation of bone mass in men (Finkelstein et al., 2016). Collectively, these studies provide strong evidence that in both sexes estrogen is the major sex steroid involved in the regulation bone physiology (Khosla, 2015). The function of testosterone in the regulation of bone mass in men appears to be as a precursor for the aromatization to estrogens, although testosterone also likely plays other important roles in periosteal apposition during growth, leading to larger bone size in men versus women (Almeida et al., 2017).

Another important question when considering the effects of estrogens and ERs (ERα and ERβ) is what might be the potential mechanisms and/or mediators of estrogen action in human bone. Based largely on rodent OVX models, genes that encode proinflammatory cytokines have emerged as one class of potential mediators of estrogen action in bone, especially on osteoclast action and bone resorption. Of particular interest, TNFα, IL1α/β, and IL6 have been the most consistent (Weitzmann and Pacifici, 2006). In humans, several interventional studies have addressed the influence of these proinflammatory cytokines on bone health. One study examined a cohort of normal women ranging from 24 to 87 years old and showed that IL6 concentrations correlated highly with age; however, using sophisticated multiple-regression statistical models, no correlation with estrogen status could be established (McKane et al., 1994). To further clarify this issue, a study was designed in which estrogen-withdrawn early postmenopausal women were placed on either an IL1 or TNFα blocker for 3 weeks, and bone resorption indices were analyzed (Charatcharoenwitthaya et al., 2007). They found a reduction in serum resorption markers suggesting that these proinflammatory cytokines mediate in part bone resorption during estrogen deficiency in humans.

Receptor activator of nuclear factor kappa-B ligand (RANKL), which is produced by both osteoblasts and osteocytes in the bone microenvironment, is another key regulator of bone remodeling by influencing the process of osteoclastic differentiation (Xiong and O'Brien, 2012). In one study designed to examine the role of estrogenic regulation of RANKL in bone, RANKL + cells were isolated from premenopausal women (control) and postmenopausal women treated with either vehicle or estradiol (Eghbali-Fatourechi et al., 2003). They found that the number of RANKL + cells increases with age and estrogenic status, and that such increases were reversible with estradiol treatment. These data suggest that loss of estrogens at menopause may contribute to increased bone resorption through the increase in the proosteoclastic factor RANKL. The increased resorption in estrogen-deficient women can be abrogated clinically through treatment with denosumab, a humanized monoclonal antibody to RANKL (Cummings et al., 2009).

Increasing evidence also exists that demonstrates that the secreted Wnt inhibitor, sclerostin, is regulated by estrogen (Drake and Khosla, 2017). Treatment of estrogen-deficient women with estrogen or the select estrogen receptor modulator raloxifene negatively regulates circulating serum sclerostin protein levels (Drake and Khosla, 2017; Chung et al., 2012; Fujita et al., 2014; Modder et al., 2011a,b). Sclerostin mRNA expression, as assessed by RNA sequencing and QPCR analyses, was also decreased in primary bone needle biopsies isolated from postmenopausal women treated with estradiol (Farr et al., 2017). The new therapeutic agent romosozumab (Cosman et al., 2016), which is a humanized monoclonal antibody directed against sclerostin, results in increases in bone formation with a concomitant decrease in bone resorption in postmenopausal women, similar to those changes observed with estrogen treatment (Drake and Khosla, 2017).

Progestins and progesterone receptors in bone biology

Clinically, progesterone has been used in addition to estradiol to treat postmenopausal osteoporosis to minimize the adverse effects of estradiol on the uterus and breast, however the effects of progestins on bone biology have been significantly less studied (Prior et al., 1990). As with estrogen and estrogen receptors, progestins exert their effects via the progesterone receptor (PR), a member of the nuclear receptor superfamily of transcription factors (Mangelsdorf et al., 1995). Activated PR can acts a progesterone response elements to alter gene expression of specific PR target genes, however nongenomic effects have also been observed (Grosse et al., 2000).

In mammals, PRs exists in two related protein isoforms, which arise from the regulated activation of alternative promoters, resulting in the PR-A and PR-B isoforms (Kastner et al., 1990; Giangrande and McDonnell, 1999). Since they are a member of the nuclear receptor superfamily of transcription factors along with ERs (Mangelsdorf et al., 1995), they share the same modular protein structure including a DBD, LBD, and AF domains (Fig. 35.2) (Hill et al., 2012). The two isoforms are identical except for an additional 164 amino acid residues on the N-terminus of PR-B, which contains an additional and unique activation function (AF-3). Interestingly, both PR isoforms are estrogen inducible (Jung-Testas et al., 1991; Harris et al., 1995; Rickard et al., 2002), suggesting cross-talk between the estrogenic and progestin pathways. In general, the PR-B isoform has a more dominant effect on transcriptional regulation, and under certain conditions, the PR-A isoform can act as an antagonist to PR-B function, as can other nuclear hormone receptors such as ERα (Kraus et al., 1995). Expression of both mRNA and protein for PRs has been demonstrated in multiple osteoblastic cell lines (Rickard et al., 2002; Wei et al., 1993; MacNamara et al., 1995, 1998) and in an age-dependent manner in mouse bone tissue (Zhong et al., 2017).

There is considerable in vitro evidence that progestins can affect osteoblast and bone marrow–derived osteoblastic progenitor cells through the regulation of both proliferation and differentiation, although the data are somewhat conflicting. Various reports have demonstrated that progesterone treatment of some osteoblast cell models has shown either an inhibition of proliferation (Canalis and Raisz, 1978), no effect on proliferation when treated alone (Slootweg et al., 1992), or a stimulation of proliferation (Tremollieres et al., 1992; Scheven et al., 1992; Manzi et al., 1994; Verhaar et al., 1994). Although these data are variable, the overall weight of the evidence suggests that progestins indeed stimulate proliferation in certain mouse and rat osteoblast cell models. Using primary rat bone explants, it was shown the progesterone stimulated

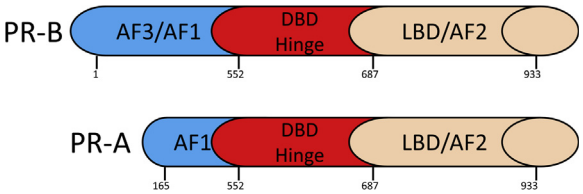

FIGURE 35.2 Structure of human PR-A and PR-B.

the formation of alkaline phosphatase positive (AP+) colonies (Ishida & Heersche, 1997, 1999), suggesting that progesterone may positively influence osteoblast differentiation. In human primary osteoblast cultures and in rat osteosarcoma cells, progesterone treatment stimulated IGF2 secretion (Tremollieres et al., 1992). This regulation of the IGF system was demonstrated to be via activation of IGFBP5, which is known to enhance IGF1/2 activity in osteoblast cultures (Boonyaratanakornkit et al., 1999). In summary, these data support the notion that progesterone positively influences the proliferation and bone-forming activities of osteoblasts.

Initial studies in the 1980s using animal models showed that progesterone has positive effects on bone metabolism in both rats (Burnett and Reddi, 1983) and dogs (Snow and Anderson, 1985). Using an OVX-induced model of bone loss in rats, it was also shown that progesterone replacement had a significant effect on the preservation of bone during sex steroid deficiency (Barengolts et al., 1990, 1996; Bowman and Miller, 1996; Schmidt et al., 2000). However other studies have failed to show an effect on trabecular bone when either treated alone or coadministered with estradiol (Fujimaki et al., 1995; Kalu et al., 1991), creating some uncertainty in the field in regard to the effects of progestins on bone metabolism. Interestingly, the PR antagonist mifepristone (RU486) was also shown to reduce OVX-induced bone loss in rats (Barengolts et al., 1995) and in a patient with Cushing's disease and severe osteoporosis (Newfield et al., 2001), although the latter effects could be due to RU486-mediated antagonism of the glucocorticoid receptor.

Due to these conflicting reports on the effects of progestins on bone metabolism in both animal and human models of osteoporosis, mutant mice have been generated where both PR-A and PR-B have been deleted (the PRKO mouse), in hopes of understanding the true nature of the effects of progestins and PRs in bone physiology. These mice exhibit severe reproductive abnormalities, and the females are infertile (Lydon et al., 1995; Conneely et al., 2001), and also exhibit an increase in trabecular bone mass and bone formation at 12 and 26 weeks of age in female mice (Rickard et al., 2008). Treatment with the PR antagonist RU486 also leads to an increase in trabecular bone mass in young wild-type mice (Yao et al., 2010). Recently, cell-type specific deletions of both PR isoforms using the Cre/LoxP system (the PRcKO mouse) have been made (Zhong et al., 2017). This report confirmed the data from the PRKO knockout mouse and RU486 antagonist data and found a significant increase in trabecular bone mass when PRs were deleted in early mesenchymal progenitor cells (using the Prx1-Cre driver), but not in mature osteoblasts (using the Ocn-Cre driver), and a modest increased trabecular bone mass phenotype following deletion in osteocytes (using the Dmp1-Cre driver). These phenotypes were observed in both sexes (see Table 35.1). Cortical bone mass was unaffected in all models. Taken together, these findings suggest that PR may play a negative role in bone homeostasis. Interestingly, in a specific PR-A mouse knockout model, progesterone had a significantly higher effect on reproductive tissues (Mulac-Jericevic et al., 2000), suggesting that PR-A plays a negative role on the actions of PR-B, although these data need to be confirmed in the skeleton.

Although the data on the effects or progestins in human physiology are somewhat controversial (Waller et al., 1996; De Souza et al., 1997), the bulk of the evidence suggests a role for progestins, albeit modest, in bone physiology. Women who have ovulatory dysfunction due to luteal phase defects have lower bone mass over 1 year compared with normal women (Prior et al., 1990; Prior, 1990), which can be reversed with progesterone replacement therapy (Prior et al., 1994). Additionally, progesterone treatment of women with postmenopausal osteoporosis could protect against further cortical bone loss (Gallagher et al., 1991; Gray et al., 1996; McNeeley Jr. et al., 1991). Although some reports have demonstrated that progesterone treatment of postmenopausal women is as effective as estradiol treatment in preventing further bone loss (Gray et al., 1996; McNeeley Jr. et al., 1991), others have shown a lesser effect when compared to estradiol alone (Prior et al., 1997; PEPI, 1996).

Summary and conclusions

In recent years, many discoveries have advanced our knowledge regarding estrogen action in the bone microenvironment. Although some of the phenotypes of the ERα and ERβ conditional knockout mouse models have been described, it is still unclear the precise mechanism(s) that ERs utilize to regulate bone metabolism, which is especially evident in the role of ERβ itself and ERα/ERβ interactions that may influence bone processes. Given how important estrogen action is for bone, it will be important to continue to define the mechanism(s) that these ERs play, including the role of nonnuclear ERs, to develop novel clinical therapies for aging-related bone diseases such as osteoporosis. It is of interest that two of the new therapies developed for osteoporosis (i.e., denosumab and sclerostin) appear to lie in the estrogen pathway in humans. Therefore, future investigation into how these mechanisms function during aging in bone will be especially important and will help in the improvement of current therapies and in the development of novel therapies for osteoporosis.

Chapter 36

Physiological actions of parathyroid hormone-related protein in epidermal, mammary, reproductive, and pancreatic tissues

Christopher S. Kovacs
Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL, Canada

Chapter outline

Introduction

A substantial breakthrough in the study of parathyroid hormone-related protein (PTHrP) was the development of genetic models that ablated the gene for PTHrP or its receptor, or overexpressed PTHrP within bone cells. These models revealed that PTHrP plays an important role in regulating the terminal differentiation of chondrocytes and the development of the endochondral skeleton; the major findings are reviewed in Chapters 1 and 25. These same models provided insight into PTHrP's previously unknown roles in the development and function of organs and tissues outside the skeleton. The actions of PTHrP in the vascular system and central nervous system are reviewed in Chapter 26, and in bone in Chapter 25. In this chapter we review the known and putative roles of PTHrP in skin, mammary gland, placenta, and other reproductive tissues as well as the islet cells of the pancreas.

Skin

Parathyroid hormone-related protein and its receptor expression

Normal human keratinocytes were the first nonmalignant cells shown to produce PTHrP (Merendino et al., 1986), and multiple studies have confirmed that rodent and human keratinocytes in tissue culture express the PTHrP gene and secrete bioactive PTHrP (reviewed in Philbrick et al., 1996). PTHrP expression has also been examined in skin in vivo using both immunohistochemistry and in situ hybridization. During fetal development in rats and mice, PTHrP is expressed principally within the epithelial cells of developing hair follicles (Karmali et al., 1992; Lee et al., 1995). In mature skin, the PTHrP gene is also expressed most prominently within hair follicles, and mRNA levels appear to vary with the hair cycle. Cho et al. (2003) found that PTHrP expression increased within the outer root sheath and isthmus of late anagen hair follicles in mice. During catagen and telogen, PTHrP transcripts were abundant within the isthmus, but expression was downregulated during early anagen (Cho et al., 2003). In addition to hair follicles, low levels of PTHrP expression may also be found throughout the interfollicular epidermis from the basal to granular layer. Some studies have suggested that PTHrP is more highly expressed in superbasal keratinocytes (Danks et al., 1989; Hayman et al., 1989), although not all studies have reported this pattern (Atillasoy et al., 1991; Grone et al., 1994). A variety of factors have been reported to regulate PTHrP production by cultured keratinocytes (see Philbrick et al., 1996 for review). For example, glucocorticoids and 1,25-(OH)2D have been shown to suppress PTHrP production, whereas fetal bovine serum, matrigel, and an as-yet-unidentified factor(s) secreted from cultured fibroblasts have been shown to enhance PTHrP production. The upregulation of PTHrP production by fibroblast-conditioned media is particularly interesting, as PTHrP in turn acts back on dermal fibroblasts, suggesting that it may function in a short regulatory loop between keratinocytes and dermal fibroblasts (Shin et al., 1997; Blomme et al., 1999a). Finally, in vivo, PTHrP expression has been shown to be upregulated at the margins of healing wounds in guinea pigs (Blomme et al., 1999b). Interestingly, in this study, PTHrP was also detected in myofibroblasts and macrophages, suggesting that keratinocytes may not be the only source of PTHrP in skin.

The general consensus has been that keratinocytes do not express the type I PTH/PTHrP receptor (PTH1R), but dermal fibroblasts do (Hanafin et al., 1995; Orloff et al., 1995). PTHrP has been shown to bind to skin fibroblasts and elicit biochemical and biological responses in these cells (Shin et al., 1997; Blomme et al., 1999a; Wu et al., 1987). In addition, studies utilizing in situ hybridization in fetal skin have demonstrated that PTH1R mRNA is absent from the epidermis yet abundant in the dermis, especially in those cells adjacent to the keratinocytes (Karmali et al., 1992; Lee et al., 1995; Dunbar et al., 1999). There are fewer data concerning the expression patterns of the PTH1R in more mature skin, but in mice, it appears that the relative amount of PTH1R mRNA in dermal fibroblasts is reduced in adult compared with fetal skin (Cho et al., 2003). As with PTHrP, there also appears to be a hair-cycle-dependent variation in the expression of the PTH1R gene in the connective tissue adjacent to the isthmus of the hair follicles. However, unlike PTHrP mRNA, PTH1R mRNA appears to be most plentiful during early anagen (Cho et al., 2003). In addition to fibroblasts, studies using sensitive PCR-based detection methods have also reported expression of the PTH1R in keratinocytes, although these studies have used cultured cells (Errazahi et al., 2003, 2004). Furthermore, studies have shown that cultured keratinocytes bind and respond to PTHrP by inducing calcium transients, suggesting the presence of PTHrP receptors, either classical PTH1R or nonclassical, alternative PTHrP receptors (Orloff et al., 1992, 1995). However, to date no such alternative receptors have been isolated, so their existence remains uncertain. Furthermore, it is not clear whether PTH1R is expressed on keratinocytes in vivo. Therefore, although the possibility of both paracrine and autocrine signaling exists, no functional studies address the relative importance of either pathway to the biology of PTHrP in skin.

Biochemistry of parathyroid hormone-related protein

As described in Chapter 25, during transcription, the PTHrP gene undergoes alternative splicing to generate multiple mRNAs, which in human cells give rise to three main protein isoforms. In addition, each isoform is subject to posttranslational processing to generate a variety of peptides of varying length. Human keratinocytes have been shown to contain mRNA encoding for each of the three main isoforms, although as in other systems, no clearly defined or unique role has yet emerged for any of the three individual isoforms (Philbrick et al., 1996). Keratinocytes have also been shown to process full-length PTHrP into a variety of smaller peptides, including PTHrP(1−36) and a midregion fragment beginning at amino acid 38 (Soifer et al., 1992). These cells have also been shown to secrete a large (<10 kDa) amino-terminal form that is glycosylated (Wu et al., 1991). There is currently no specific information regarding the secretion of COOH-terminal peptides of PTHrP in skin, but keratinocytes are also likely to produce these peptides.

Function of parathyroid hormone-related protein

Several studies suggest that PTHrP is involved in the regulation of hair growth. As noted earlier, the PTHrP gene in embryonic skin is expressed most prominently in developing hair follicles, and overexpression of PTHrP in the basal keratinocytes of skin in transgenic mice leads to a severe inhibition of ventral hair follicle morphogenesis during fetal development (Wysolmerski et al., 1994). This appears to be the result of an interaction between PTHrP and BMP signaling that normally is involved in the regulation of Msx2 expression, patterning of the mammary mesenchyme, and lateral inhibition of hair follicle development around the nipple (Hens et al., 2007) (see "Mammary Gland"). However, it is unlikely that PTHrP is critical to hair follicle morphogenesis elsewhere, because disruption of the PTHrP or PTH1R genes does not seem to affect hair follicle formation or patterning in mice except for the vicinity of the nipple (Karaplis et al., 1994; Lanske et al., 1996; Foley et al., 1998).

It has also been suggested that PTHrP may participate in the regulation of the hair cycle. Systemic or topical administration of PTH1R antagonists to mice appears to perturb the hair cycle by prematurely terminating telogen, prolonging anagen growth, and inhibiting catagen (Schilli et al., 1997; Safer et al., 2007). In a reciprocal fashion, mice overexpressing PTHrP in their skin (K14-PTHrP mice) demonstrate a delayed emergence of dorsal hair and have shorter hairs, and their hair follicles enter catagen approximately 2 days early (Cho et al., 2003; Diamond et al., 2006). These findings were associated with a lower proliferation rate in the hair matrix and a less well-developed perifollicular vasculature during anagen. Together, these studies imply that PTHrP may regulate the anagen-to-catagen transition, acting to inhibit hair follicle growth by pushing growing hair follicles into the growth-arrested or catagen/telogen phase of the hair cycle. If this hypothesis were correct, one would expect PTHrP knockout mice to exhibit findings similar to PTH1R antagonist-treated mice. However, this does not appear to be the case. In mice that lack PTHrP in their skin, the hair cycle appears to be normal (Foley et al., 1998). In fact, rather than a promotion of hair growth, these mice demonstrate a thinning of their coats over time. These conflicting results are difficult to rationalize at this point, but suggest that although PTHrP may contribute to the regulation of the hair cycle, it is unlikely to be necessary for this process to unfold normally.

PTHrP has also been implicated in the regulation of keratinocyte proliferation and/or differentiation. Data from studies in vitro have suggested that PTHrP promotes the differentiation of keratinocytes (reviewed in Philbrick et al., 1996), but studies in vivo have suggested that PTHrP inhibits keratinocyte differentiation (Foley et al., 1998). A careful comparison of the histology of PTHrP-null and PTHrP-overexpressing skin demonstrated reciprocal changes. In the absence of PTHrP, it appeared that keratinocyte differentiation was accelerated, whereas in skin exposed to PTHrP overexpression, keratinocyte differentiation appeared to be retarded (Foley et al., 1998). Therefore, in a physiological context, PTHrP appears to slow the rate of keratinocyte differentiation and to preserve the proliferative basal compartment. Remarkably, these changes in the rate of keratinocyte differentiation are exactly analogous to those noted for chondrocyte differentiation in the growth plates of mice overexpressing PTHrP compared with PTHrP- and PTH1R-null mice (Philbrick et al., 1996). Again, at present it is difficult to rationalize conflicting data regarding the effects of PTHrP on keratinocyte differentiation, but studies in genetically altered mice indicate that PTHrP participates in the complex regulation of these processes in vivo. Further research will be needed to understand its exact role.

As alluded to previously, an important but still unresolved question is whether the effects of PTHrP on keratinocyte proliferation, differentiation, and hair follicle growth are the result of its effects on keratinocytes directly or via its effects on dermal fibroblasts. At present, more data support the paracrine possibility. PTH1R is expressed on dermal fibroblasts in vivo and in culture (Lee et al., 1995; Hanafin et al., 1995). Dermal fibroblasts have been demonstrated to show biochemical and biological responses to PTHrP (Shin et al., 1997; Blomme et al., 1999a; Wu et al., 1987; Thomson et al., 2003). Furthermore, PTHrP has been shown to induce changes in growth factor and extracellular matrix production that could in turn lead to changes in keratinocyte proliferation and/or differentiation and hair follicle growth (Shin et al., 1997; Blomme et al., 1999a; Insogna et al., 1989). Of course, the autocrine and paracrine signaling pathways are not mutually exclusive, but any direct autocrine effects of PTHrP on keratinocytes would require the presence of PTHrP receptors. An alternative possibility by which PTHrP might have cell autonomous effects on keratinocytes is via an intracrine pathway involving its translocation to the nucleus (Philbrick et al., 1996). Clearly, much research is needed to define the receptors and signaling pathways by which PTHrP acts in skin. Only when this information is available will we be able to understand the mechanisms leading to the skin phenotypes that have been observed in the various transgenic models discussed earlier.

Pathophysiology of parathyroid hormone-related protein

To date, PTHrP has not been clearly implicated in any diseases of the skin. It has been suggested that skin and skin appendage findings in rescued PTHrP-null mice are reminiscent of a series of disorders collectively known as ectodermal

dysplasias (Foley et al., 1998), but PTHrP has not been formally linked to any of these diseases. It has also been noted that psoriatic skin may downregulate PTHrP expression, and a small trial of topically administered PTH suggested that stimulation of the PTH1R might improve the histological abnormalities in psoriatic plaques (Hollick et al., 2003). However, these potentially exciting results have not yet been verified in larger trials. Topical application of PTH1R antagonists may be useful for stimulating hair growth, although no data yet suggest that PTHrP is involved in the pathogenesis of alopecia(s) (Safer et al., 2007; Skrok et al., 2015). The most common tumors causing humoral hypercalcemia of malignancy (HHM) are those of squamous histology, but these tumors rarely arise from skin keratinocytes. In fact, the most common skin tumors, basal cell carcinomas, do not overexpress PTHrP and are not associated with hypercalcemia (Philbrick et al., 1996). Primary hyperparathyroidism, hypoparathyroidism, and pseudohypoparathyroidism have each been sporadically reported to have cutaneous manifestations, but whether such findings are directly the result of abnormal PTH1R signaling, abnormal calcitriol concentrations, or a consequence of hypocalcemia or hypercalcemia remains unknown (Skrok et al., 2015). Although PTHrP appears to participate in the normal physiology of the skin, it is not clear at this juncture whether it is involved in skin pathophysiology.

Mammary gland

Very soon after its discovery, PTHrP was reported to be expressed in mammary tissue and secreted into milk at high concentrations (Thiede and Rodan, 1988; Budayr et al., 1989). In retrospect, it would have been much easier to extract PTHrP from human or cow milk than from the tiny amounts expressed in the tumors from which it was first isolated. It is now appreciated that PTHrP is critically important for the proper development and functioning of the mammary gland throughout life. In addition, it has been implicated as an important modulator of the biological behavior of breast cancer. The mammary gland develops in several discrete stages and only reaches its fully differentiated state during pregnancy and lactation. PTHrP appears to serve different functions during the principle stages of mammary development: embryonic development, adolescent growth, and pregnancy and lactation. For each stage, we will first outline the pertinent developmental events in rodents, as data regarding the function(s) of PTHrP largely come from studies in mice and rats. Next, we will discuss the localization of PTHrP and PTHrP receptors and the regulation of the expression of PTHrP and its receptors. Finally, we will address the function of PTHrP.

Embryonic mammary development

In mice, there are two phases of embryonic mammary development. The first involves the formation of five pairs of mammary buds, each of which consists of a bulb-shaped collection of epithelial cells surrounded by several layers of fibroblasts known as the mammary mesenchyme (Sakakura, 1987). After the formation of these buds, mouse mammary development displays a characteristic pattern of sexual dimorphism. In male embryos, in response to androgens, the mammary mesenchyme destroys the epithelial bud and male mice are left without mammary glands or nipples (Sakakura, 1987). In female embryos, however, the mammary buds remain quiescent until embryonic day 16 (E16), when they undergo a transition into the second step of embryonic development, the formation of the rudimentary ductal tree. This process involves the elongation of the mammary bud, its penetration out of the dermis and into a specialized stromal compartment known as the mammary fat pad, and the initiation of ductal branching morphogenesis. At the time of birth, the gland consists of a simple epithelial ductal tree consisting of 15−20 branched tubes within a fatty stroma (Sakakura, 1987). This initial pattern persists until puberty, at which time the mature virgin gland is formed through a second round of branching morphogenesis regulated by circulating hormones (discussed later).

The PTHrP gene is expressed exclusively within epithelial cells of the mammary bud soon after it begins to form. PTHrP mRNA continues to be localized to mammary epithelial cells during the initial round of branching morphogenesis as the bud grows out into the presumptive mammary fat pad and begins to branch (Dunbar et al., 1998, 1999; Wysolmerski et al., 1998). At some point after birth, PTHrP gene expression is downregulated, and in the adult virgin gland, PTHrP mRNA is found only within specific portions of the duct system (Dunbar et al., 1998). In contrast to the PTHrP gene, the PTH1R gene appears to be expressed within the mesenchyme, but its expression is widespread and is not limited to the developing mammary structures. Transcripts for the PTH1R gene are found within the mammary mesenchyme but also throughout the developing dermis (Dunbar et al., 1999; Wysolmerski et al., 1998). It is not clear when the receptor gene is first expressed within the subepidermal mesenchyme. However, it is already present when the mammary bud begins to form, and it continues to be expressed within fibroblasts surrounding the mammary ducts as they begin to extend and branch (Wysolmerski et al., 1998; Dunbar et al., 1998).

Epithelial expression of PTHrP and mesenchymal expression of the PTH1R are not unique to the developing mammary gland, and this pattern has long led to speculation that PTHrP and its receptor might contribute to the regulation of epithelial−mesenchymal interactions during organogenesis. There is now solid evidence that this is the case during embryonic mammary development, where PTHrP acts as an epithelial signal that influences cell fate decisions within the developing mammary mesenchyme. Data supporting this notion come from studies in several genetically altered mouse models. First, in PTHrP or PTH1R knockout mice, there is a failure of the normal androgen-mediated destruction of the mammary bud owing to the failure of the mammary mesenchyme to differentiate properly and to express androgen receptors (Dunbar et al., 1999). Second, in PTHrP and PTH1R knockout mice, the mammary buds fail to grow out into the fat pad and initiate branching morphogenesis, again due to defects in the mammary mesenchyme (Wysolmerski et al., 1998; Dunbar et al., 1998). Finally, in keratin 14 (K14)-PTHrP transgenic mice that ectopically overexpress PTHrP within all the basal keratinocytes of the developing embryo, subepidermal mesenchymal cells, which should acquire a dermal fate, instead react to the excess PTHrP by becoming mammary mesenchyme (Dunbar et al., 1999).

As demonstrated by these studies, PTHrP signaling is essential for mammary gland formation in rodents. When the mammary gland begins to form, PTH1R is expressed in all of the mesenchymal cells underneath the epidermis, but PTHrP is expressed only within the mammary epithelial buds and not within the epidermis itself (Karmali et al., 1992; Thiede and Rodan, 1988; Wysolmerski et al., 1998). As the mammary bud grows down into the mesenchyme, PTHrP, produced by mammary epithelial cells, interacts over short distances with PTH1R on the immature mesenchymal cells closest to the epithelial bud and triggers these cells to differentiate into mammary mesenchyme. PTHrP accomplishes this, at least in part, by upregulating expression of BMP receptors on the mesenchymal cells and sensitizing them to respond in an autocrine fashion to BMP4 expressed in the ventral surface of the embryo (Hens et al., 2007). In this way, PTHrP acts as a patterning molecule contributing to the formation of small patches of mammary-specific stroma around the mammary buds and within the surrounding sea of presumptive dermis (Fig. 36.1; Foley et al., 2001). The process of differentiation set in motion by PTHrP signaling is critical to the ability of the mammary-specific stroma to direct further morphogenesis of the epithelium and to inhibit hair follicle development in the vicinity of the developing nipple. In the absence of this signaling, the mesenchyme can neither destroy the epithelial bud in response to androgens nor trigger the outgrowth of the bud and the initiation of branching morphogenesis (Dunbar et al., 1998, 1999a; Wysolmerski et al., 1998).

Although the model described earlier was developed from studies in mice, PTHrP is also critical to the formation of breast tissues in human fetuses. Blomstrand's chondrodysplasia is a fatal form of dwarfism caused by null mutations of the PTH1R gene (Jobert et al., 1998) (see Chapter 44). Affected fetuses have skeletal abnormalities similar to those caused by deletion of the PTHrP and PTH1R genes in mice (see Chapter 15) and in addition lack breast tissue and nipples (Wysolmerski et al., 1999). In normal human fetuses, the PTHrP gene is expressed within the mammary epithelial bud, and

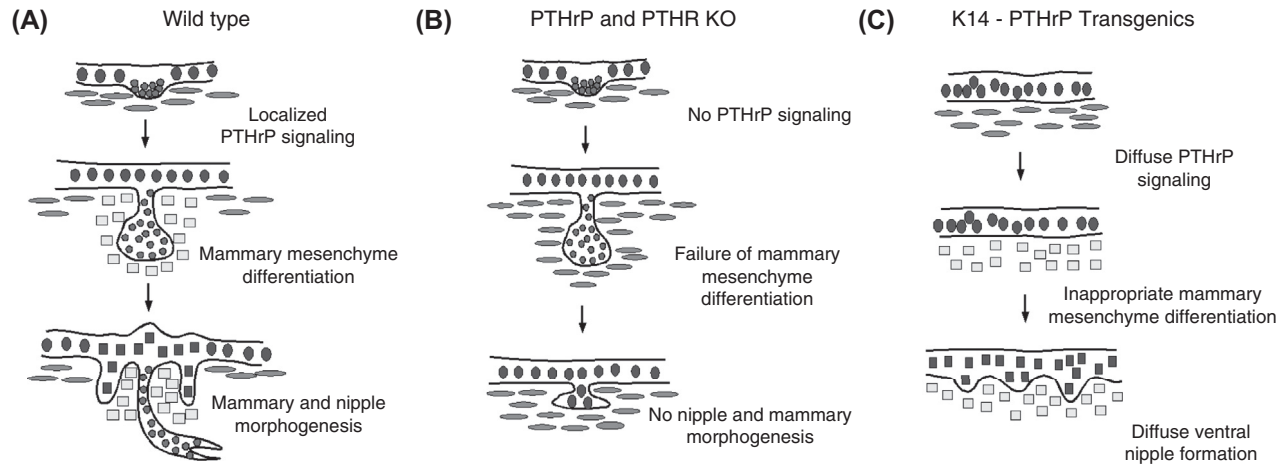

FIGURE 36.1 Model for the regulation of cell fate by PTHrP signaling during mammary gland and nipple development. (A) Normally, the mammary epithelial cells (small circles) express PTHrP after the bud starts to form. PTHrP signals to the dermal mesenchyme (ovals) near the developing bud, and as a result, these cells become mammary mesenchyme (light squares). The mammary mesenchyme maintains the mammary fate of the epithelial cells, triggers their morphogenesis, and induces the overlying epidermis (upright ovals) to become the nipple (dark squares). (B) In the absence of PTHrP signaling, no mammary mesenchyme is formed. Therefore, the mammary epithelial cells revert to an epidermal fate, no morphogenesis occurs, and the nipple does not form. (C) In the presence of diffuse PTHrP signaling, the entire ventral dermis becomes mammary mesenchyme, and the ventral epidermis becomes nipple sheath. *Reproduced from Foley, J., Dann, P., Hong, J., Cosgrove, J., Dreyer, B., Rimm, D., Dunbar, M. E., Philbrick, W., Wysolmerski, J.J., 2001. Parathyroid hormone-related protein maintains mammary epithelial fate and triggers nipple skin differentiation during embryonic mammary development. Development 128, 513−525, with permission.*

the PTH1R gene is expressed in surrounding mesenchyme (Wysolmerski et al., 1999; Cormier et al., 2003). Therefore, in humans as in mice, epithelial-to-mesenchymal PTHrP-to-PTH1R signaling is essential to the formation of the embryonic mammary gland.

Adolescent mammary development

After birth, the murine mammary gland undergoes little development until the onset of puberty. At that point, in response to hormonal changes, the distal ends of the mammary ducts form specialized structures called terminal end buds. These structures serve as sites of cellular proliferation and differentiation during a period of active growth that gives rise to the typical branched duct system of the mature virgin gland (Daniel and Silberstein, 1987). Once formed, the ductal tree remains relatively unchanged until pregnancy when another round of hormonal stimulation induces the formation of the alveolar units that produce milk.

Similar to findings in the embryonic mammary gland, during puberty PTHrP is a product of mammary epithelial cells, and PTH1R is expressed in stromal cells (Dunbar et al., 1998). However, the structure of the pubertal gland is more complex than that of the embryonic gland, and here there are conflicting data regarding the localization of PTHrP and the PTH receptor. Although there is general agreement that PTHrP is expressed in epithelial cells in the postnatal gland, there is some disagreement regarding the specific epithelial compartments in which PTHrP is found. Studies employing in situ hybridization in mice have suggested that after birth, the overall levels of PTHrP gene expression in mammary ducts are reduced except in the terminal end buds during puberty (Dunbar et al., 1998). In these structures, appreciable amounts of PTHrP mRNA were detected in the peripherally located cap cells. In other parts of the gland there was little, if any, specific hybridization for PTHrP. In contrast, studies looking at mature human and canine mammary glands using immunohistochemical techniques have suggested that PTHrP can be found in both luminal epithelial and myoepithelial cells throughout the ducts (Grone et al., 1994; Liapis et al., 1993). Furthermore, studies using cultured cells have suggested that PTHrP is produced by luminal and myoepithelial cells isolated from normal glands (Ferrari et al., 1992; Seitz et al., 1993; Wojcik et al., 1999). Fewer reports have looked at the localization of PTH1R expression in the postnatal mammary gland, but as in embryological development, it is expressed in the mammary stroma (Dunbar et al., 1998). In situ hybridization studies have found the highest concentration of PTH1R mRNA in the stroma immediately surrounding terminal end buds during puberty (Dunbar et al., 1998). This same study found lower levels of PTH1R mRNA distributed generally within the fat pad stroma but very little expression in the dense stroma surrounding the more mature ducts. In addition, these investigators found no evidence of PTH1R mRNA in freshly isolated epithelial cells (Dunbar et al., 1998). In contrast, other studies have suggested that PTH1R is expressed in cultured luminal epithelial and myoepithelial cells (Seitz et al., 1993; Wojcik et al., 1999) as well as in cultured breast cancer cell lines (Birch et al., 1995). In summary, during puberty PTHrP and its receptor are found predominantly within the terminal end buds, with PTHrP localized to the epithelium and PTH1R localized in the stroma. It remains an open and interesting question whether, at some time during mammary ductal development, epithelial cells express low levels of PTH1R.

Studies in transgenic mice have suggested that PTHrP regulates mammary morphogenesis during puberty. Overexpression of PTHrP in mammary epithelial cells using the K14 promoter results in an impairment of ductal branching morphogenesis (Wysolmerski et al., 1995). There are two aspects to the defect. First, the terminal end buds advance through the mammary fat pad at a significantly slower rate than normal. Second, there is a severe reduction in the branching complexity of the ductal tree. As seen in Fig. 36.2, this results in a spare and stunted epithelial duct system. Experiments altering the timing and duration of PTHrP overexpression in the mammary gland using a tetracycline-regulated K14-PTHrP transgene have demonstrated that the two aspects of this pubertal phenotype appear to represent separate functions of PTHrP. The branching (or patterning) defect results from embryonic overexpression of PTHrP, whereas the ductal elongation defect is a function of overexpression of PTHrP during puberty (Dunbar et al., 2001). These effects on ductal patterning provide further evidence of the importance of PTHrP as a regulator of embryonic mammary development. In addition, the localization patterns for PTHrP and PTH1R during puberty, combined with the effects of pubertal overexpression of PTHrP on ductal growth, suggest that PTHrP also functions later in mammary development. During puberty it appears to modulate the epithelial−mesenchymal interactions that govern ductal elongation.

Pregnancy and lactation

Mammary epithelial cells only reach their fully differentiated state during lactation. Under hormonal stimulation during pregnancy, there is a massive wave of epithelial proliferation and morphogenesis that gives rise to multiple terminal ductules and alveolar units. During the later stages of pregnancy, the epithelial cells fully differentiate and then begin to

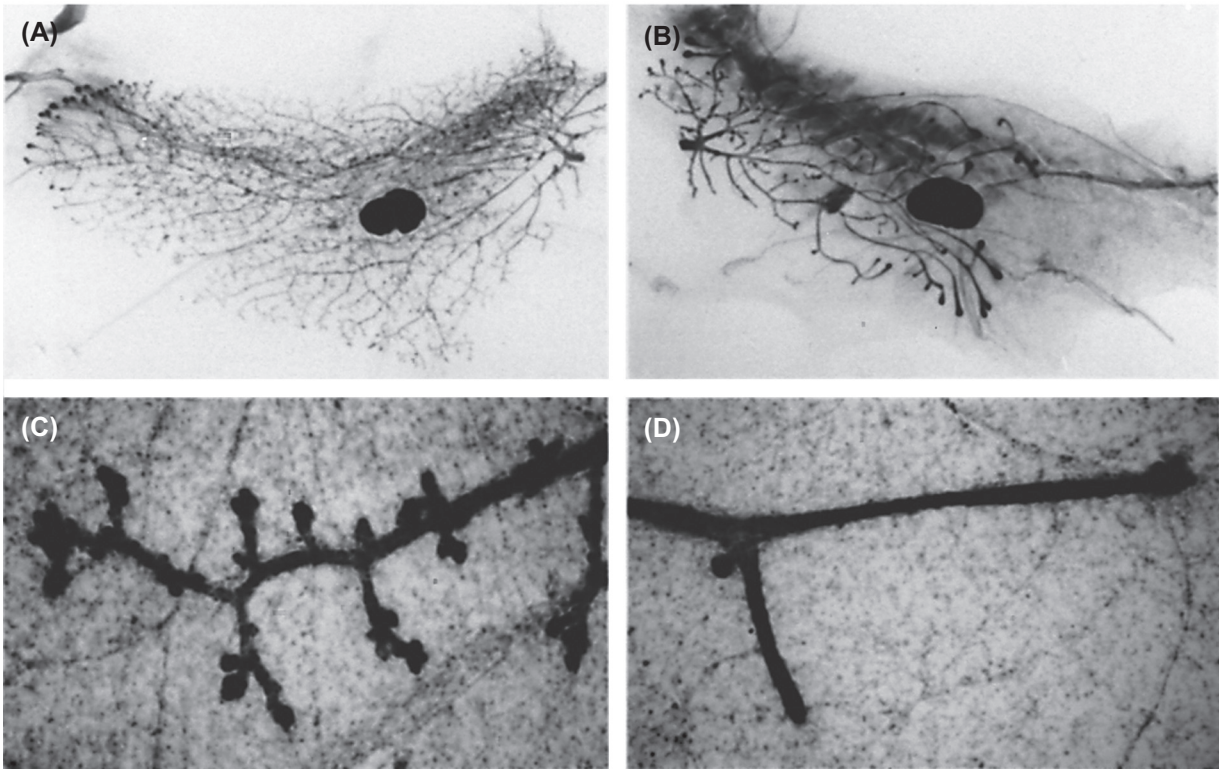

FIGURE 36.2 Overexpression of PTHrP in the mammary gland of K14-PTHrP transgenic mice antagonizes ductal elongation and branching morphogenesis during puberty. **A** and **B** represent typical whole-mount analyses of the fourth inguinal mammary glands from wild-type (A) and K14-PTHrP transgenic mice (B) at 6 weeks of age. The dark oval in the center of each gland is a lymph node. Growth of the ducts during puberty is directional, and each gland is arranged so that the primary duct (the origin of the duct system) is toward the center of the figure. Note that overexpression of PTHrP results in an impairment of the elongation of the ducts through the fat pad as well as a dramatic reduction of the branching complexity of the ductal tree. **C** and **D** represent higher magnifications of a portion of the ducts from the wild-type (C) and transgenic (D) glands demonstrating the reduction in side branching caused by overexpression of PTHrP. *Modified from Wysolmerski, J.J., McCaughern-Carucci, J.F., Daifotis, A.G., Broadus, A.E., Philbrick, W.M., 1995. Overexpression of parathyroid hormone-related protein or parathyroid hormone in transgenic mice impairs branching morphogenesis during mammary gland development. Development 121, 3539–3547 with permission.*

secrete milk during lactation. By the time lactation commences, the fatty stroma of the mammary gland is almost completely replaced by actively secreting alveoli. Upon completion of lactation, widespread apoptosis of the differentiated epithelial cells occurs, and the gland remodels itself into a duct system similar to that of the virgin animal (Daniel and Silberstein, 1987).

Localization studies in humans, rodents, and cows have all noted epithelial cells to be the source of PTHrP in the mammary gland during pregnancy and lactation (Liapis et al., 1993; Wojcik et al., 1998, 1999; Rakopoulos et al., 1992). Based on the assessment of whole-gland RNA, PTHrP expression appears to be upregulated at the start of lactation under the control of both local and systemic factors (Philbrick et al., 1996; Thiede and Rodan, 1988; Thiede, 1989; Thompson et al., 1994; Buch et al., 1992). Thiede and Rodan (1988) and Thiede (1989) originally reported that PTHrP expression in rats is dependent on suckling and on serum prolactin concentrations. However, prolactin must serve only as a permissive factor, for additional studies have shown that the suckling response is a local one and that PTHrP only rises in the milked gland (Thompson et al., 1994). Furthermore, overall PTHrP expression increases gradually over the course of lactation, and in later stages its expression becomes independent of serum prolactin levels (Bucht et al., 1992). Serotonin is now recognized as playing an important role in local control of PTHrP production by mammary tissue (Hernandez et al., 2012; Marshall et al., 2014). It is clear that much of the PTHrP made during lactation ends up in milk, in which levels of PTHrP are up to 10,000-fold higher than in the circulation of normal individuals and 1000-fold higher than in patients suffering from HHM (Philbrick et al., 1996). PTHrP concentrations in milk have generally been found to mirror RNA levels in the gland, increasing over the duration of lactation and rising acutely with suckling (Thompson et al., 1994; Yamamoto et al., 1991; Law et al., 1991; Goff et al., 1991). In addition, evidence shows that PTHrP levels may vary with the calcium content of milk (Yamamoto et al., 1992a; Law et al., 1991; Goff et al., 1991; Uemura et al., 1997; Kovacs and Kronenberg, 1997; Kovacs, 2016). In mice, the

calcium-sensing receptor (CaR) is expressed on the basolateral surface of mammary epithelial cells during lactation and regulates PTHrP production such that increased delivery of calcium to the mammary gland decreases PTHrP production and secretion into milk (VanHouten et al., 2004; Ardeshirpour et al., 2006). Selective ablation of CaR within mammary tissue results in locally increased PTHrP production and increased milk PTHrP content (Mamillapalli et al., 2013). Finally, in mice, PTHrP mRNA levels are promptly downregulated during the early stages of involution and then increase to prelactation levels about a week into the remodeling process (Wysolmerksi et al., 2008).

In contrast to PTHrP, little study has been made of the expression and regulation of PTHrP receptors during pregnancy and lactation. In early pregnancy, the PTH/PTHrP receptor is expressed at low levels in the stroma surrounding the developing alveolar units (Dunbar et al., 1998). Studies using whole-gland RNA demonstrate a reciprocal relationship between PTH1R and PTHrP mRNA levels. That is, as PTHrP expression rises during lactation, PTH1R mRNA levels decrease, and as PTHrP mRNA levels fall during early involution, PTH1R expression increases to its former level (Wysolmerski et al., 2008). This may represent active downregulation of the receptor by PTHrP or may simply reflect the changing amount of stroma within the gland at these different stages. However, in a study of cells isolated from lactating rats, it was suggested that epithelial cells, as well as stromal cells, express this receptor (Wojcik et al., 1999), so the regulation of PTH1R expression during pregnancy and lactation may be complex.

Initial reports of the presence of PTHrP in the mammary gland and milk prompted a great deal of speculation regarding its functions in breast tissue during lactation. These proposals revolved around four general hypotheses that PTHrP may be involved in (1) maternal calcium homeostasis and the mobilization of calcium from the maternal skeleton; (2) regulating vascular and/or myoepithelial tone in the lactating mammary gland; (3) transepithelial calcium transport into milk; and (4) neonatal calcium homeostasis or neonatal gut physiology. As will be discussed, there is support for all four hypotheses. The function of PTHrP in the lactating mammary gland in mice was addressed by disrupting the PTHrP gene solely in mammary epithelial cells during lactation (VanHouten et al., 2003). This experiment has supplied evidence to support the role of PTHrP in regulating maternal and neonatal calcium and bone metabolism and has shown that PTHrP plays an indirect role in mediating calcium transport into milk. This point was made clearer in experiments that used calcimimetic drugs or ablated CaR from mammary epithelial cells and found that this increased the mammary production of PTHrP and milk calcium content. It appears that PTHrP's role during lactation is a systemic one to maintain the supply of calcium to the breast tissue that supports milk production, whereas the transport of calcium into milk is locally controlled by CaR and other factors (VanHouten et al., 2004; Ardeshirpour et al., 2006; Mamillapalli et al., 2013; Kovacs, 2016).

Milk production requires a great deal of calcium, and providing an adequate supply to the mammary gland stresses maternal bone and mineral metabolism (Kovacs and Kronenberg, 1997; Kovacs, 2016). Some of the calcium required for milk comes from the diet, as calcium intake is increased owing to the orexigenic effects of suckling (Smith and Grove, 2002). In addition, renal reabsorption of calcium is increased during lactation so that urinary losses are reduced. Finally, a significant proportion of the calcium transported into milk is derived from the maternal skeleton, through the processes of osteoclast-mediated bone resorption and osteocytic osteolysis (Kovacs, 2016). All three processes (intestinal calcium absorption, renal calcium conservation, and skeletal resorption) are stimulated in part by PTHrP. The interplay between intestinal calcium absorption, renal calcium conservation, and skeletal resorption is best illustrated in the rodent, which requires both increased intestinal calcium absorption *and* increased skeletal resorption in order to provide the calcium needed to milk. Increasing the calcium content of the diet causes increased renal calcium excretion and blunts skeletal resorption, whereas a low-calcium diet causes a marked increase in skeletal resorption and reduced renal calcium excretion (Kovacs, 2016). The combination of a low-calcium diet and the use of an antiresorptive medication to block skeletal resorption leads to reduced milk calcium content, tetany, and sudden death of lactating rodents (Kovacs, 2016). In contrast to rodents, intestinal calcium absorption is normal during lactation in women, and low and high intakes of calcium do not influence the magnitude of skeletal resorption during lactation (Kovacs, 2016). Instead, during human lactation, the extent of skeletal resorption appears to be programmed by the intensity of lactation, which in turn determines the production of PTHrP. Breast milk output predicts the rise in PTHrP, and both parameters predict the magnitude of bone mineral density lost during lactation (Kovacs, 2016).

Overall rates of bone turnover are elevated during lactation, but bone resorption and formation are uncoupled, such that bone resorption outstrips bone formation to cause a rapid decline in bone mass. The average nursing woman loses between 5% and 10% of her bone mass over 6 months, especially from the trabecular spine (Kovacs, 2016), whereas rodents lose up to one-third of their skeletal mass over 21 days of lactation (VanHouten and Wysolmerski, 2003). Mobilization of skeletal calcium during lactation does not rely on any of the established calcium-regulating hormones, PTH, 1,25(OH)2D, or calcitonin (Kovacs and Kronenberg, 1997; Kovacs, 2016). Multiple investigations have confirmed that bone resorption is increased because of the combination of decreased systemic estradiol concentrations and elevated circulating PTHrP levels. Suckling directly inhibits hypothalamic gonadotropin-releasing hormone (GnRH) secretion and induces hypogonadotropic

hypogonadism (Smith and Grove, 2002). Bone loss correlates with the duration of amenorrhea in nursing women; however, the intensity of lactation predicts bone loss and the duration of amenorrhea, and bone loss has been shown to continue in women whose menses resume despite ongoing intense lactation (Kovacs, 2016). Pharmacological treatment with estradiol in lactating mice reduced bone loss by 60% (VanHouten and Wysolmerski, 2003); however, the resulting estradiol levels were fivefold higher than normal and may therefore indicate suppressed bone loss from the known pharmacological effects of estradiol rather than implicating that estradiol deficiency accounts for 60% of the bone loss that normally occurs during lactation.

Many studies have now documented elevated circulating PTHrP levels in lactating humans and rodents (Kovacs and Kronenberg, 1997; Kovacs, 2016), and PTHrP levels correlate directly with biochemical markers of bone resorption and inversely with bone mass in lactating mice (VanHouten and Wysolmerski, 2003). In addition, circulating PTHrP levels have been shown to correlate with bone density changes in lactating humans (Sowers et al., 1996). Furthermore, there have been multiple case reports of pseudohyperparathyroidism during pregnancy and lactation, in which PTHrP secretion by breasts was determined to have caused hypercalcemia with high plasma concentrations of PTHrP (see below) (Kovacs, 2016). In normal lactating women who have been followed longitudinally, the albumin-corrected serum calcium and ionized calcium rise significantly but stay within the normal range, whereas serum phosphorus rises above normal, with these effects implying the release of calcium and phosphorus from bone (Kovacs, 2016). Therefore, the condition of pseudohyperparathyroidism may represent one extreme of the normal physiology of lactation, in which PTHrP's effects to increase bone resorption lead to an increase in the circulating calcium concentration.

When the PTHrP gene was disrupted specifically in the lactating mammary gland in mice, circulating PTHrP levels declined, milk PTHrP became unmeasurable, rates of bone resorption decreased, and bone loss was reduced by 50% (VanHouten et al., 2003). The circulating PTHrP level remained above nonpregnant values; moreover, the mice developed significant secondary hyperparathyroidism, which would have supported ongoing bone resorption despite lower circulating PTHrP. Similarly, loss of the gene encoding calcitonin led to a doubling of bone loss during lactation, increased milk calcium content, increased PTHrP, and marked secondary hyperparathyroidism (Woodrow et al., 2006; Collins et al., 2013; Kovacs, 2016). Thus, it is now clear that the lactating mammary gland secretes PTHrP into both milk and the circulation, and that secondary hyperparathyroidism can contribute to increasing skeletal resorption during lactation when the demand for skeletal calcium is particularly high or PTHrP is absent. Systemic PTHrP from the breast acts together with estrogen deficiency to stimulate bone resorption and cause bone loss during lactation. As noted previously, the production of PTHrP by the lactating breast is decreased by stimulation of the CaR on mammary epithelial cells (VanHouten et al., 2004).

Fig. 36.3 displays the "breast−brain−bone" circuit, a classic endocrine feedback loop during lactation in which the mammary gland functions as an "accessory" parathyroid gland. It uses PTHrP instead of PTH to ensure an adequate flow of calcium from the maternal skeleton to make milk. If calcium delivery to the gland falls, mammary epithelial cells produce more PTHrP, which stimulates increased bone resorption. The delivery of more calcium to the mammary gland from the skeleton then stimulates the CaR and decreases PTHrP production. But milk production is controlled mainly by suckling on demand, which in turn can provoke maternal hypocalcemia (milk fever in animals) and secondary hyperparathyroidism.

Genetic removal of PTHrP from the mammary gland does not alter milk calcium levels, and PTHrP-null mammary epithelial cells are able to transport calcium in vitro at the same rate as wild-type mammary epithelial cells (VanHouten et al., 2003). Thus, unlike the placenta (see later), it does not appear that PTHrP directly contributes to the regulation of transepithelial calcium transport in the mammary gland. However, as mentioned earlier, the marked secondary hyperparathyroidism that developed in that model would have supported calcium delivery to the mammary tissues despite the absence of PTHrP's normal effects, and the circulating PTHrP level was still elevated during lactation over its nonpregnancy values. Multiple human studies have found that milk calcium content correlates with the content of PTHrP, which is consistent with PTHrP's function to supply calcium to mammary tissue, even if it does not directly stimulate pumping of calcium into milk from mammary epithelial cells (Kovacs, 2016).

The function of PTHrP in milk remains an open question. Murine pups that receive PTHrP-deleted milk accrete more skeletal mineral content over the first 12 days after birth (Mamillapalli, 2013), which suggests that PTHrP within milk may modulate either intestinal calcium absorption or skeletal mineral accretion in neonatal mice. Whether PTHrP in milk is absorbed into the neonatal circulation is an unresolved question, but some animal studies have suggested that it is absorbed intact, and might therefore have effects on the skeletal and mineral metabolism in the neonate (Kovacs, 2016). Further work is needed to understand the role of PTHrP in milk.

Another potential function of PTHrP during lactation is the regulation of vascular and/or myoepithelial cell tone. As discussed in Chapter 26, PTHrP has been shown to modulate smooth muscle cell tone in a variety of organs, including the vascular tree, where it acts as a vasodilator. Consistent with these effects, two studies have shown that PTHrP increases

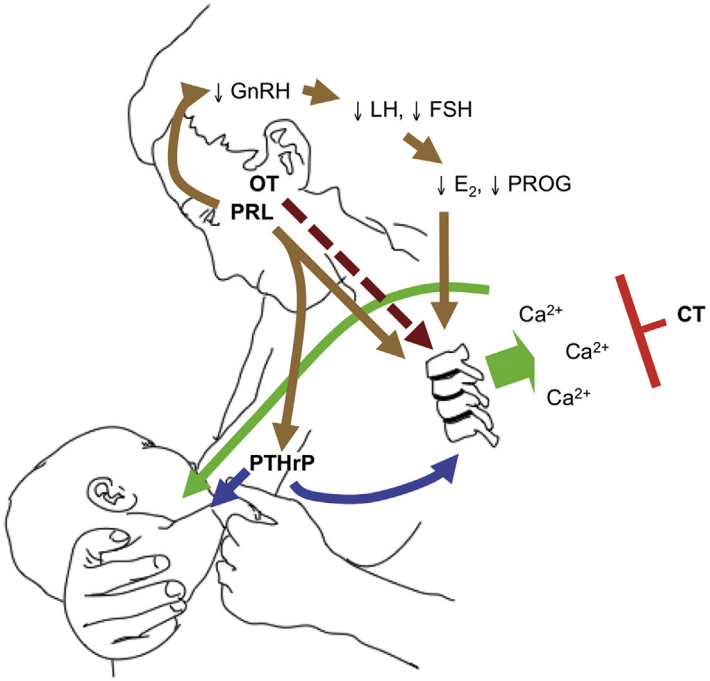

FIGURE 36.3 Breast–Brain–Bone circuit controls lactation. Suckling and prolactin [PRL] both inhibit the hypothalamic GnRH pulse center, which in turn suppresses the gonadotropins (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), leading to low levels of the ovarian sex steroids (estradiol [E_2] and progesterone [PROG]). Prolactin may also have direct effects on its receptor in bone cells. PTHrP production and release from the breast are stimulated by suckling, prolactin, low estradiol, and the calcium receptor. PTHrP enters the bloodstream and combines with systemically low estradiol levels to markedly upregulate bone resorption and (at least in rodents) osteocytic osteolysis. Increased bone resorption releases calcium and phosphate into the blood stream, which then reaches the breast ducts and is actively pumped into the breast milk. PTHrP also passes into milk at high concentrations, but whether swallowed PTHrP plays a role in regulating calcium physiology of the neonate is uncertain. In addition to stimulating milk ejection, oxytocin may directly affect osteoblast and osteoclast function (dashed line). Calcitonin may inhibit skeletal responsiveness to PTHrP and low estradiol given that mice lacking calcitonin lose twice the amount of bone during lactation as normal mice. Not depicted is that calcitonin may also act on the pituitary to suppress prolactin release, and within breast tissue to reduce PTHrP expression and lower the milk calcium content (see text). *Adapted with kind permission from Kovacs, C.S., 2005a. Calcium and bone metabolism during pregnancy and lactation. J. Mammary Gland Biol. Neoplasia 10 (2), 105–118, © Springer Science and Business Media B.V.*

mammary blood flow during lactation (Davicco et al., 1993; Thiede et al., 1992). The injection of amino-terminal fragments of PTHrP into the mammary artery of dried (nonlactating) ewes was shown to increase mammary blood flow and override the vasoconstrictive effects of endothelin (Davicco et al., 1993). Thiede and colleagues (1992) have demonstrated that the nutrient arteries of the inguinal mammary glands of rats secrete PTHrP and that its production is responsive to suckling and prolactin. Myoepithelial cells in the breast are similar in some ways to vascular smooth muscle cells and are thought to participate in the control of milk ejection by contracting in response to oxytocin (Daniel and Silberstein, 1987). Therefore, it is interesting that myoepithelial cells in culture have been shown to express PTH1R and to respond to PTHrP by elevating intracellular cAMP (Seitz et al., 1993; Wojcik et al., 1999). Furthermore, mirroring the effects of PTHrP on the endothelin-induced contraction of vascular smooth muscle, PTHrP has been shown to block the rise in intracellular calcium normally induced in response to oxytocin in myoepithelial cells (Seitz et al., 1993).

Pathophysiology of parathyroid hormone-related protein in the mammary gland

PTHrP may contribute to pathophysiology in the human breast in several instances. First, as noted previously, fetuses afflicted with Blomstrand's chondrodystrophy lack nipples and breast tissue (Wysolmerski et al., 1999). Second, some cases of PTHrP-mediated hypercalcemia during pregnancy or lactation (pseudohyperparathyroidism) have been reported to be associated with elevations in circulating levels of PTHrP (Khosla et al., 1990; Reid et al., 1992; Kovacs, 2016). Additional cases of pseudohyperparathyroidism have been caused by the placental production of PTHrP; see later. One of these cases was caused by massive breast hyperplasia, and after reduction mammoplasty, the patient's hypercalcemia and elevated PTHrP levels both resolved (Khosla et al., 1990). However, large breasts are not a requirement for pseudohyperparathyroidism to occur. A related aspect is that the production of PTHrP by the lactating mammary gland

leads to normalization of mineral and bone metabolism in hypoparathyroid women who breastfeed (Kovacs, 2016). In some cases, hypercalcemia has developed when exogenous use of calcitriol and calcium supplements has not been stopped in advance of lactation in these hypoparathyroid women. Finally, the area with the greatest potential impact on human health is the relationship of PTHrP production to breast cancer. This is evolving into a complicated topic and will be addressed only briefly here. However, it will be reviewed in more depth in Chapters 55 and 56.

It is well documented that PTHrP is produced by a number of primary breast carcinomas and that this sometimes leads to classical HHM (Isales et al., 1987). A potentially more widespread role may be the involvement of PTHrP in the osteotrophism of breast cancer (Guise et al., 1996; Yin et al., 1999). Animal models have suggested that PTHrP production by breast tumor cells is important to their ability to form skeletal metastases (Guise et al., 1996; Yin et al., 1999). However, there is conflicting evidence as to whether PTHrP production by a primary breast tumor is predictive of bone metastases in patients (Bundred et al., 1996; Henderson et al., 2001, 2006). The largest and most carefully controlled study suggested that PTHrP production by the primary tumor is actually a negative rather than positive predictor of skeletal metastases (Henderson et al., 2006). It may be that PTHrP production does not enable a tumor cell to get into the skeleton, but once there, the ability of tumor cells to upregulate PTHrP production within the bone microenvironment becomes important to their ability to grow in the skeleton (Yin et al., 1999). Several studies suggest that TGF-β released from the bone matrix during bone resorption may be particularly important in stimulating PTHrP production (Kakonen et al., 2002). More PTHrP would in turn be expected to increase osteoclast activity and release more TGF-β, setting up a potential feed-forward vicious cycle that may be important in the pathogenesis of bone destruction around the metastatic tumor.

There is a growing literature suggesting that PTHrP may also be important in controlling breast cancer cell proliferation, apoptosis, migration, and invasion. Although it is unclear whether normal mammary epithelial cells express significant levels of the PTH1R, it appears that many breast cancer cell lines do so (Birch et al., 1995). Some of the effects ascribed to PTHrP appear to be mediated by this receptor, but some appear to be mediated by midregion PTHrP fragments acting either through intracrine mechanisms or perhaps via a specific midregion PTHrP cell-surface receptor (Shen et al., 2004; Kumari et al., 2006; Shen and Falzon, 2006; Dittmer et al., 2006; Sirchia et al., 2007). In either case, the effects of midregion PTHrP apparently require that this portion of the peptide enter the nucleus via a distinct bipartite nuclear localization signal. In particular, several studies have suggested that midregion PTHrP fragments may promote cell migration by regulating α6β4 integrin expression through nuclear effects (Shen et al., 2003; Dittmer et al., 2006; Shen and Falzon, 2006). Despite these intriguing findings, at this point it is not clear whether these effects are artifacts of cell lines or will prove to be clinically relevant. Most studies in cell lines suggest that PTHrP expression by a breast tumor would contribute to increased aggressiveness or a tendency to metastasize.

However, animal models have provided seemingly contradictory data regarding PTHrP's potential influence on breast cancer tumor progression. Deletion of PTHrP promoted tumor progression in the *Neu* mouse model of spontaneous tumor development (Fleming et al., 2009), while deletion of PTHrP in the MMTV-PyMT mouse model had the opposing effect of preventing tumor progression (Li et al., 2011). These mouse studies make it unclear as to whether it would be beneficial or harmful to inhibit PTHrP expression in the primary tumors of patients with breast cancer.

On the other hand, human studies have suggested that expression of PTHrP by the primary breast tumor has beneficial effects on multiple outcomes. In the large prospective clinical study of Henderson and colleagues mentioned previously (Henderson et al., 2001, 2006), in which patients were assessed 5 and 10 years after surgery, PTHrP expression by a primary breast tumor was clearly a marker of a less aggressive course correlating with estrogen and progesterone receptor positive status, increased survival, lower rates of recurrence, and lower rates of all metastases (not just bone metastases). An analysis of the METABRIC dataset within The Cancer Genome Atlas breast cancer dataset revealed that expression of the human PTHrP gene, *PTHLH*, was upregulated (not downregulated) at the mRNA level or amplified in breast cancer patients (R.J. Johnson, A.W. Freeman and T.J. Martin, unpublished, 2018). Furthermore, patients with mRNA upregulation of *PTHLH* had significantly increased overall survival. Similar results have been gleaned from other gene expression surveys in breast cancer (www.oncomine.org; Rhodes et al., 2004). Further in vivo studies are clearly needed, but the available human data suggest that inhibiting PTHrP expression in primary breast cancers may be harmful rather than beneficial.

Reproductive tissues

Parathyroid hormone-related protein and placental calcium transport

Nearly all the calcium, and a large proportion of inorganic phosphate (85%) and magnesium (70%), transferred from mother to fetus is associated with development and mineralization of the fetal skeleton (Grace et al., 1986). The bulk of placental calcium transfer occurs rapidly over a short interval late in gestation, such that 80% occurs in the third trimester in

humans (Givens and Macy, 1933), and 96% occurs in the last 5 days of gestation in the rat (Comar, 1956). The concentrations of both total and ionized Ca in all mammalian fetuses studied during late gestation have been observed to be higher than maternal levels. As a result of studies in which the sheep was used extensively for the study of fetal calcium control, one of the first suggested physiological roles of PTHrP was that of regulating the transport of calcium from mother to fetus in the mammal, thereby making calcium available to the growing fetal skeleton (Rodda et al., 1988).

Immunoreactive PTH levels were found to be low in fetal lambs, whereas PTH-like biological activity in serum was high (Care et al., 1985), suggesting the presence of another PTH-like substance. Similar findings of low PTH and high PTHrP have been demonstrated in multiple studies of fetal mice and human cord blood (Kovacs, 2003, 2016). Parathyroidectomy in the fetal lamb resulted in loss of the calcium gradient that exists between mother and fetus as well as impairment of bone mineralization, implicating parathyroids as the source of the regulatory agent. Crude, partially purified, or recombinant PTHrP, but neither PTH nor maternal parathyroid extract that contained no immunoreactive PTHrP, restored the gradient (Rodda et al., 1988). Thus, PTHrP appeared to be the active component of the fetal parathyroid glands responsible for maintaining fetal calcium levels and suppressing fetal PTH levels. In support of this hypothesis, immunoreactive PTHrP was found to be readily detectable in sheep fetal parathyroids from the time they form (MacIsaac et al., 1991) and was also found in early placenta, suggesting that the latter tissue may be a source of PTHrP for calcium transport early in gestation.

The portion of PTHrP that appears to be responsible for regulating placental calcium transport lies between residues 67 and 86 (Care et al., 1990), but the responsible receptor has not yet been identified. Although syncytiotrophoblasts are believed to be central in the transport of calcium to the fetus, cytotrophoblasts (which differentiate to form the syncytium) are believed to be the calcium-sensing cells, and raising the extracellular calcium concentration has been shown to inhibit PTHrP release from these cells (Hellman et al., 1992). The CaR has been localized to cytotrophoblasts of human placenta (Bradbury et al., 1997), and the work of Kovacs et al. (1998) has implicated it in placental calcium transport. Specifically, ablation of CaR reduced placental calcium transport, and this was accompanied by a reduction in plasma PTHrP (Kovacs et al., 1998). Furthermore, a calreticulin-like calcium-binding protein has been isolated from trophoblast cells, and its expression is increased by treatment with PTHrP(67−84) but not with N-terminal PTHrP (Hershberger and Tuan, 1998).

Although these observations are strongly suggestive of involvement of PTHrP and the CaR, the mechanisms of placental calcium transport are still not fully understood. Support for the role of PTHrP also comes from the PTHrP gene knockout mouse, in which placental calcium transport is severely impaired (Kovacs et al., 1996). In mice homozygous for deletion of the PTHrP gene, fetal plasma calcium and maternal−fetal calcium gradient were significantly reduced. When fetuses were injected in utero with fragments of PTHrP or PTH, calcium transport was significantly restored only by treatment with a midmolecular region of PTHrP that does not act via PTH1R. Furthermore, in mice rendered null for the PTH1R gene, placental calcium transport was increased, and PTH1R-null fetuses had plasma PTHrP levels more than 10 times higher than controls (Kovacs et al., 2001). The circulating PTHrP in the fetal mice was found to be derived from several tissues, including liver and placenta, but parathyroids were excluded as a source of PTHrP in this setting (Kovacs et al., 2001). Additional studies confirmed that mice lacking parathyroid glands or parathyroid hormone did not have an alteration in circulating PTHrP, nor was placental calcium transport reduced, although the absence of fetal PTH was associated with an even greater reversal of the maternal−fetal calcium gradient than that induced by loss of PTHrP (Kovacs et al., 2001; Simmonds et al., 2010). These findings indicate that fetal parathyroids may not be a source of circulating PTHrP and are compatible with an earlier detailed examination of normal fetal rat parathyroids that found no detectable PTHrP by in situ hybridization, RT-PCR, and immunohistochemistry (Tucci et al., 1996).

Additional support for the role of PTHrP is that placental expression of PTHrP was increased in two different models in which the vitamin D receptor is ablated, and in both studies placental calcium transport was also increased (Kovacs, 2005b; Lieben, 2013).

Study of mice lacking the gene encoding PTH enabled the detection of a low level of expression of PTH mRNA in the murine placenta and alterations in the expression of genes involved in cation transport (Simmonds et al., 2010). Exogenous PTH administration also stimulated placental calcium transport in *Pth*-null fetuses but not in WT fetuses within the same litters (Simmonds et al., 2010). Therefore, the placenta appears to be an ectopic site of low-level PTH expression, but whether this has an important influence on fetal−placental mineral homeostasis in normal mice is unknown. Furthermore, whether PTH is expressed at all in the human placenta has not been examined with modern methods.

Overall, conclusions from the murine studies are similar in many respects to those in sheep, namely that PTHrP contributes to fetal skeleton calcium supply by controlling maternal−fetal calcium transport through actions mediated by a midmolecule portion of the PTHrP molecule. The murine and sheep studies differ in that the parathyroids do not appear to be a dominant source of PTHrP in rodents; the placenta may be the relevant source of PTHrP that controls placental calcium transfer and the fetal−placental gradient. Murine data support reduced placental calcium transport when PTHrP is

reduced or absent and increased placental calcium transport when circulating PTHrP concentrations or placental PTHrP expression are increased.

Uterus and extraembryonic tissues

The uterus, both pregnant and nonpregnant, is another of the many sites of production and action of PTHrP. The relaxing effect of PTH on uterine smooth muscle had been long recognized (Shew et al., 1984), and it was not surprising that PTHrP had the same effect (Shew et al., 1991). The finding that expression of mRNA for PTHrP in the myometrium during late gestation in the rat was controlled by intrauterine occupancy by the fetoplacental unit raised the possibility of a role for PTHrP in regulating uterine muscle tone (Thiede et al., 1990).

In studies in rats with or without estrogen treatment, protein and mRNA for PTHrP were localized not only in the myometrium, as had been shown in pregnancy (Thiede et al., 1990), but also in the epithelial cells lining the endometrium and endometrial glands. Indeed, the strongest PTHrP production appeared to be in these sites (Paspaliaris et al., 1992), suggesting that the endometrium and endometrial glands might be the major uterine site of PTHrP production and that PTHrP might be a local regulator of endometrial function and myometrial contractility. Estrogen treatment enhanced uterine production of PTHrP, but most significantly, the relaxing effect of PTHrP on uterine contractility in vitro was enhanced greatly by the pretreatment of noncycling rats with estrogen. In keeping with this observation, uterine horns from cycling rats in proestrous and estrous phases of the cycle showed a greater responsiveness to PTHrP than those from noncycling rats. These findings are consistent with a role for PTHrP as an autocrine and/or paracrine regulator of uterine motility and function. Furthermore, they suggest that PTHrP belongs to a class of other locally acting peptides, such as oxytocin, vasoactive intestinal peptide, and relaxin, for which pretreatment of animals with estrogen increases the response of the uterus (Ottesen et al., 1985; Mercado-Simmen et al., 1982; Fuchs et al., 1982).

Further evidence for a specific and regulated role of PTHrP in the uterus during gestation comes from the observation of a temporal pattern in the relaxation response to PTHrP by longitudinal uterine muscle during pregnancy in the rat, with maximal responses at times when estrogen levels would be high. In contrast, the circular muscle did not respond at any stage during gestation (Williams et al., 1994). The inability of PTHrP to relax uterine muscle in the last stages of gestation does not support a direct role in the onset of parturition. Treatment of pregnant rats with intraperitoneal injections of human PTHrP 1−34 resulted in a significant decrease in the expression of connexin-43 (mRNA and protein) and the oxytocin receptor mRNA in the myometrium, but it did not affect the timing of delivery, progesterone in maternal plasma, or levels of c-fos, fra-2, or PTH1R mRNA on any gestational day. These findings are compatible with the hypothesis that PTHrP may act to keep the myometrium quiescent at a time when progesterone levels are falling, but that the effects of PTHrP signaling are overridden by other factors that dictate the onset of labor (Mitchell et al., 2003). This hypothesis is supported by the demonstration (Thiede et al., 1990) that expression of mRNA was dependent on the presence of the fetus and that levels increased throughout pregnancy and decreased sharply after delivery. It seems likely, therefore, that the observed fall in PTHrP reflects the recontracted state of the uterine muscle, consistent with the observation in the bladder (Yamamoto et al., 1992), and that the level of expression is functionally related to contractility. The temporal expression of PTHrP in endometrial glands and blood vessels (Williams et al., 1994) also supports roles in other regulated functions that might include uterine growth during pregnancy and the regulation of uterine and placental blood flow (Mandsager et al., 1994).

Uterine growth restriction was induced in Wistar−Kyoto rats by ligating uterine vessels, and this resulted in a 15% decrease in fetal weight, a 21% decrease in fetal number, and a 46% decrease in placental PTHrP content, but a 2.5-fold increase in uterine PTHrP content (Wlodek et al., 2005). The increase in uterine PTHrP content may be compensatory to increase uteroplacental blood flow. Other studies have demonstrated that the vasodilatory effect of PTHrP on myometrial blood vessels is dependent upon the presence of functional endothelium, and that the effect is likely mediated by nitric oxide (Meziani et al., 2005). Conversely, treatment of pregnant rats with a PTHrP antagonist (PTHrP 7−34) resulted in evidence of growth restriction (reduced fetal weight and placental weight) and apoptosis within placentas (Thoten et al., 2005). Thus, there is some functional evidence to suggest that PTHrP plays a role in regulating uterine blood flow and growth.

Placenta and fetal membranes

PTHrP mRNA and protein have been detected in rat and human placenta in various cell types (Hellman et al., 1992; Germain et al., 1992; Bowden et al., 1994). In addition, neoplastic cells of placental origin secrete PTHrP, including hydatidiform moles and choriocarcinomas in vitro (Deftos et al., 1994). The presence of PTH/PTHrP receptor mRNA has been demonstrated in rat (Urena et al., 1993), mouse (Kovacs et al., 2002), and human (Curtis et al., 1998) placenta, and infusion of PTHrP(1−34) into isolated human placental lobules stimulates cyclic AMP production (Williams et al., 1991).

Three further sets of observations lend support to the hypothesis that PTHrP is involved in placental/uterine interactions and that its most likely role in the placenta and placental membranes is related to the growth and maintenance of the placenta itself during pregnancy. First, PTHrP production by cultured amniotic cells has been shown to be regulated by prolactin, human placental lactogen, transforming growth factor-β (TGF-β), insulin, insulin-like growth factor, and epidermal growth factor (Dvir et al., 1995). Second, PTHrP has been shown to regulate epidermal growth factor receptor expression in cytotrophoblast cultures (Alsat et al., 1993), an event associated with placental development. Third, studies of vascular reactivity in isolated human placental cotyledons preconstricted with a thromboxane A2 mimetic showed PTHrP to be a very effective vasodilator (Macgill et al., 1997). The narrow concentration range to which the tissue responded, together with the desensitization in response to repeated PTHrP infusions, was consistent with a paracrine and/or an autocrine action of PTHrP in human gestational tissues. Adequacy of the fetoplacental circulation is essential for the nutritional demands of the growing fetus, and both humoral and local factors are likely to be important in its control. It is possible that alterations of the expression, localization, and/or action of PTHrP might contribute to the genesis of conditions such as preeclampsia and intrauterine growth retardation in which placental vascular resistance is increased (Gude et al., 1996). Another related and potentially interacting influence is angiotensin II, known to be a powerful enhancer of PTHrP production in the vasculature and in human placental explants (Li et al., 1998). The ability of angiotensin II to stimulate estradiol production in human placental explants through actions upon its AT1 receptor (Kalenga et al., 1995) provides a further link with PTHrP control.

PTHrP has also been shown to regulate the differentiation of cells explanted from the murine placenta. PTHrP treatment reduced proliferation, inhibited apoptosis, and promoted differentiation into trophoblast giant cells. As well, PTHrP treatment induced the expression of transcription factors known to stimulate giant cell formation (Stra13 and AP-2gamma) and inhibited the formation of other trophoblast cell types by suppressing trophoblast progenitors and spongiotrophoblast-promoting factors (Eomes, Mash-2, and mSNA) (El-Hashashetd et al., 2005). Thus, PTHrP likely plays a role in the differentiation of cells during placentation.

The most likely source of increased amniotic fluid PTHrP concentrations during pregnancy is the amnion itself, because PTHrP mRNA expression is also highest at term and greater in the amnion than in choriodecidua or placenta (Bowden et al., 1994; Ferguson et al., 1992; Wlodek et al., 1996). In tissue from women with full-term pregnancies and not in labor, the concentration of N-terminal PTHrP has been found to be higher in amnion covering the placenta than in the reflected amnion covering the decidua parietalis (Bowden et al., 1994). Nevertheless, the concentration of N-terminal PTHrP in reflected amnion (the layer apposed to the uterus) was inversely related to the interval between rupture of the membranes and delivery. The observation that PTHrP levels in the amnion decrease after rupture of the fetal membranes has led to the proposal that PTHrP derived from the membranes may inhibit uterine contraction and that labor may occur following loss of this inhibition. Plasma levels of PTHrP increase threefold during pregnancy and reach even higher levels postpartum (Bertelloni et al., 1994; Gallacher et al., 1994; Ardawi et al., 1997; Yadav et al., 2014) with the likely sources being placenta and breast, respectively. Human fetal membranes have been shown to inhibit contractions of the rat uterus in vitro (Collins et al., 1993), so this tissue does appear to produce factors that can modulate uterine activity. Furthermore, primary cultures of human amniotic cells secrete PTHrP into the medium (Germain et al., 1992). Thus, although the physiological function(s) of amnion-derived PTHrP is currently unknown, preliminary evidence suggests that it may play a role in regulating the onset of labor. It is also possible that amniotic fluid is a source of PTHrP ingested by the fetus and acts as a growth factor in lung and/or gut development. Consistent with this hypothesis, mice lacking PTHrP have immature lungs associated with arrested type II alveolar cell development and reduced surfactant production in vivo and in vitro (Rubin et al., 2004).

In summary, although many functional studies remain to be completed, potential roles for PTHrP produced by fetal membranes and placenta include transport of calcium across the placenta, accommodation of stretch of membranes, growth and differentiation of fetal and/or maternal tissues, vasoregulation, and regulation of labor.

Implantation and early pregnancy

Some physiological functions other than control of myometrial activity were suggested by findings of Beck et al. (1993), who identified PTHrP mRNA as being limited to epithelial cells of implantation sites. This pregnancy-related expression appeared at day 5.5 in the rat fetus in the antimesometrial uterine epithelium of implantation sites, raising the possibility of a further function of PTHrP playing a part in the localization of implantation or initial decidualization. Decidual cells produced mRNA for PTHrP both in normal gestation and after the induction of deciduomata. Expression of the gene in these cells followed epithelial expression by 48 h. It was concluded from this work that the location of PTHrP gene expression in the uterus, together with the time of its expression, may play a part in implantation of the blastocyst.

Further evidence for a function of PTHrP in the implantation process came from Nowak et al. (1999), who showed that PTHrP and TGF-β were potent stimulators of trophoblast outgrowth by mouse blastocysts cultured in vitro. The TGF-β effect appeared to be mediated by PTHrP, which itself was acting through a mechanism distinct from the PTHR1.

Thus, both the timing and the localization of PTHrP gene expression suggested that it might play a part in the implantation of the blastocyst (Beck et al., 1993). Upon finding substantial levels of immunoreactive PTHrP in the uterine luminal fluid of estrogen-treated immature rats, and because the PTH/PTHrP receptor was known to be expressed in rat uterus (Urena et al., 1993), Williams et al. (1998) investigated the role of PTHrP acting through this receptor in influencing early pregnancy in the rat. Infusion of either a PTHrP antagonist peptide or a monoclonal anti-PTHrP antibody into the uterine lumen during pregnancy resulted in excessive decidualization. The latter appeared to be the result of a decrease in the number of apoptotic decidual cells in the antagonist-infused horn. In pseudopregnant rats, infusion of receptor antagonist into the uterine lumen resulted in increases in wet weight of the infused horn compared with the control side, indicating an effect on deciduoma formation.

These observations suggest that activation of the PTH/PTHrP receptor by locally produced PTHrP might be crucial for normal decidualization during pregnancy in rats, probably not by being involved in the initiation of the decidual reaction but rather in the maintenance of the decidual cell mass.

Pathophysiology of parathyroid hormone-related protein in the placenta

The breasts and placenta contribute PTHrP to maternal circulation during pregnancy, and this occasionally leads to the development of PTHrP-mediated hypercalcemia (pseudohyperparathyroidism) (Kovacs, 2016). This is accompanied by plasma PTHrP concentrations as high as 40 pmol/L and evidence of increased bone resorption. Although uncommon, it suggests that PTHrP production by breasts and placenta may also contribute to the normal regulation of maternal mineral homeostasis during pregnancy, including upregulation of calcitriol production by the maternal kidneys (Kovacs, 2016).

The clinical courses of individual cases of pseudohyperparathyroidism have made evident which of breasts versus placenta were responsible for the excess production of PTHrP. When the breasts (of normal or large size) are the source, the hypercalcemia persists and may worsen postpartum as the onset of lactation induces a further rise in mammary PTHrP production. Breast binders, dopaminergic agents, and weaning usually lead to a prompt resolution of the hypercalcemia, but occasionally it has persisted for months to years or has required a reduction mammoplasty to resolve it (Kovacs, 2016). On the other hand, when the placenta is the source of excess PTHrP, the condition reverses within a few hours of delivery. One pregnant woman with normal-sized breasts developed severe hypercalcemia (5.25 mmol/L) in the third trimester, accompanied by undetectable PTH and a serum PTHrP of 21 pmol/L (Eller-Vainicher et al., 2012). Within 6 hours after an urgent C-section, she was profoundly hypocalcemic, PTHrP had become undetectable, and PTH had risen above the normal range. The rapid reversal from hypercalcemia to hypocalcemia, elevated PTHrP to undetectable PTHrP, and undetectable PTH to high PTH revealed the placenta as the culprit source of excess PTHrP.

Some cases of pseudohyperparathyroidism have presented with vertebral compression fractures during pregnancy or lactation, confirming that the excess production of PTHrP causes marked bone resorption and can temporarily cause skeletal fragility (Kovacs, 2016).

Summary

The multiple roles of PTHrP in the reproductive tissues and cycle, and in the placenta, largely reflect its roles as a paracrine/autocrine/intracrine regulator. Of the many functions it exerts in these systems, probably the only endocrinal one is when PTHrP in the fetal circulation regulates placental calcium transport. There remains much to be learned of the place of PTHrP in reproductive and placental physiology and pathology.

Endocrine pancreas

Parathyroid hormone-related protein and its receptors

The presence of PTHrP in the pancreatic islets became apparent shortly after the identification of PTHrP in 1987. It is expressed as early as day 18 of gestation in the islet cells of fetal rodents (Campos et al., 1991). Asa et al. (1990) demonstrated that PTHrP was present in islet cells and in all 4 cell types, including the α, β, δ, and PP cells. PTHrP mRNA was shown to be present in isolated islet RNA as well (Drucker et al., 1989), demonstrating that the peptide could be produced within the islet. Gaich et al. (1993) confirmed these findings, demonstrating that PTHrP was indeed present in islet cells of all four types and that it was also present in pancreatic ductular epithelial cells. The peptide is not present in

adult pancreatic exocrine cells. Plawner et al. (1995) demonstrated that PTHrP is present in individual beta cells in culture and showed that PTHrP colocalized with insulin in the Golgi apparatus as well as in insulin secretory granules. Interestingly, in a perifusion system employing a beta-cell line, PTHrP was shown to be cosecreted with insulin from beta cells following depolarization of the cell (Plawner et al., 1995). The secreted forms of PTHrP included amino-terminal, midregion, and carboxy-terminal forms of PTHrP (see later).

The PTH1R is expressed throughout the gut epithelium, including the pancreas, from day 9 of development in fetal rodents (Karperien et al., 1994). PTH1R mRNA and protein have been confirmed to be present in adult mouse islet cells by RT-PCR and immunostaining (Fujinaka et al., 2004). There is also functional evidence for PTHrP receptors on the pancreatic beta cell, as it is clear that PTHrP(1−36) elicits prompt and vigorous responses in intracellular calcium in cultured beta-cell lines. For example, Gaich et al. (1993) have demonstrated that PTHrP(1−36) in doses as low as 10−12 M stimulates calcium release from intracellular stores. Interestingly, unlike events observed in bone and renal cell types where PTHrP receptor activation is associated with activation of cAMP/PKA, as well as the PKC/intracellular calcium pathways, only the latter is observed in cultured beta cells in response to PTH or PTHrP(1−36) (Gaich et al., 1993). Whether this reflects the presence of a different type of receptor on beta cells or differential coupling of the PTH1R to subsets of specific G-proteins or catalytic subunits in beta cells compared with bone and renal cells has not been studied.

Regulation of parathyroid hormone-related protein and its receptors

There is little information describing how or to what degree PTHrP or the PTH receptor family is regulated in the pancreatic islet. As will become clear from the sections that follow, there are physiological reasons why such regulation might occur under normal circumstances, but this area remains unexplored.

Biochemistry of parathyroid hormone-related protein

PTHrP undergoes extensive posttranslational processing. Much of what is known or inferred regarding PTHrP processing is derived from studies in the rat insulinoma line, RIN-1038 (Soifer et al., 1992; Yang et al., 1994; Wu et al., 1991). These cells model the processing of PTHrP in the regulated secretory pathway, and have been shown to serve as a model for authentic processing of other human neuroendocrine peptides, such as insulin, proopiomelanocortin, glucagon, and calcitonin. Using a combination of untransfected RIN-1038 cells, RIN-1038 cells overexpressing hPTHrP(1−139), hPTHrP(1−141), or hPTHrP(1−173), and a panel of region-specific radioimmunoassays and immunoradiometric assays, RIN cells have been shown to secrete PTHrP(1−36), PTHrP(38−94), PTHrP(38−95), and PTHrP(38−101) (Soifer et al., 1992; Yang et al., 1994; Wu et al., 1991). In addition, RIN 1038 cells have been shown to secrete a form of PTHrP that is recognized by a PTHrP (109−138) radioimmunoassay (Yang et al., 1994) and another form that is recognized by a PTHrP(139−173) radioimmunoassay (Burtis et al., 1992).

As mentioned, these data derive from rat insulinoma cells that use the regulated secretory pathway for the processing of PTHrP. On the other hand, osteoblasts, chondrocytes, and other cells of mesenchymal origin use the constitutive secretory pathway and would not be expected to use the same processing mechanisms as cells that use the regulated secretory pathway. In accord with that, the only isoform of PTHrP found to be secreted by the Ocy454 osteocyte cell line was full-length PTHrP (Ansari et al., 2018).

As described earlier, PTHrP(1−36) stimulates intracellular calcium increments in cultured beta cells (Gaich et al., 1993). PTHrP(38−94) has also been shown to stimulate intracellular calcium release in these cells (Wu et al., 1991). PTHrP(38−94) does not activate adenylyl cyclase in cultured beta cells, and other PTHrP species have not been explored in beta cells in functional terms.

Function of parathyroid hormone-related protein

Pancreas development in rodents begins at approximately day E9−10, and by day E18−19, clusters of beta cells have begun to coalesce and form immature islets (Edlund, 1998). These islet cell clusters continue to increase in number, size, and density of beta cells in the week after delivery and then decline abruptly in number through a wave of beta-cell apoptosis (Finegood et al., 1995).

The role of PTHrP in pancreatic cell development and function is poorly understood at present. The pancreas of PTHrP-null mice (Karaplis et al., 1994) develops normally in anatomic terms (Vasavada et al., 1998), but nothing is known about the function of these islets. PTHrP-null mice die immediately after delivery, so nothing is known of islet function or development following birth in the absence of PTHrP. “Rescued” PTHrP mice do exist (Wysolmerski et al., 1998),

and they survive to adulthood. These mice have normal-appearing pancreata and islets (Vasavada et al., 1998), but they have dental abnormalities, are undernourished, and grow poorly. Therefore, it is difficult to characterize their islets in functional terms, as islet mass, proliferation, and function are heavily dependent on fuel availability. Streuker and Drucker (1991) have suggested that PTHrP may play a role in beta-cell differentiation because it is upregulated in beta-cell lines in the presence of the islet-differentiating agent, butyrate.

In vitro studies have demonstrated that, similar to the actions of PTH, PTHrP(1−34) and PTHrP(1−86) can enhance glucose-stimulated insulin release from cultured islet cells, and increased insulin mRNA expression and protein content within cultured islets and islet tumor cell lines (Villanueva-Penacarrillo et al., 1999; Sawada et al., 2001). PTHrP has been shown to increase proliferation of cultured islet cells, with the effects varying by cell passage and the ambient glucose concentration (Sawada et al., 2001; Vasavada et al., 2007). Also within cell lines, there is evidence that PTHrP induces cAMP production, raises intracellular calcium through influx of calcium into the cell, and inhibits JNK1/2 activation (Mozar et al., 2014).

In an effort to understand the role of PTHrP in the pancreatic islet, Vasavada and collaborators have developed transgenic mice that overexpress PTHrP under the control of the rat insulin-II promoter (RIP) (Vasavada et al., 1996; Porter et al., 1998). RIP-PTHrP mice display striking degrees of islet hyperplasia and an increase in islet number as well as the size of individual islets. This increased islet mass is associated with increased function; RIP-PTHrP mice are hyperinsulinemic and hypoglycemic compared with their littermates (Vasavada et al., 1996; Porter et al., 1998). They become profoundly and symptomatically hypoglycemic with fasting. Interestingly, RIP-PTHrP mice are also resistant to the diabetogenic effects of the beta-cell toxin, streptozotocin. Following the administration of streptozotocin, normal mice readily develop diabetes, but RIP-PTHrP mice either fail to become diabetic or develop only mild hyperglycemia (Porter et al., 1998).

The mechanism(s) responsible for the increase in islet mass in the RIP-PTHrP mouse remains undefined. There are two levels at which this question can be addressed: identification of the source of the cells responsible for the increase in islet mass and the signaling mechanisms that are responsible for the increase. With respect to the first, islet mass can, in theory, be increased by three pathways: (1) the recruitment of new islets from the pancreatic duct or its branches distributed throughout the exocrine pancreas in a process referred to as “islet neogenesis”; (2) induction of proliferation of existing beta cells within islets; and (3) prolongation of the life span of existing beta cells. Of these options, there is evidence that PTHrP can drive beta-cell replication (Villanueva et al., 1999; Fujinaka et al., 2004), suggesting that beta-cell proliferation may account for at least part of the phenotype. The RIP promoter is restricted to expression in beta cells and therefore unable to influence pancreatic cells prior to their differentiation into beta cells, suggesting that the neogenesis of beta cells from ductal or other precursors is not a likely contributor (Vasavada et al., 1996). Finally, the bulk of evidence would support a dominant role for PTHrP in enhancing beta-cell survival, as occurs in other cell types (Cebrian et al., 2002).

More recently, daily subcutaneous injections of PTHrP(1−36) in adult mice have been shown to increase the proliferation of beta cells and improve glucose tolerance (Williams et al., 2011). Vasavada’s group has shown that after partial pancreatectomy, treatment with PTHrP(1−36) increased beta-cell proliferation over the first 30 days and led to a marked increase in beta cell mass by 90 days (Mozar et al., 2016). Therefore, PTHrP could conceivably be a treatment to improve beta cell mass in patients with diabetes. Further studies are needed.

At the signaling level, little is known regarding the mechanism of action of PTHrP on beta cells. Although it is known that PTHrP can stimulate intracellular calcium in cultured beta-cell lines (Gaich et al., 1993; Wu et al., 1991), it is not known whether this occurs in vivo in normal, nontransformed beta cells within intact islets. Nor is it known whether PTHrP stimulates adenylyl cyclase in normal beta cells in vivo or whether it participates in nuclear or intracrine signaling in beta cells as it appears to in chondrocytes, osteoblasts, vascular smooth muscle cells, or other cell types (Aarts et al., 1999; Massfelder et al., 1997; Lam et al., 1999) (see Chapter 25). These processes, too, are under study.

Pathophysiology of parathyroid hormone-related protein

From the earlier discussion, it is clear that the normal physiological role of PTHrP in the pancreatic islet remains undefined. In contrast, PTHrP plays clear pathophysiological roles in at least some pancreatic islet neoplasms. PTHrP overexpression with resultant development of HHM has been demonstrated on multiple occasions in multiple investigators’ hands (Asa et al., 1990; Stewart et al., 1986; Wu et al., 1997; Skrabanek et al., 1980). In the only large series of malignancy-associated hypercalcemia in which tumors have been fully subdivided based on histology (Skrabanek et al., 1980), islet cell carcinomas, which are not particularly common, produce HHM fully as often as pancreatic adenocarcinomas, a very common neoplasm. Historically, islet tumors were among the first in which PTHrP bioactivity was identified (Stewart et al., 1986; Wu et al., 1997). Furthermore, patients with islet carcinomas regularly demonstrate increases in circulating PTHrP as

determined by radioimmunoassay or immunoradiometric assays (Lanske et al., 1996). When assessed by immunohistochemistry, these tumors also demonstrate increased staining for PTHrP (Asa et al., 1990; Drucker et al., 1989).

The significance of these findings for islet tumor oncogenesis is not known. Is this simply a random derepression of the PTHrP gene or is it a specific upregulation of the PTHrP gene? Is there a pathological role for PTHrP in the development of pancreatic islet tumors, corresponding to the mass enhancing effects of PTHrP in the islets of the RIP-PTHrP mouse? These questions remain interesting but unanswered at present.

Conclusions

Advances in mouse genetics and transgenic technology have been a boon to the study of physiology. This has certainly been the case for the PTHrP field, where studies in genetically altered mice have provided a starting place for the study of the physiology of a protein that was discovered outside its natural context. This chapter has outlined the current state of knowledge regarding the physiological roles of PTHrP in skin, the mammary gland, placenta, uterus, extraembryonic tissues, and pancreas. Much of this information (although not all) has come from studies performed in a variety of transgenic mice. These studies have shown that PTHrP is important to both the development and physiological functioning of these organs. However, at this point, we continue to have as many questions as answers. Many experiments remain to be done before we comprehend all the nuances of the functions of PTHrP at these sites.

Acknowledgments

This chapter has been updated from a prior version cowritten with Drs. Andrew F. Stewart and John J. Wysolmerski. The work was supported by the Canadian Institutes of Health Research (#133413), the Janeway Research Foundation, and both the Discipline of Medicine and Faculty of Medicine of Memorial University of Newfoundland.

Chapter 37

The pharmacology of selective estrogen receptor modulators: past and present*

Chapter outline

Introduction

In the past decade, essentially no new significant information about the skeletal aspects of selective estrogen receptor modulators (SERMs) has appeared. Ten years ago, several promising candidate molecules were making their way through clinical trials. Some of these showed clinical efficacy in reducing vertebral fractures, particularly lasofoxifene and bazedoxifene. However, except for bazedoxifene, side effects stifled continued development. Moreover, as the efficacy and safety profiles of bazedoxifene closely resembled those of raloxifene (EVISTA, Eli Lilly & Co), which had already been available for patient care for more than 2 decades, no clear path for it to succeed as a stand-alone product was evident. Accordingly, bazedoxifene has been combined with conjugated equine estrogens as a dual preparation (DUAVEE, Pfizer, Inc.) that is FDA-approved for use in postmenopausal women for control of vasomotor symptoms and the prevention (but not treatment) of osteoporosis. Thus, raloxifene remains the only approved SERM for both the treatment and the prevention of osteoporosis.

In recent years, the pharmaceutical industry has shown little or no interest in developing other SERMs for skeletal purposes, although some interest persists in the basic science surrounding the determinants of their tissue specificity. Feng and O'Malley (2014) published some of the more current research dealing with the role of nuclear reception modulators and other coregulators in the action of SERMs. In addition, recent studies gave interesting and potentially clinically useful

* Most of this chapter is an edited version of the chapter from the third edition of this book, written by Henry U. Bryant, Eli Lilly and Company, Indianapolis, IN.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00037-3

results with SERMs in other therapeutic areas (Mirkin and Pickar, 2015), but discussion of these exceeds the scope of this chapter and of this book.

For this reason, what follows is material little changed from what was published on SERMs in the third edition of this work (2009).

The widespread distribution of estrogen receptors (ERs), and their critical role in normal physiology and various pathophysiological states when estrogen levels decline, indicate the importance of ER-targeted therapies for use in postmenopausal women. Controversy and concern over the use of estrogen replacement therapies created the opportunity to design molecules to selectively modulate estrogen action in those tissues where estrogen agonism is the desired goal while simultaneously producing an estrogen-neutral or estrogen-antagonistic effect in tissues where estrogen-related side effects are a concern. SERMs are in clinical use for the treatment and prevention of osteoporosis (raloxifene), breast cancer prevention (tamoxifen and raloxifene) and treatment (tamoxifen and toremifene), and the induction of ovulation (clomiphene). By 2008, seven different SERMs had reached advanced clinical evaluation for postmenopausal osteoporosis, with three molecules (droloxifene, idoxifene, and levormeloxifene) withdrawn for unfavorable risk/benefit profiles and three additional molecules (lasofoxifene, bazedoxifene, and arzoxifene) in phase 3 status or under regulatory review. Experience with these molecules revealed several key themes for chronic use of SERMs: (1) Each SERM generates a unique complex with the ER that influences cofactor recruitment in estrogen−target tissues responsible for the tissue-selective pharmacological profile, which translates to each SERM generating potentially an entirely unique overall safety and efficacy profile, indicating the need for thorough evaluation of each individual SERM across multiple tissue types for efficacy and safety determination. (2) Uterine safety historically has been the critical safety feature for chronic SERM use in osteoporosis therapy, and careful assessment of the potential for uterine stimulation has been a key element in the consideration of new molecules in this class. (3) The pharmacokinetic and distribution properties of SERMs offered an additional aspect influencing the magnitude of the overall biological response by either improving systemic bioavailability or altering uptake into important estrogen-responsive tissues.

Research in the ER field attracted considerable attention during the 15 years prior to 2009 with significant events ranging from very basic research discoveries, such as resolution of the liganded ER crystal structure and identification of a second ER form (ERβ), to important clinical observations regarding estrogen use in postmenopausal women from the Women's Health Initiative (WHI) trial. Estrogen exhibited a "Jekyll and Hyde" therapeutic profile, as hormone replacement (estrogen 1 progestin) was associated with distinct benefits on the menopausal syndrome including reductions in vasomotor symptoms and fracture incidence as well as other benefits such as a reduction in colon cancer. However, these benefits were offset by significant increases in risk for coronary events (myocardial infarction and stroke) and breast and uterine cancer. In the early 1990s, research around the concept of SERMs—molecules that simultaneously agonized or antagonized estrogen action in different tissue types—offered a new way of looking at ER pharmacology and served to trigger renewed interest in estrogen-related research in the mid-1990s.

Prior to the development of the "SERM-concept," ER ligands were generally thought of as falling into the category of full agonist, partial agonist, or full antagonist across all tissue types (i.e., uterus, mammary, and bone). For example, steroidal hormones such as 17β-estradiol were known to behave as full agonists both in vitro and in vivo across multiple tissue types, whereas compounds such as fulvestrant (ICI-182,780) were known to be complete ER antagonists that bound tightly to the ER but lacked intrinsic activity, and therefore completely blocked the action of full ER agonists like 17β-estradiol. These "pharmacotypes" are depicted in Fig. 37.1A and B, respectively. Conversely, compounds such as tamoxifen were known, in the presence of estrogen, to block estrogen action in estrogen-responsive tissues (i.e., breast cancer cells), but in the absence of estrogen to mimic estrogen in bone and uterus in estrogen-deficient animals and women, thus exhibiting a classical partial-agonist profile (see Fig. 37.1C). Although this profile held some attractive features for use in ER-dependent breast cancer, the profile was prohibitive for chronic use in postmenopausal women for noncancer indications (like osteoporosis), where even the potentially less robust uterine stimulation induced by tamoxifen's partial agonist action produced untenable side effects that created a risk/benefit ratio that was unfavorable for use in diseases such as osteoporosis (Kalu et al., 1991). As a result, virtually no work was being done in the pharmaceutical industry developing novel ER ligands for osteoporosis because the prevailing medical opinion at the time was that any molecule with sufficient estrogen agonism capable of producing a benefit in bone would also generate sufficient agonism (even if a partial agonist) in uterine tissue to create a risk that would unfavorably offset the bone benefit (Feldman et al., 1989).

With the first preclinical and clinical descriptions of the unique profile of raloxifene in estrogen-deficient animals and postmenopausal women (Black et al., 1994; Draper et al., 1997), the SERM concept was born, radically shifting thought around use of ER ligands in postmenopausal women and opening the door for use in chronic diseases such as osteoporosis. Accordingly, the initial goals of SERM-based therapy for osteoporosis required the molecule to have estrogen-like efficacy on bone and concomitant fracture reduction without estrogen-like stimulatory effects on the uterus or mammary tissue. As

of the writing of this chapter for the third edition of this book, only four molecules with SERM-like profiles had achieved clinical use (Table 37.1), and only one, raloxifene, had attained approval for use in the treatment and prevention of osteoporosis. However, other molecules had been evaluated clinically for postmenopausal osteoporosis and are reviewed here. In addition, some other SERM applications are presented that could potentially benefit other diseases or disorders in postmenopausal women.

Selective estrogen receptor modulator mechanism

The effects of SERMs on biological systems are predominantly mediated by specific, high-affinity interactions with ERs that are primarily located in target cell nuclei (Nilsson *et al.*, 2001). Their nuclear hormonal action involves the complex interplay of a number of protein and genomic elements that allow SERMs to regulate gene transcription and subsequent protein production by the cell. Three key elements of the SERM mechanism are depicted in Fig. 37.2, which include (1) high-affinity interaction with the ER, (2) ER–ligand dimerization and association with a tissue-specific set of coregulatory proteins, and (3) binding of the ER/adaptor protein complex to specific DNA response elements located in the promoter regions of nuclear target genes and ensuing regulation of gene transcription. Depending on the cellular and promoter context, the DNA-bound receptor can induce or inhibit the transcription of specific genes within the tissue.

The ability to specifically bind to the ER is perhaps the single most important feature of all molecules with a SERM profile. The affinities of several of the more extensively studied SERMs are provided in Table 37.2. An important determinant of the ultimate pharmacological response is the shape of the ligand–ER complex, which is unique with each individual ligand (McDonnell et al., 1995), with different SERMs leading to specific orientation of ER subunits (i.e., raloxifene; Brzozowski et al., 1997). This conformation or shape of the ligand–ER complex then determines the

TABLE 37.1 Selective estrogen receptor modulators currently approved for human use.

SERM	Trade name	Approved indications	Daily dose (mg)
Clomiphene	Clomid	Induction of ovulation	50–100
Raloxifene	EVISTA	Osteoporosis prevention	60
		Osteoporosis treatment	
		Breast cancer risk reduction in postmenopausal osteoporotic women and in high-risk postmenopausal women	
Tamoxifen	Nolvadex	Metastatic breast cancer treatment	20–40
		Adjuvant breast cancer treatment	
		Ductal carcinoma in situ	
		Breast cancer risk reduction in high-risk women	
Toremifene[a]	Fareston	Metastatic breast cancer treatment	60

subsequent protein–protein interactions that ensue. Herein lies the basis for the wide array of different pharmacological profiles produced by different SERMs, because the confirmation of the ER–SERM complex is distinct for each molecule (McDonnell et al., 1995). It is important to recognize that a second form of ER is known to exist, ERβ (Kuiper et al., 1996). ERα and ERβ display unique patterns of tissue distribution, typically with the expression levels of one subtype dominating (Saunders et al., 1997), although it should be noted that most tissues contain at least small amounts of both subtypes, and with the role of putative α/β heterodimers unknown, it is possible that a low-expression subtype may be a key rate-limiting

TABLE 37.2 Affinities of various SERMs for human estrogen receptors ERα and ERβ.

ER ligand	ERα(IC_{50})	ERβ(IC_{50})
17β-Estradiol	0.3–0.8[a]	0.9–2.5[a]
Tamoxifen	72–138	173–1204
4-Hydroxytamoxifen	0.22–0.98	1.5–2.46
Raloxifene	0.4–1.31	5.6–13.0
Fulvestrant (ICI-182,780)	0.8–1.0	1.12–3.6

[a]*All values are in nM. As binding data often can vary from laboratory to laboratory, and various approaches can be taken to attaining binding affinities, ranges for ERα and ERβ obtained from representative references are presented (Sun et al., 1999; Brady et al., 2001; de Boer et al., 2004; He et al., 2005; Leblanc et al., 2007).*

step in ultimate nuclear activity. All SERMs that have reached advanced clinical evaluation show high affinity for both ERα and ERβ with sufficient circulating and tissue exposure to ensure binding of both subtypes, indicating that for these molecules at least, differential ERα or ERβ activation does not explain the tissue-selective pharmacological effects.

In addition to ERs themselves, a number of other coregulatory proteins, such as coactivators (which enhance transcription) and corepressors (which reduce transcription), play an essential role in determining the ultimate response of an individual cell to liganded ER. A number of coactivators and corepressors that interact with ligand-bound ER have been identified and are reviewed thoroughly elsewhere (Smith, 2006).

The relative tissue expression of the different cofactors and the ability of the ER–ligand complex to interact with those cofactors determine the tissue-selective agonist/antagonist profile of the various SERM molecules. Cofactor tissue expression can also be altered with various pathophysiological states, such as breast cancer (Bautista et al., 1998). The important nature of the tissue-relevant cofactor context was demonstrated by Shang and Brown (2002), who compared the effects of two SERMs, tamoxifen and raloxifene, with estrogen in two tissue contexts, a breast cancer cell line and a uterine endometrial carcinoma cell line. In the mammary cells that proliferate in response to estrogen, 17β-estradiol recruited coactivators leading to increased gene expression. In these same cells, where tamoxifen and raloxifene both display estrogen antagonist pharmacology, the ligand–SERM complex with both molecules recruited corepressors and not the coactivators observed with 17β-estradiol on ER-mediated transcription. However, in a uterine cell line where tamoxifen exhibits estrogen agonist pharmacology and raloxifene is a complete antagonist, tamoxifen was associated with the recruitment of a coactivator protein complex that is expressed at higher levels in uterine cells. The coactivator requirements for estrogen-stimulated gene expression in uterine cells were distinct from those for tamoxifen, indicating multiple signaling mechanisms even for the agonist response. Conversely, raloxifene failed to recruit a coactivator construct and rather induced a corepressor construct in uterine cells (Shang and Brown, 2002). Thus, the relative abundance of ER-associated coactivators and corepressors is an important factor in the tissue-specific pharmacology of SERMs.

In addition to the layers of complexity provided by multiple ER–SERM conformations and tissue-selective cofactor recruitment, the mechanism of tissue selectivity of SERMs is further complicated by the existence of multiple DNA response elements. Many estrogen-responsive genes contain the classical estrogen response element and a number of DNA response elements, such as activator protein-1 and steroidogenic factor-1 response element (Vanacker et al., 1999). The mechanism for SERM activation (or inactivation) of ER-mediated function is further complicated by the presence of novel DNA response elements that are more apparent following formation of the ER–SERM cofactor complex.

Although there have been considerable strides in understanding the molecular biology of SERM action in a general sense, with the critical role of the ER, specific cofactors that are recruited to the transcriptional complex, and the specific DNA response elements activated, it is important to recognize that each SERM has the potential to produce a unique fingerprint of pharmacological activity at the whole-organism level. Contributing to the eventual profile are the molecular mechanisms reviewed earlier as well as other factors, such as absorption, distribution, excretion, and metabolism of the SERM, that add another layer of complexity for ultimate pharmacological response, creating the need to fully characterize the tissue-specific effects of each individual SERM in an in vivo paradigm.

Selective estrogen receptor modulator chemistry

A key element in determining the pharmacological profile of each distinct SERM is influenced heavily by the chemical makeup of the SERM including the basic scaffold, the placement of the hydroxyl moieties, and the positioning and nature of the basic side chain. Crystal structures of various ligands bound to the ER indicate that small molecules can induce a spectrum of receptor conformations. As described previously, the specific SERM−ER conformation has a tremendous impact on cofactor recruitment and ultimate genomic activation or inhibition by the SERM. Chemical scaffolds that have produced SERMs in current clinical use, or at least that have reached phase 3 clinical evaluation in humans, are depicted in Fig. 37.3 and include triphenylethylenes (i.e., tamoxifen, droloxifene, idoxifene, clomiphene, and toremifene), benzothiophenes (raloxifene and arzoxifene), tetrahydronaphthalenes (lasofoxifene and nafoxidine), indoles (bazedoxifene), and benzopyrans (acolbifene and levormeloxifene). Key structural features of these molecules, which are indicated in Fig. 37.4 for raloxifene versus 17β-estradiol, are typical for the entire class, with the most important features being the hydroxyl moieties and the basic side chain, as described thoroughly elsewhere (Grese et al., 1997).

Selective estrogen receptor modulator pharmacology

Given the wide distribution of ER and the pleiotropic nature of estrogen and its multiple metabolites, SERMs should be expected to likewise affect multiple organ systems, and this is indeed the case. Because one area of focus in this volume is skeletal pharmacology, emphasis here will be placed on the pharmacologic effects of SERMs on bone and other tissues that are of relevance to safety in the clinical setting. Accordingly, emphasis is placed on those SERMs where osteoporosis and

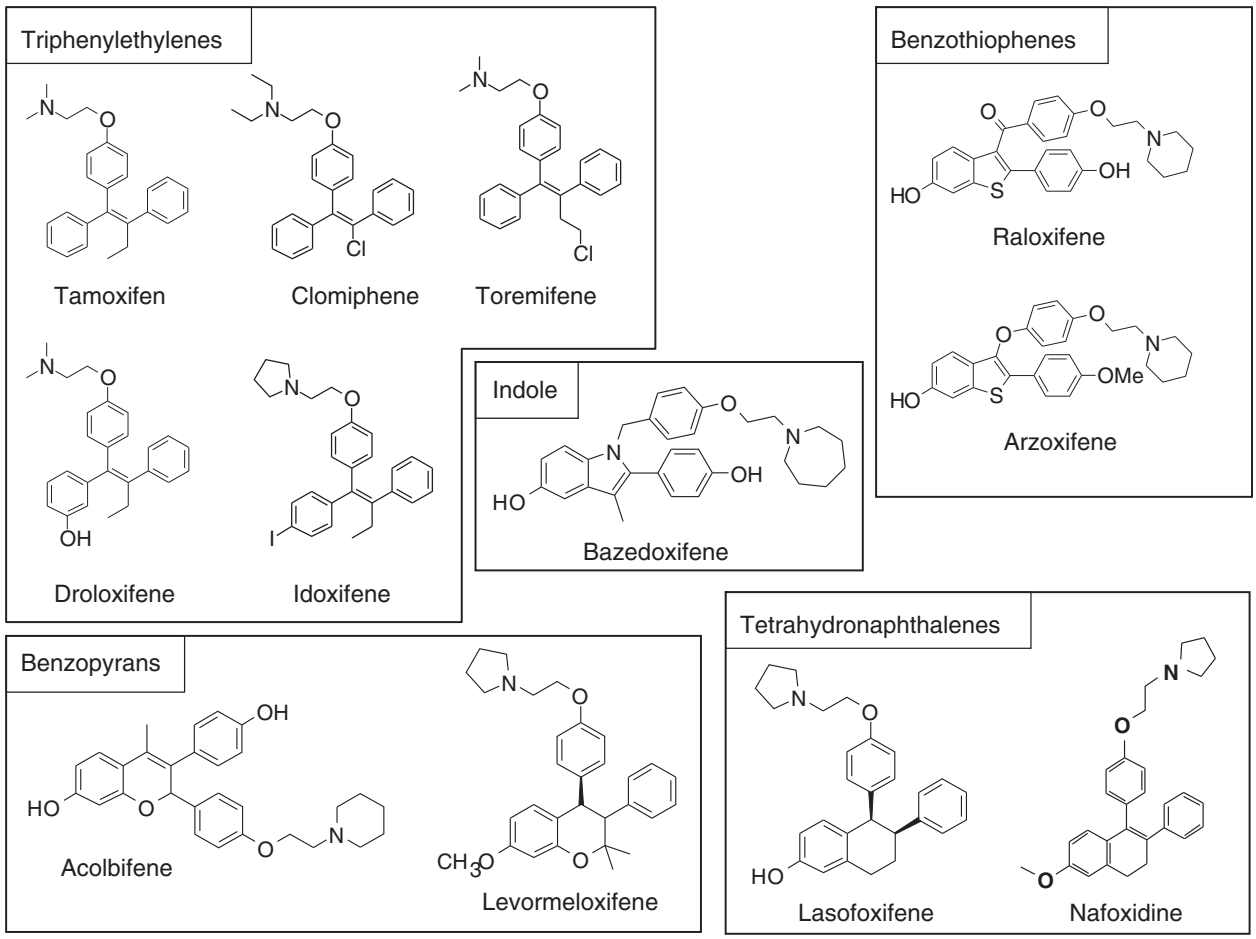

FIGURE 37.3 Structures and chemical classes of selective estrogen receptor modulators currently in clinical use or that have reached phase 3 clinical trials in women.

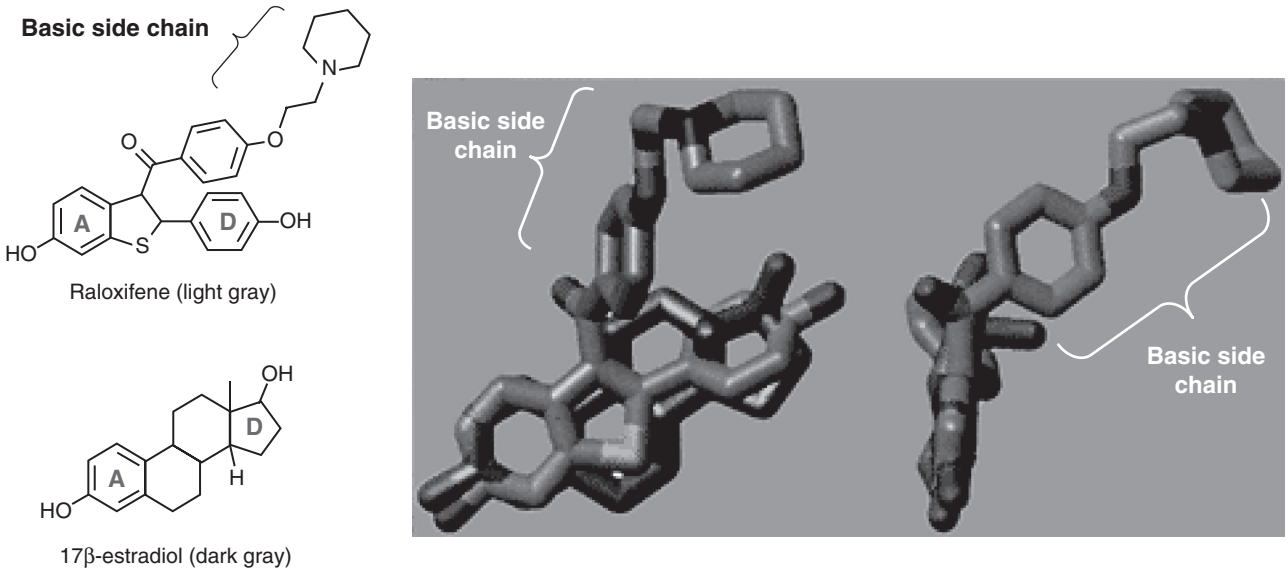

FIGURE 37.4 Key structural features of raloxifene versus 17β-estradiol.

bone have been the primary focus of research. SERMs used primarily for other indications (present or with future potential) will be briefly summarized as well.

Skeletal system

Preclinical studies

Much as in postmenopausal women, estrogen deficiency in ovariectomized (OVX) animals leads to a rapid increase in bone turnover, where excessive osteoclast resorptive activity results in a marked decline in trabecular bone mass and strength with a concomitant increase in fractures. In rats, ovariectomy produces a rapid osteopenic response that can be discerned within 5 weeks. All of the SERMs depicted in Fig. 37.3 have been evaluated in the OVX rat and demonstrate estrogen-like protection from bone loss induced by estrogen deficiency. In the OVX rat model, SERMs like raloxifene (Black et al., 1994), arzoxifene (Sato et al., 1998), tamoxifen (Sato et al., 1996a,b), droloxifene (Ke et al., 1995), idoxifene (Nuttall et al., 1998), clomiphene (Jiminez et al., 1997), bazedoxifene (Komm et al., 2005), lasofoxifene (Ke et al., 1998), levormeloxifene (Galbiati et al., 2002), toremifene (Qu et al., 2000), and acolbifene (Martel et al., 2000) prevent the loss of bone in vertebrae, distal femur, and proximal tibia, all trabecular-rich bone sites. In addition to maintaining bone mass, SERMs also preserve bone strength through improvements in bone microarchitecture (i.e., raloxifene; Turner et al., 1994). For both bone mass and bone strength, the absolute magnitudes of the effects of most SERMs in OVX rats are indistinguishable from those of estrogen and can approach values attained for sham-surgery controls when the SERM is administered in a preventative mode. However, differences in potency for these bone-protective effects can occur, with third-generation SERMs like arzoxifene, bazedoxifene, and lasofoxifene producing efficacy equivalent to that of raloxifene in OVX rat trabecular BMD responses at approximately 10% of the dose (Ke et al., 1998; Sato et al., 1998). There had been preclinical hints of improved efficacy of some of these latter agents as well, for example with arzoxifene, which improves cortical bone strength to a greater degree than observed with maximally effective doses of either estrogen or raloxifene (Sato et al., 1998). Similarly, with bazedoxifene, improved biomechanical properties in trabecular bone were observed relative to estrogen after 1 year of treatment in OVX rats (Komm et al., 2007).

As with estrogen, the primary activity of SERMs that is responsible for the beneficial effect on bone is antiresorptive. Mechanistic studies in vitro demonstrated that raloxifene and estrogen exert their antiresorptive effects primarily as inhibitors of osteoclast differentiation, rather than as direct inhibitors of activated osteoclasts. Raloxifene acts to suppress mediators of osteoclast differentiation, such as the receptor activator of nuclear factor-kappa-β (RANK) and RANK-ligand (Bashir et al., 2005), and increase endogenous antiresorptive factors such as osteoprotegerin (Viereck et al., 2003). Biochemical markers of bone turnover (i.e., serum osteocalcin and urinary collagen cross-links) are suppressed in OVX rats in a manner similar to that observed with estrogen (Frolik et al., 1996). Histomorphometric analysis of bone from raloxifene-treated OVX rats confirmed the antiresorptive mechanism of action for raloxifene (Evans et al., 1994). Similar

studies with the other SERMs discussed here indicate the same antiresorptive mechanism for bone protection. Of likely importance with respect to long-term safety in the skeleton is the finding that SERMs such as raloxifene produce their inhibitory action on bone resorption with minimal suppressive effects on bone formation, leaving bone formation rates at levels comparable to those of sham-operated control animals (Evans et al., 1994). The molecular fingerprint of SERMs in estrogen-deficient rat trabecular bone, as assessed by DNA microarray, is unique for each SERM, although it is clear that some SERMs are less suppressive of bone formation. For example, in OVX rats, raloxifene returned a cluster of genes associated with bone formation to ovary-intact control levels, as opposed to a bisphosphonate (alendronate), estrogen, or even another SERM (acolbifene), which exhibited a greater suppressive effect on bone formation−associated genes (Helvering et al., 2005a,b). The overall SERM profile on bone then represents a sharp distinction from the marked suppression of bone formation that occurs with other bone antiresorptives, such as the bisphosphonates. A final bone cell type that may be of relevance to the skeletal-protective effect of SERMs is the osteocyte. Whereas relatively less work has been done with this bone cell owing to technical challenges, work in MLO-Y4 cells (an osteocyte-like cell line) has indicated that raloxifene prevents oxidative stress−induced apoptosis and inhibits the generation of reactive oxygen species with oxidative insults, such as hydrogen peroxide (Mann et al., 2007).

Clinical studies

The abundance of preclinical information on the effects of SERMs on bone was easily matched by a plethora of long-term clinical trials conducted on a number of different SERM molecules, either as the primary element of registration trials for postmenopausal osteoporosis or as part of the safety assessment for use in breast cancer. Certainly the most extensively studied SERM on the human skeleton has been raloxifene, which has been investigated in nearly 40,000 clinical trial subjects enrolled in prospective, randomized trials (placebo or active comparator) that have ranged in duration from 1 to 8 years. In postmenopausal women, raloxifene (60 mg/day) exhibited an antiresorptive action, as evidenced by reductions in accelerated bone turnover as measured by biochemical markers of bone resorption (Ettinger et al., 1999), while only modestly suppressing bone formation. In calcium tracer kinetic studies in postmenopausal women, Heaney and Draper (1997) showed suppression of bone resorption with raloxifene, whereas bone formation was not affected after 31 weeks of treatment. The observation of resorption inhibition with minimal formation suppression by raloxifene was confirmed by histomorphometric analysis of iliac crest bone biopsies (Ott et al., 2002). This antiresorptive activity is associated with an approximately 2.5% increase in vertebral BMD relative to placebo-treated controls. This increase in spine BMD that occurs following raloxifene treatment in postmenopausal women is less marked than observed with a bisphosphonate (alendronate; Johnell et al., 2002). However, this magnitude of BMD improvement in the spine underestimates the mechanical improvement produced by raloxifene as evidenced by the 55% reduction in new vertebral fractures in women with prevalent fractures (Ettinger et al., 1999), a rate comparable to that produced by bisphosphonates. This observation led to increased attentiveness to the potential effects of raloxifene (and putatively other SERMs in the future) on bone quality. The eventual resistance of bone to fracture was the result of both the content, or mass of the material (i.e., BMD), and the quality of that material, which was likely the result of bone microarchitecture and the nature of the mineralized matrix itself. In animal models, increased trabecular thickness and the maintenance of platelike (vs. rodlike) trabecular structures, both of which correlate with improved biomechanical strength of bone, were observed in OVX mice (Cano et al., 2008). Although BMD is a noninvasive, easily quantifiable parameter in clinical trials, bone quality remains more difficult to quantify because it is primarily revealed by the eventual incidence of fracture. A number of efforts targeted better understanding and quantifying of bone quality in instances where raloxifene had shown some benefits over other antiresorptive therapies such as histomorphometric analyses of trabecular bone architecture and microcrack frequency in bone (Allen et al., 2006; Li et al., 2005). One area where some aspect of bone quality was beginning to be elucidated is the proximal femur, where imaging technologies had been applied to postmenopausal clinical trial subjects to show an increase in resistance to axial and bending stresses in raloxifene-treated women (Uusi-Rasi et al., 2006), indicating improved structural components of bone strength and stability with the SERM. Raloxifene produced positive effects on hip BMD, which increased 2.1% versus placebo after 3 years in postmenopausal women (Ettinger et al., 1999), although without a significant effect on nonvertebral fracture rates (Ettinger et al., 1999). However, an interesting trend was noted in a subset of women who entered the trials with severe vertebral fractures. In this subset of more severely osteoporotic women, raloxifene produced a 50% reduction in nonvertebral fractures (Delmas et al., 2003). Finally, in addition to the reduction of vertebral fractures in osteoporotic women, raloxifene provided fracture risk protection to osteopenic women (Kanis et al., 2003).

A number of other SERMs had attempted unsuccessfully to register for an osteoporosis prevention/treatment indication. The failure of those molecules to achieve regulatory approval for osteoporosis was primarily based on safety and risk/

benefit analysis, as each demonstrated some level of improvement on skeletal parameters in earlier clinical trials. Prior to discontinuation of levormeloxifene phase 3 clinical trials because of gynecological-associated adverse events, phase 2 clinical trials demonstrated positive effects of this SERM on BMD and bone turnover (Alexandersen et al., 2001). Idoxifene, a triphenylethylene also discontinued in phase 3 for uterine-adverse events, produced clinically relevant increases in BMD in osteopenic postmenopausal women (Chesnut et al., 1998). The third-generation molecules, lasofoxifene and bazedoxifene, are both very potent SERMs with relatively high bioavailability (Gardner et al., 2006; Patat et al., 2003) and produced advanced clinical testing results for osteoporosis. In a 2-year trial in 410 postmenopausal women, lasofoxifene at 0.25 or 1 mg/day suppressed bone turnover similarly to raloxifene, but lasofoxifene increased lumbar spine BMD by 3.6% and 3.9% (respectively by dosage), which outpaced the increase observed with raloxifene (McClung et al., 2006). A 2-year BMD trial and 3-year fracture prevention trial demonstrated the skeletal protective effects of bazedoxifene relative to raloxifene. In the 3-year trial, nearly 7500 women were treated with 20 or 40 mg/day bazedoxifene, placebo, or 60 mg/day raloxifene. In this trial, bazedoxifene produced a significant reduction in relative risk for new vertebral fractures of 37% for the higher dose and 42% for the lower dose, with raloxifene producing a comparable 42% reduction in relative risk of new vertebral fractures (Silverman et al., 2007). Mean lumbar spine BMD was significantly improved, relative to placebo, by bazedoxifene with a magnitude of response comparable to raloxifene, and biochemical markers of bone turnover were also significantly lowered with bazedoxifene (Miller et al., 2007).

A number of clinical trials have focused on the bone-sparing effects of two triphenylethylene SERMs used for breast cancer treatment, tamoxifen and toremifene. Although most studies demonstrated a skeletal benefit for these two agents, trials have typically been small and not placebo-controlled in design. A consistent benefit was observed with tamoxifen and toremifene primarily at trabecular bone sites, which was consistent with observations made with raloxifene in postmenopausal women. After 3 years of use, tamoxifen or toremifene in breast cancer patients led to a less-than-expected decline in vertebral BMD (Tiitinen et al., 2004). In shorter trials (1 year), similar effects were observed, with the effect of tamoxifen somewhat stronger than that of toremifene (2% higher BMD with tamoxifen vs. toremifene, which basically prevented age-related decline over the 1-year trial; Marttenun et al., 1998). Although many studies had reported similar benefits on BMD in postmenopausal breast cancer patients, particularly with tamoxifen (e.g., Love et al., 1992), there was at least one indication that the use of tamoxifen in normal premenopausal women was associated with a reduction in bone mineral density (Powles et al., 1996).

Reproductive system

Uterus

Atrophy of the uterus accompanies estrogen deficiency in humans and most animal species, and cessation of menses is a hallmark feature of menopause in women. A major side effect of most current ER-based therapies is stimulation of the uterus resulting in part from estrogen-induced proliferation of uterine endometrial tissue. The cancer concern associated with this proliferative effect and the resumption of menses (when combined with progestin regimens as hormonal replacement therapy) have been major limitations to estrogen replacement therapeutic approaches. These uterine side effects of estrogen are often the primary deterrent in the risk/benefit decision for postmenopausal women to utilize or remain compliant with hormonal estrogen therapies for chronic use with diseases such as osteoporosis. For postmenopausal women, a major and significant advantage of SERMs like raloxifene over hormonal estrogen therapies is the lack of uterine stimulation with the SERM. However, not all SERMs share the same degree of uterine safety observed with raloxifene, and thus effects on the uterus also serve as an important distinguishing feature among various SERMs. In this regard, SERMs that have failed in phase 3 clinical trials have done so primarily because of an untenable degree of uterine stimulation or uterus-related adverse events. The accumulated clinical experience with uterine safety for a number of SERMs helps one determine which preclinical models and parameters provide optimal predictive value for uterine safety. The use of in vitro systems, estrogen-depleted animals, and estrogen-replete animals to assess antagonist potential formed a triangulated approach for the uterine safety assessment of SERMs.

Estrogen agonism in the uterus

Initial indication of the uterine estrogenic potential of SERMs was demonstrated using Ishikawa cells, a human endometrial cancer cell line. Ishikawa cell proliferation is stimulated by 17β-estradiol, tamoxifen, and 4-hydroxytamoxifen (active metabolite of tamoxifen), but not by uterine-sparing SERMs such as raloxifene (Koda et al., 2004). More subtle changes among various SERMs were detected by evaluating their effects on ER-mediated alkaline phosphatase production, creatine kinase production, and expression of progesterone receptor. The more uterine-stimulatory SERMs produced greater

induction of alkaline phosphatase and progesterone receptor expression and were less effective antagonists of 17β-estradiol-stimulated responses in Ishikawa cells (Bramlett et al., 2003). Of note, whereas uterine-safe SERMs like raloxifene failed to stimulate creatine kinase production in Ishikawa cells, raloxifene induced this activity in cell lines with an osteoblast background, consistent with the "SERM" activity profile (Koda et al., 2004).

Lack of biologically meaningful stimulation of the uterus in the estrogen-depleted state (e.g., in postmenopausal women and OVX animals) was the crux of SERM uterine-safety evaluation. The uterine effects of tamoxifen and raloxifene had been thoroughly evaluated in numerous clinical settings as well as in a variety of preclinical models. Raloxifene did not produce estrogen-like stimulatory effects in the uterus of OVX rats (Black et al., 1994). In the OVX rat model, a slight non-dose-related elevation of uterine weight was frequently observed. However, this phenomenon contrasted markedly with the robust dose-related elevation of uterine weight produced by estrogen in these animals. Raloxifene failed to stimulate other estrogen-sensitive markers in the uterus of OVX rats, such as uterine eosinophilia or uterine epithelial cell height (Black et al., 1994). In large-scale clinical trials, after 8 years of chronic use in postmenopausal women, extensive uterine safety evaluation revealed no significant uterine-stimulatory effects of raloxifene in humans (Delmas et al., 1997). Indeed, a significant reduction in endometrial cancer of the uterus was noted in postmenopausal women using raloxifene (Delmas et al., 1997).

As indicated, not all SERMs exhibit the uterine safety profile demonstrated with raloxifene. This is perhaps most evident in the extensive work done with tamoxifen. Studies in the uterus of OVX rats demonstrated robust dose-related stimulatory effects of tamoxifen on uterine weight, uterine epithelial cell height, and uterine eosinophilia (Adrian et al., 1996). Clinical experience with tamoxifen is consistent with these observations, as uterine bleeding and significant elevation of endometrial cancer has been observed in women exposed to tamoxifen in long-term studies (Fisher et al., 1994).

Thus, raloxifene and tamoxifen serve as bookend profiles for uterine safety for chronic SERM use in postmenopausal women, where molecules can be assessed for either a "raloxifene-like" profile of little or no uterine stimulation or a more estrogenic "tamoxifen-like" profile. Several SERMs have advanced to clinical research and corroborated the preclinical observations for those molecules. For example, droloxifene, idoxifene, and levormeloxifene all produced dose-related elevation of uterine weight, uterine epithelial height, and uterine eosinophilia in the OVX rat (Adrian et al., 1996) and were eventually halted in clinical development on the basis of uterine liabilities such as increased bleeding, increased endometrial thickness, and polyps that developed in phase 3 studies for osteoporosis (Silfen et al., 1999). The other triphenylethylenes used clinically, clomiphene and toremifene, also exhibit an overall uterine stimulatory profile in OVX rats (Turner et al., 1998; Carthew, 1999), although uterine safety is less of a concern with acute therapeutic use of clomiphene, and the risk/benefit profile for toremifene use in breast cancer treatment has a different weighting of risk. Mixed effects have been observed with lasofoxifene, which in some preclinical reports produced significant dose-related stimulation of uterine epithelial cell height and uterine eosinophilia (Cole et al., 1997), but not in others (Ke et al., 1998). The outcome of clinical trials with lasofoxifene is incomplete, although initial observations indicate statistically significant uterine stimulation with an approximately 80% increase in endometrial thickness relative to placebo-treated controls and an increased incidence of leukorrhea (McClung et al., 2006). On the other hand, bazedoxifene, arzoxifene, and acolbifene produced very little stimulation of the uterus in OVX rats (Komm et al., 2005; Sato et al., 1998; Martel et al., 2000), and at least with bazedoxifene, studies in postmenopausal women have corroborated the animal work (Adachi et al., 2007).

A significant uterine-related adverse event that emerged in a number of clinical trials is relaxation of the pelvic floor, typically with associated prolapse of the uterus. Estrogen therapy was traditionally thought to improve the structural integrity of pelvic tissue with expected favorable effects on symptoms such as urinary incontinence. However, data from both the WHI trial and the Heart and Estrogen/progestin Replacement Study (HERS) provided evidence for the increased incidence of urinary incontinence in association with estrogen use (Hendrix et al., 2005). Related to this, pelvic organ prolapse was associated with both levormeloxifene and idoxifene within 1 year of therapy (Fleischer et al., 1999; Goldstein et al., 2002). These observations, taken together, suggest that these uterine wall−associated adverse events with idoxifene and levormeloxifene might be due to their more estrogen-like uterine activity. The mechanism by which estrogen and some SERMs compromise the uterine wall in postmenopausal women may be linked to an increase in collagen-degrading enzymes, such as metalloproteinase-2 (MMP-2), based on OVX rat studies. In OVX rats, uterine MMP-2 levels were reduced relative to those of ovary-intact animals. Estrogen, as well as levormeloxifene, produced marked increases in uterine MMP-2 expression (Helvering et al., 2005a,b). Not all SERMs, however, have been associated with pelvic floor problems, because no increase in this adverse event has been related to the chronic use of tamoxifen, toremifene, bazedoxifene, or lasofoxifene (Fisher et al., 1994; Maenpaa et al., 1997; McClung et al., 2006; Adachi et al., 2007). Consistent with its uterine-safe overall profile, the extensive uterine safety evaluations with raloxifene showed no increase in the incidence of problems associated with pelvic floor relaxation. Rather, in at least one report, raloxifene produced benefit

with a significant reduction in the frequency of surgery for pelvic floor relaxation in a population of postmenopausal women (Goldstein et al., 2001).

Estrogen antagonism in the uterus

The final important component in assessing the uterine safety profile of SERMs relied primarily on preclinical data—the ability of SERMs to antagonize the uterine-stimulatory effects of estrogen. Further insight into the uterine activity profile of SERMs was gleaned from effects on the uterus in the presence of estrogen, because this allowed assessment of the uterine estrogen antagonist potential for these compounds. As in the estrogen-deficient state, the various SERMs also produced one of two general activity profiles in estrogen-replete animals: that of either a complete estrogen antagonist or a partial agonist at the ER. In the uterus of either estrogen-treated immature or adult OVX rats, SERMs producing desirable uterine safety profiles in postmenopausal women, such as raloxifene, arzoxifene, and bazedoxifene, produced a complete estrogen antagonistic effect (Adrian et al., 1996; Sato et al., 1998; Komm et al., 2005). This effect is most clearly demonstrated in the estrogen-treated immature rat, a model classically used to determine uterine liability of ligands for the ER. In this model, raloxifene blocks the uterotrophic effects of estrogen with an ED_{50} of 0.3 mg/kg (Silfen et al., 1999), whereas arzoxifene and bazedoxifene completely antagonizes the estrogen response with greater potency (Sato et al., 1998; Komm et al., 2005). A key feature of this antagonistic effect with SERMs like raloxifene in the immature rat uterus is the complete antagonism of the uterotrophic effect of estrogen. That is, the uteri from estrogen-treated immature rats given doses of raloxifene exceeding 3 mg/kg are indistinguishable from those of non-estrogen-treated immature rats (Adrian et al., 1996). This is in dramatic contrast to other SERMs—this is best exemplified by tamoxifen, which behaves as a classical partial agonist in the uterus. That is, tamoxifen does significantly antagonize the effects of estrogen in the immature rat uterus. However, in the case of tamoxifen, the maximal degree of this antagonism is only approximately 50% (Adrian et al., 1996). The primary reason for this incomplete antagonistic effect of tamoxifen is that at higher doses, the inherent uterine stimulatory capacity of tamoxifen limits further suppression of estrogen-induced uterotrophic response. Other triphenylethylene SERMs, as well as levormeloxifene (Adrian et al., 1996), produce partial estrogen agonist profiles in estrogen-stimulated immature rats.

In addition to the usefulness of this parameter for SERM uterine safety assessment, the complete estrogen antagonistic effects of SERMs like raloxifene were utilized successfully in a variety of preclinical models of estrogen-stimulated uterine pathologies with some limited success in clinical studies. For example, in vitro and in vivo models of uterine leiomyoma (fibroids) demonstrated favorable responses to raloxifene (Porter et al., 1998) with some reports of successful use of high-dose raloxifene to prevent the progression of uterine leiomyomas in small groups of premenopausal and postmenopausal women, either alone or in combination with a GnRH agonist (Jirecek et al., 2004; Palomaba et al., 2002b, 2005) via a combined antiproliferative/proapoptotic effect. However, other small clinical trials have failed to detect a benefit of raloxifene on uterine leiomyoma (Palomba et al., 2002a), indicating the need for randomized, well-controlled clinical trials for this indication, which would be necessary to balance the benefit on leiomyoma status versus the additional risk of ovarian stimulation from SERM use in premenopausal women (discussed later; note: raloxifene was not indicated for any uses in premenopausal women). In a rat model of another estrogen-dependent, uterine-related pathology, endometriosis, raloxifene inhibited the estrogen-dependent growth of peritoneal uterine explants (Swisher et al., 1995). In monkeys with spontaneous endometrial lesions, raloxifene eliminated the occurrence of peritoneal endometriosis lesions (Fanning et al., 1996).

The uterine estrogen antagonist effect of SERMs is also of potential benefit in the treatment of endometrial cancer, the most common neoplasm of the female urogenital tract. In many cases, endometrial cancer is susceptible to hormonal-targeted therapies involving both progestin-based and estrogen-depletion strategies. Given the role of estrogens both directly and indirectly via the regulation of progesterone receptor, SERM approaches have been explored. Tamoxifen was evaluated in a small cohort of advanced or recurrent endometrial carcinoma patients with limited success, dissuading the use of tamoxifen as a single agent for this tumor type (Thigpen et al., 2001). Promising efficacy in endometrial cancer treatment was reported with the third-generation SERM, arzoxifene. In early studies in a small number of treatment-refractory endometrial cancer patients, arzoxifene produced a favorable clinical response rate and stabilized the disease in a substantial number of women (Burke and Walker, 2003). In a phase 2 open-label study, ER-positive and progesterone receptor-positive patients with recurrent/advanced endometrial cancer also exhibited a high response rate and duration of response with a favorable side effect profile after administration of arzoxifene (McMeekin et al., 2003).

Mammary

The effects of estrogens on mammary tissue in normal adult animals and women are not typically as clear and robust as those effects observed in the uterus. However, clearly a majority of mammary tumors are ER-positive and respond

favorably to estrogen antagonism (Wakeling et al., 1987). The role of estrogen replacement in the risk of breast cancer continues to be a controversial topic, and clearly the concomitant use of progestins in most hormonal replacement therapy paradigms is confounding. In the WHI trial, a significant increase in breast cancer risk in postmenopausal women was a key finding (Writing Group for WHI Investigators, 2002), contributing to dramatic reductions in the use of estrogen replacement strategies for various postmenopausal indications. The role of progestin in this observation was suggested by a follow-up study of hysterectomized women using unopposed conjugated equine estrogens for more than 7 years, where no increase in breast cancer risk was observed (Stefanick et al., 2006). Although some controversy remains over the exact potential for breast cancer risk with estrogen therapies, it is clear that concern over this risk has limited patient compliance with steroidal estrogen therapies. A major advantage of the SERM class of molecules is the lack of this cancer concern with respect to mammary tissue. Indeed, SERMs as a class have demonstrated a benefit in either treating or preventing breast cancer in animal models and women. The effects of SERMs in normal mammary tissue, as breast cancer therapies and preventatives, will be summarized here.

In normal mammary tissue, the effects of SERMs are largely unnoticeable. Extensive use of tamoxifen in both premenopausal and postmenopausal women for the use of breast cancer risk reduction has not been associated with untoward effects on mammary tissue, although in developing mammary glands in mice, tamoxifen impaired the growth of mammary ducts and increased mammary alveolar development (Hovey et al., 2005). A cautionary note in interpreting animal data with respect to SERMs and mammary tissue is worth mentioning. The rat is unique in that male mammary tissue exhibits a layering of epithelial cells with a somewhat hypertrophic appearance, which is an androgen-dependent phenotype in rats. SERMs with highly effective estrogen antagonism in mammary tissue can sufficiently block estrogen influence on mammary epithelia in rats, permitting the low ambient level of androgen in the female rat to predominate and convert the mammary histological phenotype to resemble that of the male rat (Rudmann et al., 2005), a phenomenon known not to exist in humans. Caution should be taken not to confuse this female/male phenotype conversion in the rat with hypertrophy of mammary tissue.

The antitumor effects of SERMs can be demonstrated readily in mammary tumor cell lines (i.e., MCF-7, T-47D, ZR-75-1) in vitro. Each SERM depicted in Fig. 37.3 is an estrogen antagonist in one or all of these cell lines (Short et al., 1996; Simard et al., 1997; Komm et al., 2005). The MCF-7 human mammary tumor cell line is an excellent, estrogen-dependent, in vitro system for determining antagonism of estrogen-induced proliferative activity of compounds. Most SERMs inhibit estrogen-stimulated proliferation in the 0.2−1 nM range in this assay, although for those triphenylethylene SERMs requiring the formation of active metabolites, such as tamoxifen and toremifene, one must evaluate the active metabolite to see this level of potency. For example, the IC_{50} for tamoxifen in MCF-7 cells is 200, vs. 1.2 nM for 4-hydroxytamoxifen (Suh et al., 2001). Des-methylarzoxifene, a likely active metabolite of arzoxifene, is the most potent inhibitor of MCF-7 proliferation, with an IC_{50} value of 0.05 nM (vs. 0.4 nM IC_{50} for arzoxifene in this cell line; Suh et al., 2001). Also of relevance in the MCF-7 tumor cell line, raloxifene fails to induce proliferation of these cells in the absence of exogenous estrogen, contrasting raloxifene with other SERMs, such as tamoxifen, that produce a low level of MCF-7 proliferation in estrogen-deficient cell culture media (Sato et al., 1995).

Consistent with the mammary tumor cell culture work are the estrogen antagonist effects of SERMs in animal models of estrogen-dependent breast cancer. Various animal models have shown the ability of SERMs such as tamoxifen, toremifene, and raloxifene to blunt the growth of established mammary tumors induced by carcinogens such as dimethylbenzanthracene (Clemens et al., 1983; Robinson et al., 1988) or in breast cancer tumor cell line xenografts in athymic mice (Fuchs-Young et al., 1997; Qu et al., 2000). Tamoxifen, raloxifene, and lasofoxifene are also effective in preventing mammary tumors induced by other chemical carcinogens, such as nitrosomethylurea (Gottardis et al., 1987; Anzano et al., 1996; Cohen et al., 2001). Of great interest is the apparent increase in mammary tumor efficacy that has been demonstrated preclinically for some of the more recently developed SERMs. For example, arzoxifene, a third-generation SERM molecule, produced significantly improved efficacy in preventing mammary tumor growth in vivo (Suh et al., 2001).

With respect to treatment of human breast cancer, numerous options have been in use that employ endocrine-based strategies, with some patients considered suitable for estrogen reduction or antagonism strategies alone (i.e., estrogen-positive tumors) and others using endocrine manipulation approaches as an adjunct to traditional tumor chemotherapy. Two SERMs, tamoxifen and toremifene, are approved for chemo/endocrine treatment in the management of postmenopausal women with node-positive breast cancer. With respect to breast cancer, tamoxifen has been in use the longest of any SERM, with greater than 20 years of clinical use. When used as an adjunct, tamoxifen reduces the risk of recurrent cancer and also decreases the risk of new tumors arising in the other breast. Both tamoxifen and toremifene show similar efficacy in terms of 5-year overall survival and disease-free survival rates (the disease-free rate for tamoxifen is 69%, and for toremifene is 72%) for early-stage breast cancer and also demonstrate similar efficacy as first-line therapy for metastatic breast cancer in postmenopausal women (Cuzick et al., 2002 and 2003). As of 2009, the only other SERM in late-stage

clinical development with clinical assessment of breast cancer treatment potential was arzoxifene, which was evaluated in several phase 2 trials in advanced breast cancer patients, where some benefit in terms of time to progressive disease and clinical benefit rate were observed (Baselga et al., 2003).

The other significant application of SERMs is in breast cancer prevention. A number of environmental and genetic factors are associated with increased risk of developing breast cancer in women including advanced age, family history of breast cancer, and a greater lifetime estrogen exposure (assessed via surrogate indicators such as estradiol levels, use of estrogen therapy, age at menopause, and body mass index). One of the best tools for overall assessment of breast cancer risk is the Gail model, where a risk factor of greater than or equal to 1.67 defines a woman at risk (Costantino et al., 1989). Tamoxifen was the first SERM to show reduced risk of breast cancer through a number of large, placebo-controlled trials. In the Breast Cancer Prevention Trial, tamoxifen was evaluated in a cohort of 13,388 women at increased risk of breast cancer and produced a 49% reduction in the relative risk of invasive breast cancer, with a 69% reduced risk of ER-positive mammary tumors (Fisher et al., 1998). However, despite this substantial reduction in risk and inclusion of breast cancer risk reduction as an approved use for tamoxifen, the clinical use of tamoxifen for this indication has been rather lackluster—primarily owing to a side effects profile that tilts the risk/benefit ratio in a negative direction in the minds of most physicians and women. Side effects profiles will be reviewed in subsequent sections, but for tamoxifen, side effects include endometrial cancer, uterine sarcoma, stroke, venous thrombus events, and cataracts. The increase in endometrial cancer in postmenopausal women likely stems from the uterine stimulatory properties of tamoxifen and represents one area for improvement in other SERMs. In this regard, raloxifene received approval for reducing the risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women at high risk for invasive breast cancer. After 8 years of monitoring 4011 postmenopausal women with osteoporosis, a 66% reduction in the incidence of invasive breast cancer was observed with raloxifene use (Martino et al., 2004). In the Study of Tamoxifen and Raloxifene (STAR) trial, a head-to-head comparison of the two SERMs was conducted in 19,000 postmenopausal women at high risk of breast cancer, where tamoxifen and raloxifene were found to produce similar reductions in the incidence of invasive breast cancer (Vogel et al., 2006), with the primary benefit being a reduced risk of ER-positive invasive breast cancers (Barrett-Conner et al., 2006). The most significant differences between raloxifene and tamoxifen in the STAR trial were significantly fewer uterine-associated adverse events with raloxifene (most notably the lack of endometrial cancer), whereas tamoxifen appeared to have a greater effect on noninvasive breast cancer incidence than raloxifene (Vogel et al., 2006). These differences between tamoxifen and raloxifene, although subtle, indicated a difference from preclinical and even early clinical indicators, and as such demonstrated the need for thorough clinical evaluation before accurate therapeutic risk/benefit assessment and approval of indications can be made for human use. In this regard, several SERMs in development, such as acolbifene and bazedoxifene (Labrie et al., 2004; Adachi et al., 2007), had preclinical and early clinical profiles that were promising for potential use in reduction of the risk for breast cancer, but clinical evaluation was needed to predict the ultimate utility of these molecules in this regard.

The mechanism by which SERMs such as tamoxifen, raloxifene, and toremifene inhibit breast cancer development or progression is likely the result of multiple beneficial effects. Direct antagonism of estrogen action at the ER in target cells in breast tissue, as previously described, is a key component of the action of the SERMs, given the strong positive linkage of estrogen exposure to relative risk for developing breast cancer and the fact that SERMs are much more effective versus ER-positive breast cancers. However, it is also likely that antitumor effects that reduce estrogen bioavailability as well as effects independent of estrogen contribute to the ultimate anti—breast cancer effect. Raloxifene is known to elevate levels of sex hormone-binding globulin (Reindollar et al., 2002), which would be expected to reduce bioavailable estrogen levels and thereby further reduce the risk of estrogen-associated breast cancer. Other beneficial indirect SERM effects include (1) modification of signaling proteins with a role in tumor cell biology, as is observed with tamoxifen on protein kinase C, TGFβ, calmodulin, ceramide, and MAP-kinases (Mandlekar and Kong, 2001); (2) induction of apoptosis in mammary tumor cell lines, as with tamoxifen, raloxifene, and toremifene (Mandlekar and Kong, 2001; Diel et al., 2002; Houvinen et al., 1993); and (3) dampening of growth factor systems known to play a role in tumor progression. The effect of growth factors in the pathogenesis of breast cancer continues to attract considerable attention. The insulin-like growth factor (IGF) system, inclusive of signaling factors, IGF receptors, and IGF-binding proteins, has strong connections to the malignant transformation of normal breast epithelium and thus is implicated in the development and progression of breast cancer (Ward et al., 1994). The IGF system protects cancer cells from apoptosis, thus promoting their survival. Beneficial effects of SERMs on the IGF system were demonstrated in postmenopausal women after 2 years of raloxifene treatment. Raloxifene reduced circulating IGF-1 levels and increased IGF-binding protein-3 levels, which would be expected to be associated with reductions in bioavailable IGF-1 (Lasco et al., 2006).

Mammographic density of the breast depends on the contributions of the predominant cell types in the breast: stromal, epithelial (both of which are higher-density tissue types), and fat tissue (which is relatively radiolucent by standard

mammography). Although the role of breast density in the prediction of relative breast cancer risk remains a topic of debate, most investigators agree that breast cancer risk is higher in women with higher-density breast tissue (Boyd et al., 1995). Whether this is related to a protective effect of increased abundance of fatty tissue or simply impedance in detecting small amounts of cancerous tissue in higher-density breast is not clear. However, it is clear that estrogen use is associated with a significant increase in mammographic density (Breendale *et al.*, 1999). Conversely, SERMs, specifically raloxifene and arzoxifene, were associated with a reduction of breast density in postmenopausal women (Lasko et al., 2006; Kimler et al., 2006).

Other

In addition to the uterus and mammary tissue, other components of the female reproductive system are under the direct or indirect control of estrogen and thus are also susceptible to the effects of SERMs. Depending on the patient, those SERM effects may be desirable, undesirable, or neutral.

Ovarian effects

The ovary is an important regulator of cyclicity in the female reproductive system and the predominant source of circulating estrogen, and it is indirectly regulated via estrogen action on the hypothalamic−pituitary−ovarian (HPO) axis. In mice, 15- to 24-month exposure to tamoxifen, toremifene, or raloxifene is associated with ovarian tumors. However, there is no evidence of increased ovarian cancer risk with these agents in women. Careful evaluation of multiple randomized, placebo-controlled studies indicates that raloxifene did not increase ovarian cancer in postmenopausal women compared with placebo (Neven et al., 2002). Thus, the murine observations may be owing to species differences in ovarian responses in terms of tumor development between mice and humans. The endocrine system plays a key role in the production of ovarian tumors in mice, particularly when gonadotropins are sustained at elevated levels for extended periods (Murphy et al., 1973). In this regard, raloxifene produces a sustained, dose-related increase in serum luteinizing hormone (LH) levels and inhibition of ovarian follicle maturation in mice, both effects being reversible upon discontinuation of the SERM (Cohen et al., 2000). In vitro, raloxifene is an antagonist of 17β-estradiol in pituitary gonadotrophs (Ortmann et al., 1988), suggesting that the elevation of LH with SERMs is related to blockade of the feedback-inhibitory properties of estrogen on the HPO axis.

Hormonal effects

In women, the most striking effects of SERMs on ovarian function are primarily through hormonal effects on the HPO axis. Because ovarian function obviously has major differences between the premenopausal and postmenopausal state, the effects of SERMs are likewise different with each state of ovarian function. The HPO axis is a complex endocrine system for which normal physiology requires the interplay of a number of steroid and peptidyl hormones including GnRH from the hypothalamus, follicle-stimulating hormone (FSH), prolactin and LH from the anterior pituitary, and estradiol as a hormone primarily originating from the ovary (although multiple tissue types possess the necessary enzymes to interconvert estrogen and testosterone as well as to generate multiple estrogen metabolites).

In premenopausal women, SERMs predominantly exert a stimulatory effect on the HPO axis and ovulation, with stimulatory effects on GnRH, FSH, and LH and marked increases in serum estradiol levels (Adashi et al., 1996). Depending on the situation, this may be a desired therapeutic goal or an undesirable side effect. This effect has been taken advantage of for more than 40 years with the widespread use of clomiphene for induction of ovulation in women with ovulatory dysfunction who desire pregnancy. For this indication, clomiphene has been used acutely to induce ovulation and increase the number of follicles produced in a given cycle. Use of clomiphene for more than 12 cycles in women who failed to become pregnant has been associated with an increase in ovarian cancer, leading to the recommendation to limit use of this agent to no more than six cycles if a pregnancy does not occur (Rossing et al., 1994). The other two SERMs currently approved for use in premenopausal women are tamoxifen and toremifene, used in the management of breast cancer. In these women, chronic treatment with the SERM results in ovarian-associated adverse effects. Of note are the induction of ovarian cysts and high circulating levels of estradiol that frequently occur with tamoxifen in reproductive-age women (Cook et al., 1995). Although these ovarian cysts can cause discomfort, they rarely require surgical intervention.

By far, the predominant use of SERMs in postmenopausal women has been for osteoporosis treatment or prevention (raloxifene), breast cancer treatment (tamoxifen or toremifene), and breast cancer risk reduction (tamoxifen or raloxifene). After menopause or in estrogen-deficient OVX animals, estrogen levels drop, and the lack of negative feedback provided by estrogen on the hypothalamus-anterior pituitary leads to an increase in FSH and LH levels or pulses. In general, SERMs

exhibit a partial agonist effect on the HPO axis in postmenopausal women. Raloxifene, tamoxifen, and toremifene are associated with reductions in LH and FSH levels in postmenopausal women (Cheng et al. 2004; Ellmen et al., 2003). HPO axis-related adverse effects, such as ovarian cysts, have not been typically seen in postmenopausal women and have been reported only occasionally with tamoxifen use (Shushan et al., 1996).

Another important estrogen-regulated hormonal product of the anterior pituitary is prolactin. In premenopausal women, raloxifene failed to alter circulating prolactin levels (Faupel-Badger et al., 2006). In postmenopausal women, raloxifene (Cheng et al., 2004) and clomiphene (Garas et al., 2006) reduced serum prolactin, operating either directly on lactotropes in the anterior pituitary or via increasing opiatergic tone in the hypothalamus (Lasco et al., 2002).

Vaginal effects

The drop in circulating estradiol levels associated with menopause is responsible for various vaginal-related symptoms including itching, dryness, and dyspareunia. Various forms of estrogen and hormone replacement, via both systemic and local delivery routes, have been widely used to provide relief for postmenopausal women who have these symptoms. SERMs demonstrate a range of profiles on vaginal symptoms of menopause. Most reports in postmenopausal women indicated estrogen-like maturation of vaginal epithelial cells with tamoxifen and toremifene (Ellmen et al., 2003; Friedrich et al., 1998). Conversely, there was some indication for antagonism of estrogen influence on vaginal tissue because both toremifene and tamoxifen produced a fourfold increase in vaginal dryness in postmenopausal women (Marttunen et al., 2001) and toremifene partially antagonized the effect of estrogen on vaginal epithelium in postmenopausal women (Homesley et al., 1993). The background estrogen status of the individual may be an important determinant, because in women with a high estrogenic activity (with respect to hormonal cytology), tamoxifen produced no vaginal estrogen-like effects, whereas women with lower estrogen levels saw an increase in vaginal tissue maturation index (Shiota et al., 2002). Even with these modest estrogen-like effects produced by toremifene and tamoxifen on the vagina, no beneficial or untoward urogenital effects of either agent had been observed in postmenopausal women (Marttunen et al., 2001). Raloxifene use in postmenopausal women was associated with a more neutral profile on vaginal tissue in postmenopausal women because it failed to affect vaginal epithelium in this population (Komi et al., 2005) and was not associated with adverse vaginal symptoms (Davies et al., 1999). Raloxifene also did not antagonize the beneficial effect of vaginal estrogen cream or an estradiol-releasing ring on vaginal atrophy or sexual function in postmenopausal women (Kessel et al., 2003). One SERM that was extensively studied for potential beneficial effects on postmenopausal vaginal-associated symptoms in phase 3 clinical trials is lasofoxifene. In clinical trials, lasofoxifene improved the vaginal epithelium maturation index (as was observed with tamoxifen and toremifene) but also reduced vaginal pH and reduced the incidence of dyspareunia (Portman et al., 2004; Bachmann et al., 2004). These unique effects of lasofoxifene might be related to the increased vaginal mucus formation observed in vaginal tissue from OVX rats treated with lasofoxifene (Wang et al., 2006)—effects that were not observed with raloxifene and tamoxifen.

Cardiovascular system

Menopause is associated with a dramatic increase in cardiovascular disease and characteristic changes in a number of heart disease-associated risk factors, such as an increase in serum cholesterol and specifically LDL-cholesterol, a decline in the cardioprotective HDL-cholesterol, elevated levels of lipoprotein(a) [Lp(a)], and increased insulin resistance and fat mass, resulting in a classic "metabolic syndrome" profile for heart disease risk (Spencer et al., 1997). Unfavorable markers of vascular endothelial damage, such as elevations in homocysteine levels and C-reactive protein (CRP), also accompany declining ovarian function during menopause (Hak et al., 2000). The fact that women enjoy a relatively "cardioprotected" status prior to menopause relative to their male counterparts historically presented the impression that estrogen replacement should be beneficial for reducing cardiovascular disease in postmenopausal women. Certainly, in both estrogen-deficient animal models and postmenopausal women, estrogen produces a number of effects that would be associated with an improvement in risk for cardiovascular disease, such as reduction of total circulating cholesterol levels, LDL-cholesterol in particular, and a concomitant increase in HDL-cholesterol. Accordingly, observational clinical trials suggested a significant reduction of cardiovascular disease in women who used hormone replacement therapy after menopause (i.e., Stampfer and Colditz, 1991). Thus, it was an unanticipated result when randomized clinical trials conducted to confirm the beneficial effects of hormone replacement therapy on the cardiovascular system indicated the opposite effect—an increase in cardiovascular disease associated with estrogen/progestin use. The first trial to indicate this was the HERS trial, where no reduction in coronary heart disease was detected, but an increase in cardiovascular-related deaths in the initial year of therapy was observed (Hulley et al., 1998). Similarly, the WHI trial failed to demonstrate any beneficial effects of estrogen

use, but again an increased risk of adverse cardiovascular outcomes including increased incidence of myocardial infarction and stroke (Manson et al., 2003). Finally, the Women's Estrogen for Stroke Trial (WEST) indicated an early increase in risk of fatal stroke during the first year of estrogen use in women with preexisting cerebrovascular disease (Viscoli et al., 2001). Both observational and randomized, placebo-controlled studies in postmenopausal women indicated a significant increase in the risk of deep venous thrombosis and pulmonary embolism in association with hormone replacement (Manson et al., 2003).

Thus, it is clear that two important considerations related to SERMs needed to be addressed. First, and foremost, the cardiovascular safety profile of SERMs in postmenopausal women has to be thoroughly evaluated based on the risk ascribed to hormone replacement therapy by trials such as HERS, WHI, and WEST. The second consideration revolves around potential beneficial effects on cardiovascular risk factors, which might be instructive in determining the additional benefit of these molecules. However, if we are to learn a lesson from the hormone replacement field, one needs to be careful to rely on randomized, well-controlled trials to make these assessments. The cardiovascular safety of SERMs in clinical use and their potential cardiovascular benefits are discussed here.

Cardiovascular safety of selective estrogen receptor modulators

The primary adverse event associated with every chronically used ER ligand is the occurrence of venous thrombolic events (VTEs), typically as deep vein thromboses or pulmonary emboli. The relative frequency of VTEs with SERMs is typically two- to threefold greater than for placebo when assessed in randomized clinical trials, a rate that is comparable to that observed with the use of oral estrogen replacement therapy (Cosman and Lindsay, 1999). Such an increase in venous thromboses was described with tamoxifen and toremifene use in breast cancer patients (Cuzick et al., 2003; Harvey et al., 2006) and raloxifene use in osteoporotic patients (Duvernoy et al., 2005). Comparable rates of venous thromboses were also reported in the 2- and 3-year phase 3 clinical trials for lasofoxifene and bazedoxifene (Adachi et al., 2007; McClung et al., 2006). The incident rate of VTEs was elevated in postmenopausal women subjected to prolonged periods of inactivity (i.e., extended bed stay during invasive surgical procedures), and as such, SERMs used chronically carry a recommendation to discontinue drug therapy during periods of anticipated immobility of several hours or more (Cuzick et al., 2002; Seeman, 2001). The mechanism for the increased incidence of VTEs with SERMs is not clear, although a number of clinical trials noted procoagulant changes with estrogen replacement, tamoxifen, or raloxifene along with impairment of anticoagulant factors with these three regimens. Although there was some variability in the results of different studies with respect to specific factor changes, such as fibrinogen that is increased by raloxifene in some reports (Sgarabotto et al., 2006) but decreased in others (Walsh et al., 1998), some clear trends have emerged. In a randomized, placebo-controlled trial in healthy postmenopausal women (Cosman et al., 2005), estrogen replacement increased coagulation factor VII and reduced the anticoagulation factors antithrombin and plasminogen activator inhibitor-1 (PAI-1). Tamoxifen generated an overall procoagulant profile, although via an increase in clotting factor VIII, factor IX, and von Willebrand factor on the coagulant side, and decreases in antithrombin, protein C, and PAI-1 on the anticoagulant side. Raloxifene produced a different pattern of changes with some similarity to that of tamoxifen, although without elevation in clotting factor IX or reduction of protein C (Cosman et al., 2005). In a separate study, Dahm et al. (2006) demonstrated that estrogen replacement, tamoxifen, and raloxifene all acted to reduce human endothelial production of tissue factor pathway inhibitor-1 (TFPI), an anticoagulant factor. Thus, some clear trends have emerged as the most critical determinants for VTE occurrence with estrogen or SERMs, those being the reduction of important factors such as antithrombin, PAI-1 and TFPI, all anticoagulant functional proteins. However, this is more of a correlative hypothesis because no chronically used SERM seemed to avoid the 2%−3% rate of VTE occurrence. No preclinical models or predictors are available to predict the relative likelihood for VTEs in humans with SERMs or estrogens.

With respect to the more severe cardiovascular adverse events observed with hormone replacement in the HERS, WHI, and WEST clinical trials, reports were mixed regarding the incidence of stroke or myocardial infarction with various SERMs. Although a coronary heart disease neutral profile was reported initially with tamoxifen in the breast cancer prevention trial, an increased risk for stroke with tamoxifen was eventually observed (Reis et al., 2001). The long-term clinical trials that supported raloxifene approval for osteoporosis indications found no change in the incidence of myocardial infarction relative to placebo (Martino et al., 2005). Analysis on a per-year basis showed no increase in cardiovascular events in the first year of raloxifene use, which contrasts with the pattern reported for estrogen replacement in the HERS and WHI trials (Keech et al., 2005). Cardiovascular events were the primary outcome of the Raloxifene Use for The Heart, or RUTH, trial, where no increase in coronary events or stroke incidence was observed, but a statistically significant increase in stroke-associated mortality was reported (Barrett-Conner et al., 2006).

Potential cardiovascular benefit of selective estrogen receptor modulators

Although the large, randomized, placebo-controlled trials conducted with SERMs did not show a significant reduction in cardiovascular events, smaller trials and subsets of larger placebo-controlled trials demonstrated some favorable trends, leaving open the possibility that SERMs may offer a degree of cardioprotection. With tamoxifen, one clinical study concluded a slight reduction in cardiac death and reduced risk for myocardial infarction (Rutqvist et al., 1993). In the raloxifene osteoporosis registration clinical trial, a positive effect on the incidence of cardiovascular events was observed in a subset of women at high risk for heart disease (Barrett-Connor et al., 2002). Despite the lack of verifiable cardiovascular outcomes with SERMs, most SERMs evaluated in both clinical and preclinical settings showed largely favorable effects on most cardiovascular risk factors for heart disease including lipid metabolism, clotting factors, and vessel wall factors. However, the "fingerprint" of each SERM on the wide array of cardiovascular surrogates is strikingly distinct, suggesting that each SERM needs careful clinical evaluation before a complete assessment of cardiovascular benefit or risk can be ascribed.

The most clear and robust effect observed with SERMs on cardiovascular-relevant parameters in preclinical models was the reduction of serum cholesterol levels (i.e., raloxifene, Black et al., 1994; tamoxifen, Sato et al., 1996a,b; clomiphene, Turner et al., 1998; toremifene, Qu et al., 2000; acolbifene, Martel et al., 2000; lasofoxifene, Ke et al., 1998; bazedoxifene, Komm et al., 2005; arzoxifene, Palkowitz et al., 1997). As with the skeletal responses in OVX rats, all SERMs depicted in Fig. 37.3 were capable of reducing serum cholesterol by roughly the same magnitude, thus mimicking the response to estrogen in this animal model, although differences in potency are evident. This hypocholesterolemic effect of SERMs is mediated by the ER, as demonstrated in the case of raloxifene by a very close correlation of ER-binding affinity and cholesterol-lowering in vivo for a series of raloxifene analogues (Kauffman et al., 1997).

In clinical trials, most of the SERMs depicted in Fig. 37.3 reduced total serum cholesterol and LDL-cholesterol (Reid et al., 2004; Joensuu et al., 2000; McClung et al., 2006) even in hypertriglyceridemic women (Dayspring et al., 2006), with raloxifene and tamoxifen also reducing Lp(a) (Love et al., 1994; Mijatovic et al., 1999)—all effects that are cardioprotective with respect to cardiovascular disease risk factors. Neither tamoxifen nor raloxifene elevated HDL-cholesterol (Love et al., 1994; Walsh et al., 1998), a cardiovascular-beneficial effect of estrogen replacement. Triglyceride elevation, an undesired effect often associated with estrogen replacement, was increased in most clinical trials with tamoxifen, although a triglyceride-neutral profile was observed with raloxifene and toremifene (Walsh et al., 1998; Kusama et al., 2004).

Preclinical models focused on the vessel wall have produced beneficial effects after SERM administration. In rats, neointimal thickening following aortic denudation injury was reduced by either raloxifene or tamoxifen, with both SERMs shown to regulate vascular smooth muscle cell function, indicating a potential benefit against restenosis following percutaneous transluminal coronary angioplasty (Savolainen-Peltonen et al., 2004). Even though SERMs are linked to increases in VTEs in clinical studies, preclinical work has indicated a beneficial effect of raloxifene in a model of carotid artery thrombosis. In OVX mice, estrogen deficiency amplifies thrombosis following carotid photochemical injury. In this model system, raloxifene as well as estrogen significantly reduces intraarterial thrombosis prolonging time to occlusion, likely via a mechanism that involves reduced platelet adhesion and increased expression of COX-2 (Abu-Fanne et al., 2008). Vascular antiinflammatory effects of raloxifene were also linked to vasorelaxant properties (Pinna et al., 2006).

Cardiovascular disease surrogates associated with vessel wall function and inflammation were also generally improved in clinical studies following raloxifene and tamoxifen. CRP, a marker linked to vascular injury that reflects inflammatory activity in the vascular wall, was elevated with estrogen replacement (Cushman et al., 1999) but reduced with raloxifene and tamoxifen (Cushman et al., 2001; Walsh et al., 2000), as was homocysteine (Anker et al., 1995; De Leo et al., 2001), a circulating factor linked to toxicity of vascular endothelial cells. Improved endothelial function with tamoxifen (Stamatelopoulos et al., 2004) and reduction in endothelin-1 (Saitta et al., 2001), an endogenous vasoconstrictor, have also been described.

Clearly, other factors in addition to circulating lipids influence the ultimate potential cardiovascular benefit provided by compounds such as the SERMs. In this regard, direct effects of SERMs on cardiovascular tissue have been investigated extensively, and agents such as raloxifene produced a number of effects of potential cardiovascular benefit. For example, raloxifene produced an antioxidant effect on serum lipoproteins (Zuckerman and Bryan, 1996), inhibited vascular smooth muscle migration (Wiernicki et al., 1996), and elevated vascular endothelial cell nitric oxide production (Saitta et al., 2001). Preclinical studies in models of atherogenesis have provided mixed results. Raloxifene failed to prevent the reduction of the coronary artery intimal area in cholesterol-fed OVX monkeys (Clarkson et al., 1998). However, 6-month exposure to raloxifene did reduce aortic atherogenesis in cholesterol-fed OVX rabbits (Bjarnason et al., 1997) and improved the coronary artery intimal area in OVX sheep (Gaynor et al., 2000). Given that nearly all direct cardiovascular

studies with SERMs in postmenopausal women have been conducted with raloxifene, it is difficult to know whether these particular effects can be generalized across the SERM class or whether, as in the uterus, distinct cardiovascular SERM profiles might emerge. Additional research would be needed.

Central nervous system

The mixed biological results observed with estrogen in the cardiovascular system are paralleled by the profile of estrogen activity in the central nervous system (CNS). Extensive in vitro and animal studies suggest neuroprotective and other beneficial effects of estrogen on central processes ranging from cognition to fine motor control and mood. However, translational work to human neurodegenerative disease has failed to corroborate the preclinical data, and as in the cardiovascular system, suggests potential untoward effects of estrogen on the human CNS.

Clearly, ER is broadly distributed throughout the brain. Original thoughts were that ER was predominantly restricted to the hypothalamus and associated with well-known functions such as regulation of reproductive hormones in the periventricular nucleus and thermoregulation in the lateral hypothalamus. The discovery of the ERβ subtype and improved antibodies for the detection of ERβ, however, led to the reconstruction of ER distribution neuroanatomical charts to include higher brain regions such as the cortex and hippocampus, specifically neurons associated with learning and memory, such as pyramidal cells throughout the CA1 and CA3 regions of the hippocampus and cortex (Shugrue and Merchenthaler, 2001).

Estrogen produces a number of beneficial effects in vitro and in animal models. In neuronal cell culture, 17β-estradiol has neurotrophic effects and inhibits neuronal damage induced by neurotoxicants (O'Neill et al., 2004). In OVX rats, estrogen increases hippocampal choline acetyltransferase activity, which leads to increased levels of acetylcholine, a neurotransmitter associated with cognition (Wu et al., 1999). Estrogen also reduces neural damage after experimental forebrain ischemia (Simpkins et al., 1997) and produces beneficial effects in animal models of Parkinson's disease (Gomez-Mancilla and Bedard, 1992). Estrogen also affects central serotonergic neurotransmission in animal models, leading to increased serotonin production and firing and reduced degradation (Bethea et al., 2002a,b). Dopaminergic neurotransmission in the striatum is influenced by estrogen (Landry et al., 2002), as are glutamate receptors (Cyr et al., 2001).

The preclinical data are consistent in indicating a beneficial effect of estrogen on CNS function. However, clinical data have not supported this conclusion. Certainly, early observational studies suggested up to a 30% reduction in risk of dementia with estrogen use (Yaffe et al., 1998). However, because these trials were not well-controlled prospective studies, there was considerable room for group-related artifacts (e.g., educational status) that may affect data interpretation. In this regard, in large, randomized, placebo-controlled trials, estrogen not only failed to reduce the incidence of dementia but also was associated with increased risk of dementia and stroke (Shumaker et al., 2003). Additional data are clearly needed, because the role of progestin in studies where hormone replacement is employed is a complicating factor—although even with estrogen-only use, a similar profile was observed (Shumaker et al., 2004). Other potential effects of estrogen on the brain (e.g., on mood) are equally controversial. Clearly, in consideration of SERMs, careful attention must be paid not only to potential beneficial effects but also to CNS safety.

Central nervous system safety of selective estrogen receptor modulators

No outwardly neurotoxic effects of tamoxifen, raloxifene, or any SERM depicted in Fig. 37.3 have been reported in neuronal cell culture and animal studies. Some differences among various SERMs have been reported with respect to their ability to antagonize estrogen effects in the brain. For example, tamoxifen blocks the effect of estrogen on serotonin 2A receptor expression in the forebrain or dorsal raphe of rats (Sumner et al., 1999), whereas raloxifene fails to show an antagonist profile on this receptor subtype in these brain regions (Cyr et al., 2000).

In clinical studies, use of tamoxifen for 5 years in women for breast cancer therapy did not alter performance on a series of cognitive tests compared with breast cancer patients who had never used tamoxifen, although an increase in physician visits for memory problems was noted (Paganini-Hill and Clark, 2000b). The confounding variable of ongoing disease state in these women must be considered, though, because studies conducted in elderly women found no differences in mental functional tests or speed of response with tamoxifen use (Ernst et al., 2002). In pilot studies conducted to evaluate the safety of raloxifene on cognitive function in postmenopausal women with osteoporosis, no negative effects on memory function were detected as determined by a number of mental acuity tests (Nickelsen et al., 1999). Follow-up work in more than 7700 postmenopausal women with osteoporosis confirmed the initial observation of no negative effects of raloxifene

on cognitive performance (Yaffe et al., 2001). Consistent with the latter observation, no untoward effects of raloxifene were observed on mood, sexual behavior, or sleep in postmenopausal women.

Central nervous system efficacy of selective estrogen receptor modulators

Much as with estrogen, SERMs are largely associated with preclinical profiles that suggest neuroprotection and an overall positive CNS profile, although certain subtle differences can be observed among different SERMs, further indicating the need to thoroughly evaluate each specific SERM molecule. Positive effects of SERMs can be demonstrated in vitro; as in a neural cell line, raloxifene increased neurite outgrowth in culture (Nilsen et al., 1998). Raloxifene and tamoxifen were neuroprotective in a neuroepithelial cell line by conferring resistance to β-amyloid-induced toxicity via elevation of seladin-1 (Benvenuti et al., 2005), a factor known to be downregulated in brain regions affected by Alzheimer's disease (Greeve et al., 2001).

Neurotransmitter-related changes within the CNS by various SERMs can be similar for some transmitters in some brain regions but differ in other neurotransmitter systems. Much as with estrogen, raloxifene and tamoxifen increase hippocampal choline acetyltransferase activity (Wu et al., 1999). Indicating comparable effect of these two SERMs on the neurotransmission of acetylcholine, a neurotransmitter associated with cognition. Raloxifene and tamoxifen, however, produce different overall profiles on serotonin neurotransmission in the brain. In both rats and monkeys, raloxifene produces a spectrum of changes in the forebrain that are favorable for serotonin neurotransmission, such as increased tryptophan hydroxylase, increased serotonin 2A receptor expression, and reduced serotonin transporter (Cyr et al., 2000; Smith et al., 2004). In contrast, tamoxifen does not affect serotonin transporter and reduces tryptophan hydroxylase activity in the forebrain (Sumner et al., 1999), a profile unfavorable for serotonin neurotransmission. Of note, the SERM arzoxifene produces a pattern of effects on forebrain serotonin neurotransmission that parallels that produced by raloxifene (Bethea et al., 2002a,b). Other differences on neurotransmitter profiles can be observed with dopaminergic systems, as with lateral striatum dopamine receptor expression, which is increased in response to raloxifene but not affected by tamoxifen (Landry et al., 2002).

Distinct SERM efficacy profiles can also be detected in various CNS pathology animal models. Hippocampal neurodegeneration can be induced in rats by systemic injection of kainic acid, which leads to induction of inflammatory astroglia and neural loss that is protected by pretreatment with estrogen. In OVX rats injected with kainic acid, hippocampal neural loss was prevented in each case by tamoxifen, raloxifene, and bazedoxifene without affecting the reactive gliosis component (Ciriza et al., 2004), a profile distinct from that of 17β-estradiol, which was both neuroprotective and antiinflammatory in this model. Again, not all SERMs behaved the same in this model system, as lasofoxifene failed to exhibit a neuroprotective profile (Ciriza et al., 2004). Neuroprotective effects of SERMs in other animal models have also been observed. In separate studies, tamoxifen and arzoxifene reduced neural damage following occlusion of the middle cerebral artery in OVX rats, an experimental model for stroke (Mehta et al., 2003; Rossberg et al., 2000). The mechanism for SERM protection from focal cerebral ischemia in these animal models is unclear, because raloxifene induced a relaxation of rat cerebral arteries in vitro via inhibition of L-type calcium channels (Tsang et al., 2004), although direct effects on cerebral blood flow were ruled out in one study (Rossberg, 2000). Attenuation of excitatory amino acid release and putative antioxidant effects have also been demonstrated as potentially contributing to the neuroprotective effects of tamoxifen and raloxifene (Osuka et al., 2001; Siefer et al., 1994). Finally, neuroprotective effects of tamoxifen and raloxifene were observed in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine-induced dopamine depletion in a Parkinsonian model (Obata and Kubota, 2001; Grandbois et al., 2000).

A number of metabolic-based imaging and cognitive performance clinical trials suggested potential CNS benefits with some SERMs. Proton magnetic resonance spectroscopy in elderly women who had taken tamoxifen for at least 2 years for breast cancer treatment demonstrated a reduction in myoinositol, a glial marker that reflects glial proliferation in response to brain injury (Ernst et al., 2002), suggesting a neuroprotective effect of tamoxifen. Although the disease status of these women complicated interpretation of the data, it was interesting to note that in a comparable population of women taking estrogen replacement therapy but without breast cancer, a similar effect on myoinositol was observed (Ernst et al., 2002). Assessment of adverse CNS events in the randomized, placebo-controlled osteoporosis registration studies for raloxifene revealed no negative effects during the course of safety assessment. These studies did suggest some interesting trends for raloxifene-related improvement in cognitive performance, specifically higher verbal memory and attention scores; decreases in these areas are putative harbingers of mild cognitive impairment and Alzheimer's disease (Nickelsen et al., 1999; Yaffe et al., 2001). Women over the age of 70 in particular experienced smaller declines in memory and attention on raloxifene (Yaffe et al., 2005). In studies focused on the risk for Alzheimer's disease in postmenopausal women with osteoporosis, Yaffe and colleagues (2005) reported a one-third reduction in the risk of mild cognitive impairment with a

trend for reduced risk of Alzheimer's disease. In both studies where cognitive improvement was suggested with raloxifene, it is worth noting that the benefit was primarily observed in women receiving 120 mg/day of raloxifene. These benefits of raloxifene were not observed in similar women taking 60 mg/day of raloxifene, the standard and approved daily dose for osteoporosis prevention and treatment and breast cancer risk reduction. The potential requirement for a greater dose of raloxifene to generate meaningful CNS benefits was consistent with preclinical literature, such as increased hippocampal choline acetyltransferase activity, which also requires higher doses of raloxifene than are necessary for the bone effects in OVX rats (Wu et al., 1999), and the recognition that raloxifene has poor penetration of the blood−brain barrier (Bryant et al., 1997). The relative estrogen background may be a complicating factor because women with undetectable circulating estrogen levels prior to administration of raloxifene showed a greater benefit for mild cognitive impairment risk than women with higher circulating estrogen levels at baseline (Yaffe et al., 2005). The precise process of cognitive function that SERMs affect would require additional research. Although executive function/decision-making is the ultimate output of cognitive networks, these activities depend on more basic processes, such as alertness and arousal, to be operational. In this regard, it is interesting to note that in a study conducted in a small cohort of elderly men using functional magnetic resonance imaging, raloxifene improved memory function via increased arousal during initial encoding of information, likely via a neurogenic effect (Goekoop et al., 2006).

The important principle of drug exposure for SERMs will be reviewed in the next section, but particularly germane to the brain, as a central pharmacological tenant, is that for agents to exert their effect on a receptor, they must be available to the receptor. The limited brain exposure with raloxifene predicted by preclinical models is certainly an important factor. ER-binding studies also suggest reduced exposure of tamoxifen in the brain relative to peripheral tissues, such as the uterus (Bowman et al., 1982). Clearly, the functional studies with various SERMs in animal models with raloxifene and tamoxifen argue strongly that there is sufficient exposure to exert a biological response to these SERMs in the brain. However, critical factors such as dose, duration, and agonist/antagonist potential may be severely or subtly affected by the ability of the molecule to penetrate the brain. As a result, dose−response relationships that are expected based on peripheral tissues may not be monitored for effects within the CNS.

General safety profile and other pharmacological considerations

Other safety

In addition to the adverse events already reviewed (i.e., VTEs observed with all SERMs and uterine stimulation observed with some SERMs), SERMs are associated with other untoward effects that should be considered in the risk/benefit decision for each patient. Of these other adverse events observed in clinical trials, leg cramps and the induction of hot flushes were observed in women, to at least some extent, with all the SERM molecules depicted in Fig. 37.3. Hot flushes, or vasomotor symptoms, are a hallmark indicator of menopausal transition occurring in up to 70% of US women. The incidence of hot flushes is likely reflective of declining or changing estrogen status and typically abates when circulating estrogen levels reach their postmenopausal steady-state concentration. However, in a small percentage of women, vasomotor symptoms can be severe and extend well into menopause. Estrogen replacement clearly is effective in relieving postmenopausal hot flushes. With SERM use, however, it is likely that an estrogen withdrawal-like response is initiated, producing a state similar to that experienced by women who are estrogen depleted and have subsequent hot flushes. Although it is unclear whether this phenomenon is caused by the estrogen antagonist or agonist properties of the SERM at the ER in hypothalamic thermoregulatory centers, SERM-induced hot flushes are transient in nature, because with continued use in most cases, this side effect subsides typically within 6 months, likely as the thermoregulatory set point reestablishes (Tataryn et al., 1980). Consistent with this proposed mechanism, proximity to the climacteric state may influence the incident rate and severity of SERM-induced hot flushes. In postmenopausal women over the age of 55, significantly fewer hot flushes were observed in response to raloxifene compared with those observed in younger postmenopausal women. In a similar context, tamoxifen-induced hot flushes tended to be more severe in premenopausal breast cancer patients than in postmenopausal patients.

One problem in the assessment of the incident rate of hot flush induction following SERM administration is the relatively high placebo response rate in the postmenopausal population. In observational studies performed on randomized, placebo-controlled trials, the rate of reported hot flushes in postmenopausal women receiving placebo was 21% over a 30-month trial period (Cohen and Lu, 2000). In this study, the incidence of hot flushes in postmenopausal women using raloxifene was 28%. Others have confirmed an approximately 7% increase in hot flush incidence as a side effect of raloxifene use (Davies et al., 1999). Of note, the hot flushes induced by raloxifene were in the mild to moderate category in terms of severity, as severe hot flushes in postmenopausal women using raloxifene occurred at a rate indistinguishable from

that of placebo controls. Finally, the increase in hot flush incidence with raloxifene was transient, because no differences relative to placebo controls were observed after 6 months (Davies et al., 1999).

The observation of hot flush incidence is typical for other SERM molecules as well. Tamoxifen use in both premenopausal and postmenopausal women for breast cancer treatment has long been associated with hot flushes as a side effect in 10%−20% of patients and is more common in women with higher estrogen levels (Legha, 1988). Toremifene also induces hot flushes at rates equivalent to or slightly greater than that of tamoxifen (Hays et al., 1995). Clomiphene use for induction of ovulation increases hot flushes as well (Derman and Adashi, 1994). Levormeloxifene (Alexanderson et al., 2001), lasofoxifene (McClung et al., 2006), and bazedoxifene (Adachi et al., 2007) also increase hot flush incidence in postmenopausal women.

An interesting note of relevance to hot flushes and SERMs is the potential application of SERMs in combination with estrogen for the treatment of hot flushes. In a small study of postmenopausal women using 17β-estradiol in combination with raloxifene, a significant decrease in hot flushes was observed (compared with raloxifene treatment alone), although signs of endometrial stimulation were detected as well with this combination (Stoval et al., 2007). Large, randomized, placebo-controlled clinical trials have evaluated the combination of bazedoxifene and conjugated equine estrogens as a potential alternative for the treatment of hot flushes (and potentially other menopausal symptoms) without the need to include a progestin for the maintenance of uterine safety. Uterine assessment at 1- and 2-year intervals demonstrated a lack of endometrial hyperplasia for the bazedoxifene/conjugated equine estrogens combination (Pickar et al., 2007), indicating that the SERM had effectively blocked the potent stimulatory action of the estrogenic component of the combination. The combination also produced an increase in lumbar spine BMD in postmenopausal women that was superior to that of both placebo and raloxifene (Lindsay et al., 2007). Full assessment of the risk/benefit ratio of the bazedoxifene/conjugated equine estrogens combination for use in the relief of menopausal symptoms requires full assessment of hot flush and other symptom efficacy as well as effects on other adverse events, such as VTEs.

Other adverse events not already discussed and associated with some triphenylethylene SERMs are those associated with the eye. These ocular-related untoward effects include retinopathy, macular crystal formation, corneal keratopathies, and cataracts. Eye pathologies have been primarily associated with the use of tamoxifen and toremifene, with comparable incidence of 7%−10% (Hays et al., 1995). Visual disturbances were also noted with clomiphene use (Asch and Greenblat, 1976) but were not increased with nontriphenylethylene SERMs, such as with raloxifene use in postmenopausal women (Cohen and Lu, 2000). Length of therapy increased the risk of cataract development with tamoxifen use (Paganini-Hill and Clark, 2000a). One mechanism that has been proposed to address cataract formation with tamoxifen is the blockade of the chloride channels in the lens of the eye, which are important for the maintenance of lens hydration (Zhang et al., 1994). Of importance, this effect of tamoxifen on chloride channels in the lens seems to be independent of interaction with ER, and as such is likely off-target toxicity for certain triphenylethylene SERMs.

Pharmacokinetics

Pharmacokinetic properties of the SERMs are an important consideration in the overall effects of these molecules and served as a focal point for the development of novel and improved agents. For example, the third-generation SERMs arzoxifene, bazedoxifene, and lasofoxifene all have pharmacokinetic properties that represent improvements over raloxifene and tamoxifen. The ultimate advantage of these improvements to patients would require additional research, but as noted earlier in this chapter, much of the research and development has been redirected.

As previously indicated, tamoxifen generates active metabolite(s) with greater affinity and efficacy at the ER (Coezy et al., 1982). After a single oral dose of tamoxifen, maximal plasma levels are reached within several hours with an elimination half-life of 5−7 days (Fromson et al., 1973). Steady-state concentrations are attained within 3−4 weeks of chronic dosing (Adam et al., 1980). The potential for preferential tissue distribution was suggested in animal studies, where greater levels of radioactive tamoxifen were detected in mammary gland, uterus, and liver than in blood (Furr and Jordan, 1984). In humans, elevated uterine levels of tamoxifen with respect to circulating concentrations were observed, with endometrial levels twice those of myometrial or cervical concentrations (Fromson and Sharp, 1974). The primary route of elimination of tamoxifen follows hepatic metabolism, primarily glucuronidation, and subsequent biliary excretion with fairly little of the parent molecule being excreted in the urine and the potential for enterohepatic recirculation suggested in animal studies (Furr and Jordan, 1984).

Toremifene also is a triphenylethylene SERM that generates active metabolites (i.e., deaminohydroxy-toremifene; DeGregorio et al., 2000). Peak plasma concentrations of toremifene occur within 2−4 h after a single oral dose with nearly complete absorption, and plasma levels are linear with dose over a fairly wide dose range (Anttila et al., 1990). The elimination half-life of toremifene is 5 days, and steady-state circulating concentrations are reached within 2−4 weeks of

chronic dosing. There is evidence in animal models for relatively increased tissue distribution of toremifene in some tissues, with mammary gland uptake similar to tamoxifen (Kargas et al., 1989). Toremifene is extensively metabolized in the liver via demethylation, hydroxylation, and side-chain oxidation modifications (Anttila et al., 1990), and the primary route of elimination is fecal elimination following enterohepatic recirculation (Anttilla et al., 1990). Hepatic impairment significantly increases the half-life of toremifene, nearly doubling it (Anttila et al., 1995).

Clomiphene is the only triphenylethylene SERM in current clinical use for which there are no known active metabolites. Clomiphene is a racemic mixture of cis- (zuclomifene) and trans- (enclomiphene) isomers that is rapidly absorbed following oral administration. Peak plasma concentrations are achieved in approximately 6 h, with a half-life of approximately 5 days (Dickey and Holtkamp, 1996), although metabolites have been detected up to 6 weeks after a single dose, suggesting likely enterohepatic recirculation (Kausta et al., 1997). Clomiphene is hepatically metabolized and fecally excreted (Adashi, 1996).

The pharmacokinetics of raloxifene, a benzothiophene SERM, have some features similar to those of triphenylethylenes but also some considerable differences. Like tamoxifen and its relatives, raloxifene is rapidly absorbed from the gastrointestinal tract after oral administration, with peak blood levels attained in approximately 6 h and 60% of the oral dose absorbed (Heringa, 2003). Raloxifene is also highly bound to plasma proteins (approximately 95%; Heringa, 2003). However, in contrast to triphenylethylenes, the elimination half-life of raloxifene is considerably shorter at 28 h, and there are no known active metabolites of raloxifene in humans or rodents. Although there is virtually no P450 metabolism of raloxifene in the liver, it is extensively metabolized by first-pass hepatic glucuronidation, yielding an absolute oral bioavailability of only approximately 2% in humans (Snyder et al., 2000). Raloxifene is widely distributed, and as with triphenylethylenes, very little is excreted in the urine, with the bulk of clearance through biliary excretion and loss in the feces (Knadler et al., 1995).

Relatively less information is available on pharmacokinetic profiles of the third-generation SERMs arzoxifene, bazedoxifene, and lasofoxifene. Lasofoxifene demonstrates improved bioavailability because the molecule was designed to resist intestinal wall glucuronidation (Gennari et al., 2006). The elimination half-life of lasofoxifene is 165 h, and there is a linear relationship between plasma concentrations and dose (Gardner et al., 2006). The primary metabolic route for lasofoxifene is hepatic oxidation and subsequent conjugation (Branson et al., 2006). Bazedoxifene produces an absolute bioavailability of 6.2% following an oral dose, which is about threefold greater than that produced by raloxifene. Bazedoxifene demonstrates kinetic linearity at dose levels of 5−40 mg (Ermer et al., 2003). Maximal circulating concentrations of bazedoxifene are achieved within 1−2 h after oral exposure, and the elimination half-life is approximately 28 h with steady-state circulating levels attained in 7 days (Ermer et al., 2003). As with raloxifene, there is very little P450-mediated metabolism of bazedoxifene, and glucuronidation is the major metabolic route. The primary route of elimination is the feces, with evidence for enterohepatic recirculation (Chandrasekaran et al., 2003). Arzoxifene also exhibits pharmacokinetic advantages over raloxifene. Over a dosage range of 10−100 mg, blood levels of arzoxifene increase linearly with respect to dose, with maximal levels attained at 2−6 h and an elimination half-life of 30−35 h over this dose range (Munster et al., 2001). Arzoxifene is metabolized (demethylated) to desmethylarzoxifene, which is an active metabolite with a high binding affinity for the ER (Rash and Knadler, 1997).

Future directions with selective estrogen receptor modulators

In addition to the use of SERMs for osteoporosis, breast cancer, and the induction of ovulation, the ability of ER-activity-modulating agents to favorably impact other diseases and syndromes, in both women and men, is under discovery and clinical development efforts. The overall scope of these drug discovery efforts is broad, changing rapidly, and beyond the focus of this review.

Summary

SERMs are a diverse class of molecules that affect a broad spectrum of biological systems, with potential therapeutic benefit for a variety of diseases. Current concern over long-term use of estrogen-containing regimens has created an opportunity for the application of SERMs to chronic indications such as osteoporosis treatment or prevention. The unique SERM profile also potentially allows their use in other chronic indications of interest to postmenopausal women, most notably breast cancer risk reduction and treatment. However, safety considerations are very important for SERM use in these chronic indications. The pleiotropic nature of the ER and its role in numerous physiological systems raise the importance of considering potential SERM benefits and/or adverse events in the cardiovascular system and other tissues.

Chapter 38

Thyroid hormone and bone

Peter A. Lakatos[1,a], Bence Bakos[1,a], Istvan Takacs[1] and Paula H. Stern[2]

[1]1st Department of Medicine, Semmelweis University Medical School, Budapest, Hungary; [2]Department of Pharmacology, Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Chapter outline

Introduction

Thyroid hormone is essential for skeletal development and also affects mature bone. Depending on the hormone concentration and stage of life, the effects of thyroid hormone can be either beneficial or deleterious to the skeleton. This chapter focuses on the intracellular and cellular effects of thyroid hormone on bone cells as well as its relationship to the observed effects of the hormone on the skeleton in vivo in both experimental animals and humans. Studies published since the previous edition provide information on thyroid hormone effects on additional genes of interest in osteoblasts and further assessment of the skeletal risks of excess thyroid hormone.

New data regarding nuclear and nongenomic actions of thyroid hormone are discussed. These aspects of hormone effects are accompanied by an expansion of the section on in vivo responses of the skeleton to thyroid function alterations including subclinical conditions.

Intracellular mechanism of thyroid hormone action

Nuclear actions of thyroid hormones

Thyroid hormone receptors (TRs) are members of the nuclear receptor (NR) superfamily (Germain et al., 2006). All of these receptors share a common modular structure with a centrally located DNA-binding domain composed of two zinc fingers, an amino-terminal A/B domain involved in transcription modulation, and a carboxy-terminal ligand-binding domain that is also involved in receptor dimerization and interactions with coactivators and corepressors. TRs are

[a]participated equally in the work.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00038-5

nuclear proteins capable of binding to cognate DNA elements in the absence of their ligands. Binding of the ligand to the receptor alters the receptor conformation and subsequently enables the activation or repression of specific genes.

Thyroid hormone response elements (TREs) in the promoters of T3 target genes share a common hexanucleotide "half-site" sequence of (A/G)GGT(C/A/G)A. Pairs of this structure may occur as direct, everted, or inverted repeat. Promoters of certain genes have clusters of TREs with differing structures (Yen, 2001).

Activated TRs bind to TREs in the target genes' promoter either as monomer, homodimer, or as heterodimer formed with other members of the NR superfamily. These latter include the vitamin D receptor, retinoid X receptor, and retinoic acid receptors. Heterodimerization is an important modulatory mechanism of TR function and also a means of cross talk with other signaling pathways. In bone (Williams et al., 1994, 1995), as in other tissues (Glass, 1994; Brent et al., 1991), DNA binding and transcriptional activation are enhanced when the thyroid hormone receptor isoforms are present as heterodimers with retinoid or vitamin D receptors. In osteoblast cell lines, interactions among the retinoid, vitamin D, and thyroid hormone ligands appeared to mediate specific responses (Williams et al., 1994, 1995). Studies on the effects of treatment combinations on the expression of osteoblast phenotypic genes in the cell lines revealed complex responses that indicated the importance of dose, treatment duration, and degree of confluence in dictating the magnitude of response (Williams et al., 1995). In primary rat osteoblastic cells, alteration of the ligand combinations did not influence the responses (Bland et al., 1997).

In addition to differences between TREs of specific genes, variations of TR dimerization patterns and tissue-specific and developmental stage-dependent expression of different TR isoforms (discussed later), as well as cellular response to thyroid hormones, are also altered by a number of different nuclear coregulator proteins.

Coactivator proteins that bind to the liganded TR are members of the SRC/p160 family (McKenna et al., 1999; McKenna and O'Malley, 2002) or the TR-associated protein (TRAP) complex (Sharma and Fondell, 2002; Burakov et al., 2002). Besides enhancing transcriptional activity, SRC/p160 proteins such as steroid hormone receptor CoA are characterized by histone acetyltransferase activity.

Thyroid hormone receptors have a dual functionality and may act as repressors on the TRE in the absence of T3. This process is mediated by the interaction of the TR with corepressor proteins including nuclear receptor corepressor, silencing mediator of retinoid and thyroid hormone receptor, Sin3, and histone deacetylases (Torchia et al., 1998; Yen et al., 2006). This results in the condensation of chromatin structure and repression of transcription through decreased access of transcription factors (Koenig, 1998; Wu and Koenig, 2000).

TRs are products of two genes located on two different chromosomes. The TRα gene found on chromosome 17 encodes one isoform (TRα1) with T3 binding capacity, and two C-terminal splice variants (TRα2, TRα3) lacking it (Izumo and Mahdavi, 1988; Chassande et al., 1997). Truncated variants of the TRα1 isoform (TRΔα1, TRΔα2), retaining T3 binding capacity but missing the A/B domain, also exist (Plateroti et al., 2001).

Three T3 binding isoforms (TRβ1, TRβ2, TRβ3) varying only in the A/B domain are encoded by the TRβ gene situated on chromosome 3 (Williams, 2000). TRΔβ3 has T3 binding activity but lacks both the A/B and DNA binding domains.

TR isoforms are expressed in a complex, tissue, and developmental stage-dependent manner, suggesting functional differences between subtypes. TRα1 is constitutionally expressed during embryonic development and is subsequently the dominant TR isoform in the brain, heart, and bone (Vella and Hollenberg, 2017). TRβ is identified as the major isoform in the liver, kidneys, ears, retinas, the hypothalamus, pituitary, and thyroid. Differences in function between TR subtypes are confirmed by studies of thyroid hormone resistance in humans and genetically engineered mice models.

In skeletal tissues, mRNAs for TRα1, TRα2, and TRβ are found in MG63, ROS 17/2.8, and UMR-106 cell lines (Williams et al., 1994; Allain et al., 1996). TRβ2 mRNA has been found in osteoblasts (Abu et al., 2000). mRNA for TRα1 was 12 times higher than TRβ1 mRNA in tibia and femur of 7-week-old male mice (O'Shea et al., 2003). TRα1, TRα2, TRβ1, and TRβ2 mRNAs were expressed in chondrocytes at all stages of differentiation. TRα1, TRα2, and TRβ1 mRNAs were highly expressed in osteoblasts at bone-remodeling sites; and mRNAs for all isoforms were present and highly expressed in multinucleated osteoclastic cells from an osteoclastoma (Abu et al., 1997). TRα1, TRα2, and TRβ1 mRNA have also been detected in rat femurs and vertebrae (Milne et al., 1999). Immunohistochemical staining with antibodies recognizing a TRα epitope or specific TRα2 and TRβ revealed the presence of receptor protein in osteoblast cell lines and in osteoclasts in tissue smears from a human osteoclastoma (Allain et al., 1996). In contrast to mRNA expression, TRα1 protein expression was not seen in the osteoclastoma cells and was limited to osteoblasts at sites of remodeling and undifferentiated chondrocytes (Abu et al., 2000).

The syndrome of resistance to thyroid hormones (RTH) caused by dominant-negative mutations of the TRβ gene was recognized as early as 1967. Over 3000 cases have occurred, and since the identification of the first causal genetic abnormality in 1989, over 120 different mutations have been documented. In contrast, similar mutations in the TRα gene, and corresponding conditions, have only been recognized since 2012 (Bochukova et al., 2012; van Mullem et al., 2012; Moran et al., 2013).

RTHβ is characterized by an autosomal dominant inheritance, elevated thyroid hormone, and unsuppressible TSH levels. Symptoms manifest with variable expressivity and include short stature, decreased weight, goiter, cognitive impairment, tachycardia, and hypacusis. All reported cases except one are genetically heterozygous. The mutations are clustered and largely located within domains in the carboxy-terminal region. They are mainly nucleotide substitutions that result in single amino acid changes (Refetoff et al., 1993). The mutant alleles act by a dominant-negative mechanism to inhibit the ability of the normal allele to elicit normal receptor function (Chatterjee et al., 1991; Sakurai et al., 1990). The dominant-negative action appears to be at the level of DNA binding (Kopp et al., 1996).

Skeletal alterations include retarded bone age and stippled epiphyses, similar to characteristics of hypothyroidism, with a resulting short stature. In other patients there is accelerated bone age, accelerated chondrocyte maturation, and early epiphyseal closure, again resulting in short stature (Behr et al., 1997). The target sites at which resistance occurs (pituitary or peripheral) may determine the phenotype.

Patients with RTHα present with normal levels of TSH accompanied by low/normal T4 and high/normal T3 concentrations and a decreased FT4/FT3 ratio. While cognitive and motor abnormalities often vary, skeletal development is markedly delayed. Disproportionate growth retardation, delayed bone age, patent skull sutures, macrocephaly, flattened nasal bridge, short stature, epiphyseal dysgenesis, and defective bone mineralization are reported (Tylki-Szymańńska et al., 2015). Radiographic features are suggestive of hypothyroidism. Phenotype is largely dependent on the severity of the underlying genetic abnormality, the resulting hormone binding potential, and dominant-negative activity of the TRα1 receptor. Consequently, the response to T4 treatment also varies between patients. A recent report detailed the case of a patient with a mutation affecting both TRα1 and TRα2 leading to a severe, atypical skeletal phenotype with intrauterine growth retardation, macrocephaly, hypertelorism, micrognathia, short and broad nose, clavicular and 12th rib agenesis, elongated thorax, ovoid vertebrae, scoliosis, congenital hip dislocation, short limbs, humeroradial synostosis, and syndactyly (Espiard et al., 2015).

A syndrome resulting in advanced bone age was associated with a mutation in the MCT8 thyroid hormone transporter gene (Herzovich et al., 2007). A single nucleotide change (Q261X) in exon 3 on the X chromosome resulted in low serum T4 and free T4, elevated serum T3 and free T3, slightly elevated TSH. The child had severe neurological abnormalities and normal growth, which had been previously noted in other patients with mutations in this gene (Dumitrescu et al., 2004).

Knockin mice models of RTH have helped shed more light on the roles of different TR isoforms in bone and other tissues (Kaneshige et al., 2001; O'Shea et al., 2006). Carrying a C-terminal frame-shift mutation derived from a patient with severe RTH, the TRβPV mouse has TRβ receptors that are dominant-negative antagonists incapable of transactivation and T3 binding. The resulting phenotype is consistent with human RTHβ, showing serum lipid abnormalities, growth retardation, hearing loss, neurological dysfunctions, and markedly elevated TSH and thyroid hormone levels.

The bone phenotype in these mice is reminiscent of skeletal thyrotoxicosis, with advanced endochondral and intramembranous ossification, premature closure of the growth plates, and shortened body length along with increased mineralization and craniosynostosis. The narrower growth plate appears to be a consequence of faster transition through the proliferative zone. Trabecular bone mass is also decreased with more resorption and a greater number of TRAP-positive cells. Expression of fibroblast growth factor receptor-1 (FGFR1), a skeletal T3-target gene, is increased.

Mice carrying PV and other types of dominant-negative mutations in the TRα1 gene were also created (Kaneshige et al., 2001; O'Shea et al., 2006; Quignodon et al., 2007; Bassett et al., 2014). With the TRα1PV protein being a dominant-negative antagonist of both TRα1 and TRβ, the mutation was lethal in homozygotes. Heterozygotes showed mild elevation in TSH levels, accompanied with normal FT3 and FT4. Bone phenotype was hypothyroid with growth retardation, wider growth plates, delayed intramembranous and endochondral ossification, transiently decreased bone calcification, decreased resorption, and TRAP-positive cells. FGFR1 expression and adult bone remodeling were also reduced.

These findings support TRβ being the predominant regulator of the negative feedback loop of the HPT axis. Changes in the skeleton of RTH patients and PV mice models suggest TRα1 to be the dominant TR isoform in bone.

Studies done with knockout mice also illustrate the complex roles of different TR isoforms. Hormone levels in TRα1−/− mice show mild central hypothyroidism with no gross impairments of skeletal development (Wikstrom et al., 1998; Gauthier et al., 1999; Gothe et al., 1999; Gloss et at., 2001). TRα2−/− animals have mild thyroid dysfunction with decreased peripheral hormone levels accompanied by normal TSH. Growth was not impaired, but adult bone density was decreased (Saltó et al., 2001).

TRα−/−, TRα1−/− TRβ−/−, and TRα−/− TRβ−/− animals exhibit different degrees of similarly impaired bone development with growth retardation, disorganized bone plates, and delayed endochondral ossification (Fraichard et al., 1997; Gauthier et al., 1999; Göthe et al., 1999). TRα−/− mice are hormonally hypothyroid while double-knockout mice lacking TRβ have increased TSH, T3, and T4 levels. TRα0/0 mice missing not just TRα1 and TRα2 but also TRΔα1 and

TRΔα2 transcripts are hormonally euthyroid. Similarly to TRα−/− mice, they exhibit growth retardation and delayed endochondral ossification but have increased adult BMD due to defective remodeling (Bassett et al., 2007).

TRβ−/− animals exhibit elevated TSH and thyroid hormone levels, and signs of skeletal thyrotoxicosis not unlike those seen with TRβPV mice. Accelerated endochondral and intramembranous ossification, advanced bone age, increased mineral deposition, persistent short stature, and later on progressive osteoporosis, are reported (Bassett et al., 2007).

Mice lacking DIO2, the activating deiodinase catalyzing the intracellular synthesis of T3 from T4, show pituitary resistance to T4 resulting in increased TSH, slightly elevated T4, and normal T3 levels. Though postnatal skeletal development and linear growth are normal in DIO2−/− mice, osteoblast function and bone formation in adulthood were shown to be severely impaired (Bassett et al., 2010).

Differential expression and only partial overlap in functions of TR isoforms allow for the development of thyroid hormone analogs that have tissue specificity owing to their preferential interaction with one receptor isoform. As previously outlined, TRβ1 is the predominant isoform in the liver and most peripheral tissues, while heart rate and bone metabolism are influenced mostly via TRα1. Potential benefits of selective TRβ1 agonists would be lowering of body weight, serum lipid, and cholesterol levels without deleterious cardiac or skeletal side effects. Selective and partial TRα1 agonists are hoped to produce positive inotropic cardiac effects while lowering peripheral resistance in heart failure patients. Though no selective TR agonist is in clinical use at the time of writing, several compounds are under different stages of development and investigation. Selective TRβ1 agonists of interest include kb-141 (Grover et al., 2003), GC1 (Chiellini et al., 2002), eprotirome (Ladenson et al., 2010), and tiratricol (Sherman et al., 1997). DITPA is a thyroid hormone analogue tested in the treatment of chronic heart failure (Goldman et al., 2009).

Nongenomic actions of thyroid hormones

Although high-affinity binding sites for thyroid hormones on the plasma membrane were identified as early as the 1980s, specific receptors on the cell membrane, in the cytoplasm, and in mitochondria have been established and their modes of action increasingly elucidated in recent years (see reviews by Davis et al., 2008, 2011, 2013, 2016). The effects are mediated through rapid activation of signaling pathways, leading in various tissues to increased nitric oxide (NO) synthase (Hiroi et al.), mitogen-activated protein kinase (MAPK) (Davis et al., 2000; Lei et al., 2008), and the Akt activator phosphatidylinositol-3-kinase (Hiroi et al., 2006; Moeller et al., 2006). Subsequent cellular responses can result from activation of nuclear transactivator proteins or the direct effects of signaling intermediates on the plasma membrane (Davis et al., 2016). The integrin $\alpha_v\beta_3$ acts as a low-affinity membrane receptor for thyroid hormone (Bergh et al., 2005), mediating angiogenic actions and effects on platelets and neurons as well as on bone cells (Davis et al., 2011). In human osteoblastic MG63 and SaOS2 cells, an $\alpha_v\beta_3$-blocking antibody inhibited thyroid hormone stimulation of the MAPK pathway and thymidine incorporation (Scarlett et al., 2008), suggesting a role of the pathway in bone formation. The resorptive effects of thyroid hormone may also involve $\alpha_v\beta_3$, based on the finding that a vitronectin receptor antagonist inhibited thyroxin-induced bone resorption (Hoffman et al., 2002). A novel high-affinity plasma membrane TRα associated with caveolin domains in human primary osteoblasts mediated the rapid effects of T3 on NO, cyclic guanosine monophosphate (cGMP), Src phosphorylation, and activation of MAPK and Akt, leading to cell proliferation and survival (Kalyanaraman et al., 2014). Hypothyroid mice exhibited cGMP deficiency with osteocyte apoptosis and impaired bone formation (Kalyanaraman et al., 2014). Treatment with T3 rapidly decreased Src Y416 autophosphorylation, thereby stimulating osteocalcin expression in primary calvarial osteoblasts from neonatal mice (Asai et al., 2009).

Rapid (within 30 s) increases in inositol mono-, bis-, and triphosphates were elicited by treatment of fetal rat limb bones with 100 nM and 1 μM T3 (Lakatos and Stern, 1991). The inactive analogs diiodothyronine and rT3 did not increase inositol phosphates. This effect of T3 was inhibited by indomethacin and could represent an initiation pathway for the prostaglandin-dependent effects of thyroid hormones on bone resorption, discussed later. Thyroid hormones at high doses inhibit cyclic AMP phosphodiesterase (Marcus, 1975). T3 at 0.1 and 1 nM increased ornithine decarboxylase and potentiated the responses of this enzyme to parathyroid hormone (PTH) (Schmid et al., 1986).

Thyrotropin as an independent agent of bone metabolism

In the past 10−15 years, thyrotropin (TSH) has been implicated as playing a direct regulatory role in many extrathyroidal tissues. TSH receptor (TSHR) expression has been established in the brain, the pituitary, orbital preadipocytes and fibroblasts, the kidney, ovary and testis, skin and hair follicles, heart, adipose tissue, hematopoietic and immune cells, and bone. In vitro and in vivo studies of TSH action suggest multifaceted regulatory functions as well as a role in disease states such as endocrine ophthalmopathy.

TSHR is expressed on chondrocytes, osteoblasts, and osteoclasts (Abe et al., 2003; Endo and Kobayashi, 2013). Besides systemic TSH, other potential local ligands have been implied for these receptors, such as Tshb, a splice variant expressed by bone marrow derived macrophages (Vincent et al., 2009), and thyrostimulin, a glycoprotein TSH-activating hormone expressed by both osteoblasts and osteoclasts (Bassett et al., 2015).

The physiologic role of TSHR in bone cells, the pathway downstream from the receptor, and the potential effects of TSH in bone metabolism are still contradictory. In certain studies, osteoblastogenesis, type I collagen-, bone sialoprotein-, and osteocalcin expression were inhibited in osteoblasts treated with TSH, presumably via the Wnt signal pathway (Abe et al., 2003). Others found a stimulatory effect on osteoblast differentiation and function on various cell lines and animal models (Sampath et al., 2007; Baliram et al., 2011; Boutin et al., 2014). In other studies the presence and physiologic function of TSHR on osteoblasts were proposed to be insignificant (Tsai et al., 2004; Bassett and Williams, 2008). Most findings point toward a potential inhibitory role of TSH on osteoclast function, an effect mediated primarily via TNFα (Hase et al., 2006; Ma et al., 2011; Sun et al., 2013; Zhang et al., 2014).

Intermittent low-dose TSH treatment of ovariectomized rats resulted in a decrease in resorption markers, an increase in formation markers, and an improvement in BMD and overall bone strength (Sampath et al., 2007; Sun et al., 2008; Dumic-Cule et al., 2014).

Genetically modified mice models investigating the roles of TSH on bone metabolism also reported somewhat conflicting results. TSHR knockout mice that have severe congenital hypothyroidism with extremely elevated TSH levels show growth retardation and BMD reduction with histomorphometric signs of increased bone turnover; though when supplemented with thyroid extract, these animals regain normal weight following a "catch-up" growth, while bone density and calvarial thickness remain reduced. Compared with the wild genotype, a 3-week treatment with supraphysiologic thyroxine resulted in increased bone loss in TSHR knockout animals. Furthermore, while Tshr ± mice are hormonally euthyroid, have normal formation and resorption marker levels, and normal calvarial thickness, BMD was still found to be slightly reduced at sites. These findings suggest that TSH has an inhibitory effect on bone remodeling (Abe et al., 2003; Baliram et al., 2012). Comparison of the skeletal phenotype of Pax8−/− and hyt/hyt mice, however, implies that TSH has no or a minimal effect on bone metabolism. The former have impaired thyroid development due to the lack of a critical transcription factor with resulting hypothyroidism, accompanied by a 2000-fold elevation in TSH levels but an intact TSHR (Mansouri et al., 1998). Hyt/hyt mice are characterized by a loss of function mutation of TSHR also resulting in hypothyroidism and extreme elevation of TSH levels (Beamer et al., 1981). Despite the fundamental difference in TSHR function, both mice models have similar defects of skeletal metabolism typical of severe hypothyroidism. Chondrocyte, osteoblast, and osteoclast activities are decreased while impaired linear growth, delayed endochondral ossification, reduced cortical bone mass, defective trabecular bone remodeling, and reduced bone mineralization are evident (Bassett and Williams, 2008).

Thyrostimulin deficient Gpb5−/− mice show an increase in infantile bone production that is resolved by adulthood (Bassett et al., 2015). However, somewhat contrary to this finding, in vitro treatment of osteoblasts thyrostimulin resulted in no notable change in differentiation or function.

Cellular effects of thyroid hormones on the bone

Thyroid hormones exert a complex, developmental stage, and dose-dependent influence on bone formation, growth, and remodeling, affecting several critical constituents of skeletal metabolism. As we have previously discussed, the dominant TR isoform in the bone is TRα1. While compared with TRβ it is present in bone cells at 10-fold higher levels (O'Shea et al., 2003), recent studies also suggest a role for the latter (Monfoulet et al., 2011). Thyroid receptors are most notably present on reserve zone and proliferating chondrocytes (Ballock et al., 1999; Robson et al., 2000; Stevens et al., 2000), osteoblasts, and osteoblastic bone marrow stromal cells (Rizzoli et al., 1986; Allain et al., 1996; Milne et al., 1999; Siddiqi et al., 2002). Their presence and role on osteocytes and osteoclasts are still unclear (Bassett and Williams, 2003). Differentiated chondrocytes have no TR expression.

The activating deiodinase DIO2, a catalyzing intracellular formation of T3 from T4, is expressed primarily in osteoblasts (Bassett et al., 2010), and in animal models has been demonstrated to be present from early embryonal stages of skeletal development (Gouveia et al., 2005; Capelo et al., 2008). The inactivating DIO3 deiodinase has been found in all skeletal cell lines, with the highest activity in growth plate chondrocytes.

The presence of several thyroid hormone transport proteins such as MCT8, MCT10, LAT1, and LAT2 also has been demonstrated in growth plate chondrocytes, osteoblasts, and osteoclasts (Williams et al., 2008; Capelo et al., 2009; Abe et al., 2012).

Wide concentration ranges of thyroid hormones have been used in experimental studies, especially in vitro, and often markedly different dosages are required to obtain the same response in a different cell line, model system, or laboratory. The differentiation state and the production of modulating factors are potential variables that can affect the response in a given system. In addition, the presence of thyroid hormone in the added sera or the presence of binding sites in stripped sera can dramatically influence the free hormone available to the cells or tissue. Several studies have estimated the amount of free hormone available under the experimental conditions used (Sato et al., 1987; Allain et al., 1992). In one study, an equilibrium dialysis method was used to determine free T4 and T3 after treating fetal calf serum with AG1-X8 resin (Sato et al., 1987). T4 and T3 concentrations in the fetal calf serum prior to extraction were 11.1 μg/dL and 157 ng/dL, respectively. It was determined that the addition of 10 nM T4 to the stripped serum provided 80 p.m. free T4, and that addition of 1 nM T3 provided 40 p.m. free T3. In the other study, in which 10% neonatal calf serum was used, the free T3 was measured by radioimmunoassay (Allain et al., 1992). It was determined that the addition of 10 p.m. T3 yielded a free T3 concentration of 2.1 p.m., that 0.1 nM yielded 4 p.m., that 1 nM yielded 2.1 p.m., and that 10 nM yielded 0.39 p.m. (Allain et al., 1992). Although the type and percentage of serum would influence the final values, these measurements and calculations are of value in comparing studies and in relating in vitro concentrations to the concentrations of thyroid hormones in normal serum.

Osteoblasts

T3 may produce varying responses in osteoblasts in vitro depending on species, anatomical origin of cells, stage of differentiation, passage number, cell confluence, dose of T3, and duration of treatment (Rizzoli et al., 1986; Williams et al., 1994; Cray et al., 2013). Most results suggest a stimulating role of T3 on osteoblast proliferation (Ernst and Froesch, 1987; LeBron et al., 1989; Luegmayr et al., 1996), differentiation (Ohishi et al., 1994; Klaushofer et al., 1995), and function (Fratzl-Zelman et al., 1997).

T3 can increase proliferation of rodent and human osteoblastic cells (Ernst and Froesch, 1987; Kassem et al., 1993). In the rodent cell cultures, 0.01 and 1 nM were stimulatory, and 10 nM was inhibitory in longer term cultures (Ernst and Froesch, 1987). Cell number was decreased after 8 days of incubation with T4 in MC3T3-E1 cells; inhibition was observed with 10 nM T3 and was maximal at 1 μM (Kasono et al., 1988). In other investigations, T3 did not significantly affect the growth of ROS 25/1, UMR-106, and ROS 17/2.8 cells (Sato et al., 1987; LeBron et al., 1989; Williams et al., 1994).

In response to T3 treatment, an increase is seen in the expression of osteoblastic phenotypic markers, such as osteocalcin (Gouveia et al., 2001; Varga et al., 2003), osteoprotegerin (Varga et al., 2004), osteopontin, type I collagen (Kawaguchi et al., 1994a; Varga et al., 2010), and alkaline phosphatase (Sato et al., 1987; Kasono et al., 1988; Banovac and Koren, 2000). Effects are seen at concentrations in the physiologic range; however, the dose-dependence of the response is quite variable and may be dependent on cell type and culture conditions. Levels of IL-6, IL -8, MMP9, MMP13 (Varga et al., 2009), and tissue inhibitor of metalloproteinase-1 are also elevated, as are IGF-1, IGFBP-2, -3, and -4, and FGFR1, which are thought to be major secondary mediators of T3-mediated osteoblast activation (Schmid et al., 1992; Varga et al., 1994; Glantschnig et al., 1996; Huang et al., 2000; Stevens et al., 2003). IGF-I has significant anabolic effects on bone, increasing cell replication and both collagen and noncollagen protein synthesis (Canalis, 1980; Hock et al., 1986; McCarthy et al., 1989; Centrella et al., 1990; Pirskanen et al., 1993). T3 increased IGF-I expression more markedly in cells from vertebral marrow than in cells from femoral marrow (Milne et al., 1998). Interference with IGF-I action by decreasing expression or function of the IGF-I receptor by the use of antisense oligonucleotides, antibodies, and antagonist peptide decreased the anabolic effects of T3 on MC3T3-E1 cells and primary mouse calvarial osteoblasts, including effects on alkaline phosphatase, osteocalcin, and collagen synthesis (Huang et al., 2000). The effects of thyroid hormones on IGFs may be modulated by changes in IGF-binding proteins (IGFBPs). The physiological role of IGFBPs is not fully understood; however, they can influence the cellular uptake and turnover of IGF-I.

Treatment of osteoblasts with T3 stimulated expression of FGFR1 mRNA and protein (Stevens et al., 2003). PTH and PTHrp receptors are also upregulated in response to T3 treatment in osteoblastic cell lines (Schmid et al., 1986; Gu et al., 2001). Osteoblastic cell morphology, cytoskeleton formation, and cell adhesion molecules also respond to T3 stimulus in vitro (Luegmayr et al., 1996, 2000; Fratzl-Zelman et al., 1997).

Osteoclasts

T3 stimulates resorption in bone organ cultures. Fetal rat limb bones (Mundy et al., 1976; Hoffmann et al., 1986; Lakatos and Stern, 1992) and neonatal mouse calvaria (Krieger et al., 1988; Klaushofer et al., 1989; Kawaguchi et al., 1994) are the models that have been studied most extensively. Compared with the effects of PTH, T3 responses are slower to develop,

with the dose–response curves being generally shallow (Mundy et al., 1976; Krieger et al., 1988; Klaushofer et al., 1989; Kawaguchi et al., 1994b), and maximal effects are lower. Further evidence for the differing actions of T3 and PTH is supplied by the contrast in their interaction with TGFβ (Lakatos and Stern, 1992). TGFβ enhanced the early responses to PTH and inhibited later effects, whereas interaction with T3 displayed a somewhat reversed time course.

It is still unclear whether the increased osteoclastogenesis and bone resorption seen in vitro in response to T3 and in vivo in thyrotoxicosis is mediated by a direct effect of T3 on osteoclasts or is exclusively secondary to changes in the function of osteoblast, stromal osteocytes, or other bone marrow cells (Mundy et al., 1976; Klaushofer et al., 1989). T3 failed to activate isolated osteoclasts; however, when mixed bone cells were added to the cultures, a significant response was observed with 1 μM T3, although not with lower concentrations (Allain et al., 1992).

Various osteoblast-derived secondary mediators, growth factors, and cytokines have been implicated. In neonatal mouse calvaria, resorption was inhibited by indomethacin, suggesting a prostaglandin-dependent pathway (Krieger et al., 1988; Klaushofer et al., 1989; Kawaguchi et al., 1994b). Other studies have shown prostaglandin-independent effects (Conaway et al., 1998) involving other mediators, such as the RANKL/OPG pathway (Varga et al., 2004), IGF-1 (Stracke et al., 1986; Lakatos et al., 1993),TGFβ (Lakatos and Stern, 1992; Klaushofer et al., 1995), interleukins (Tarjan et al., 1995; Siddiqi et al., 1998; Schiller et al., 1998), and interferon-γ.

Remodeling

Most in vitro studies have focused on either anabolic or catabolic effects of thyroid hormone under conditions designed to optimize the study of the particular response. However, because there are dose-dependent biphasic effects on formation parameters and delayed (Klaushofer et al., 1989) and submaximal (Mundy et al., 1976; Krieger et al., 1988; Lakatos and Stern, 1992) effects on resorption, it may be that neither effect can be studied to the exclusion of the other, and the net effects on bone remodeling may be accessible to in vitro investigation. A model system designed to study growth, mineralization, and resorption in radii and ulnae of 16-day fetal mice (Soskolne et al., 1990) revealed interesting differences between effects of T3 and PTH. Effects of T3 were studied over a 0.1nM–10μM dose range. T3 concentrations in the 10nM–0.3 μM range resulted in increases in diaphyseal length, increased calcium, phosphate, and hydroxyproline content, and decreased 45Ca release. At higher concentrations (1 and 10 μM), T3 stimulated 45Ca release. In contrast, when PTH was studied over a 1pM–0.1 μM range, only resorptive effects were observed, these being at concentrations of 1 nM and higher.

Chondrocytes

Thyroid hormones exert a complex regulatory effect on chondrocyte function including proliferation, matrix synthesis, mineralization, chondrocyte maturation, endochondral ossification, and linear bone growth. In different cultures, T3 is mostly shown to inhibit chondrocyte proliferation, induce hypertrophic differentiation, and help sustain the structure and ossification of epiphyseal cartilage (Burch et al., 1982a, 1982b; Böhme et al., 1992; Quarto et al., 1992; Ballock et al., 1994; Alini et al., 1996; Ishikawa et al., 1998; Rosenthal et al., 1999; Miura et al., 2002). T3 was approximately 50 times more potent than T4 in promoting expression of the hypertrophic markers in prehypertrophic chondrocytes in cells cultured with insulin/transferrin/selenium (Alini et al., 1996). There was a biphasic dose-dependency of the effects of T3 and T4 to stimulate the synthesis of type II collagen and chondroitin sulfate-rich proteoglycans in cultured rabbit articular chondrocytes (Glade et al., 1994). The shift toward hypertrophic phenotype is mainly mediated via the upregulation of cyclin-dependent kinase inhibitors (Ballock et al., 2000). T3 also stimulates the synthesis of extracellular matrix proteins and enzymes involved in mineralization and matrix degradation including collagen X, matrix proteoglycans, ALP, MMP13, and aggrecanase-2.

In vivo responses of the skeleton to thyroid hormones: animal studies

Hypothyroidism

Animal models of hypothyroidism include the use of the antithyroid agents propylthiouracil and methimazole to block the synthesis of thyroid hormones. Treatment of young rats with methimazole for 7 weeks resulted in a marked increase in trabecular bone volume of the subchondral spongiosa of the mandibular condyles and a decrease in cartilage cellularity (Lewinson et al., 1994). IGF-I was present in the condyles of control rats but lacking in hypothyroid rats. Replacement of T4 during the last 2 weeks of treatment restored the parameters to normal (Lewinson et al., 1994). Histomorphometric

studies in iliac crest biopsies of young rats made hypothyroid by a 12-week treatment with propylthiouracil showed that both osteoid surfaces and eroded surfaces were reduced, and cancellous bone volume was increased (Allain et al., 1995). In a study in which 21-day rats were made hypothyroid by administration of methimazole, T4 given daily at doses of 2−64 μg/kg/day for 21 days elicited biphasic effects on epiphyseal growth plate width and longitudinal growth rate (Ren et al., 1990). The dose−response curve paralleled that of serum IGF-I concentrations, which were postulated to contribute to the growth responses (Ren et al., 1990). An interesting animal model for hypothyroidism utilizes transgenic mice (line TG66-19) in which the bovine thyroglobulin promoter drives the expression of the herpes simplex type I virus thymidine kinase gene in thyrocytes. This enzyme converts ganciclovir to ganciclovir-59-phosphate, which inhibits DNA replication, resulting in loss of thyrocytes, loss of follicles, and undetectable T3 and T4; levels of PTH and CT are unaffected (Wallace et al., 1991, 1995). In this transgenic mouse model, administration of 15 or 50 μg of ganciclovir to mouse dams during days 14−18 of gestation resulted in growth delay in pups carrying the transgene (Wallace et al., 1995). The authors point out that the reason their effects were more dramatic than those obtained with the hyt/hyt mouse, a strain that has an inactivating mutation in the TSH receptor, is that in the latter model, circulating T4 is still 10%−20% of normal (Adams et al., 1989). Effects of mutations in thyroid hormone receptors in mouse models were discussed earlier.

Hyperthyroidism

A range of T4 regimens has been used to elicit hyperthyroidism in animal models. The duration of treatment is generally at least 3 weeks and dosages range from 200 μg to 1 g per day. Lower concentrations have been used in animals previously made hypothyroid with antithyroid drugs (Lewinson et al., 1994). When thyroid hormones are administered to young rats, bone growth is enhanced (Glasscock and Nicoll, 1981). This response is not seen in older rats, suggesting that the stage of cellular differentiation or the environment in terms of other hormones and local factors can influence the manifestation of thyroid hormone responses. T3 treatment of neonatal rats elicited a narrowing of the sagittal suture and increased mineral apposition rates at the osseous edges of the sutures (Akita et al., 1994). Histomorphometric analysis was consistent with the conclusion that T3 is critical for bone remodeling (Allain et al., 1995). When the animals were rendered hyperthyroid by treatment with T4 (200 μg/day for 12 weeks), the mineral apposition and formation rates were increased markedly, with a smaller increase in eroded surfaces (Allain et al., 1995). A greater sensitivity of cortical bone (femur) than trabecular bone (spine) to thyroid hormone-induced bone loss has been noted in animal models of hyperthyroidism (Ongphiphadhanakul et al., 1993; Suwanwalaikorn et al., 1996, 1997; Gouveia et al., 1997; Zeni et al., 2000). Tooth movement was greater in T3-treated rats undergoing orthodontic procedures than in control untreated animals, probably reflecting greater root resorption (Shirazi et al., 1999). Rats at 10 days old, treated with 100 μg/kg/day for up to 60 days, displayed altered parameters of cranial width, narrowing of the suture gap of the sagittal suture, and intense immunohistochemical staining for IGF-I along the suture margins, consistent with the possibility that local IGF-I is involved in the effect of thyroid hormone to cause premature suture closure (Akita et al., 1996). Ovariectomized rats treated with a low dose of T4 (30 μg/kg/day for 12 weeks) showed increased bone turnover and decreased bone density compared with controls; however, in the presence of 17β-estradiol, their bone mass and mineral apposition rate were greater than those of controls (Yamaura et al., 1994). T4 (250 μg/kg/day for 5 weeks) increased serum osteocalcin and urinary pyridinoline and produced a greater loss of bone mineral compared with either ovariectomy or T4 alone (Zeni et al., 2000). In contrast to the effects of these high doses of T4, administration of a more physiological concentration (10 μg/kg/day) to ovariectomized rats resulted in a generalized increase in bone mineral density at both lumbar and vertebral sites (Gouveia et al., 1997). Estradiol prevented T3-stimulated decreases in bone mineral density in ovariectomized thyroidectomized rats, but had no effect in animals that were not treated with T3 (DiPippo et al., 1995). These results raise the possibility of cross talk at the level of binding of estradiol and T3 receptors to DNA target sites.

Pathophysiological effects of altered thyroid hormone status in humans

Hypothyroidism

With an incidence of 1:1800, hypothyroidism is the most common congenital endocrine disorder, while primary hypothyroidism caused mostly by chronic autoimmune thyroiditis is the leading cause of hypothyroidism in childhood and adolescence. Approximately 2% of US adolescents have elevated TSH. Bone turnover is decreased in hypothyroidism (Mosekilde and Melsen, 1978), which in juvenile cases leads to abnormal endochondral ossification, delayed skeletal maturation and bone age, epiphyseal dysgenesis and short stature. Due to screening efforts in the Western world, the skeletal changes of untreated congenital hypothyroidism are rarely seen today. These might include complete cessation of

bone maturation, growth arrest and skeletal dysplasia with a broad face, broad flat nasal bridge, hypertelorism, persistently patent sutures, scoliosis, vertebral immaturity and absence of ossification centers, and congenital hip dislocation. In a study of children with congenital hypothyroidism treated with T4, the bone age at 1.5 years was correlated positively with the dose of T4 administered during the first year and with the concentrations of serum T4 (Heyerdahl et al., 1994).

Adult-onset hypothyroidism leads to reduced remodeling rates with both the activity of osteoblasts and osteoclasts decreased. To present date, there are only a few studies reporting on changes of bone turnover markers in adult hypothyroidism. Urinary pyridinium cross-links (Nakamura et al., 1996) and serum IGF-I (Lakatos et al., 2000) were shown to be reduced in these patients. Changes in bone volume and density are hard to assess, as no patient remains untreated for a significant enough time. Most data come from patients with restored euthyroidism. Nevertheless, low turnover seems to result only in no change or even a slight increase in bone volume and density (Paul et al., 1988; Stamato et al., 2000; Vestergaard et al., 2002; González-Rodríguez et al., 2013).

Consistent with the lack of significant changes in bone density, the few studies that are available suggest that hypothyroidism or elevated TSH does not increase fracture risk in itself. However, as detailed below, larger doses of T4 supplementation or frank overtreatment of hypothyroidism is shown to be an independent risk factor for fracture (Cummings et al., 1995; Melton et al., 2000; Van Den Eeden et al., 2003; Ahmed et al., 2006; Flynn et al., 2010).

Subclinical hypothyroidism

Subclinical hypothyroidism—that is, elevated TSH accompanied with thyroid hormone concentrations in the normal range—is extremely prevalent, especially among the elderly. While some degree of decline in bone turnover is demonstrable in these patients (Meier et al., 2004), no association was shown with changes in BMD or fracture risk (Waring et al., 2013; Garin et al., 2014; Blum et al., 2015). Current treatment recommendations do not include skeletal considerations.

Hyperthyroidism

With Graves' disease being the leading cause, thyrotoxicosis is much less common in infants and adolescents than hypothyroidism. It results in accelerated growth and skeletal development. Advanced bone age due to the increase in chondrocyte differentiation in the epiphyseal growth plates leads to early cessation of growth and persistent short stature (Schlesinger and Fisher, 1951; Saggese et al., 1990). In severe early onset cases, craniosynostosis might occur.

In adults, hyperthyroidism shortens the bone turnover cycle, leading to high turnover rates. Histomorphometric analyses show increased osteoclast numbers and resorbing surfaces, with loss of trabecular bone volume (Mosekilde and Melsen, 1978). Histomorphometric data yield a kinetic model demonstrating accelerated bone remodeling, with a disproportionately greater increase in resorption and a net loss of bone with each cycle of remodeling (Eriksen, 1986). Since the initial description of bone loss and the "worm eaten" appearance of long bones in thyrotoxicosis by von Recklinghausen (1891) more than a century ago, substantial additional evidence has shown that excessive thyroid hormone production can lead to bone loss. In patients with hyperthyroidism, markers of bone turnover are increased in correlation with disease severity. Pyridinoline and hydroxypyridinoline cross-link excretion are elevated (Harvey et al., 1991; Garnero et al., 1994; Nagasaka et al., 1997; Engler et al., 1999), as are urinary N-terminal telopeptide of type I collagen (Mora et al., 1999; Pantazi et al., 2000) and serum carboxyterminal-1-telopeptide (Loviselli et al., 1997; Miyakawa et al., 1996; Nagasaka et al., 1997). Evidence of activation of osteoblasts in hyperthyroidism is the elevation of alkaline phosphatase (Mosekilde and Christesen, 1977; Cooper et al., 1979; Martinez et al., 1986; Nagasaka et al., 1997; Pantazi et al., 2000), osteocalcin (Martinez et al., 1986; Lee et al., 1990; Mosekilde et al., 1990; Nagasaka et al., 1997; Loviselli et al., 1997; Pantazi et al., 2000), and carboxyterminal propeptide of type I procollagen (Nagasaka et al., 1997). Consistent with the molecular studies (Varga et al., 2004) showing that T3 increases OPG in osteoblastic cells, elevated OPG has been reported in patients with Graves' disease (Amato et al., 2004; Mochizuki et al., 2006). Greater increases in the resorption markers than the formation markers verify the imbalance between resorption and formation, leading to bone loss (Garnero et al., 1994; Miyakawa et al., 1996).

Decreases in bone mineral content are established by several studies (Fraser et al., 1971; Krolner et al., 1983; Toh et al., 1985; Guo et al., 1997; Udayakumar et al., 2006; Majima et al., 2006), and a concomitant increase in fracture risk (Fraser et al., 1971; Wejda et al., 1995; Bauer et al., 2001; Vestergaard et al., 2000, 2005; Vestergaard and Mosekilde, 2003 and mortality (Franklyn et al., 1998; Patel et al., 2014) is also well documented. These latter changes are suggested by some to be only partly a result of thyrotoxicosis induced bone loss and partly a result of other aspects of the disease (Cummings et al., 1995). The skeletal effects of hyperthyroidism seem to be especially pronounced in postmenopausal women.

Recovery of bone loss in hyperthyroid patients following antithyroid treatment has been inconsistent (Fraser et al., 1971; Toh et al., 1985; Saggese et al., 1990; Diamond et al., 1994; Mudde et al., 1994; Olkawa et al., 1999; Kumeda et al., 2000; Barsal et al., 2004) but may be achieved more readily in younger individuals (Fraser et al., 1971; Saggese et al., 1990). Studies have documented protective effects of methimazole (Langdahl et al., 1996a; Nagasaka et al., 1997; Mora et al., 1999). Surgery and radioactive iodine also prevented bone loss in hyperthyroid patients (Langdahl et al., 1996b; Arata et al., 1997; Karunakaran et al., 2016) but were less protective than methimazole (Vestergaard et al., 2000a). Calcium supplementation with or without calcitonin (Kung and Yeung, 1996), estrogen (Lakatos et al., 1989), and bisphosphonates (Ongphiphadhanakul et al., 1993; Rosen et al., 1993a; Yamamoto et al., 1993; Rosen et al., 1993b; Kung and Ng., 1994; Lupoli et al., 1996) were also investigated and shown to be protective against ongoing bone loss in hyperthyroidism.

Additional to the treatment of the underlying condition, the therapy for hyperthyroidism-related osteoporosis does not differ from that of other secondary causes. Where data are available, novel antiporotic medications also seem to retain their efficacy in this clinical setting (Mirza and Canalis, 2015; Mana et al., 2017).

Subclinical hyperthyroidism

Subclinical hyperthyroidism is suggested to increase bone turnover rates. However data on whether this is actually the case and if so, whether this translates to an actual loss of bone mass and an increase in fracture risk is still controversial.

Data is derived from multiple sources including patients with endogenous subclinical hyperthyroidism and patients treated with suppressive thyroxine doses primarily for thyroid cancer and in rarer cases for euthyroid goiter. The question whether endogenous subclinical hyperthyroidism or larger amounts of exogenously administered thyroid hormones increase the risk of bone loss, especially among individuals already at risk for osteoporotic fractures, is of particular interest.

Bone turnover markers are shown to be elevated in certain studies while remaining physiologic in others (Nystrom et al., 1989; Karner et al., 2005; Reverter et al., 2005; El Hadidy et al., 2011; Lee et al., 2014). The situation regarding BMD and fracture risk is quite similar. A number of heterogeneous studies conducted in different age, gender, and disease groups show disparate degrees of TSH suppression. Densitometry was performed at varying anatomical locations using different methodologies. There are also large differences in the duration of follow-up. Effects of subclinical hyperthyroidism are thus reported to range from insignificant (Franklyn et al., 1992; Lee et al., 2014; Waring et al., 2013; Garin et al., 2014) to major (Kung and Yeung, 1996, Jódar et al., 1998; Tauchmanovà et al., 2004; Sugitani and Fujimoto, 2011; Kim et al., 2015). Where fracture risk was shown to be increased at all (Bauer et al., 2001; Turner et al., 2011; Abrahamsen et al., 2014, 2015), values of relative risk were reported between 1.25 (Vadiveloo et al., 2011) and 5 (Lee et al., 2010).

While many papers report on some degree of bone loss and increase in fracture risk, the dose of thyroxine treatment, the degree and duration of TSH suppression, sex, and postmenopausal status in women seem to be major determinants. The protective effect of adequate calcium intake was also suggested in one paper (Kung and Yeung, 1996). Meta-analyses seem to confirm these differences (Faber et al., 1994; Uzzan et al., 1996; Quan et al., 2002; Heemstra et al., 2006; Wirth et al., 2014; Blum et al., 2015). The available evidence regarding decreased BMD and increased fracture risk in subclinical hyperthyroidism of both endogenous and exogenous origin is most robust in postmenopausal women.

A few studies have also been conducted on the potential skeletal effects of variations in thyroid markers within the physiologic range. With lower TSH levels and thyroid function at the upper end of the normal range, osteoporosis and fracture risk were found to be increased again, primarily in postmenopausal women (Kim et al., 2006; Morris et al., 2007; Murphy et al., 2010; Lin et al., 2011; van Rijn et al., 2014; Noh et al., 2015; Hwangbo et al., 2016). In the case of premenopausal women and men, changes in bone metabolism related to subclinical hyperthyroidism or normal variations in TSH are much less convincing. For further assessment, possibly more prospective studies are needed.

Overview and future directions

Thyroid hormones play a major role in skeletal physiology and pathology both during development and in adult bone maintenance. Their lack results in cessation of bone maturation, growth, and remodeling, while their excess is associated with accelerated bone maturation and accelerated bone loss in adulthood. Thyrotoxicosis is a prevalent cause of secondary osteoporosis, while subclinical hyperthyroidism, suppressive doses of thyroxine treatment, and possibly higher thyroid activity within the normal range are all associated with increased bone loss and fracture risk, especially in postmenopausal women.

Osteoblasts and chondrocytes are the primary target cells of thyroid hormones, while secondary paracrine mediators are implied in the effects of T3 on osteoclasts. Different isoforms of thyroid hormone receptors, mediating their genomic

action, are well characterized, with TRα1 being the main isoform in bone. RTHα, a condition presenting with marked skeletal changes, is caused by the dominant negative mutations of the TRα gene. The disease has only been recognized in the past few years, and additional studies might bring further insights into the role of thyroid hormones on skeletal physiology. Selective thyroid receptor analogues may present a therapeutic option for metabolic syndrome or chronic heart failure in the future.

Nongenomic actions of thyroid hormones mediated via membrane and cytoplasmic receptors are increasingly recognized and pose an interesting subject for further research. The presence of a pituitary−bone axis and the potential role of TSH as a quasi-independent regulator of bone development and remodeling have also recently been posited. Though still contradictory, results are promising in this challenging topic.

Chapter outline

Introduction

More than 80 years ago, Harvey Cushing described 12 patients presenting with either pituitary or adrenal adenomas. Most of these patients were found to have severe osteoporosis and Cushing noted that their "bones were easily cut with a knife" during postmortem examination (Cushing, 1932). The cause of the skeletal pathology of what is known today as "Cushing's disease" or "Cushing's syndrome" was later discovered to be the adrenal steroid hormone, 11β,17α,21-trihydroxypregn-4-ene-3,20-dione, or cortisol. In 1949, Hench and colleagues published on the use of cortisone, a glucocorticoid closely related to cortisol, in patients with rheumatoid arthritis, a report which revolutionized clinical medicine through the discovery of the potent and even today unrivaled antiinflammatory and immunosuppressive properties of glucocorticoids (Hench et al., 1949). Since then, these naturally occurring hormones as well as their pharmaceutical derivatives have been used with great benefit in the treatment of countless conditions including arthritis, inflammatory bowel disease, allergy and hypersensitivity disorders, chronic obstructive pulmonary disease, cancer, and transplant rejection.

While the clinical benefits of glucocorticoid therapy can hardly be overestimated, the use of these drugs is unfortunately associated with numerous unwanted effects such as bone loss and osteoporosis (Reid et al., 2009), insulin resistance and diabetes (Gonzalez- Gonzalez et al., 2013; Niewoehner et al., 1999), proximal myopathy, cataract, skin atrophy, delayed

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00039-7

wound healing, and increased risk of infection, to name only a few (Kanda et al., 2001; Natsui et al., 2006). These unwanted outcomes create a significant dilemma for clinicians, as improvements in the primary condition often seem to be achievable only by accepting significant adverse effects that are often hard to prevent or treat.

In this chapter, we will review our current understanding of the mechanisms underlying the physiology and pathophysiology of glucocorticoid action on the skeleton and discuss present and future treatments for glucocorticoid-induced osteoporosis (GIO). As a general note, it is important to realize that the actions of glucocorticoids on bone and mineral metabolism are strongly dose and time dependent. Thus, at physiological concentrations, glucocorticoids are key regulators of mesenchymal cell differentiation and therefore bone development, with additional regulatory roles in renal and intestinal calcium handling. However, at supraphysiological—i.e., therapeutic—concentrations, glucocorticoids affect the very same systems in different and often unfavorable ways. Thus, glucocorticoids can act on the skeleton in both anabolic and catabolic ways.

The physiological role of glucocorticoids in bone

Glucocorticoid signaling and prereceptor metabolism

Endogenous glucocorticoids are essential to life, as they control electrolyte and fluid homeostasis, fuel metabolism, and immune and stress responses. These actions are primarily mediated through the glucocorticoid receptor (GR) within target tissues. As such, both GR expression levels and ligand binding affinity influence glucocorticoid actions at the tissue level. The GR resides predominantly in the cytoplasm, complexed with heat-shock protein 90 (Hsp90) and several immunophilins such as FKBP51 (Zhou and Cidlowski, 2005). Upon ligand binding, the GR dissociates from this complex and undergoes a number of conformational changes that result in receptor dimerization and subsequent nuclear translocation (Lu and Cidlowski, 2006). Within the nucleus, the dimerized ligand-receptor complex binds directly to highly conserved glucocorticoid response elements (GREs) in the promoter region of target genes. This process is known as "transactivation" and usually facilitates gene transcription. The ligand-bound homodimer can also bind to negative GREs, thereby inhibiting gene transcription, an effect known as transrepression. On the other hand, the monomeric ligand-receptor complex binds to DNA-bound transcription factors such as STAT5, which enhances gene expression in a process known as tethered transactivation. The monomer can also bind to proinflammatory signaling molecules in the cytosol, preventing interaction with effector transcription factors such as AP-1 or NF-κB. This process is known as indirect or tethered transrepression (Moutsatsou et al., 2012) (Fig. 39.1). The traditional view of glucocorticoid action was that the antiinflammatory effects of glucocorticoids are caused by transrepression, whereas adverse outcomes largely arise from its transactivation capacities (Newton and Holden, 2007). However, it is now clear that this model was oversimplistic, with some antiinflammatory responses being due to transactivation—e.g., transaction induces the expression of the antiinflammatory protein dual specificity phosphatase 1 (DUSP1)—and some adverse outcomes due to transrepression—e.g., glucocorticoid inhibition of bone formation (Cooper et al., 2012; Rauch et al., 2010). Further adding to the diversity of glucocorticoid signaling mechanisms, many of the actions of the glucocorticoid receptors at the level of DNA may in fact by due to monomeric complexes (Meijsing et al., 2009). There is additionally evidence for nongenomic actions of glucocorticoids which typically happen more rapid than traditional genomic responses. These nongenomic mechanisms may involve non-GR-mediated interactions of glucocorticoids with cell membranes, nongenomic effects mediated by cytosolic GRs, or interactions of glucocorticoids with membrane-bound glucocorticoid receptors (Stahn and Buttgereit, 2008).

Endogenous glucocorticoid levels are systemically regulated via the hypothalamic−pituitary−adrenal axis. However, glucocorticoid action depends not only on plasma and interstitial fluid hormone concentrations, but also on cellular glucocorticoid levels. Within specific tissues, the 11β-hydroxysteroid dehydrogenase (11βHSD) enzymes metabolize glucocorticoids at the prereceptor level and control intracellular hormone availability via interconversion of biologically active and inactive ligands (Stewart and Krozowski, 1999). Thus, 11β-HSD type 1 (11βHSD1) predominantly catalyzes formation of active cortisol (in humans) and corticosterone (in rodents) from inactive cortisone and 11-dehydrocorticosterone, respectively, leading to increased intracellular glucocorticoid concentrations. This enzyme also converts inactive prednisone to active prednisolone—individuals who lack this activity are unresponsive to prednisone treatment but remain sensitive to prednisolone. In contrast, 11β-HSD type 2 (11βHSD2) unidirectionally catalyzes conversion of active glucocorticoids to their inactive metabolites (Fig. 39.1). The latter enzyme is primarily expressed in mineralocorticoid target tissues such as the kidney, where it protects the mineralocorticoid receptor from illicit activation by cortisol (Stewart and Krozowski, 1999). Of note, cytokines, growth factors, and certain other enzymes are able to modulate glucocorticoid metabolism via changing 11β-HSD enzyme activities on a predominantly local level (Cooper et al., 2001).

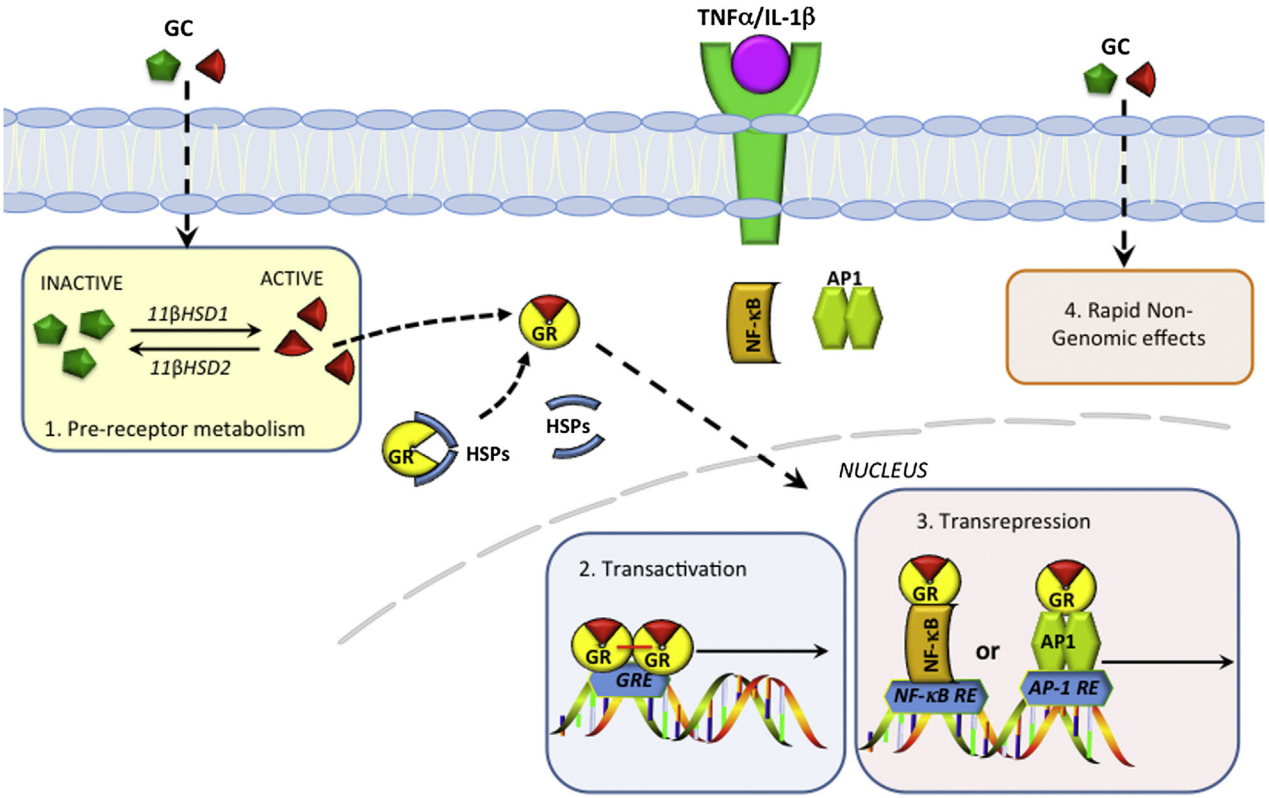

FIGURE 39.1 Glucocorticoid signaling. Glucocorticoids are lipophilic and cross the cell membrane freely. In many tissues, glucocorticoids undergo prereceptor metabolism by the cytosolic 11β-HSD enzymes. Thus, 11β-HSD type 1 converts inactive glucocorticoids (cortisone in humans, dehydrocorticosterone in rodents) to the active form (cortisol and corticosterone, respectively). Conversely, 11β-HSD type 2 converts cortisol and corticosterone into their inactive pendants. Active glucocorticoids bind to the cytoplasmic glucocorticoid receptor to form a complex that is able to translocate to the nucleus, where it either binds to its specific response element or to other transcription factors such as AP-1 (fos and jun) or NF-κβ, resulting in transactivation or transrepression of gene expression. Rapid nongenomic effects have also been described.

Local glucocorticoid metabolism in bone

As discussed above, local metabolism of glucocorticoids impacts their actions within bone. Expression of the 11βHSD1 enzyme has been extensively characterized in bone (Cooper et al., 2000; Weinstein et al., 2010b). Human bone tissue has the ability to interconvert cortisone and cortisol, but the kinetics of the reaction indicate the presence of the 11βHSD1 enzyme rather than 11βHSD2 (Cooper et al., 2000). This is supported by immunohistochemistry and in situ hybridization studies that localize the expression of 11βHSD1 primarily to osteoblasts. In ex vivo studies, the activity of 11βHSD1 in primary human osteoblasts is dependent on donor age, with expression low in young donors but high in osteoblasts isolated from older donors (Cooper et al., 2002). An age-related change in expression is paralleled in mice in vivo (Weinstein et al., 2010b). Mice with global deletion of 11βHSD1 have no overt abnormality in bone structure (Justesen et al., 2004); however, the bone phenotype of aged 11βHSD1 knockout animals has not been examined. In elderly humans, a negative correlation between plasma cortisone levels and osteocalcin has been observed, a relationship independent of plasma cortisol (Cooper et al., 2005). This study suggests that 11βHSD1 activity has functional consequences on osteoblasts in vivo. A similar negative association between cortisone and spine bone density was also seen in this study. Genetic association studies have linked the presence of allelic variants of *HSD11B1* (the gene for 11βHSD1) that predict low activity of 11βHSD1 with an increase in bone density and a reduction in vertebral fracture risk (Hwang et al., 2009). These data suggest that some of the adverse age-related changes in bone could be glucocorticoid mediated, but with exposure restricted to the osteoblast through local production by the 11βHSD1 enzyme. An analogous role for 11βHSD1 and endogenous glucocorticoids in skin aging has recently been demonstrated (Tiganescu et al., 2013).

Novel insights from targeted disruption of glucocorticoid signaling in bone

Investigating the effects of endogenous glucocorticoids on tissue function has been difficult, as global deletion of the GR in mice leads to early postnatal lethality (Cole et al., 1995). Over the past 2 decades, advances in cell-specific disruption of glucocorticoid signaling in mouse models have greatly improved our understanding of the physiological role of glucocorticoids in bone development and structure. Osteoblast-targeted deletion of the GR ($GR^{Runx2Cre}$) in mice results in an overall reduction in bone volume (Rauch et al., 2010). Correspondingly, calvarial osteoblast cultures derived from $GR^{Runx2Cre}$ mice demonstrate a reduction in osteoblast differentiation and the ability to form mineralized nodules (Rauch et al., 2010). Although not expressed naturally in postnatal bone cells, the 11βHSD2 enzyme has been used as a tool to examine the effects of endogenous glucocorticoids on the skeleton by targeted transgenic expression of 11βHSD2 within bone cells. This has the added advantage over GR deletion models that other possible signaling pathways in osteoblasts such as the mineralocorticoid receptor are also targeted. Transgenic mice in which 11βHSD2 expression is driven by a 2.3 kb collagen type I (Col2.3) promoter are characterized by targeted disruption of glucocorticoid signaling exclusively in mature osteoblasts and osteocytes (Sher et al., 2004, 2006). These mice (usually referred to as "Col2.3-11βHSD2 transgenic" mice) exhibit a phenotype of delayed calvarial bone development. Thus, embryonic and neonatal Col2.3-11βHSD2 transgenic mice display calvarial bone hypoplasia, osteopenia, increased suture patency, ectopic differentiation of cartilage in the sagittal suture, and a defect in the postnatal removal of parietal cartilage (Zhou et al., 2009). Similar to $GR^{Runx2Cre}$ mice, Col2.3-11βHSD2 transgenic adult mice of both sexes have reduced bone volume, lower trabecular number, and lower cortical bone mass (Kalak et al., 2009; Sher et al., 2004).

In a different model, the 11βHSD2 transgene is driven by the 3.6 kb collagen type I promoter ("Col3.6-11βHSD2 transgenic mice"). These animals exhibit a phenotype similar to that of Col2.3-11βHSD2 transgenic mice, including defects in calvarial bone development (Yang et al., 2010). Together, these findings strongly support the notion that endogenous glucocorticoids play a critical role in mesenchymal and osteoblast differentiation, accrual of bone mass, and the development of a healthy skeletal structure (Kalak et al., 2009; Rauch et al., 2010; Sher et al., 2004, 2006).

Endogenous glucocorticoids promote osteoblastogenesis

It has long been known from osteoblast cultures that the addition of glucocorticoids to the culture medium is crucial for the formation of mineralized nodules (Bellows et al., 1987), suggesting that these hormones are essential for differentiation of mesenchymal cells into mature osteoblasts (Haynesworth et al., 1992; Herbertson and Aubin, 1995). Evidence obtained from Col2.3-11βHSD2 transgenic mice indicates that this action of glucocorticoids is not through direct effects on mesenchymal progenitor cells but rather mediated indirectly through mature osteoblasts (Sher et al., 2006). Thus, calvarial cell cultures derived from Col2.3-11βHSD2 transgenic mice exhibit greatly reduced osteoblastogenesis and increased adipogenesis compared with cultures from animals with intact osteoblastic glucocorticoid signaling (i.e., wild-type mice). This phenotypic shift in mesenchymal progenitor cell commitment is accompanied by a reduction in Wnt7b and Wnt10b mRNA expression and β-catenin protein levels in transgenic compared with wild-type cultures. In addition, in the calvarial cell culture system, mature osteoblasts appear to be the dominant source of Wnt proteins, in particular Wnt7b, Wnt10b and Wnt9a, which are important stimulators of osteoblastogenesis. Thus, at physiological concentrations, glucocorticoids directly stimulate osteoblasts to produce and release Wnt proteins, which then act in a paracrine manner to activate the canonical Wnt signaling cascade in mesenchymal stem cells (MSCs). This results in the accumulation of β-catenin and the expression of the master regulator of osteoblast differentiation, runt-related transcription factor 2 (RUNX2) in MSCs, which drives the differentiation of these pluripotent cells toward the osteoblastic lineage. The Wnt signaling cascade in MSCs is further enhanced by the glucocorticoid-induced downregulation of potent Wnt suppressors such as sFRP1 (secreted frizzled-related protein 1) (Fig. 39.2) (Mak et al., 2009; Zhou et al., 2008). These pathways act synergistically to direct MSCs away from the adipogenic and toward the osteoblastic lineage. This mechanism is proven to be of importance in cranial bone development in vivo.

The skeletal changes in these mice are due to a lack of paracrine Wnt signaling by Col2.3-11βHSD2 transgenic osteoblasts. In addition to controlling lineage commitment, the glucocorticoid-induced increase in osteoblastic paracrine Wnt signaling affects the surrounding chondrocytes by inducing the expression of matrix metalloproteinase 14 (Mmp14). Mmp14 is central to the breakdown of extracellular matrix during development and tissue remodeling, and vital for cartilage removal during the process of ossification (Zhou et al., 2009). These concurrent and tightly interconnected pathways establish a novel role for both glucocorticoids and osteoblasts in the intricate process of intramembranous bone development.

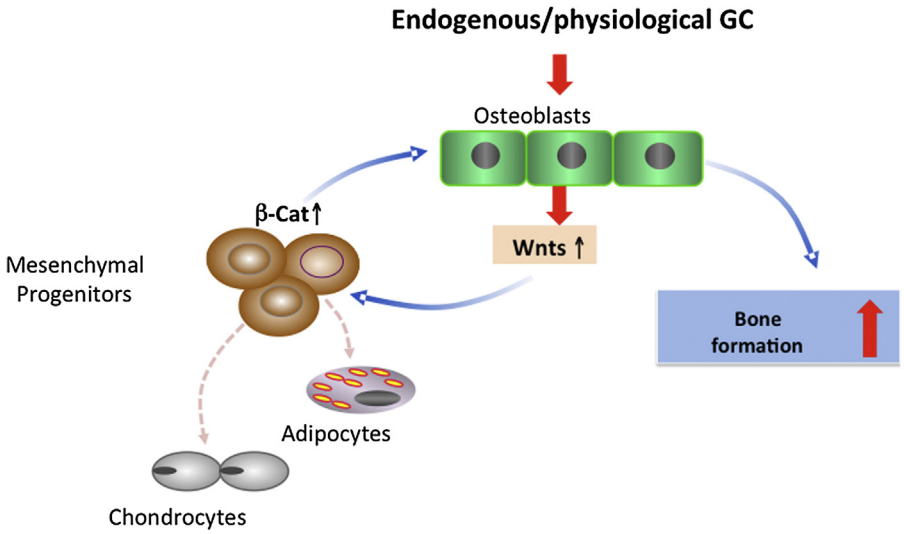

FIGURE 39.2 Schematic illustration of the effects of endogenous glucocorticoids on bone. At physiological concentrations, glucocorticoids stimulate mature osteoblasts to produce canonical Wnt proteins, which activate the β-catenin signaling cascade in mesenchymal progenitor cells. This in turn promotes differentiation of these immature cells toward the osteoblastic cell linage, with negative effects on chondro- and adipocytogenesis. Endogenous glucocorticoid signaling in osteoblasts therefore favors bone formation.

In summary, it is now clear that endogenous glucocorticoids control osteoblast differentiation, skeletal development during normal intramembranous bone formation, and trabecular and cortical bone mass accrual in mice.

Glucocorticoid excess and the skeleton

Nearly 65 years after their introduction into clinical practice by Hench and colleagues (Hench et al., 1949), glucocorticoids are still the most widely and frequently used class of antiinflammatory drugs. Survey data from 1996 estimated that in the UK, 0.5% of the population, 1.75% of women aged over 55 years, and up to 68% of patients with rheumatoid arthritis are on continuous treatment with oral glucocorticoids (Walsh et al., 1996). Later studies, also from the UK, found that up to 2.5% of people aged between 70 and 79 years receive oral glucocorticoids on an ongoing basis (van Staa et al., 2000a). A more recent multinational population-based study indicated that globally, up to 4.6% of postmenopausal women are taking oral glucocorticoids (Diez-Perez et al., 2011). In the US, data from several NHANES survey cycles demonstrate that the prevalence of glucocorticoid use remains above 1% of the general population (Overman et al., 2013) (Fig. 39.3). The major reason for the widespread use of therapeutic glucocorticoids is their unsurpassed antiinflammatory and immunomodulatory efficacy (reviewed in Buttgereit et al., 2011).

Therapeutic glucocorticoids, particularly when used over extended periods, cause significant off-target effects that are similar to the clinical signs and symptoms of endogenous hypercortisolism (Cushing's disease/syndrome). These include but are not limited to musculoskeletal conditions such as osteoporosis, osteonecrosis, myopathy, and sarcopenia, as well as metabolic effects resulting in glucose intolerance or diabetes mellitus, dyslipidemia, and excessive and abnormal fat accrual (Pereira and Freire de Carvalho, 2011; Schakman et al., 2008). Other adverse effects of prolonged glucocorticoid therapy include skin atrophy, hypertension, adrenal suppression, glaucoma, cataract, delayed wound healing, increased risk of infection, and in children, growth retardation.

Recognized as the most common form of secondary osteoporosis, GIO represents an iatrogenic problem of major clinical relevance across numerous specialties. Thus, one in five patients treated with oral glucocorticoids suffers an osteoporotic fracture within the first 12 months of therapy (Adachi et al., 1997; Cohen et al., 1999). This number increases to 50% after 5−10 years (Walsh et al., 1999, 2002), with most fractures occurring in the spine, proximal femur, and ribs. The relative risk of fracture increases as a function of glucocorticoid dose and duration of therapy, while absolute fracture risk is determined by a range of additional clinical risk factors such as age, gender, and comorbidities. Fracture risk is highest during the first few months following commencement of treatment (van Staa et al., 2000b, 2002) and decreases when therapy is ceased. Of note, even daily doses as low as 2.5 mg of prednisolone equivalent have been associated with increased fracture rates (van Staa et al., 2000b) (Fig. 39.4). Long-term inhaled glucocorticoid therapy in children and adults is also associated with significant bone loss (Wong et al., 2000). Despite the clear evidence for the detrimental effects of

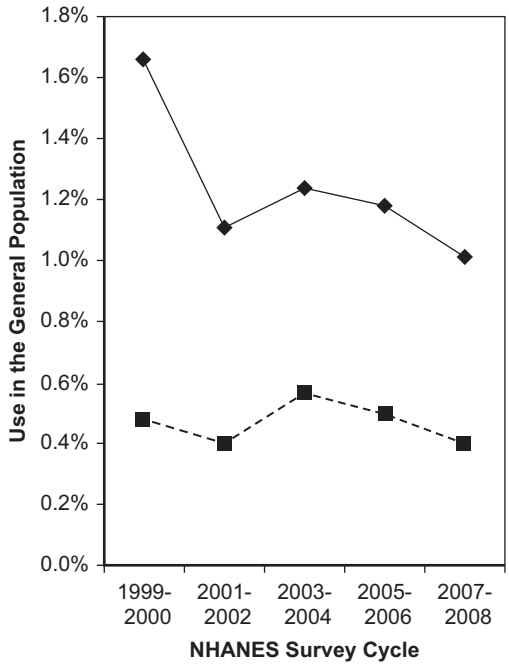

FIGURE 39.3 Prevalence of glucocorticoid use and antiosteoporosis therapy. Data were extracted from five National Health and Nutrition Examination Surveys. Diamonds represent glucocorticoid use. Squares represent concomitant antiosteoporosis therapy (Overman et al., 2013).

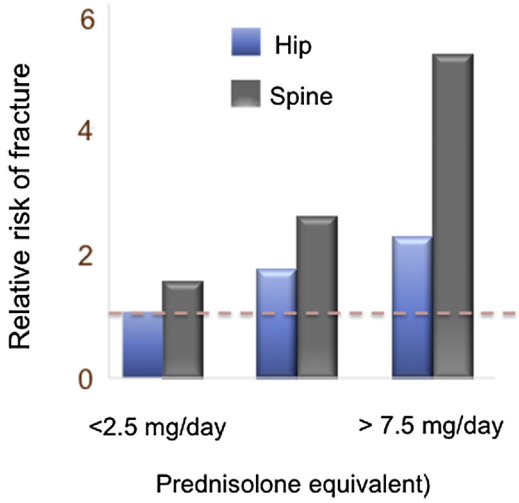

FIGURE 39.4 Relative risk of vertebral and hip fracture according to daily glucocorticoid dose. Note that even glucocorticoid doses considered by most clinicians as "low" (i.e., less than 2.5 mg prednisolone equivalent per day) are associated with a significant increase in fracture risk over time. *Adapted from van Staa, T.P., Leufkens, H.G., Abenhaim, L., Zhang, B., Cooper, C., 2000b. Oral corticosteroids and fracture risk: relationship to daily and cumulative doses. Rheumatology (Oxford) 39, 1383–1389.*

glucocorticoids on bone health, only a small proportion of patients receiving these medications are being treated to prevent bone loss and fractures (Overman et al., 2013) (Fig. 39.3).

Pathogenesis of glucocorticoid-induced osteoporosis

The main mechanisms underlying GIO are the direct action of glucocorticoids on bone cells, in particular on osteoblasts and osteocytes. Other effects are related to mineral metabolism such as decreased intestinal calcium absorption and increased renal calcium clearance (Canalis et al., 2007; Kuroki et al., 2008) as well as decreased growth hormone secretion (Mazziotti and Giustina, 2013) and alteration in sex steroid metabolism (Manolagas, 2013) (Table 39.1).

TABLE 39.1 Extraskeletal pathways contributing to glucocorticoid-induced osteoporosis.

Signaling pathway	Effect	References
Altered calcium balance	Glucocorticoid-induced decrease in calcium resorption and increase in calcium secretion may interfere with bone metabolism	Canalis et al. (2007)
Increased proteolysis in skeletal muscle	May contribute to a higher frequency of falls and fractures	Canalis et al. (2007), Pereira and Freire de Carvalho (2011), Schakman et al. (2008)
Growth hormone (GH) deficiency	Glucocorticoid-induced suppression of GH may contribute to the severity of GIO	Mazziotti and Giustina (2013)
Altered sex hormones	Glucocorticoid-induced suppression of testosterone and/or estrogen may contribute to GIO	Canalis et al. (2007), van Staa (2006)
Altered PTH pulsatility	Glucocorticoids may alter PTH pulsatility, which may contribute to bone loss	Bonadonna et al. (2005), Canalis et al. (2007)

In bone, glucocorticoid excess affects osteoblasts, osteocytes, and osteoclasts. Earlier, mostly histomorphometric studies indicated that the predominant feature of GIO is a suppression of osteoblast activity and hence of bone formation while osteoclast numbers are either unchanged or slightly increased (Weinstein et al., 1998). These data were sufficient to understand that the pathogenesis of GIO was fundamentally different from that of postmenopausal osteoporosis. The mechanisms by which glucocorticoids exert their actions on bone remained elusive, however. With the advent of more sophisticated technologies, we now have a more detailed (although still incomplete) understanding of the cellular and molecular actions of glucocorticoids in bone.

Although the individual effects of glucocorticoid excess on osteoblasts, osteocytes, and osteoclasts have been well characterized in vitro, the high degree of reciprocal interconnectivity between bone cells has made it difficult to dissect the skeletal actions of glucocorticoids in vivo. In this context, the development of genetically modified mouse models in which only one specific subset of bone cells has been shielded from the effects of exogenous glucocorticoids has provided useful information on the main target cells and molecular mechanisms involved in the pathogenesis of GIO. Thus, recent studies in rodents have demonstrated that protecting the *osteoclast* from excessive glucocorticoid signaling partly prevents the increase in osteoclast lifespan and bone resorption normally seen with glucocorticoid treatment (see also below) (Jia et al., 2006; Kim et al., 2006). However, as a consequence of the ongoing suppression of osteoblast and osteocyte function, bone formation remains compromised in most of these models (Jia et al., 2006; Rauch et al., 2010), inevitably leading to reduced bone strength over a prolonged period. Thus, in the long-term, the direct effects of glucocorticoids on osteoclasts appear to contribute little to the loss of bone mass and strength seen in GIO.

Conversely, protecting the osteoblast (and with that the osteocyte) from excessive glucocorticoid exposure and signaling not only prevents osteoblast and osteocyte apoptosis, but in fact preserves osteoblast function and bone formation (O'Brien et al., 2004). Furthermore, in these animal models, bone strength and quality are maintained despite the presence of supraphysiological plasma glucocorticoid levels (Henneicke et al., 2011; O'Brien et al., 2004; Rauch et al., 2010). Abrogating glucocorticoid signaling in osteoblasts/osteocytes also prevents the increase in osteoclast number and activity in addition to changes in bone vascularity and the lacunar–canalicular system normally seen with glucocorticoid excess (Henneicke et al., 2011; Weinstein et al., 2010b). Therefore, some of the effects of exogenous glucocorticoids on the osteoclast are preventable when the osteoblast/osteocyte system is shielded from excessive glucocorticoid signaling, pointing to the cells of the osteoblast lineage as the main target of exogenous glucocorticoids within the skeleton.

Glucocorticoid excess and its effects on osteoblast differentiation

It has been well established that glucocorticoid excess inhibits both osteoblast differentiation and function, while at the same time inducing osteoblast apoptosis, resulting in a rapid (within hours) and profound suppression of bone formation (Kauh et al., 2012; Weinstein et al., 1998). In recent years, a number of molecular targets and mechanisms underlying these osteoblast-specific glucocorticoid actions have been identified. For example, exposure to supraphysiological glucocorticoid concentrations suppresses the very pathways that at physiological levels promote osteoblastogenesis, namely Wnt and bone morphogenetic protein 2 (BMP-2) signaling: At high concentrations, glucocorticoids inhibit the synthesis and release of

Wnt-related transcription factors by mature osteoblasts (Mak et al., 2009). Downregulation of Wnt signaling leads to impaired osteoblast differentiation via a reduction in molecular downstream signals such as β-catenin and RUNX2 transcription factors (see above). Additionally, high intracellular levels of glucocorticoids enhance β-catenin degradation via increased glycogen synthase kinase 3 beta expression, a protein, which drives β-catenin ubiquitinylation and proteasomal degradation (Wang et al., 2009) and promotes the osteoblastic expression of Wnt inhibitors (Hayashi et al., 2009; Kato et al., 2018; Mak et al., 2009). These glucocorticoid-inducible soluble antagonists act on MSCs, inhibiting Wnt/β-catenin signaling and thereby reducing osteoblast differentiation (Yao et al., 2008; Zhou et al., 2008). Moreover, glucocorticoid excess concurrently increases expression of transcription factors critical for adipocyte differentiation such as peroxisome proliferator-activated receptor γ (Yao et al., 2008), suggesting that the commitment of MSC to the adipocyte lineage limits the pool of cells available to differentiate into osteoblasts. However, this hypothesis requires further investigation.

Another key regulator of osteoblast differentiation, BMP-2, is profoundly inhibited in mice receiving glucocorticoids at therapeutic concentrations (Yao et al., 2008). In addition, dexamethasone treatment of osteoblast cultures has been reported to substantially increase the expression of follistatin and Dan, two BMP-2 antagonists (Hayashi et al., 2009), thus exacerbating the inhibition of BMP-2 signaling in osteoblasts. Recent studies have demonstrated that the monomeric glucocorticoid-GR complex is sufficient to significantly impair osteoblast differentiation (Rauch et al., 2010), most likely due to interference with the proinflammatory transcription factor AP-1 and suppression of IL-11 (Rauch et al., 2011). The latter cytokine has previously been shown to promote bone formation (Takeuchi et al., 2002). Indeed, the addition of IL-11 to glucocorticoid-treated osteoblast cultures protects these cells from glucocorticoid-induced reduction in differentiation potential. IL-11 has also been shown to promote BMP-2 signaling (Takeuchi et al., 2002) and more recently demonstrated to suppress the production of Wnt antagonists (Matsumoto et al., 2012). Thus, a reduction in IL-11 activity appears to attenuate two critically important signaling pathways that control differentiation in osteoblasts. Analyzing bone specimens from patients with GIO and prednisolone-treated mice, a recent study (Liu et al., 2017a) documented increased levels of casein kinase-2 interacting protein-1 (CKIP-1), a ubiquitination-related protein facilitating Smurf1-mediated Smad1/5 ubiquitination (Lu et al., 2008). Interestingly, mice with osteoblast-specific CKIP-1 deletion maintained normal BMP signaling and were protected from glucocorticoid-induced bone loss (Liu et al., 2017a).

In recent years, microRNAs (miRs) have been discovered to play an important role in osteoblast differentiation. Excess glucocorticoids modulate the expression pattern of microRNAs, impairing osteoblastogenesis. Thus, miR-29a expression in bone has been demonstrated to decrease with glucocorticoid exposure. Overexpression of miR-29a in transgenic mice mitigates glucocorticoid-induced bone loss by protecting against impaired osteogenic differentiation (Ko et al., 2015). Glucocorticoids promote HDAC4 signaling, subsequently accelerating RUNX2 and β-catenin ubiquitination.

Overexpressing miR-29a significantly attenuates glucocorticoid-mediated RUNX2 deacetylation and β-catenin ubiquitination via inhibiting HDAC4 action (Ko et al., 2013, 2015). Dexamethasone treatment upregulates miR-199a-5p expression, inhibiting osteoblast proliferation through reducing FZD4 and Wnt2 expression. Deletion of miR-199a-5p attenuates dexamethasone-induced inhibition of osteoblast proliferation (Shi et al., 2015). More recently, it has been reported that silencing miR-106b expression provides protection from glucocorticoid-induced bone loss through restoring BMP2 expression, which consequently maintains osteoblast differentiation and bone formation (Liu et al., 2017b). In contrast to these catabolic microRNAs, miR-34a-5p promotes osteoblast differentiation through suppression of Notch signaling. Glucocorticoids reduce the expression of miR-34a-5p, thereby inhibiting osteogenic differentiation (Kang et al., 2016).

The simultaneous reduction in both Wnt/β-catenin and BMP-2 signaling during glucocorticoid excess leads to a significant shift in MSC differentiation, a reduction in osteoblastogenesis, and consequently a loss of osteoblast-generated proteins such as collagen and osteocalcin (Moutsatsou et al., 2012; Yao et al., 2008).

Glucocorticoids prevent osteoblast cell cycle progression

Exposure of osteoblasts to high concentrations of glucocorticoids in vitro has been shown to disrupt physiological cell cycle progression (Chang et al., 2009). A marked decrease in cyclin D2 and an increase in cyclin-dependent kinase inhibitor 1B ($p27^{kip1}$) following dexamethasone treatment of human osteoblasts has been observed, consistent with cell cycle arrest at the G0 and G1 phase (Chang et al., 2009). Dexamethasone has also been reported to increase the expression of DUSP1 in cultured osteoblasts, with a corresponding decrease in the phosphorylation status of mitogen-activated protein kinase 1 (MAPK1). The dephosphorylation of MAPK1 impairs osteoblast response to mitogenic signaling, inhibiting cell proliferation (Horsch et al., 2007). Furthermore, dexamethasone suppresses the osteoblastic expression of cyclin A, a protein crucial for the transition from G1 to S phase during or after commitment to the osteoblast lineage (Gabet et al.,

2011). Cell cycle progression via the canonical Wnt signaling pathway requires the association of β-catenin with LEF/TCF transcription factors, both of which are inhibited by high glucocorticoid levels. In the face of reduced Wnt and β-catenin signaling, the reduction in LEF/TCF further inhibits the G1 to S phase transition (Jia et al., 2006).

Glucocorticoids induce osteoblast apoptosis

Pharmacological doses of glucocorticoids induce osteoblast apoptosis both in vitro and in vivo through a number of proapoptotic pathways. Administration of dexamethasone to osteoblast cultures dose-dependently increases proapoptotic factors of the Bcl-2 family such as Bim (Espina et al., 2008). Correspondingly, knockdown of Bim in osteoblasts significantly reduces glucocorticoid-induced apoptosis (Espina et al., 2008). Furthermore, silencing E4BP4, a basic leucine zipper transcription factor, attenuates glucocorticoid-induced Bim expression and blocks osteoblast apoptosis induced by dexamethasone treatment (Chen et al., 2014). In addition, glucocorticoid-induced increases in Bak, another proapoptotic member of the Bcl-2 family, as well as a decrease in Bcl-XL expression, a prosurvival Bcl-2 protein, further drive osteoblasts toward cell death (Chang et al., 2009). Exposure of osteoblasts to dexamethasone in vitro also results in upregulation of the tumor suppressor and apoptosis regulator, p53, and subsequent Bcl-2 mediated cell apoptosis (Li et al., 2012). Glucocorticoids have also been found to induce osteoblast apoptosis via a reduction in β1-integrin expression, which leads to a loss of cell-matrix adhesion (Naves et al., 2011). High-dose glucocorticoids may induce osteoblast apoptosis through activation of $p66^{shc}$ and an increase in reactive oxygen species (ROS), which in turn leads to constitutive activation of the JNK pathway (Almeida et al., 2011) or induces endoplasmic reticulum (ER) stress (Sato et al., 2015). Opposing ER stress by inhibiting eIF2α dephosphorylation prevents osteoblast and osteocyte apoptosis and attenuates osteoblast dysfunction induced by glucocorticoids in vitro and in vivo (Sato et al., 2015).

In summary, glucocorticoids at supraphysiological or pharmacological concentrations are detrimental to the skeleton through potent suppression of osteoblastogenesis, induction of osteoblast dysfunction, diversion of MSC to the adipocyte lineage, as well as promotion of osteoblastic cell cycle arrest and apoptosis (Fig. 39.5). Overall, exposure to high dose glucocorticoids not only compromises the skeleton's ability to form new bone, but also profoundly disturbs the regulatory balance between bone formation and resorption, which eventually leads to a reduction in bone mass and an increase in fracture risk.

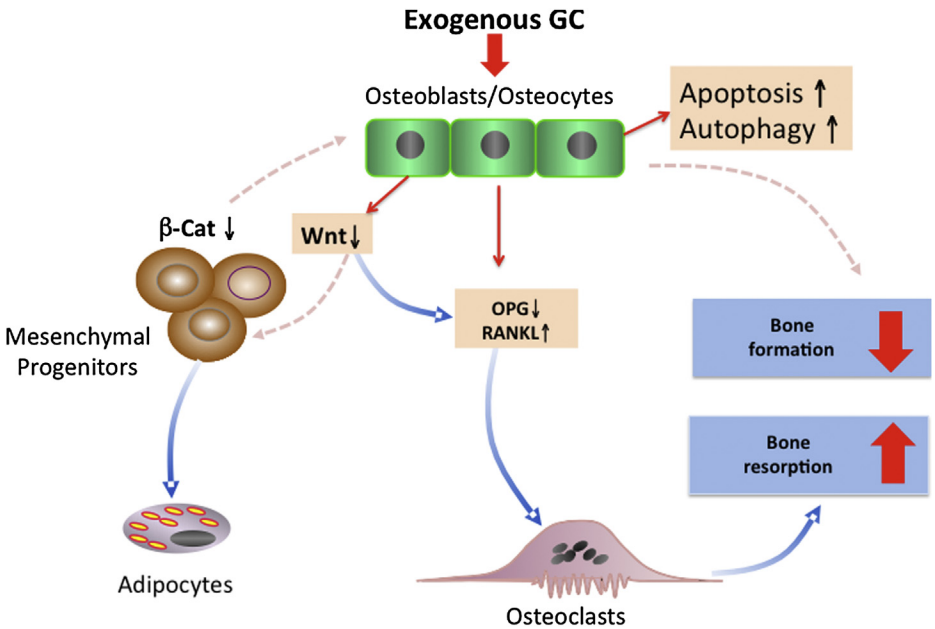

FIGURE 39.5 Schematic illustration of the effects of exogenous glucocorticoid on bone. High-dose glucocorticoids negatively impact osteoblast and osteocyte function through (1) inhibition of Wnt protein expression in mature osteoblasts (which results in mesenchymal progenitor cells differentiating preferentially toward adipocytes and away from osteoblasts); (2) stimulation of RANKL and inhibition of OPG expression (resulting in an increase in the RANKL/OPG ratio which favors bone resorption); and (3) induction of osteoblast and osteocyte apoptosis (which reduces bone formation).

Glucocorticoid excess and the osteocyte

The osteocyte is the most abundant cell type in the skeleton, representing 90%–95% of the entire cell mass (Crockett et al., 2011). The complex osteocyte network functions as a mechanosensor, which maintains bone integrity through the recruitment of osteoblasts and osteoclasts to the sites of active bone remodeling (Temiyasathit and Jacobs, 2010). Furthermore, this system as well as its fluid content has been shown to lend the skeleton a high degree of stiffness (Weinstein et al., 2010b). High glucocorticoid concentrations not only lead to a substantial loss of intraosseous vasculature, but also to a decrease in the solute transport from the circulation to the lacunar–canalicular system (Weinstein et al., 2010a, 2010b). The reduction in overall intraskeletal fluid content is strongly associated with the glucocorticoid-induced decrease in bone strength but not necessarily bone mass (Weinstein et al., 2010a).

Treatment with pharmacological doses of glucocorticoids has been shown to cause intracellular damage and induce osteocyte autophagy both in vitro and in vivo (Jia et al., 2011; Xia et al., 2010). With prolonged exposure to glucocorticoids, pathological buildup of autophagosomes occurs, and as the osteocyte is embedded in the bone matrix, the degraded materials expelled from the autophagosomes create an environment toxic to the cell, leading to cellular demise (Jia et al., 2011). Glucocorticoid-induced autophagy subsequently results in connexin43 degradation, thereby impairing osteocyte cell-cell connectivity (Gao et al., 2016). Additionally, higher rates of osteocyte apoptosis have been linked to activation of proapoptotic kinases, Pyk2 and JNK, in osteocytes (Bellido, 2010). While activation of JNK leads to an increase in ROS and eventually programmed cell death, activation of the protein tyrosine kinase Pyk2 results in the reorganization of the cytoskeleton, cell detachment, and ultimately apoptosis (Bellido, 2010).

In summary, recent evidence has highlighted both the osteocyte and the lacunar–canalicular network as important targets of glucocorticoid-induced damage to bone. The reduction in skeletal fluid content in conjunction with decreased osteocyte viability represents an important novel mechanism by which excessive levels of glucocorticoids may compromise bone stability without affecting actual bone mass.

Glucocorticoid excess and the osteoclast

During the initial stage of glucocorticoid therapy, there is a rapid but transient increase in bone resorption due to an increase in osteoclast number and activity (Dovio et al., 2004; Henneicke et al., 2011; Jia et al., 2006). In humans, biochemical markers of bone resorption increase within 24 h of exposure to therapeutic levels of glucocorticoids (Dovio et al., 2004). Experimental studies have established that glucocorticoids directly extend the lifespan of mature osteoclasts by delaying apoptotic signaling, which over time leads to a significant increase in osteoclast numbers (Jia et al., 2006; Kim et al., 2006). Osteoclast formation is further amplified indirectly through glucocorticoid-induced changes in osteoblast gene expression. For example, high levels of glucocorticoids stimulate the production of RANKL by cells of the osteoblast lineage while simultaneously reducing the expression of the RANKL decoy receptor, OPG (Hofbauer et al., 1999; Sivagurunathan et al., 2005). This imbalance in the RANKL-OPG ratio leads to a profound increase in osteoclast activity and bone resorption.

Furthermore, the effect of glucocorticoids on osteoblastic RANKL expression appears to be mediated by miR-17/20a (Shi et al., 2014).

Under physiological conditions, the major source of RANKL and hence the primary driver of osteoclastogenesis is the osteocyte rather than the osteoblast (Nakashima et al., 2011; Xiong et al., 2011). In vitro studies show that the osteocyte presents membrane-bound RANKL to osteoclast precursors at the extremities of their dendritic processes rather than secreting soluble RANKL (Honma et al., 2013). Whether this process is affected by glucocorticoids is yet to be determined. Apoptosis of osteocytes leads, seemingly paradoxically, to an increase in RANKL concentrations, possibly due to signaling of dying cells to surrounding healthy osteocytes, which then in turn express RANKL (Kennedy et al., 2012). However, another study reported that osteocyte apoptotic bodies strongly induce osteoclastogenesis in vitro, although this occurred independently of RANKL expression (Kogianni et al., 2008). As glucocorticoids are known to induce osteocyte apoptosis, the subsequent induction of RANKL or other signaling pathways may contribute to the increase in osteoclastogenesis observed following glucocorticoid exposure.

Apart from its function as a potent inhibitor of osteoblast function, sclerostin may also have a role as a potential inductor of osteoclast activity and bone resorption (Li et al., 2008). Recent studies provide in vivo evidence that sclerostin-induced bone resorption may be an important contributor to bone loss under conditions of glucocorticoid excess (Henneicke et al., 2017; Sato et al., 2016). When exposed to high concentrations of glucocorticoids, sclerostin-deficient mice are protected from increased bone resorption and bone loss. However, sclerostin deficiency does not prevent glucocorticoid-induced osteoblast/osteocyte apoptosis and impaired bone formation (Sato et al., 2016). A similar

mechanism may play a role in relaying the effects of chronic stress on bone resorption. Chronic stress exposure leads to elevated levels of circulating glucocorticoids, resulting in bone loss, increased bone resorption, and enhanced Sost/sclerostin expression in wild-type mice but not in mice where glucocorticoid signaling has been disrupted in osteoblasts and osteocytes (Henneicke et al., 2017). These results indicate that stress-related bone loss is mediated via the effects of glucocorticoids on osteoblasts/osteocytes and subsequent activation of osteoclasts through amplified expression of Sost/sclerostin (Henneicke et al., 2017).

Despite an initial increase in bone resorption, prolonged glucocorticoid excess appears to suppress osteoclast number and function, directly blocking the induction of cytoskeletal changes in the osteoclast required for bone resorption (Kim et al., 2007). There is also evidence that glucocorticoids suppress the proliferation of osteoclast precursors, or more specifically, uncommitted bone marrow macrophages (Kim et al., 2006, 2007).

Overall, exposure to exogenous glucocorticoids causes an initial rise in bone resorption, which contributes to the early and rapid loss of bone mineral density. During long-term therapy, however, the disruptive effects of glucocorticoids on the cytoskeleton and suppression of osteoclastogenesis appear to be the predominant feature as far as the osteoclast is concerned (Fig. 39.5).

Glucocorticoid excess and local glucocorticoid metabolism

Local steroid metabolism through expression of the 11βHSD1 enzyme is also likely to influence glucocorticoid impacts on bone. Prednisone and prednisolone, the main oral glucocorticoids used clinically, are metabolized by this enzyme in a similar fashion to cortisone and cortisol (Cooper et al., 2002). Systemic measures of 11βHSD1 obtained in healthy control subjects strongly predict the extent to which oral glucocorticoids have an impact on bone formation markers such as osteocalcin (Cooper et al., 2003). However, 11βHSD1 expression in osteoblasts is regulated by a range of factors that are likely to be of relevance to people treated with glucocorticoids. Both proinflammatory cytokines and glucocorticoids increase expression and activity of 11βHSD1 (Cooper et al., 2001, 2002; Kaur et al., 2010), potentially increasing the sensitivity of bone to glucocorticoids during inflammatory illness. However, 11βHSD1 expression is also increased in a range of tissues during inflammation (Kaur et al., 2010). Global deletion of 11βHSD1 in mice increases the severity of a range of models of experimental inflammation (Coutinho et al., 2012). It is therefore possible that any increased sensitivity of bone to glucocorticoids through an increase in 11βHSD1 will be matched by increased sensitivity of the underlying disease being treated. No association of systemic 11βHSD1 activity and bone loss was seen in a trial of patients with inflammatory bowel disease treated with high-dose oral prednisolone (Cooper et al., 2011).

Indirect mechanisms for glucocorticoid-induced osteoporosis

The mechanisms described so far concern the direct consequences of glucocorticoid action on bone cells and their molecular signaling. However, particularly when given at higher doses, glucocorticoids have further systemic effects (Table 39.1), not all of which have been clearly delineated. Changes in renal and intestinal calcium handling, as well as sex and growth hormone action, have been well documented. Thus, glucocorticoids reduce intestinal calcium absorption while inhibiting calcium reabsorption in the kidney (Ritz et al., 1984). This leads to a negative net calcium balance, which may adversely affect bone mineralization. It was previously thought that glucocorticoid-mediated alteration of (and in particular increased) PTH secretion was also a common feature to account for bone loss (Fucik et al., 1975). However, many studies have subsequently failed to find direct links to between glucocorticoids and increased PTH signaling, and it is now considered that changes in PTH secretion or action do not play a central role in GIO (Rubin and Bilezikian, 2002). Clearly, however, increased PTH secretion can be a secondary and appropriate response in the context of a prolonged negative net calcium balance induced by glucocorticoids.

When given at higher doses, glucocorticoids can induce hypogonadism through suppression of the HP axis, which in turn may contribute to bone loss and increased fracture risk (Chrousos et al., 1998). Other hormones have also been implicated in indirect effects of glucocorticoids on bone. In particular, glucocorticoids cause a reduction in IGF1, a powerful stimulator of osteoblast function, and thus any reduction in its levels might result in a reduced anabolic action on bone. However, studies involving calvarial bones from mice with deletion of the IGF1 receptor demonstrated that glucocorticoids still have a major negative effect on collagen synthesis, suggesting that changes in IGF1 signaling are not a major part of the actions of glucocorticoids on osteoblasts (Woitge and Kream, 2000). Although a small observational study in children with arthritis treated with glucocorticoids suggested a protective effect of growth hormone (GH) treatment on bone density GH/IGF1, treatment has not been evaluated in the context of a randomized controlled trial in patients taking glucocorticoids.

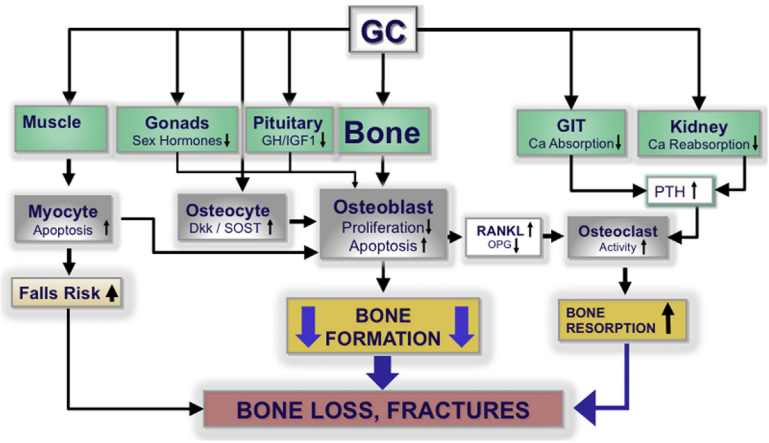

FIGURE 39.6 Schematic summary of the detrimental effects of therapeutic or excess glucocorticoids on skeletal and nonskeletal organ systems. While the skeletal adverse outcomes are mediated mainly through effects on osteoblasts, many other systems contribute to the increase in fracture risk in patients on long-term glucocorticoid therapy.

Proximal myopathy is a well-recognized feature of glucocorticoid excess (Pereira and Freire de Carvalho, 2011) and is thought to affect bone health directly (through its effects on bone strength) and indirectly (through an increase in falls risk) (Fig. 39.6).

Glucocorticoid excess and systemic fuel metabolism

Insulin resistance, dyslipidemia, and abnormal body fat accrual and distribution belong to the most common and problematic adverse effects of glucocorticoid therapy (reviewed in Rafacho et al., 2014). Short-term treatment with glucocorticoids is associated with impaired release of insulin from the pancreas. However, this mode of action does not feature prominently during long-term glucocorticoid use (Beard et al., 1984; Hazlehurst et al., 2013; Nicod et al., 2003; Petersons et al., 2013). Thus, patients with rheumatoid arthritis treated chronically with prednisolone tend to develop insulin resistance (Petersons et al., 2013). For most individuals, blood glucose levels remain in the nondiabetic range, but this is only achieved through a rise in plasma insulin levels. However, a significant proportion of glucocorticoid-treated individuals will develop glucose intolerance or overt diabetes mellitus. These patients tend to be those that already have a degree of insulin resistance due to their age, genetic or ethnic background, or other comorbidities (van Raalte et al., 2009). Many patients exposed to high doses of therapeutic glucocorticoids for prolonged periods also develop changes in body fat accrual and distribution. The basis for the changes in fat redistribution is unclear, but differences in response to glucocorticoids of subcutaneous and visceral adipose tissue have been proposed (Fernandez-Rodriguez et al., 2009).

Until recently, these metabolic changes were thought to be due to the direct effects of glucocorticoids on liver, pancreas, and adipose tissue. However, recent research has raised the possibility that the adverse effects of glucocorticoids on fuel metabolism are mediated, at least in part, through their action on bone. As mentioned above, glucocorticoids suppress osteoblast function and inhibit synthesis of osteocalcin, an osteoblast-derived peptide previously reported to be involved in normal glucose metabolism (Lee et al., 2007). Using transgenic and gene therapy approaches, experimental studies in mice found that the suppression of osteoblast function and associated reduction in osteocalcin signaling may be central to the pathogenesis of glucocorticoid-induced dysmetabolism (Brennan-Speranza et al., 2012). Thus, mice in which glucocorticoid signaling has been disrupted in osteoblasts and osteocytes (Col2.3-11βHSD2 transgenic mice) are not only protected from the bone-wasting effects of glucocorticoid excess but maintain normal insulin sensitivity, glucose tolerance, and body weight despite high-dose glucocorticoid treatment (Brennan-Speranza et al., 2012). Very similar effects were achieved by replacing osteocalcin in the circulation via gene therapy in glucocorticoid-treated animals.

The above studies point toward bone, and specifically the osteoblast and its product, osteocalcin, being significant regulators of energy metabolism in the context of glucocorticoid treatment. This may have clinical implications, since the metabolic adverse effects of glucocorticoids are difficult to counteract clinically. There is only a limited amount of clinical data relating to the relationship between glucocorticoids, osteocalcin, and changes in energy metabolism. The situation is particularly complicated, since most people treated with glucocorticoids will have an underlying disease that itself could influence systemic energy balance and glucose homeostasis (van Staa et al., 2000c). This is compounded by the lack of

availability of clinical approaches to selectively raise serum osteocalcin levels. One recent study has overcome some of these limitations by examining patients treated with bisphosphonates, teriparatide (PTH1-34), or calcium/vitamin D alone for GIO (Stockbrugger et al., 2002). Teriparatide is known to stimulate osteocalcin synthesis whereas bisphosphonates achieve the opposite effect. Over 12 months of therapy, bisphosphonates or calcium/vitamin D had no effect on glycemic control, whereas in teriparatide-treated patients, a small but statistically significant improvement in HbA1c was observed. This finding suggests that a treatment that stimulates osteocalcin has the potential to improve glycemic control in the setting of chronic glucocorticoid treatment.

In summary, there is now good evidence that the effects of glucocorticoid excess on fuel metabolism are at least in part mediated through the skeleton. While animal data suggest a relatively strong relationship, clinical studies that fully address this link in humans are lacking. Additionally, the detailed molecular mechanisms by which osteocalcin exerts its action, including the exact receptor(s) and tissues of action, remain uncertain. Although certainly a matter of future research, it is conceivable that the mechanisms related to the actions of osteocalcin and related osteoblast-derived proteins on fuel metabolism may become the basis of future therapies for the prevention and treatment of glucocorticoid-induced dysmetabolism (Ferris and Kahn, 2012).

Treatment of glucocorticoid-induced osteoporosis

While the negative effects of glucocorticoids on bone health have been known to clinicians for many years, GIO remains underdiagnosed and undertreated. Despite increasing awareness of the various forms of osteoporosis among patients and health care providers, recognition of the potentially devastating consequences of glucocorticoid therapy on the skeleton, and the knowledge of how to prevent or treat these outcomes, are still inadequate (Curtis et al., 2005; Feldstein et al., 2005; Overman et al., 2013) (Fig. 39.3). In part, this deficit may be due to the "osteoporosis care gap"—i.e., a lack of adequate medical care that worldwide leaves 70%–80% of patients with osteoporotic fractures undiagnosed and untreated (Eisman et al., 2012). In addition, the complex actions of glucocorticoids in bone and elsewhere, and the uncertainties regarding intervention thresholds for the prevention and treatment of the disease, may contribute to current inadequacies in the recognition and management of patients with GIO.

Assessment of the patient with glucocorticoid-induced osteoporosis

Oral or parental glucocorticoids are almost always used to treat systemic inflammatory conditions, which through increased inflammatory cytokine output affect bone health independent of medication-induced adverse effects (Hardy and Cooper, 2009). This is best demonstrated in rheumatoid arthritis, where inflammatory disease activity can have a substantial negative impact on bone health through the stimulation of osteoclastogenesis and bone erosions and suppression of bone formation (Bultink et al., 2005; Gough et al., 1994; Matzelle et al., 2012). Low-dose glucocorticoid therapy has been reported to suppress inflammation in patients with early arthritis, and despite the possible negative effects of glucocorticoids on bone, results in better bone status. As such, the impact of the underlying disease on bone needs to be balanced against potentially beneficial effects of glucocorticoid therapy that may result in overall beneficial effects on skeletal health if it reduces the inflammatory activity of the underlying inflammatory disease (and hence circulating cytokine levels) (Guler-Yuksel et al., 2008; Landewe et al., 2002; van der Goes et al., 2013). These partly conflicting factors need to be considered when making the clinical decision to intervene. Nevertheless, the use of therapeutic glucocorticoids—particularly at high doses—is associated with a substantial increase in fracture risk (Fig. 39.4) (van Staa et al., 2000b, 2005).

In contrast to postmenopausal osteoporosis, measurement of bone mineral density has limited value in determining fracture risk in the context of glucocorticoid therapy (Van Staa et al., 2003). As a rule, the "fracture threshold" seems to be lower in patients on glucocorticoid therapy—i.e., fractures occur at higher bone mineral density than what has been established for women with postmenopausal osteoporosis. Although new imaging techniques such as high-resolution computed tomography and volumetric quantitative computed tomography have been found to reasonably predict fracture risk even in the context of GIO, their use outside clinical studies currently remains limited (Kalpakcioglu et al., 2011).

A comprehensive review of potential risk factors for bone loss and fracture therefore remains essential to the clinical work-up of patients with GIO. Some guidelines also recommend the use of fracture risk calculators (Grossman et al., 2010; Lekamwasam et al., 2012), although these recommendations are not without controversy. For example, instead of individual or cumulative doses, FRAX uses a fixed ("average") glucocorticoid dose to calculate fracture risk, while the Garvan fracture risk calculator does not account for glucocorticoid treatment at all. It is therefore likely that both algorithms underestimate fracture risk in patients receiving glucocorticoids at therapeutic doses.

While standard diagnostic measures such as bone mineral density testing and laboratory parameters are of limited value in the work-up of the patient with GIO, they can be useful in monitoring treatment efficacy or disease progression. Since bone loss in GIO can vary considerably between individuals, monitoring changes in bone mineral density may be helpful in identifying patients particularly susceptible to the skeletal effects of glucocorticoids. Evaluation of hepatic and renal function as well as determination of serum vitamin D, calcium, phosphate, and parathyroid hormone levels are usually recommended before commencement of treatment (Grossman et al., 2010; Lekamwasam et al., 2012).

Management of glucocorticoid-induced osteoporosis

One of the core principles of treating patients with GIO is to minimize glucocorticoid use. This is easier said than done, as more often than not reductions in glucocorticoid dosing are followed by a flare-up of the underlying condition. In these cases, concomitant treatment with a bone-sparing agent is necessary. Dose, timing, and duration of such "adjuvant therapies" are a matter of ongoing debate and vary across studies and guidelines (Grossman et al., 2010; Hansen et al., 2011; Lekamwasam et al., 2012), but there is some consensus that in patients with low bone mineral density or genuinely increased fracture risk, treatment with a bisphosphonate or teriparatide should coincide with the initiation of glucocorticoid therapy (Table 39.2). In addition, supplementation with calcium and vitamin D as required is recommended (Grossman et al., 2010; Lekamwasam et al., 2012). Thus, the 2017 American College of Rheumatology Guidelines for the Prevention and Treatment of Glucocorticoid-Induced Osteoporosis (Buckley et al., 2017), while noting the "limited evidence regarding the benefits and harms of interventions" in patients treated with glucocorticoids, recommends "treating only with calcium and vitamin D in adults at low fracture risk, treating with calcium and vitamin D plus an additional osteoporosis medication (oral bisphosphonate preferred) in adults at moderate-to-high fracture risk, continuing calcium plus vitamin D but switching from an oral bisphosphonate to another anti-fracture medication in adults in whom oral bisphosphonate treatment is not appropriate, and continuing oral bisphosphonate treatment or switching to another anti-fracture medication in adults who complete a planned oral bisphosphonate regimen but continue to receive glucocorticoid treatment" (Buckley et al., 2017).

TABLE 39.2 Recommended pharmacological interventions for the prevention and treatment of glucocorticoid-induced osteoporosis.

Intervention	Dose	Evidence grade		References[b]
		(BMD)	(Fracture)[a]	
Calcium	Oral: 1000–1500 mg daily	A[c]	–	Amin et al. (1999), Buckley et al. (1996), Sambrook et al. (1993)
Vitamin D	Oral: 800–1000 IU daily	A[d]	–	Amin et al. (1999), Buckley et al. (1996), Sambrook et al. (1993)
Alendronate	Oral: 70 mg once/week	A	B	Adachi et al. (2001), Stoch et al. (2009), Yilmaz et al. (2001)
Risedronate	Oral: 35 mg once/week	A	A	Cohen et al. (1999), Eastell et al. (2000), Reid et al. (2000), (2001), Wallach et al. (2000)
Zoledronic acid	Intravenous: 5 mg once/year	A	–	Kauh et al. (2012), Sambrook et al. (2012)
Teriparatide	Subcutaneous: 20 mg once/day	A	A	Gluer et al. (2013), Karras et al. (2012), Saag et al. (2007), (2009)
Etidronate	Oral: 400 mg daily for 2 weeks every 3 months	A	A	Adachi et al. (1997), Cortet et al. (1999), Roux et al. (1998), Struys et al. (1995)

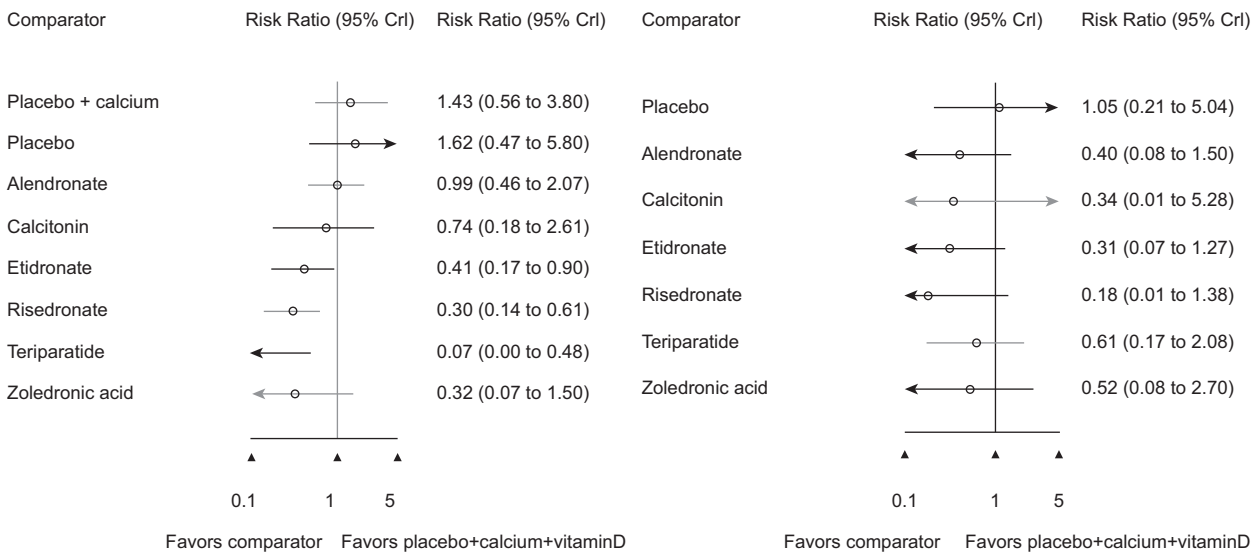

FIGURE 39.7 Efficacy of osteoporosis pharmacotherapies in preventing fracture among oral glucocorticoid users. Forest plots showing risk ratios for fracture for patients on "active" treatment versus placebo. Upper panel: Vertebral fracture. Lower panel: Nonvertebral fracture (Amiche et al., 2016).

Bisphosphonates

Bisphosphonates are the current standard in the prevention and therapy of GIO (Grossman et al., 2010; Lekamwasam et al., 2012). A recent Cochrane review concludes that "there was high-certainty evidence that bisphosphonates are beneficial in reducing the risk of vertebral fractures with data extending to 24 months of use. There was low certainty evidence that bisphosphonates may make little or no difference in preventing non-vertebral fractures" (Allen et al., 2016).

Given orally or intravenously, bisphosphonates generally act by inducing osteoclast apoptosis, thereby reducing the rate of bone resorption. While bisphosphonates prevent rapid loss of bone mineral density during the initial phase of glucocorticoid therapy, their longer-term effect on fracture risk is less well documented (de Nijs et al., 2006; Grossman et al., 2010; Saag et al., 1998). Some reports show significant reductions in vertebral or hip fracture risk (Amiche et al., 2018; Axelsson et al., 2017) but the effect on nonhip, nonvertebral fracture risk is either weak or unknown (Fig. 39.7). Most studies investigating the use of bisphosphonates in the context of GIO are underpowered to detect significant differences in fracture rates and therefore use changes in bone mineral density or other surrogates as the primary outcome measure (Lekamwasam et al., 2012). The absence of reliable fracture data is particularly problematic since glucocorticoids not only affect bone remodeling but also compromise bone strength through a number of different mechanisms that are not targeted by bisphosphonates. As outlined above, glucocorticoid-induced activation of osteoclasts and subsequent loss of bone mineral density is only one of several causal factors in the pathogenesis of GIO. Rodent models suggest that bone strength is closely linked to osteoblast and osteocyte viability, which is readily compromised under conditions of glucocorticoid excess (Weinstein et al., 2010b). Even though bisphosphonates have been shown in animal models to partially prevent glucocorticoid-induced cell apoptosis (Plotkin et al., 1999, 2005), their effects on osteoclast function always leads to a significant reduction in osteoblast activity (Saag et al., 1998). The resulting decline in bone formation comes on top of the glucocorticoid-induced suppression of osteoblast function, which poses a conundrum in regards to the use of bisphosphonates in the setting of GIO.

Denosumab

Denosumab is a potent RANKL inhibitor, and like all antiresorptive agents, acts by inhibiting osteoclast function and bone resorption. Denosumab effectively reduces fracture risk in postmenopausal osteoporosis (Brown et al., 2009), but its use in GIO has thus far not been fully assessed. A subgroup analysis of glucocorticoid-treated patients with rheumatoid arthritis demonstrated a significant increase in lumbar spine and hip bone mineral density after 12 months of treatment with denosumab (60 mg s.c. every 6 months) (Dore et al., 2010).

A recent study of 29 patients on chronic glucocorticoid therapy for a variety of systemic inflammatory conditions found that denosumab was effective in preventing bone resorption and bone loss, with increases in bone density at both the lumbar spine and hip (Sawamura et al., 2017).

In a 12-month study of patients receiving an oral bisphosphonate for chronic glucocorticoid therapy, switching to denosumab resulted in greater gains of lumbar spine bone mineral density and more pronounced suppression of bone turnover markers. The study was not powered for fracture as an end point (Mok et al., 2015). Similar findings were reported in another small study from Japan (Ishiguro et al., 2017). Since denosumab not only reduces osteoclast function but also osteoclast recruitment, activation, and survival together with a significant reduction in osteoblastic bone formation, its use in GIO may compromise bone quality over time. Additional long-term studies of GIO are therefore of paramount importance.

Raloxifene

The selective estrogen receptor modulator raloxifene has been shown to reduce fracture risk in women with postmenopausal osteoporosis (Ettinger et al., 1999). In a recent randomized double-blind placebo-controlled trial, 12 months of raloxifene (60 mg daily) significantly increased spinal and hip bone mineral density in women receiving longer-term glucocorticoids for a number of various conditions. The study was underpowered to measure the effect of raloxifene on fracture risk (Mok et al., 2011).

Teriparatide

Osteoanabolic treatments may have greater beneficial potential in GIO, particularly in patients undergoing long-term treatment. In a mouse model of GIO, intermittent treatment with parathyroid hormone (PTH) not only averted the adverse effects of glucocorticoids on bone turnover but also preserved osteocyte viability (Weinstein et al., 2010a). While the anabolic effects of PTH on bone-forming cells and their molecular pathways are not fully understood, PTH has been shown to induce several molecular pathways that are suppressed by glucocorticoid excess. For example, PTH directly induces canonical Wnt signaling in osteoblasts, a signal profoundly inhibited by supraphysiological levels of glucocorticoids (Keller and Kneissel, 2005; Weinstein et al., 2010a). This anabolic PTH signal is further amplified by the suppression of the Wnt antagonist sclerostin in osteocytes (Anastasilakis et al., 2010; Gatti et al., 2011). Intermittent administration of PTH also induces the expression of Cyclin D1 in osteoblasts and preosteoblasts (Datta et al., 2007) as well as the expression of RUNX2 (Hisa et al., 2011). As mentioned above, both of these factors are key regulators of osteoblast proliferation and differentiation and are suppressed by glucocorticoids at pharmacological doses. Overall, PTH treatment has been shown to induce differentiation of osteoblast precursors and prolong osteoblast and osteocyte survival, thereby increasing osteoblast/osteocyte numbers and overall activity.

On a structural level, PTH treatment increases the amount of trabecular bone (e.g., at the spine), while its anabolic impact is much less pronounced at cortical sites (Dempster et al., 2001; Gluer et al., 2013; Orwoll et al., 2003). This pattern is distinctively different from that of bisphosphonates, which cause smaller increases in bone mineral density across both trabecular and cortical sites (Gluer et al., 2013; Saag et al., 2007, 2009). Clinical studies indicate that the risk of vertebral fractures rises substantially with ongoing glucocorticoid therapy, whereas that of nonvertebral fracture increases only moderately (van Staa et al., 2000c). Given that PTH has its anabolic effects predominantly in trabecular bone (such as the spine), PTH may have greater therapeutic benefits in preventing vertebral fractures than bisphosphonates do. Indeed, an 18-month randomized controlled trial of alendronate versus teriparatide (recombinant human PTH[1−34]) in patients with GIO found teriparatide to be associated with increased markers of bone formation and a greater increase in areal bone mineral density at both the spine and the hip (Saag et al., 2007) (Fig. 39.8). Of note, even though the study was not adequately powered to detect differences in fracture incidence, three incident vertebral fractures occurred among the 173 patients in the teriparatide group and 13 incident vertebral fractures among the 169 patients receiving alendronate (Saag et al., 2007). Similar differences were seen at the 36-month follow-up (Saag et al., 2009). In a recent 18-month RCT of men with GIO, Gluer and colleagues compared the effect of teriparatide versus risedronate on lumbar spine bone mineral density (Gluer et al., 2013). The authors found greater increases in lumbar spine areal density with teriparatide. Interestingly, a subanalysis utilizing high-resolution quantitative CT of the T12 vertebra at 18 months of treatment revealed a greater increase in trabecular bone mineral density for teriparatide compared with risedronate (14.5% vs. 2.0%), while cortical density changed similarly in both groups (8.0% vs. 6.1%). In addition, there was a substantially greater increase in vertebral strength in the teriparatide group compared with the bisphosphonate group (Gluer et al., 2013). These results seem to confirm some predictions from rodent models regarding the effectiveness of osteoanabolic treatments versus bisphosphonates. Specifically, these data and a recent meta-analysis (Amiche et al., 2016) (Fig. 39.7) support the notion that teriparatide has greater efficacy in preserving or even increasing spinal bone strength, and reducing fracture risk in the setting of glucocorticoid treatment.

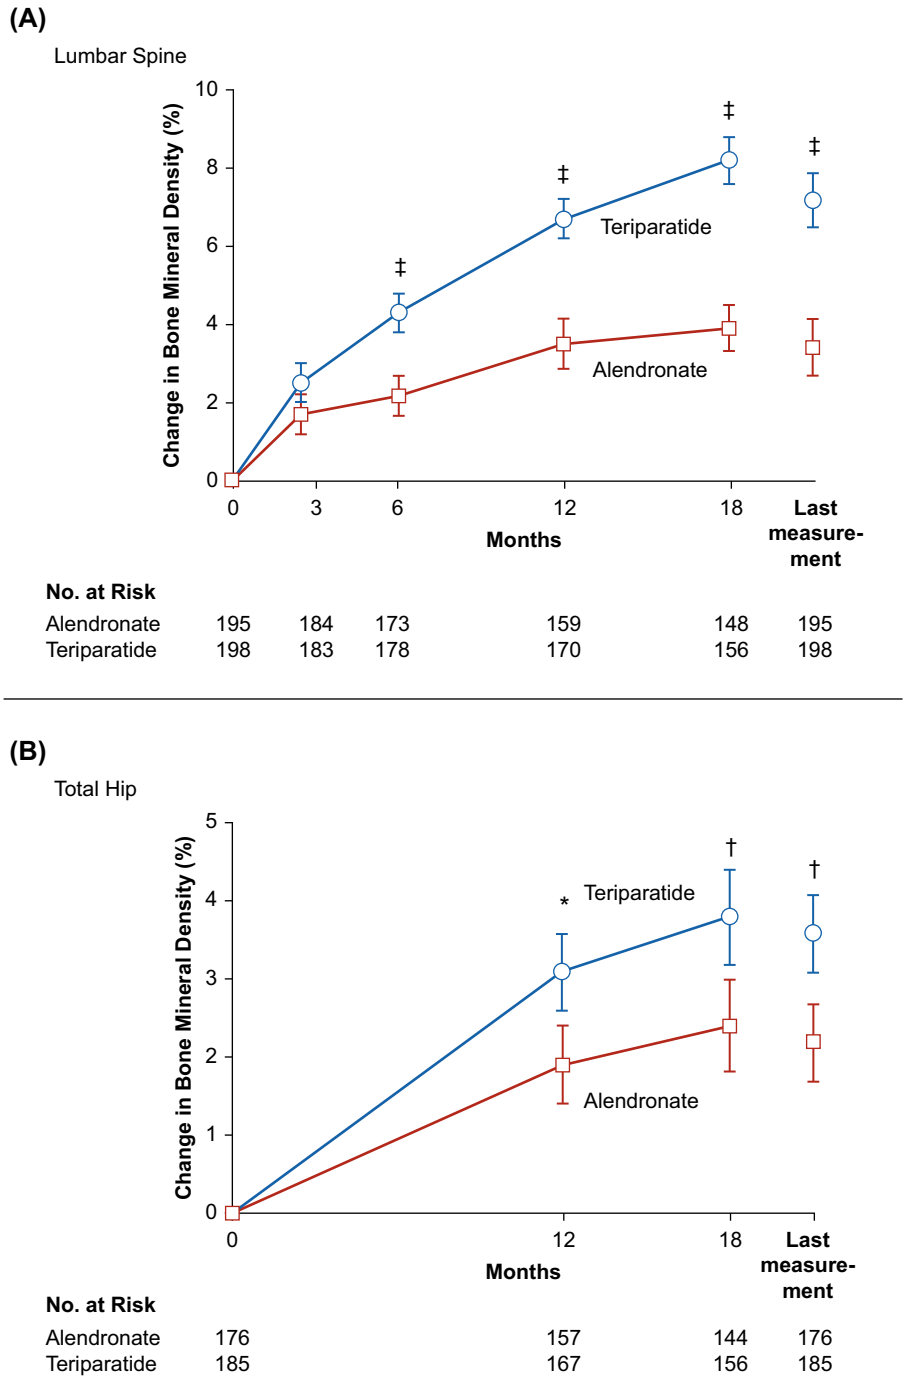

FIGURE 39.8 Effect of teriparatide or alendronate treatment on bone mineral density in patients with glucocorticoid-induced osteoporosis. The graphs show the percent change in mean bone mineral density from baseline to 18 months or last measurement. *P*-values are *< 0.05, † < 0.01, ‡< 0.001. Bars are standard error.

While these results are certainly promising, further clinical studies are required to confirm the effectiveness of osteoanabolic treatments in the management of GIO. In particular, long-term studies large enough to assess fracture rates—not bone mineral density—as a primary outcome are now required. Combinations of antiresorptive agents (such as bisphosphonates) with osteoanabolic agents (such as teriparatide) have recently been studied, with some success in the context of postmenopausal osteoporosis (Cosman et al., 2011). Whether such combination therapies yield beneficial results in GIO remains to be seen.

Sex hormone replacement

Hypogonadism is a known adverse outcome of high-dose, long-term glucocorticoid therapy (Chrousos et al., 1998; Pearce et al., 1998). Many but not all guidelines recommend sex hormone replacement in glucocorticoid-treated patients diagnosed with proven sex hormone deficiency. However, the evidence base for these recommendations is weak, as hormone replacement therapy has been studied in only a few small short-term studies. After due consideration of risks and benefits, hormone replacement might be used as either adjuvant therapy or second-line treatment in patients who cannot be treated with bisphosphonates or teriparatide.

Timing and monitoring of therapy

There is wide agreement that patients should remain on bone-protective treatments for as long as they require therapy with glucocorticoids. Drug holidays, sometimes considered in patients with postmenopausal osteoporosis, are usually not an option in GIO (Grossman et al., 2010; Nawata et al., 2005; Soen, 2011). As adherence with oral bisphosphonates is usually low, continuous surveillance and encouragement of the patient is a necessity. The introduction of intravenous bisphosphonates offers a viable and effective alternative in nonadherent patients.

There is limited data concerning the monitoring of patients with GIO. In patients whose fracture risk is deemed low, baseline and serial measurements of bone mineral density are usually recommended, although there is no clear evidence at what intervals these scans should be performed and what degree of glucocorticoid-induced bone loss should trigger an intervention. Many guidelines do, however, recommend intervening when the T-score at any site is −1.5 or lower. Patients should be carefully monitored for incident minimal trauma fractures, as these are a clear indication for the commencement of therapy. Despite the limitations of bone mineral density as a tool to monitor treatment efficacy, most guidelines recommend that patients on current bone-protective therapy have yearly bone mineral density scans. Serial determinations of bone turnover are usually not recommended.

New and emerging therapies

Despite their limitations, current treatments for GIO have proven to provide a significant degree of protection against bone loss and fracture. New therapies in this area would need to be more efficacious than existing medications, have fewer adverse effects, or have additional nonskeletal benefits.

Selective glucocorticoid receptor activators

In an attempt to develop agents with superior glucocorticoid-like properties but fewer off-target effects, a number of pharmaceutical companies have invested in the development of so-called selective glucocorticoid receptor activators (SEGRAs) (Oakley and Cidlowski, 2013; Schacke et al., 2007; Sundahl et al., 2015). This was on the basis that beneficial antiinflammatory effects of glucocorticoids could be "dissociated" from the adverse effects on bone and carbohydrate metabolism. Unfortunately, few agents able to dissociate these actions have been identified so far. The concept of GR transactivation as the cause of most adverse effects, and transrepression as the basis of most antiinflammatory effects, of glucocorticoids may be overly simplistic. Thus, some important antiinflammatory genes such as DUSP1 are clearly transactivated, and some of the adverse effects, such as the effect of glucocorticoids on bone, are primarily caused by transrepression (Rauch et al., 2010; Tchen et al., 2010). Despite this, there are clearly some agents, such as Compound A, that have useful differential effects on various GR-mediated responses (Lesovaya et al., 2015; Thiele et al., 2012). In a mouse model of GIO, mice were treated with equivalent antiinflammatory doses of prednisolone and Compound A. Prednisolone, as expected, caused a reduction in bone formation and an increased RANKL/OPG ratio (Thiele et al., 2012). These effects were not seen, however, with Compound A, indicating that it has some "bone-sparing" properties. Unfortunately, the therapeutic index for Compound A appears too narrow for use in humans. The attraction of pursuing the development of SEGRAs is their potential to reduce adverse effects on a range of tissues rather than just bone.

Antisclerostin/DKK1

As discussed above, the canonical Wnt signaling pathway is critical to bone formation. Glucocorticoid treatment causes increases in DKK1 and sclerostin, both powerful inhibitors of the Wnt pathway. Antibodies capable of neutralizing these targets are now being evaluated clinically in postmenopausal and cancer-induced bone loss. In contrast to DKK1, sclerostin

expression and action appears exclusive to osteoblasts and osteocytes. The antisclerostin antibody romosozumab has been studied in women with postmenopausal osteoporosis, where 12 months of treatment led to remarkable increases in bone mineral density and significant reductions in fracture risk (Cosman et al., 2016; Langdahl et al., 2017; Saag et al., 2017). However, so far no RCT data on the efficacy of romosozumab are available in patients with GIO.

Conclusions and future perspectives

Our understanding of the pleiotropic effects of glucocorticoids on bone cells and their signaling behavior has greatly improved over the past 2 decades, resulting in a clearer and more complete picture of the mechanism behind the developmental anabolic, and the detrimental catabolic, actions of glucocorticoids on the skeleton.

It is now evident that endogenous glucocorticoids at physiological levels are vital for the commitment and differentiation of osteoblasts and play a pivotal role in the control of skeletal development and maintenance of healthy bone. At supraphysiological levels, however, glucocorticoids become largely detrimental to bone and cause bone loss and skeletal fragility. While high levels of glucocorticoids affect all bone cells, rodent models and human studies reliably demonstrate that their key targets in the skeleton are osteoblasts and osteocytes. Newer research indicates that the adverse effects of glucocorticoids on fuel metabolism and body fat accrual are at least in part mediated through their skeletal actions on osteoblasts and osteocytes. These cells are now at the core of new and promising interventional strategies uniquely suited to offset the detrimental effects of glucocorticoids on molecular as well as structural levels.

Although the study was not powered for fracture outcomes, there was a significant difference for vertebral fractures between the alendronate (6.1%) and teriparatide (0.6%) arms ($P < .01$) (Saag et al., 2007). Similar differences were seen at the 36 months follow-up (7.7% vs. 1.7%, $P < .01$) (Saag et al., 2009).

Chapter outline

Introduction

The term "diabetic bone disease" is used to describe the changes in bone growth, remodeling, and density as well as fracture risk imparted by the presence of type 1 diabetes mellitus (T1DM) or type 2 diabetes mellitus (T2DM). T1DM is caused by pancreatic β-cell destruction, usually leading to an absolute insulin deficiency; northern Europeans are among the populations with the highest prevalence of T1DM. However, T2DM is currently by far the most prevalent form of diabetes on all continents. Its pathophysiology is heterogeneous, ranging from predominantly insulin resistance—i.e., at any of the classical insulin-sensitive tissues, liver, skeletal muscles, and adipose tissue—with relative insulin deficiency to a predominantly insulin secretory defect with variable insulin resistance. Hence, insulin levels in T2DM vary widely, anywhere between hyper- and hypoinsulinemia. The majority of patients with T2DM are obese, and obesity itself aggravates insulin resistance. Body weight is, therefore, an important confounding factor when examining the pathophysiology of bone in T2DM individuals.

Effects of diabetes and insulin on endochondral bone growth

Effects of insulin on growth plate cartilage in nondiabetic animal models and in vitro

The classic experiments of Salter and Best (Salter and Best, 1953) demonstrated that insulin administration increased growth plate width in hypophysectomized rats. This could be a local effect, because insulin injection into the proximal tibial growth plate (Heinze et al., 1989) or insulin infusion into one hindlimb (Alarid et al., 1992) produced widening of the treated growth plates only. Such local effect might be mediated by in situ production of insulin-like growth factor 1 (IGF-1), because the trophic effect of insulin was nullified by coinfusion of an IGF-1 antiserum (Alarid et al., 1992). Mice with absent expression of insulin receptors (IRs) in bone showed normal bone length (Irwin et al., 2006). However, they overexpressed the IGF-1 receptor, which could represent a compensatory response.

In vitro studies have documented the presence of IRs in a chondrosarcoma cell line (Foley et al., 1982). Chondrocyte proliferation and $^{35}SO_4$ incorporation were stimulated by insulin in several tissue and cell culture systems (Foley et al., 1982; Heinze et al., 1989; Maor et al., 1993). These effects were obtained at physiological levels of insulin, as low as 1 nM, but equimolar IGF-1 was more potent than insulin.

Collectively, the available data suggest that growth hormone (GH) and IGF-1 are more important than insulin for chondrocyte proliferation and maturation (Yakar and Isaksson, 2016).

Skeletal growth in T1DM

Animal models

The most frequently used animal models are rats or mice with T1DM induced by β-cell-destroying drugs, alloxan or—in the large majority of studies—streptozotocin (STZ), and BB (Bio-Breeding) rats with spontaneous immune-mediated diabetes. Although T1DM can be drug induced at any age, BB rats develop diabetes past the peak growth rate (7 weeks). In both rodent models, insulin levels are very low or undetectable. The growth plate width as well as the endochondral bone growth—assessed by double fluorochrome labeling of the calcifying cartilage—at the proximal tibia was consistently lower in untreated, severely hyperglycemic STZ-induced or spontaneously diabetic BB rats, and was remedied by systemic insulin treatment (Bain et al., 1997; Epstein et al., 1994; Scheiwiller et al., 1986; Verhaeghe et al., 1992). The femur was shorter after 28 days of STZ diabetes (Lucas, 1987).

The effect of insulin on bone growth might be direct and/or indirect, for example, by restoring the depressed hepatic release of IGF-1. Although it was reported that systemic administration of IGF-1 in T1DM rats partly normalized growth plate width (Scheiwiller et al., 1986), this finding was not corroborated in a subsequent study (Verhaeghe et al., 1992). The low $^{35}SO_4$ uptake by rib cartilage explants from T1DM rats was also unresponsive to exogenous IGF-1 (Kelley et al., 1993). These data suggest that diabetic cartilage is, at least in part, resistant to the actions of IGF-1. Blunted stimulatory actions of IGF-1 on osteoblasts due to high concentrations of advanced glycation end products (AGEs) and hyperglycemia may also contribute (McCarthy et al., 2001; Terada et al., 1998).

Children

At the onset of T1DM, there is no difference in height compared with nondiabetic children. In fact, most studies have documented that children are slightly taller at the onset of diabetes compared with reference values (Bonfig et al., 2012; Holl et al., 1998). Increased growth velocity has even been associated with risk of islet autoimmunity in children at risk for T1DM (Beyerlein et al., 2014; Lamb et al., 2009; Yassouridis et al., 2017).

However, growth is affected from the clinical onset onward. In the preinsulin era, prepubertal growth virtually stopped, and stunted growth (Mauriac syndrome) was frequently observed in later decades of irregular insulin treatment. In addition, there was a delay in pubertal development and growth. Retarded growth and pubertal development remain common to this day among African children with T1DM (Elamin et al., 2006). In Western countries, the majority of recent studies have documented a mild reduction in growth from height-for-age (z) charts. This deficit was more pronounced in children with a prepubertal compared with a pubertal onset of T1DM (Holl et al., 1998). Poor glycemic control predicts growth retardation: indeed, glycated hemoglobin A1c (HbA1c) levels (a reflection of glycemic control in the previous 2−3 months) correlated inversely with height velocity (Danne et al., 1997; Holl et al., 1998), and patients with good glycemic control (HbA1c $< 7\%$) had normal near-adult height (Bonfig et al., 2012). In the larger analysis conducted so far, mean near-adult height was reduced by 0.16 SD scores in patients with onset of diabetes before age 10 years (Bonfig et al., 2012).

Considering that mean height at onset of diabetes was +0.25 SD scores (i.e., at diagnosis, children with diabetes were taller than average), 0.41 SD scores were lost since diabetes onset to near-adult age.

At diagnosis, bone maturation—determined by radiographs of hand and wrist—was not different compared with nondiabetic children (Danne et al., 1997; Holl et al., 1998). However, there was a small but significant retardation of bone maturation with increasing T1DM duration (i.e., a 1-year difference between chronological and bone age after 11 years of diabetes) (Danne et al., 1997; Holl et al., 1998). Dysregulation of the GH−IGF-1 axis, which promotes chondrocyte proliferation, differentiation, and hypertrophy, may play a role in the pathogenesis of impaired skeletal growth in T1DM (Raisingani et al., 2017).

Effects of T1DM on bone

T1DM and fracture risk

The available epidemiologic studies concur that the risk of fractures is substantially increased in individuals with T1DM, more than could be explained by the mild bone mineral density (BMD) deficit; in effect, a 1-SD reduction in areal BMD (aBMD) would translate into a twofold increased risk of hip fracture (Johnell et al., 2005). A caveat is that many studies contained few incident fractures in the diabetic group ($n = 1-18$).

In a large meta-analysis that included 7,185,572 participants from 16 prospective and 9 retrospective cohort studies, patients with T1DM had 1.5 times greater risk of total fractures, 4.4 times greater risk of hip fractures, 1.8 times greater risk of upper arm fractures, and 2 times greater risk of ankle fractures compared with nondiabetic individuals (Wang et al., 2019). Compared with T2DM, T1DM was associated with a greater risk of total, hip, and ankle fracture. There was no increase in the risk of forearm or vertebral fractures. Previous meta-analyses reported relative risks ranging from 3.2 to 6.3 for any fracture (Janghorbani et al., 2007; Shah et al., 2015), 3.8 to 6.9 for hip fracture (Fan et al., 2016; Shah et al., 2015; Vestergaard, 2007), and 2.9 for spine fracture (Shah et al., 2015). A meta-analysis that specifically addressed fracture risk in patients with T1DM ages 18−50 years ($n = 35{,}925$) compared with nondiabetic controls ($n = 2{,}455{,}016$) found that T1DM was associated with a nearly twofold increase in the risk of any fracture and a more than fourfold increase in the risk of hip fracture, this increase being greater in women than in men (Thong et al., 2018). Overall, these findings indicate that younger age does not protect against the increase in fracture risk associated with T1DM.

In T1DM, the possible association between BMD and HbA1c is still a matter of debate. One possible explanation of the discordant findings is that the relation between BMD and glycemic control, is, in fact, multifactorial, and therefore may be hardly detectable by traditional statistics. Eller-Vainicher and colleagues (Eller-Vainicher et al., 2011) adopted a special mathematic approach, the artificial neural networks (ANNs), to study 175 eugonadal T1DM patients and 151 age- and body mass index (BMI)-matched controls. The authors found that T1DM subjects had lower spine and femur BMD. Interestingly, spine BMD was independently associated with BMI and daily insulin dose (DID), whereas femur BMD was associated with BMI and creatinine clearance (CrCl). The authors found that a BMI below 23.5 kg/m^2, a DID > 0.67 units/kg, and a CrCl <88.8 mL/min were associated with low BMD. Data were also analyzed using the supervised ANNs and a semantic connectivity map that showed that low BMD at both sites was indirectly connected with HbA1c through the link with chronic diabetes complications. A 2019 large nested case−control analysis corroborated these observations, showing that T1DM patients with poor glycemic control (HbA1c $>8\%$) were 1.4 times more likely to have an incident nonvertebral low-trauma fracture than those with good glycemic control (HbA1c $\leq 7\%$) (Vavanikunnel et al., 2019). Furthermore, fracture risk was associated with comorbidities related to micro- and macrovascular complications, such as diabetic retinopathy and ischemic heart disease.

Few studies have investigated the prevalence of asymptomatic vertebral fractures in T1DM. In a study by Zhukouskaya and coauthors, patients with T1DM had a lower BMD at both spine and femur than controls and a higher prevalence of vertebral fractures (24.4% vs. 6.1%) (Zhukouskaya et al., 2013). Age, diabetes duration, age at diabetes onset, HbA1c, BMD, and the prevalence of chronic complications were similar in patients with and without fractures. Interestingly, the elevated prevalence of asymptomatic vertebral fractures was associated with the presence of T1DM independent of BMD, suggesting that impaired bone quality may contribute the increased fracture risk in T1DM.

T1DM and bone turnover

Animal models of T1DM

Several animal models have been used for T1DM (mainly alloxan- or STZ-induced diabetic rats and mice, spontaneously diabetic BB rats, and nonobese diabetic [NOD] mice). Untreated severe T1DM (hyperglycemia >300 mg/dL) was

associated with low bone formation as shown by biochemical markers, in particular osteocalcin (OC) concentrations. Plasma OC dropped exponentially after onset of T1DM in BB rats to 25% of nondiabetic levels after 5 weeks (Verhaeghe et al., 1997). Plasma OC gradually returned to the control range with increasing insulin dosage in BB rats (Verhaeghe et al., 1997) and was normalized by pancreas transplantation in STZ-diabetic rats (Ishida et al., 1992).

Histomorphometry consistently showed low bone formation on all bone surfaces (trabecular—endosteal, endocortical, and periosteal) in STZ-diabetic and BB rats. Static morphometry demonstrated a marked decline in osteoblast and osteoid surface or volume, and dynamic morphometry a decrease in both mineralizing surface and mineral apposition rate. These changes were (partly) reversed by insulin (Bain et al., 1997; Epstein et al., 1994; Glajchen et al., 1988; Shires et al., 1981; Verhaeghe et al., 1992). Electron microscopy of the endocortical surface confirmed that active, cuboidal osteoblasts are virtually absent in STZ-diabetic rats and are replaced by inactive bone-lining cells with flattened nuclei and little or no endoplasmic reticulum (Sasaki et al., 1991). Thus, most of the bone surface is in a quiescent state in severely hyperglycemic animals.

OC but not Runx2 or alkaline phosphatase mRNA levels were reduced in tibias from STZ-diabetic mice (Botolin et al., 2005), reinforcing the conclusion that loss of mature osteoblasts is a key finding in T1DM.

Regarding bone resorption, T1DM rats displayed diminished total and creatinine-corrected deoxypyridinoline excretion (Horcajada-Molteni et al., 2001; Verhaeghe et al., 2000). Most but not all histomorphometric data confirmed that the osteoclast surface/number is decreased moderately to severely in T1DM murine models and this is reversed by insulin treatment (Glajchen et al., 1988; Peng et al., 2016; Shires et al., 1981; Verhaeghe et al., 1992). Electron microscopy showed that most osteoclasts in T1DM rats lack a ruffled border—clear zone complex and that acid phosphatase activity is rarely detected (Kaneko et al., 1990). Bacterial inoculation of the scalp in *db/db* mice also generated fewer osteoclasts (He et al., 2004).

Greater marrow adiposity has been a consistent finding in animal models of T1DM compared with nondiabetic controls. Interestingly, bone marrow adiposity was increased in STZ-diabetic mice and NOD mice, with upregulation of adipogenic genes such as peroxisome proliferator-activated receptor γ_2 (PPARγ_2), adipocyte fatty acid—binding protein 2, and resistin (Botolin et al., 2005). STZ-diabetic mice and NOD mice had significant trabecular bone loss, and tended to have cortical bone loss. Despite similar earlier markers of osteoblast differentiation compared with controls, OC mRNA, a marker of mature osteoblasts, was significantly reduced (Botolin and McCabe, 2007). Bone marrow adiposity, but not bone loss, was prevented by treatment with leptin or with a PPARγ antagonist (Botolin and McCabe, 2006; Motyl and McCabe, 2009), indicating that these two manifestations of diabetic bone disease result, at least in part, from different mechanisms.

Clinical data

Only few data on bone histomorphometry are available, and the measurement of biochemical markers of bone formation/mineralization produced variable results. A case—control study of 18 patients with T1DM with varying degrees of glycemic control and a wide range of disease duration showed no significant differences between diabetics and controls in histomorphometric parameters (Armas et al., 2012). However, in the T1DM group, patients with a history of fracture tended to have histomorphometric parameters suggestive of lower bone remodeling compared with nonfractured patients.

No definitive data have been produced regarding biochemical markers of bone resorption in T1DM. In some studies, resorption markers were unchanged, or even slightly increased. A systematic review and meta-analysis of studies that assessed bone turnover markers in diabetes found no difference in procollagen type 1 N-terminal propeptide (P1NP), bone-specific alkaline phosphatase, tartrate-resistant acid phosphatase (TRAP), osteoprotegerin, and N-terminal telopeptide (NTX) (Hygum et al., 2017). Sclerostin, a potent inhibitor of bone formation, was significantly higher, and C-terminal telopeptide of type I collagen (CTX) and OC significantly lower, in patients with T1DM compared with controls. OC levels were affected by plasma glucose levels, whereas HbA1c was a significant effect modifier for sclerostin.

It has also been reported that time-related changes in circulating bone turnover markers in patients with T1DM are not different from those in the general population, with no relevant changes in women and a decrease in the bone formation markers OC and P1NP and a trend toward a decrease in the bone resorption marker CTX (Hamilton et al., 2018).

Although the evidence supports the notion that T1DM is characterized by low bone turnover, what bone turnover markers reflect in T1DM and whether they predict fracture risk have not been fully understood. As an example, an inverse association between sclerostin levels and fracture risk in T1DM has been reported (Starup-Linde et al., 2016a).

In contrast to animal models, most human studies of T1DM did not show a significant increase in bone marrow adiposity, possibly due to the relatively small number of subjects included (Abdalrahaman et al., 2015; Slade et al., 2012).

T1DM, bone density, and bone structure

Animal models of T1DM

Experimental T1DM had a negative effect on bone size (wet and dry weight, diaphyseal width) that was related to at least three factors: earlier age at which diabetes was induced or occurred spontaneously, longer diabetes duration, and more severe hyperglycemia (Dixit and Ekstrom, 1980; Einhorn et al., 1988; Locatto et al., 1993; Lucas, 1987). Thus, the impact on bone size was modest in T1DM models with onset of diabetes past the peak growth rate (Verhaeghe et al., 1994, 2000).

T1DM negatively affects both cortical bone and trabecular bone. The reduction in trabecular bone volume was the result of thinner trabeculae, while the number and separation of trabeculae remained the same (Botolin et al., 2005; Epstein et al., 1994; Suzuki et al., 2003; Thrailkill et al., 2005a). In locations with dense trabecular bone (e.g., femur, mandible), the effect of hyperglycemia was less than that in areas without dense trabecular bone such as the tibial region (Hua et al., 2018).

Clinical data

Reduced trabecular bone density and cortical thickness have been reported in children and adolescents with T1DM (Maratova et al., 2018). Similarly, lower cortical and trabecular volumetric BMD (vBMD) as well as deterioration in bone microarchitecture has been reported in adult patients with T1DM compared with nondiabetic controls (Shanbhogue et al., 2015; Verroken et al., 2017), these reductions being more evident in patients with microvascular disease (Shanbhogue et al., 2015).

Reductions in bone size and bone strength have been reported in prepubertal children with T1DM (Bechtold et al., 2006, 2007; Franceschi et al., 2018). Some (Bechtold et al., 2006, 2007) but not all (Roggen et al., 2013) studies suggest that normalization of bone size occurs after puberty.

Women with long-standing T1DM had higher BMD at the lumbar spine and lower BMD at the femoral neck and higher rates of fragility fractures compared with age- and sex-matched controls, suggesting that factors other than BMD influence fracture risk in long-standing T1DM (Alhuzaim et al., 2019). No difference in BMD was evident between men with long-standing T1DM and age-matched nondiabetic men (Alhuzaim et al., 2019; Maddaloni et al., 2017). Thus, most but not all available data indicate that there is an early but mild BMD deficit in T1DM individuals that does not appear to deteriorate over time (Hamilton et al., 2018; Krakauer et al., 1995; Moyer-Mileur et al., 2004; Shah et al., 2017). Furthermore, BMD in women with T1DM remains similar to that expected for age, BMI, and postmenopausal status (Hamilton et al., 2018). Whether long-term glycemic control is a determinant of the BMD deficit in T1DM remains a matter of controversy (Hough et al., 2016). Inhibition of the bone-anabolic Wnt pathway, as suggested by an increase in circulating sclerostin and dickkopf-1 in T1DM children, may play a role (Faienza et al., 2017; Tsentidis et al., 2017), although not all studies point toward this direction (Tsentidis et al., 2016). The aBMD deficit is more pronounced among T1DM adults with microvascular complications (Campos Pastor et al., 2000; Clausen et al., 1997; Eller-Vainicher et al., 2011; Munoz-Torres et al., 1996; Rozadilla et al., 2000; Strotmeyer et al., 2006).

T1DM and bone strength

Animal models of T1DM

The breaking strength of the femoral or tibial midshaft was assessed in several T1DM models (STZ-diabetic and BB rats, NOD mice) by various methods (perpendicular pressure, torsion, three-point bending) (Dixit and Ekstrom, 1980; Einhorn et al., 1988; Horcajada-Molteni et al., 2001; Silva et al., 2009; Thrailkill et al., 2005a; Verhaeghe et al., 1990, 1994, 2000). Most, though not all, of these studies concluded that strength parameters were reduced after a critical period of diabetes (e.g., 8 weeks in rats), even when correcting for their smaller bone size.

Diabetic bone brittleness may be related to alterations of collagen quality (collagen glycation, integrity, and secondary structure) rather than changes in the mineral component of the bone matrix (Mieczkowska et al., 2015) and appears to increase with increasing duration of T1DM (Nyman et al., 2011). In WBN/Kob rats, a model of spontaneous T1DM occurring at an advanced age (i.e., from 12 months), enzymatic collagen cross-links in femoral bone were reduced from the prediabetic stage (8 months), while nonenzymatic (glycosylated) cross-links increased from 12 months. Interestingly, the collagen cross-link parameters in prediabetic/diabetic WBN bones strongly correlated with biomechanical properties (Saito et al., 2006). Similarly, STZ-induced young diabetic rats had markedly reduced trabecular bone, a relative deficit in cortical bone, and significant deficits in whole bone stiffness and strength (i.e., structural mechanical properties) (Silva et al., 2009). These changes were associated with a significant increase in nonenzymatic cross-links.

Of note, daily subcutaneous injections of insulin nearly restored the diabetes-related loss in peak force endured by the femur midshaft during three-point bending (Rao Sirasanagandla et al., 2014) and peak bending stress of the tibia midshaft (Bortolin et al., 2017) in STZ-induced diabetic rats.

Clinical data

No studies have directly measured bone strength in T1DM. However, bone strength can be estimated using quantitative computed tomography (QCT), which allows three-dimensional noninvasive assessment of bone macro- and micro-architecture (e.g., cortical porosity and trabecular connectivity). In a study that used central QCT to estimate vBMD and strength in femoral bone subfractions of 17 male T1DM patients and 18 sex-matched nondiabetic controls ages 18–49 years, cross-sectional moment of inertia, section modulus (a geometric index of bending stress), and buckling ratio (BR; an index of cortical instability) in the femoral neck and femoral shaft were similar in the two groups (Ishikawa et al., 2015). However, BR in the intertrochanteric region was higher in patients with T1DM. This associated with lower vBMD, cortical cross-sectional area, and cortical thickness in the intertrochanteric region, possibly indicating increased susceptibility to intertrochanteric fractures in young and middle-aged men with T1DM. Another study used high-resolution peripheral QCT (HR-pQCT) to assess peripheral bone microarchitecture and bone strength in T1DM patients, with or without microvascular disease, compared with nondiabetic controls (Shanbhogue et al., 2015). Patients with T1DM and microvascular disease had significant deficits in both cortical and trabecular bone microarchitectural parameters and estimated bone strength at the distal radius and tibia compared with matched nondiabetic control subjects, suggesting a role for microvascular disease in the pathogenesis of diabetic bone disease.

Effects of T2DM and insulin on bone

T2DM and fractures

Fracture risk is elevated in individuals with T2DM, but much less so than in T1DM. Large cohorts—the Study of Osteoporotic Fractures (Schwartz et al., 2001) and, in particular, the Women's Health Initiative Observational Study (Bonds et al., 2006)—confirmed a mildly increased risk (between one- and twofold). The latter study documented an elevated age-adjusted risk of fracture at all skeletal sites except the forearm/wrist/hand. A meta-analysis of cohort studies confirmed that fracture risk in patients with T2DM is 1.24 times greater than in nondiabetic individuals (Ni and Fan, 2017).

However, comprehensive meta-analyses have confirmed a nearly doubled risk of hip fracture in T2DM (Janghorbani et al., 2007; Wang et al., 2019). An association between T2DM and risk for upper arm and ankle fractures has also been reported (Wang et al., 2019), whereas the risk of spine fractures appears to be similar to that in nondiabetic subjects (Napoli et al., 2018b; Wang et al., 2019). Several mechanisms contribute to bone loss and increased fracture risk in T2DM (Fig. 40.1), as will be detailed in the following paragraphs.

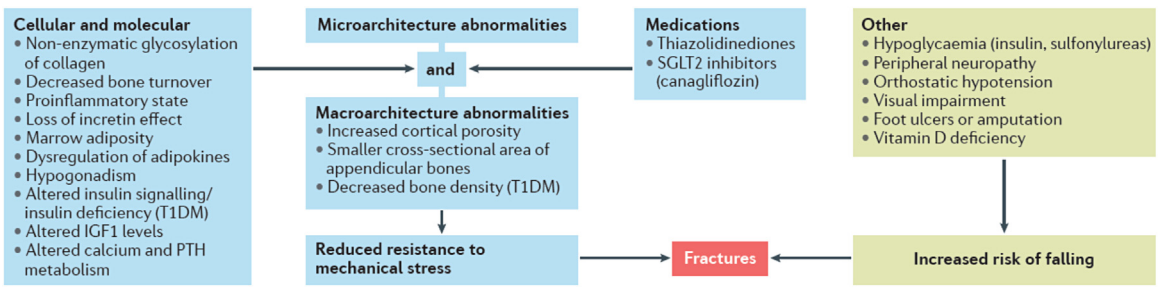

FIGURE 40.1 Mechanisms underlying bone loss and fractures in type 2 diabetes mellitus. Multiple mechanisms can contribute to the increased fracture risk observed in diabetes mellitus. Nonenzymatic glycosylation of collagen, decreased bone turnover, a proinflammatory state, and microvascular disease determine both micro– and macro–bone architecture abnormalities that cause reduced resistance to mechanical stress. Several studies have shown a different trend in terms of bone mineral density, which is generally decreased in type 1 diabetes mellitus (*T1DM*) and normal or increased in type 2 diabetes mellitus (T2DM). Alterations in bone structure in T2DM include increased cortical porosity and reduced cortical density. Insulin treatment is an additional risk factor for falls and fractures, probably because of the increased rate of hypoglycemic episodes in patients treated with insulin. The negative effect of thiazolidinediones on bone health is well known. In patients with T2DM, evidence suggests a potential negative effect also for some sodium/glucose cotransporter-2 (*SGLT2*) inhibitors. In this clinical scenario characterized by increased bone fragility, typical diabetic complications such as poor balance, diabetic retinopathy, impaired renal function, and neuropathy have been associated with an increased risk of falls and fractures. All these complications have even a greater effect in patients with T1DM. *IGF1*, insulin-like growth factor 1; *PTH*, parathyroid hormone. *Source: Napoli N et al. 2017.* Nat Rev Endocrinol. *13, 208–219.*

Limited evidence indicates that diabetes (T1DM or T2DM) delays the healing of clinical fractures, taking about twice as long (Loder, 1988; Marin et al., 2018). Furthermore, T2DM patients have a 30% increased postfracture mortality compared with nondiabetics, and a significant excess in absolute mortality risk (Martinez-Laguna et al., 2017).

T2DM and bone turnover

Animal models of T2DM

Several rodent models have been used for the study of skeletal fragility in T2DM. These models encompass various T2DM etiologies (spontaneous or diet-induced, single gene or polygenic), body types (obese or lean), and timings of T2DM onset (before or after skeletal maturity). However, current animal models are limited in their ability to mirror key metabolic features of adult-onset, obesity-related T2DM and their impact on bone metabolism, bone mass, and strength (Fajardo et al., 2014). In contrast to observations in humans, in which decreased bone formation and normal or reduced bone resorption are reported, rodent models of T2DM exhibit decreased or normal bone formation and high bone resorption, often resulting in low BMD (Devlin et al., 2014; Ducy et al., 2000; Reinwald et al., 2009; Tanaka et al., 2018; Turner et al., 2013; Zhang et al., 2009). Furthermore, the onset of diabetes is often before skeletal maturation, and inconsistent findings have been reported in some models of T2DM with respect to bone turnover. As an example, both reduced and normal levels of bone formation markers were reported for ZDF rats (Hamann et al., 2011; Liu et al., 2007; Mathey et al., 2002). Similarly, contrasting findings have been reported for bone resorption markers in this model (Hamann et al., 2011, 2013; Mathey et al., 2002).

Clinical data

Like T1DM, T2DM is accompanied by low bone formation and remodeling. In a small but interesting series of eight diabetic subjects (ages 37−67, diabetic for 2−36 years, six with T2DM), a transiliac bone biopsy was performed because of a low BMD; histomorphometry showed a significant decrease in osteoid thickness, mineralizing surface, and mineral apposition rate (Krakauer et al., 1995). Data from Dr. Rubin's group at Columbia University have proved that T2DM patients present significant reductions in mineralizing surface, bone formation rate, and osteoblast surface ($n = 9$) (Manavalan et al., 2012). Moreover, lower RUNX2 expression and an inverse association between glucose levels and mineral apposition rate in T2DM versus nondiabetics was detected (Manavalan et al., 2012).

Biochemical bone remodeling markers are also lower than in nondiabetics.

Most studies showed that the bone formation markers P1NP and OC, as well as the bone resorption marker CTX, are decreased in patients with T2DM compared with nondiabetic controls (Starup-Linde, 2013; Starup-Linde and Vestergaard, 2016). The reduction in markers of bone formation appears to be greater in T2DM than in T1DM (Starup-Linde et al., 2016b). Moreover, Starup-Linde and colleagues demonstrated an inverse relationship between glycemic control (HbA1c) and OC levels, and a similar trend for CTX and P1NP (Starup-Linde et al., 2016b). Interestingly, there appears to be a J- or U-shaped relationship between bone remodeling and fracture risk (Heaney, 2003). It has been postulated that diabetes impairs the healing of microdamage in load-bearing bones because of suppressed bone formation and that accumulated microdamage may predispose diabetic individuals to overt fractures (Krakauer et al., 1995).

Circulating levels of sclerostin are increased in T2DM, possibly accounting for the reduced bone turnover in patients with diabetes (Gaudio et al., 2012; van Lierop et al., 2012). Furthermore, sclerostin levels have been associated with fracture risk in some reports (Heilmeier et al., 2015; Yamamoto et al., 2013). Osteoprotegerin, NTX, and bone-specific alkaline phosphatase are not significantly different between T2DM patients and controls (Hygum et al., 2017).

Impaired fasting glucose was associated with lower OC (Mitchell et al., 2018), CTX, and P1NP (Holloway-Kew et al., 2019; Jiajue et al., 2014) in women, and lower β-CTX and P1NP in men (Holloway-Kew et al., 2019), suggesting that prediabetes is also associated with reduced bone turnover (Starup-Linde et al., 2016b).

T2DM, bone density, and bone structure

Hyperinsulinemia, insulin resistance, and bone density

Hyperinsulinemia is the compensatory answer to peripheral insulin resistance; when inadequate, impaired fasting glucose and/or postload hyperglycemia (impaired glucose tolerance) ensues. Several population studies have demonstrated a correlation between, on one hand, fasting insulin, the homeostatic model of insulin resistance (HOMA-IR), and/or postchallenge glucose and insulin concentrations and, on the other hand, the aBMD at the hip and/or the spine (Conte et al., 2018). The data suggest that aBMD progressively increases with worsening glucose metabolism, i.e., from normal fasting glucose to overt T2DM (Mitchell et al., 2018). Yet adjusting for BMI or fat mass often attenuates or abolishes the

correlation between aBMD and glucose metabolism parameters. Higher insulin resistance, as estimated with HOMA-IR, was associated with greater vBMD and generally favorable bone microarchitecture at both non-weight-bearing and weight-bearing skeletal sites, independent of body weight, in postmenopausal nondiabetic women (Shanbhogue et al., 2016). On the other hand, an inverse association between insulin resistance and indices of bone strength has been reported (Ahn et al., 2016; Srikanthan et al., 2014). In older nondiabetic adults participating in the Health ABC Study ($n = 2398$), increasing insulin resistance was associated with lower risk of fracture in unadjusted models (Napoli et al., 2019). However, after adjusting for BMI and BMD this relationship was lost, suggesting that higher BMD and BMI associated with insulin resistance accounted for the inverse association.

Animal models of T2DM

In contrast to T1DM, bone size was increased in T2DM models such as the Goto-Kakizaki rat, particularly at the diaphysis. Whereas cortical BMD, measured by QCT, was only mildly affected, trabecular BMD was markedly (33%−53%) decreased in these rats (Ahmad et al., 2003). T2DM may well have complex effects on bone with divergent responses generated by obesity and hyperglycemia. Disruption of leptin or leptin signaling in mice creates massive obesity with T2DM and increases bone mass via central nervous system pathways, some of which still need to be uncovered (Idelevich and Baron, 2018). As mentioned, however, concerns exist regarding the correlation between human obesity/T2DM and rodent models to study skeletal changes in obesity/T2DM (Lai et al., 2014; Rendina-Ruedy and Smith, 2016), particularly with regard to BMD, which is generally low in rodent models (Devlin et al., 2014; Ducy et al., 2000; Reinwald et al., 2009; Tanaka et al., 2018; Turner et al., 2013; Zhang et al., 2009).

Clinical data

The seminal report by Meema and Meema (Meema and Meema, 1967) that the cortical thickness at the radius was higher in aged (65−101 years) white women with T2DM than in nondiabetics was followed by numerous studies using dual-energy X-ray absorptiometry. The majority of these studies showed that aBMD is significantly increased in T2DM subjects and correlates positively with BMI and insulin levels (Ma et al., 2012). For example, in the Study of Osteoporotic Fractures, T2DM ($n < 500$) was associated with a 4.8% increase in aBMD at the radius and a 3.4% increase in aBMD at the femoral neck in multivariate analyses (Bauer et al., 1993; Orwoll et al., 1996). In the Rotterdam Study, lumbar spine and the femoral neck aBMD were also 3%−4% higher in T2DM individuals ($n = 578$) (van Daele et al., 1995). Similarly, in the Health ABC Study, total hip aBMD was 4%−5% higher in black and white men and women with T2DM ($n = 566$) after adjusting for their altered body composition (i.e., higher fat and lean mass) (Strotmeyer et al., 2004). However, total hip aBMD was inversely related to T2DM duration (Strotmeyer et al., 2004), and white women with T2DM showed increased aBMD loss compared with their nondiabetic counterparts (Schwartz et al., 2005).

Data from diabetic men enrolled in the Osteoporotic Fractures in Men (MrOS) Study have shown significantly higher aBMD (Napoli et al., 2014) and spine vBMD in T2DM subjects compared with nondiabetic ones (Napoli et al., 2018b). Importantly, higher trabecular vBMD was more strongly associated with incident vertebral fractures in nondiabetic men (odds ratio [OR] 0.33; 95% CI 0.24 to 0.45), compared with men with diabetes (OR 0.64; 95% CI 0.36 to 1.13).

Samelson and colleagues investigated the association between T2DM and cortical and trabecular bone microarchitecture and density (HR-pQCT), as well as total bone density and bone area in 1069 male and female members of the Framingham Offspring Cohort (Samelson et al., 2018). After adjustment for age, sex, weight, and height, T2DM subjects had significantly lower cortical vBMD, higher cortical porosity, and smaller cross-sectional area at the tibia, but not the radius. Furthermore, decreased cortical density and increased cortical porosity at the tibia differentiated between T2DM with prior fracture and non-T2DM with prior fracture. Trabecular indices did not differ or were more favorable in patients with T2DM than in nondiabetic subjects.

T2DM and bone strength

Animal models

In general, bone mechanical properties are reduced in murine models of T2DM. In young and adult C57BL/6 mice with high-fat diet (HFD)-induced obesity and hyperglycemia, femoral strength, stiffness, and toughness were dramatically lower than in control mice, possibly due to reduced structural quality (inferior lamellar and osteocyte alignment) (Ionova-Martin et al., 2011). HFD-fed mice demonstrated normal whole-body aBMD and femoral aBMD, but reduced spine aBMD. In Zucker diabetic fatty (ZDF) rats, shear stress testing of the femoral neck demonstrated significantly decreased maximum load and stiffness compared with nondiabetic rats, probably due to lower bone volume (Hamann et al., 2013).

An impairment in bone biomechanical properties is supported by the finding of larger indentation distances in cortical bone of murine models of T2DM (Acevedo et al., 2018; Gallant et al., 2013), possibly due to an increase in AGE content (Acevedo et al., 2018; Devlin et al., 2014).

Humans

Most studies have used HR-pQCT to assess bone microarchitecture and strength indices in humans. In a cross-sectional study of 19 elderly women with T2DM, trabecular microarchitecture was preserved but cortical porosity was higher in the radius and tibia compared with nondiabetic controls (Burghardt et al., 2010). In the radius, compressive bone strength, estimated using finite element analysis (FEA), was significantly lower. In older men with T2DM participating in the MrOS study, total bone cross-sectional area in the radius and tibia was lower in those with diabetes compared with nondiabetics, and bending strength relative to body weight was decreased in cortical regions (Petit et al., 2010). In trabecular regions, bone strength was similar between T2DM and non-T2DM older men. Fractured postmenopausal women with T2DM had significantly greater cortical porosity and lower bone strength parameters (stiffness, failure load, and cortical load fraction) compared with those without fracture (Heilmeier et al., 2016). These indices did not differ between nondiabetic women with or without fracture.

Bone microindentation allows direct assessment of the mechanical characteristics of cortical bone in humans by measuring the distance that a metal probe can enter the tibia for a given applied force (Diez-Perez et al., 2010, 2016; Nilsson et al., 2017). The bone material strength index (BMSi), assessed by bone microindentation, reflects the ability of bone to resist microcrack generation and propagation. Postmenopausal women with T2DM had lower BMSi compared with nondiabetic controls despite similar BMD (Farr et al., 2014; Furst et al., 2016; Nilsson et al., 2017), suggesting a deficit in diabetic bone material properties. In older women (75−80 years) with T2DM, BMSi by reference point indentation was lower than in nondiabetic controls despite generally better measures of trabecular and cortical bone microarchitecture and bone strength estimated by FEA (Nilsson et al., 2017). Furthermore, BMSi was inversely correlated with HbA1c levels over the prior 10 years (Farr et al., 2014) and with duration of diabetes (Furst et al., 2016).

Clinical risk factors for fractures in T1DM and T2DM

Regarding T1DM, a Swedish study (Miao et al., 2005) reported that the age-adjusted risk of hip fracture increased with longer diabetes duration. Poor glycemic control has also been associated with increased fracture risk in T1DM (Vavanikunnel et al., 2019). Longer diabetes duration and poorer glycemic control mean a greater likelihood of micro- and macrovascular complications; indeed, the risk of fracture was particularly high among T1DM patients with eye, nephropathic, neurologic, or cardiovascular complications (Miao et al., 2005; Vavanikunnel et al., 2019).

For T2DM, the elevated risk of fractures was observed in both white and black US women (Bonds et al., 2006). BMI is not a critical factor, because the risk was comparably elevated in nonobese and obese T2DM women, and controlling for BMI did not meaningfully alter the risk ratio (Janghorbani et al., 2006; Nicodemus et al., 2001; Schwartz et al., 2001). In some studies, the risk appeared to be higher among insulin-treated versus non-insulin-treated T2DM individuals (Janghorbani et al., 2006; Napoli et al., 2014; Ottenbacher et al., 2002). This may reflect the association between longer duration of T2DM and fracture: in individuals with >12 years of T2DM, the risk was increased more than twofold (Janghorbani et al., 2006; Nicodemus et al., 2001; Schwartz et al., 2001). Indeed, insulin-treated T2DM individuals showed a fourfold increased risk of falls (Schwartz et al., 2002), and repeated falls in diabetic individuals with a foot ulcer predisposed to fractures (Wallace et al., 2002). Moreover, these patients also have a longer clinical history of other complications like retinopathy or neuropathy. In the Australian Blue Mountains Eye Study, which examined 216 subjects (ages 49−97) with T1DM or T2DM, cortical cataract and especially retinopathy increased the risk of fractures (Ivers et al., 2001). Neuropathy with or without foot ulcers was another important predisposing factor for fractures in general (Strotmeyer et al., 2005), and foot fractures in particular (Cavanagh et al., 1994).

In contrast, studies performed in the Joslin "medalists," long-standing T1DM survivors (at least 50 years) with low cardiovascular risk, showed a very low prevalence of osteoporosis and fractures (Maddaloni et al., 2017). Another possible risk factor is glycemic control, tested in different studies with single measurements of HBA1c. Although limited by the short exposure (3 months), in general there is a progressive increase in risk of fractures in patients with higher HBA1c, mostly in those with levels >9% (Li et al., 2015). However, in a 2019 nested case−control analysis that used the mean of HbA1c values over 3 years to estimate glycemic control, there was no association between poor glycemic control (HbA1c >8%) and risk of nonvertebral low trauma fractures in patients with T2DM (Vavanikunnel et al., 2019). Diabetic individuals with eye, neuropathic, and vascular complications—and poor physical health in general—are more likely to fall.

It is likely, therefore, that falls mediate a significant part of the diabetes-associated risk of fractures. As a corollary, effective fall prevention strategies should be developed to prevent fractures in individuals with long-standing diabetes or diabetes complications. According to guidelines released by the American Diabetes Association/European Association for the Study of Diabetes and by the American College of Physicians (American Diabetes Association, 2019; Qaseem et al., 2018), a less stringent target in glucose control should be achieved in diabetic patients, mostly if affected by diabetes-related complications. This approach will limit the risk of hypoglycemic events, which are a main risk factor for cardiovascular mortality but also for fractures.

Effect of diabetes treatments on bone

Weight loss is recommended for overweight/obese patients with diabetes (American Diabetes Association, 2019). Due to mechanical unloading of the skeleton, weight loss might have a negative impact on bone health. An intensive lifestyle intervention resulting in long-term weight loss was not associated with an increased risk of incident total or hip fracture in overweight/obese adults with T2DM, but the risk of frailty fracture increased following weight loss (Johnson et al., 2017). Body weight loss of $\geq$ 20% from maximum weight is a significant risk factor for fragility fractures in patients with T2DM (Komorita et al., 2018). Bariatric–metabolic surgery has been recognized as an effective approach for the treatment of T2DM in obese patients (Rubino et al., 2016). Patients with T2DM undergoing bariatric surgery (roux-en-Y gastric bypass) exhibit higher bone turnover, lower aBMD, and impaired HR-pQCT-derived measurements of bone mass, structure, and strength, and more than double the likelihood of having osteopenia or osteoporosis despite adequate calcium and vitamin D supplementation compared with nonoperated patients (Madsen et al., 2019). These observations suggest that strict monitoring of bone health should be implemented for patients expected to lose large amounts of weight.

Metformin, unless contraindicated, is recommended as the first-line treatment for patients with T2DM. Most studies reported that metformin has a neutral or even favorable effect of fracture risk. In preclinical studies, metformin was shown to enhance bone-anabolic pathways, stimulating osteoblast differentiation and bone formation (Palermo et al., 2015). Treatment with metformin was associated with a 19% reduction in the risk of any fracture, although no effect on the risk of forearm, spine, or hip fracture was observed in patients with T2DM (Vestergaard et al., 2005). In the same case–control study, diabetic individuals who used sulfonylureas had a lower risk of hip fracture than diabetic individuals in general (Vestergaard et al., 2005). Another study found that treatment with a sulfonylurea was associated with reduced risk of vertebral fracture (Kanazawa et al., 2010). Data from the MrOS cohort indicate that metformin has a neutral effect on fracture risk, whereas there was an increased risk of hip fractures in patients treated with sulfonylureas (Napoli et al., 2014). However, it is likely that sulfonylureas do not exert a direct negative effect on bone but rather are associated with increased risk of hypoglycemia (Monami et al., 2014), which in turn is associated with increased fracture risk (Johnston et al., 2012). Thiazolidinediones (TZDs) or PPARγ agonists (e.g., pioglitazone, rosiglitazone) worsen diabetic bone disease. Indeed, aBMD loss at the spine and the whole body was higher among women—but not men—with T2DM who used a TZD (Schwartz et al., 2006). In line with these data, in the ADOPT trial, which compared metformin, glyburide, and rosiglitazone for 4 years in 4360 T2DM patients, the number of fractures (any site) was higher among women—but not men—treated with the TZD compared with the other two drugs (Kahn et al., 2006). Finally, a meta-analysis of randomized controlled trials of at least 12 months' duration found that TZDs were associated with a 45% increase in fracture, although the increase was significant only in women (Loke et al., 2009). In mice, TZD treatment enhanced bone marrow adiposity and caused trabecular bone loss by uncoupling resorption (activated) and formation (suppressed) (Li et al., 2006), the latter perhaps as a result of osteoblast/osteocyte apoptosis (Sorocéanu et al., 2004). Incretin-based treatments, namely, inhibitors of dipeptidyl peptidase-4 (DPP-4), an enzyme that rapidly inactivates gastric inhibitory polypeptide (GIP) and glucagon-like peptide 1 (GLP1), and GLP1 receptor agonists (GLP1RA), appear to have a neutral effect on bone, although limited data are available. Data on animals indicate that GLP1RAs may improve bone mass and architecture (Lu et al., 2015; Pereira et al., 2015). However, meta-analyses of both randomized clinical trials and population-based real-world data showed no effect of GLP1RAs on fracture risk (Driessen et al., 2017; Mabilleau et al., 2014). Conflicting data exist on DPP-4 inhibitors, which were reported to either reduce (Monami et al., 2011) or have no effect on (Driessen et al., 2017) fracture risk. Sodium/glucose cotransporter-2 (SGLT-2) inhibitors decrease plasma glucose levels by inhibiting glucose reuptake by SGLT-2 in the proximal tubule of the kidney. These drugs may affect calcium and phosphate homeostasis and potentially increase fracture risk (Meier et al., 2016). The SGLT-2 inhibitor canagliflozin was associated with a significant increase in both all fractures and low-trauma fractures in patients with T2DM (Watts et al., 2016). However, no increased risk of fracture was evident in four meta-analyses of placebo-controlled randomized controlled trials of dapagliflozin, canagliflozin, and empagliflozin (Kohler et al., 2018; Ruanpeng et al., 2017; Tang et al., 2016; Wu et al., 2016). In a nested case–control study, the use of SGLT-2 inhibitors was not associated with an increased risk of fractures of the upper or

lower limbs compared with use of DPP-4 inhibitors in patients with T2DM (Schmedt et al., 2019). Although these data are reassuring, further evidence is needed to confirm the bone safety of SGLT-2 inhibitors.

Insulin has anabolic effects of bone. Intensive insulin treatment in patients with T1DM was associated with stabilization of BMD over 7 years and a marked decrease in bone resorption, as assessed by circulating bone turnover markers (Campos Pastor et al., 2000). In contrast, a large body of evidence indicates that insulin treatment is associated with increased fracture risk in T2DM (Gilbert and Pratley, 2015). A 2018 population-based study including more than 12,000 patients with T2DM found that insulin monotherapy was associated with a 63% increase in fracture risk compared with metformin monotherapy (Losada et al., 2018). The increased fracture risk associated with insulin treatment in T2DM might be due to more advanced disease, with increased vascular complications, in insulin-treated T2DM patients.

Statins are another frequently used class of drugs in diabetic patients. In the general population, statin use was associated with reduced risk of osteoporosis (Lin et al., 2018), although the effect on fracture risk is uncertain (Toh and Hernandez-Diaz, 2007). A small study suggested that statins increase bone density at the hip in T2DM patients (Chung et al., 2000), and an inverse association of fracture risk with statin use has been reported (Martinez-Laguna et al., 2018).

Bone repair in T1DM and T2DM

Fracture healing in patients with diabetes is delayed by nearly 90%, and the risk of complications such as delayed union, nonunion, re-dislocation, or pseudoarthrosis is more than threefold compared with nondiabetic individuals (Jiao et al., 2015). Several experimental models have demonstrated an impaired bone repair in T1DM with less new bone formed, as assessed by radiographic, micro-computed tomographic, and histomorphometric analyses (Follak et al., 2004; Funk et al., 2000; Gandhi et al., 2006; Kawaguchi et al., 1994; Kayal et al., 2007; Santana et al., 2003; Thrailkill et al., 2005a). Overall, bone formation was approximately 7% lower ($P < .001$) in T1DM models compared with controls (Camargo et al., 2017). Both endochondral and periosteal postfracture repair mechanisms were defective. Both increased cartilage resorption, due to greater osteoclast number (Kayal et al., 2007), and impaired cartilage resorption, due to decreased osteoclast function (Kasahara et al., 2010), have been reported in STZ-diabetic rats. However, some local treatments also (partially) reversed the defective fracture repair, e.g., local administration of insulin (Gandhi et al., 2005; Paglia et al., 2013).

In models of T2DM, bone regeneration was significantly decreased due to impairments in angiogenesis and osteogenesis that could be reversed by local application of fibroblast growth factor 9 and, to a lesser degree, vascular endothelial growth factor (VEGF) A (Wallner et al., 2015). Increased callus adiposity due to the shift of mesenchymal stem cells toward the adipogenic lineage (Brown et al., 2014), delayed periosteal mesenchymal osteogenesis, premature apoptosis of cartilage callus, impaired microvascularization (Roszer et al., 2014), and impairment in osteoblast differentiation (Hamann et al., 2011) may also be responsible for delayed fracture healing in T2DM. Animal studies suggest that DPP-4 inhibitors may enhance fracture healing by altering stem cell lineage allocation (Ambrosi et al., 2017).

Bone and systemic metabolism: a two-way interaction?

Metabolic control of glucose and insulin in bone

Both osteoblasts (Ferron et al., 2010) and osteoclasts (Thomas et al., 1998) express the IR on their surface, insulin signaling through the IR being essential for normal bone acquisition (Fulzele et al., 2010; Thrailkill et al., 2014). In fact, insulin increases osteoblast proliferation and enhances osteoblast differentiation, collagen synthesis, alkaline phosphatase production, and glucose uptake, and inhibits osteoclast activity, leading to increased bone formation (Cornish et al., 1996; Pramojanee et al., 2013; Pun et al., 1989; Thomas et al., 1998; Thrailkill et al., 2005b; Yang et al., 2010). Osteoblasts also express the IGF-1 receptor on their surface (Fulzele et al., 2007). IGF-1 binds both the IGF-1 receptor and, with lower binding affinity, the IR, thus triggering the insulin signaling pathway. Studies investigating the effects of insulin on osteocytes are lacking, as expression of the IR on the osteocyte surface is minimal or absent.

Supraphysiological glucose concentrations and/or AGEs were shown to reduce the expression of proosteogenic markers in human osteoblasts (Ehnert et al., 2015; Miranda et al., 2016), suppress mineralization (Ogawa et al., 2007), and inhibit the Wnt signaling pathway, which is critical for osteogenic differentiation (Lopez-Herradon et al., 2013; Picke et al., 2016). Furthermore, exposure to AGEs induced osteoblast and mesenchymal stem cell apoptosis (Alikhani et al., 2007; Kume et al., 2005). Hyperglycemia inhibits osteoclastogenesis (Wittrant et al., 2008) and impairs osteoclast differentiation and activity, as measured by TRAP in embryonic stem cells (Dienelt and zur Nieden, 2011). Osteocytes exposed to high glucose concentrations increase expression of sclerostin, which inhibits bone formation by antagonizing the Wnt/β-catenin

canonical signaling pathway (Tanaka et al., 2015). Osteocyte exposure to AGEs increases sclerostin and decreases expression of receptor activator of nuclear factor κB ligand (RANKL), a member of the tumor necrosis factor (TNF) superfamily that is necessary for osteoclast formation, differentiation, activation, and survival (Tanaka et al., 2015). In addition, hyperglycemia impairs osteocyte response to mechanical stimulation, a mechanism essential for their function (Seref-Ferlengez et al., 2016; Villasenor et al., 2019).

Bone hormones control systemic metabolism

Evidence indicates a reciprocal regulation of glucose and bone metabolism (Conte et al., 2018). The osteoblast-derived bone matrix protein OC acts as a hormone, stimulating β-cell proliferation and insulin secretion. Consistently, OC-knockout mice displayed decreased β-cell proliferation, glucose intolerance, and insulin resistance (Wei et al., 2014a). In vitro, insulin secretion increased when pancreatic β cells were cocultured with osteoblasts or in the presence of supernatants from cultured osteoblasts, suggesting that an osteoblast-derived factor stimulates insulin secretion by β cells (Ferron et al., 2008; Lee et al., 2007) acting upon GPRC6A receptors (Ferron et al., 2008; Wei et al., 2014b). Administration of OC significantly decreased plasma glucose and increased insulin secretion in C57BL/6J wild-type mice (Ferron et al., 2008). In addition to stimulating insulin secretion, OC indirectly improved insulin sensitivity by stimulating the secretion of adiponectin, a white adipocyte-derived insulin-sensitizing adipokine.

Evidence from preclinical studies indicates that only undercarboxylated OC (ucOC) exerts endocrine actions (Lee et al., 2007). OC decarboxylation is a pH-dependent mechanism that occurs during bone resorption, when bone matrix is acidified by osteoclasts. However, treatment with bisphosphonates, which inhibit bone resorption and therefore pH-dependent decarboxylation of OC, is not associated with worsening glucose metabolism (Schwartz et al., 2013a). Treatment with denosumab, a fully human monoclonal antibody that inhibits bone resorption by binding to RANKL, has been associated with reductions in fasting plasma glucose in diabetic subjects (Napoli et al., 2018a). Blockade of nuclear factor κB, a proinflammatory master switch that controls the production of inflammatory markers and mediators, has been postulated as the mechanism responsible for this observation. A number of human studies have explored the relationship between OC and glucose homeostasis. OC levels have been reported to be lower in T2DM compared with healthy subjects (Oz et al., 2006), inversely related to BMI, fat mass, and plasma glucose (Kanazawa et al., 2009, 2011b; Kindblom et al., 2009; Zhou et al., 2009), but also to atherosclerosis and inflammatory parameters such as high sensitive C-reactive protein and interleukin-6 (IL-6) (Pittas et al., 2009). However, OC-stimulated IL-6 release has been postulated as a mechanism to support muscle function during exercise, through enhanced glucose and fatty acid uptake into myofibers (Mera et al., 2016a, 2016b; Tsuka et al., 2015).

Studies investigating the effects of medications or conditions that may affect OC levels yielded conflicting results, questioning the OC−glucose relationship in humans. For example, alendronate therapy, which decreases OC levels, was associated with reduced diabetes risk (Vestergaard, 2011); treatment with vitamin K, which reduces the ucOC/OC ratio, improved insulin resistance (Beulens et al., 2010; Choi et al., 2011; Yoshida et al., 2008); chronic hyperparathyroidism, which is characterized by increased OC release, was associated with increased insulin resistance and impaired glucose regulation (Taylor and Khaleeli, 2001). Less evidence is available for T1DM. No association between OC and β-cell function was found in subjects with new-onset T1DM (Napoli et al., 2013). However, in T1DM, total OC was inversely correlated with BMI and HbA1c, and ucOC was inversely correlated with HbA1c in T1DM patients with mean disease duration of 21 years (Neumann et al., 2016). Despite relevant clinical and preclinical data supporting a positive feedback between osteoblasts and β cells, it is possible that, in a condition of continuous autoimmune damage against β cells such as in T1DM, the ability of OC to modulate β-cell function is lost. On the other hand, Thrailkill et al. reported a positive effect of OC on endogenous insulin production (assessed as C-peptide/glucose ratio) (Thrailkill et al., 2012) in subjects with long-standing disease. The relationship between OC and glucose metabolism requires further investigation.

What causes diabetic bone disease?

The diabetic hormonal milieu

Lower circulating insulin-like growth factor 1

Lower circulating IGF-1 is probably a crucial factor. Downregulation of hepatic IGF-1 release resulted in a 73% drop in serum IGF-1 levels in children with new-onset T1DM (Bereket et al., 1995); circulating IGF-1 remained below control levels in T1DM adolescents and adults receiving insulin treatment (Bouillon et al., 1995; Leger et al., 2006). IGF-1 had

powerful effects on osteoblast proliferation and bone matrix formation in vitro (Hock et al., 1988). Also, disruption of the IGF-1 gene resulted in 25%−40% smaller bones in prepubertal mice and prevented periosteal expansion and BMD gain during puberty; serum OC levels in IGF-1-knockout mice were reduced by 24%−54% (Mohan et al., 2003). Depletion of circulating IGF-1 (while skeletal expression of IGF-1 remained normal) equally resulted in decreased growth and periosteal expansion, which was restored by exogenous IGF-1 (Yakar et al., 2002). Insulin and IGF-1 initiate cellular responses by binding to and activating the insulin and IGF-1 (tyrosine kinase) receptors, and phosphorylation of IR substrate (IRS)-1. As would be predicted, IRS-1-knockout mice showed smaller bones with thinner growth plates, lower trabecular and cortical bone volume, thin trabeculae, and low bone formation and resorption (Ogata et al., 2000). These mice also were hyperinsulinemic. Studies in T1DM animals showed a strong correlation between plasma IGF-1 and OC levels (Verhaeghe et al., 1997). Similarly, IGF-1 concentrations were correlated with biochemical bone formation markers in T1DM individuals (Bouillon et al., 1995). In addition, serum IGF-1 was an independent predictor of total body bone mineral content in children and adolescents with T1DM (Leger et al., 2006). Upregulation of the hepatic expression of IGF-binding protein-1 (IGFBP1) by insulin deficiency caused a sevenfold increment in circulating IGFBP1 in children with new-onset T1DM (Bereket et al., 1995). Through the accrued formation of binary IGF-1:IGFBP1 complexes (Frystyk et al., 2002), the decrement in circulating free (bioavailable) IGF-1 in T1DM is more pronounced than that of total IGF-1. It is not surprising, therefore, that IGFBP1 inhibited the osteoblastic effects of IGF-1 (Campbell and Novak, 1991). Elevated IGFBP1 levels might also explain, in part, why bone growth and remodeling in T1DM rats were resistant to the anabolic effects of exogenous IGF-1 (Verhaeghe et al., 1992).

Using the Cre-loxP technique to disrupt IGF-1R in osteoblasts in vitro, Fulzele and colleagues were able to examine insulin signaling in primary osteoblasts exclusively through its cognate receptor (Fulzele et al., 2007). In osteoblasts engineered for conditional disruption of the IGF-1R, insulin signaling was markedly increased and insulin treatment rescued the defective differentiation and mineralization, suggesting that IR signaling can compensate, at least in part, for loss of IGF-1R signaling.

Several in vivo studies have shown that the stimulatory actions of IGF-1 on osteoblasts are blunted by high concentrations of AGEs and that high glucose concentrations or AGEs might induce osteoblast resistance to the actions of IGF-1 (McCarthy et al., 2001; Terada et al., 1998). Serum levels of IGF-1 were found to be inversely associated with the presence of vertebral fractures in postmenopausal women with T2DM independent of age, glycemic control, renal function, insulin secretion, or lumbar spine BMD, and with the number of prevalent vertebral fractures in these women independent of lumbar spine BMD (Kanazawa et al., 2011a).

In 2018, a Japanese group studying a cohort of about 1000 T2DM subjects found that an IGF-1 cutoff value of 127 ng/mL was associated with higher risk of vertebral fracture (Kanazawa et al., 2018). In particular, lower IGF-1 and lower T scores were associated with significantly increased risk of vertebral fractures compared with higher IGF-1 and higher T scores, both in postmenopausal women and in men. Further evidence is needed to validate the predictive value of IGF-1 on fracture risk in individuals with diabetes.

Hypercortisolism

Several studies suggest that T2DM patients with chronic complications have an increased cortisol secretion even though within the normal range (Chiodini et al., 2006, 2007). In a case−control study on 99 T2DM postmenopausal women with good glycemic control without hypercortisolism and 107 matched nondiabetic controls, vertebral fractures were associated with cortisol secretion and sensitivity, as mirrored by the sensitizing polymorphism glucocorticoid receptor gene (Zhukouskaya et al., 2015). Thus, it is possible to hypothesize that in the presence of T2DM complications a slightly enhanced cortisol secretion may contribute to bone damage (Eller-Vainicher et al., 2017). The same authors found that trabecular bone score (TBS) was not different between T2DM postmenopausal women with good glycemic control and matched nondiabetic controls. However, TBS was reduced in T2DM patients with vertebral fractures compared with nonfractured T2DM patients. Interestingly, the presence of a TBS $\leq$ 1.130 or BMD Z score at the femoral neck below −1.0 had the best diagnostic accuracy for detecting T2DM fractured patients with a sensitivity and negative predictive value above 80% (Zhukouskaya et al., 2016).

Calciotropic hormones

There is a great deal of controversy regarding the effects of T1DM on circulating parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$). Intermittent administration of human PTH(1−34) to T1DM rats improved trabecular bone formation, volume, and strength (Suzuki et al., 2003); however, intermittent PTH is a powerful anabolic agent for

trabecular bone in various osteopenic conditions not necessarily associated with hypoparathyroidism (e.g., postmenopausal or glucocorticoid-induced osteopenia). Although T1DM rats displayed a higher metabolic clearance rate of $1,25(OH)_2D_3$ and lower (i.e., total but not free) circulating $1,25(OH)_2D_3$, $1,25(OH)_2D_3$ infusion did not affect the osteoblast and osteoid surface on histomorphometry and barely raised serum OC (Verhaeghe et al., 1993).

Clinical data have shown that high blood glucose may increase urinary calcium excretion and PTH levels (Hofbauer et al., 2007; McNair et al., 1979; Raskin et al., 1978). Conversely, improvement of blood glucose control may reduce calcium and phosphate urinary excretion and $1,25(OH)_2D_3$ levels (Okazaki et al., 1997). Numerous studies have shown that both patients with T1DM and those with T2DM have low vitamin D levels (Scragg et al., 1995). Obesity itself is also associated with low vitamin D levels, although the pathophysiology of this is unclear. One mechanism may be related to the deposition of vitamin D in adipocytes (Wortsman et al., 2000), although altered 25-hydroxylation in the liver of obese individuals is another possibility. It is a matter of debate if vitamin D levels may predict risk of diabetes (Ebeling et al., 2018). Indeed, although higher levels of 25(OH)D have been associated with reduced risk of diabetes, other studies have not found an association between baseline vitamin D and incident diabetes (Napoli et al., 2016; Schafer et al., 2014). Vitamin D supplementation aimed at raising 25(OH)D levels above 30 ng/mL had no effect on insulin secretion, insulin sensitivity, or the development of diabetes compared with placebo (Davidson et al., 2013). Importantly, patients with new-onset T1DM have reduced levels of $1,25(OH)_2D$ and 25(OH)D compared with healthy controls (Pozzilli et al., 2005). A causative role of vitamin D deficiency in diabetes has been suggested although vitamin D supplementation in early diagnosed patients with T1DM has not improved measures of glucose control nor insulin need nor bone turnover markers (Bizzarri et al., 2010; Maddaloni et al., 2018; Napoli et al., 2013).

Low amylin

Amylin is a peptide cosecreted with insulin by pancreatic β cells in response to nutrient stimuli. Amylin treatment of STZ-diabetic rats resulted in some improvement of the diabetic syndrome, and prevented the low-formation osteopenia observed in untreated rats (Horcajada-Molteni et al., 2001). The role of amylin must be clarified in future research.

Impaired vascularization of diabetic bones

It has been postulated by some that diabetic bone disease is another manifestation of microangiopathy, but evidence supporting this hypothesis is lacking. More research on the vascularization of diabetic bones (including the growth plate), and the factors that regulate vascularization (e.g., VEGFs), is sorely needed.

Altered collagenous bone matrix

Increased collagen glycosylation

Nonenzymatic protein glycosylation and oxidation results in the gradual accumulation of AGEs in serum and various tissues. Proteins with a long half-life such as collagen are particularly susceptible to glycosylation. AGE accumulation in bone occurs with normal aging but is much accelerated in diabetes (Katayama et al., 1996). Accumulation of AGEs in aging bone was associated with increased brittleness (Wang et al., 2002), and may also be a determinant of diabetic bone brittleness. Moreover, AGE accumulation in diabetic bones affected bone cell function through inhibition of osteoblastic cell differentiation and function (Katayama et al., 1996) and stimulation of osteoblast apoptosis (Alikhani et al., 2007). RAGE, one of the receptors for AGEs, was overexpressed in healing bone tissue of STZ-diabetic mice, and local delivery of a RAGE ligand delayed bone healing in nondiabetic mice (Santana et al., 2003). These data would indicate that accumulation of AGEs explains in part the impaired fracture repair in diabetes. In a 2018 study, proximal femur specimens from T2DM ($n = 20$) and nondiabetic ($n = 33$) subjects undergoing total hip replacement surgery were imaged by micro-computed tomography, tested by cyclic reference point indentation, and quantified for AGE content (Karim et al., 2018). Bone specimens from patients with T2DM had similar cortical porosity but altered cortical bone biomechanical properties (greater creep indentation distance and indentation distance increase) and tended to have greater AGE content in cortices compared with nondiabetic bones. Conversely, biomechanical properties and AGE content of trabecular bone were similar between T2DM and nondiabetic subjects. The normal trabecular bone and modest cortical bone alterations suggest that other factors than altered bone microstructure could contribute to increased fracture risk in T2DM. A 2019 study by the Donnelly group investigated differences in material properties, microarchitecture, and mechanical performance of trabecular bone in men with and without T2DM undergoing total hip arthroplasty (Hunt et al., 2019).

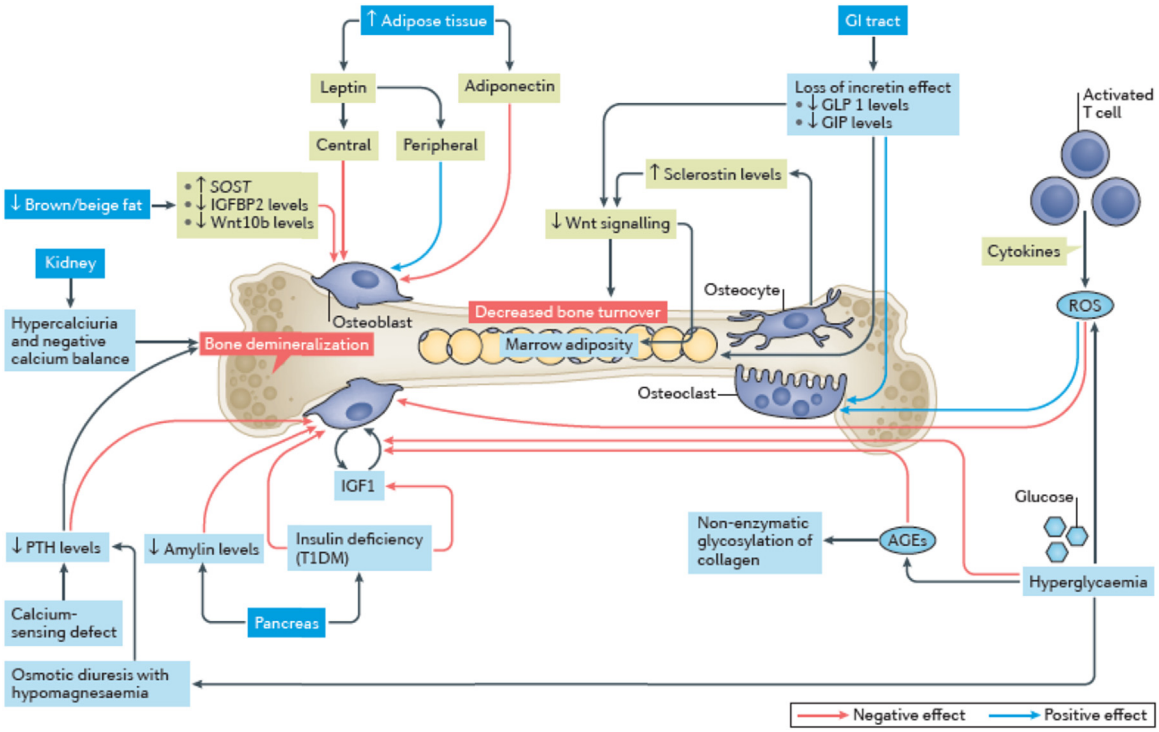

FIGURE 40.2 Cellular and molecular mechanisms of bone diseases in diabetes mellitus. Although several reports consistently indicate an increased risk of fractures in patients with diabetes mellitus, the underlying mechanisms are unclear and there is not enough evidence for a conclusive model of bone fragility in diabetes mellitus; however, some factors should be highly considered. With the decline of β-cell function, chronic hyperglycemia causes oxidative stress, inflammation, and the production of reactive oxygen species (*ROS*) and advanced glycation end products (*AGEs*), causing organ damage and reduced bone strength. In particular, accumulation of AGEs in diabetic bone collagen determines reduced material properties and increased susceptibility to fracture. AGEs and hyperglycemia also directly inhibit bone formation via suppression of osteoblast function. Low bone formation is also caused by disturbances to the Wnt signaling pathway, with increased sclerostin (*SOST*) expression, higher sclerostin levels, and decreased levels of insulin-like growth factor-binding protein 2 (*IGFBP2*) and protein *Wnt10b*. In type 1 diabetes mellitus (*T1DM*) and in the late stages of T2DM, bone formation is also decreased by insulin deficiency through an inhibitory effect on osteoblasts, either directly or through alterations in insulin-like growth factor 1 (*IGF1*) levels. Other factors typically linked to T2DM and obesity interfere with bone health. Dysregulation of adipokines like adiponectin and leptin has a negative effect through complex central and peripheral mechanisms. New evidence also indicates a negative effect on bone health by loss of the incretin effect, with reduced bone formation and increased osteoclastogenesis. Finally, alterations of the calcium−parathyroid hormone (*PTH*) axis result in a negative calcium balance, thereby contributing to bone demineralization in diabetes mellitus. *GI*, gastrointestinal; *GIP*, gastric inhibitory polypeptide; *GLP1*, glucagon-like peptide 1. *Source: Napoli N et al. 2017.* Nat Rev Endocrinol. *13, 208−219.*

Bone specimens from men with T2DM had significantly greater content of the AGE pentosidine (+36%) and sugars bound to the collagen matrix (+42%) compared with specimens from nondiabetic men. Mineral content was significantly higher (+7%) and, consistent with previous reports of increased BMD at the femoral neck and hip in T2DM, bone volume fraction (BV/TV) tended to be greater (+24%) in specimens from diabetic men. These effects favorably influenced bone strength. However, the greater values of pentosidine in T2DM men decreased post-yield strain and toughness. Overall, these findings indicate a beneficial effect of T2DM on trabecular microarchitecture, but an impairment of collagen matrix. High concentrations of AGEs can offset the favorable effect of greater mineral content, thus increasing bone fragility (Fig. 40.2).

Reduced enzymatic collagen cross-linking

Spontaneously diabetic WBN/Kob rats showed reduced serum vitamin B_6 (pyridoxal and pyridoxamine) and immature enzymatic collagen cross-links in femoral bone from the prediabetic stage onward; however, mature cross-links (pyridinoline and deoxypyridinoline) remained normal, while nonenzymatic cross-links increased from the diabetic stage. As mentioned earlier, the altered collagenous matrix composition was correlated with reduced bone strength parameters (Saito et al., 2006).

Increased bone marrow adiposity

In recent years, bone marrow fat (BMF) has received increasing attention as a determinant of bone health that is also involved in whole-body energy regulation, hematopoiesis, and possibly further functions (Veldhuis-Vlug and Rosen, 2017). A positive association between osteocyte-derived sclerostin and BMF has been described in men (Ma et al., 2014), indicating that osteocytes may influence marrow adipogenesis via inhibition of the Wnt signaling pathway, thus favoring adipogenesis at the expense of osteogenesis.

In a cross-sectional analysis of men participating in the MrOS study, a large epidemiological study of nearly 6000 men, those with diabetes ($n = 38$) had significantly higher spine BMF (59% vs. 55%), spine BMD, and total hip than nondiabetic men, despite similar body weight, BMI, and waist circumference (Sheu et al., 2017). BMF was inversely correlated with BMD in diabetic men, but not in controls. Schwartz and colleagues investigated the relationships between vertebral BMF, BMD by QCT, and fracture in 257 older adults (mean age 79 years) (Schwartz et al., 2013b). Mean BMF was 54% in men and 55% in women. Those with prevalent vertebral fracture (21 men, 32 women) had significantly higher mean BMF (57% vs. 54%) after adjustment for age, gender, and trabecular spine vBMD. When men and women were analyzed separately, gender-related differences emerged. The difference in BMF between those with or without a prevalent fracture remained statistically significant only in men. BMF was associated with lower trabecular vBMD at the spine (−10.5% difference for each 1 SD increase in BMF), total hip, and femoral neck, but not with cortical vBMD, in women. In men, BMF was marginally but significantly associated with trabecular spine vBMD (−6.1%). Total hip and spine aBMD were negatively correlated with BMF in women only.

Patients with T1DM appear to have similar marrow adiposity compared with nondiabetics. No differences in BMF were identified between male patients with T1DM and healthy controls (Armas et al., 2012; Carvalho et al., 2018), and neither duration of disease nor glycemic control was related to bone marrow adiposity. This lack of association between BMF and T1DM was confirmed in young women with T1DM compared with healthy controls (Abdalrahaman et al., 2017). Irrespective of the presence of diabetes, in young women BMF was inversely associated with BMD (Abdalrahaman et al., 2017). Carvalho and colleagues showed that BMF quantity and lipid composition (saturated and unsaturated lipids) were similar between T1DM subjects and controls (Carvalho et al., 2018). There was, however, a significant inverse correlation between BMF saturated lipids and BMD.

Inflammation and oxidative stress

Chronic low-grade inflammation underlies several metabolic diseases, including T1DM, T2DM, and associated micro- and macrovascular complications (Clark et al., 2017; Lontchi-Yimagou et al., 2013). Chronic low-grade inflammation could also have a role in diabetic bone disease. Elevated cytokine levels can activate osteoclastogenesis and suppress osteoblast differentiation (Gilbert et al., 2000; Glajchen et al., 1988). Several proinflammatory cytokines that are elevated in both T1DM and T2DM may have detrimental effects on bone health. TNF has been shown to stimulate osteoclastogenesis (Glantschnig et al., 2003) and inhibit osteoblastogenesis (Gilbert et al., 2000). Local production of inflammatory cytokines in bone tissue has been described in murine models of STZ-induced T1DM (Coe et al., 2011; Motyl et al., 2009). Furthermore, systemic exposure to proinflammatory cytokines such as IL-1, IL-6, and TNF results in increased oxidative stress, which affects differentiation and survival of osteoclasts, osteoblasts, and osteocytes (Manolagas, 2010). Mesenchymal stem cells may also be affected, as hyperglycemia-induced oxidative stress was shown to influence mesenchymal stem cell differentiation, with adipogenesis being favored over bone formation (Aguiari et al., 2008). Although these studies point toward a detrimental effect of chronic inflammation and oxidative stress on bone, further studies are needed to better define their contribution to diabetic bone disease.

Loss of incretin effect

Incretins, namely GIP and GLP1, are gut-secreted hormones that are responsible for the "incretin effect," i.e., the greater insulin response to oral versus intravenous glucose administration. Patients with T2DM have a reduced incretin effect, with impaired GLP1 production after a meal (Knop et al., 2007). GLP1 promotes proliferation of mesenchymal stem cells and prevents their differentiation into adipocytes (Sanz et al., 2010). GLP1 receptor knockout mice showed increased osteoclast numbers, bone resorption rate, and bone fragility and low calcitonin levels (Yamada et al., 2008). Increasing doses of exendin-4, a GLP1 mimetic, resulted in proportional increases in BMD, bone strength, and bone formation in rats (Ma et al., 2013). Whether loss of incretin effect contributes to bone fragility in T2DM in humans has not been established. Two

categories of incretin-based therapies are available for the treatment of T2DM: inhibitors of DPP-4, and GLP1RA. Observational studies indicate that incretin mimetics have a neutral effect on bone health in humans (Driessen et al., 2017; Mabilleau et al., 2014; Monami et al., 2011), and interventional trials are lacking.

Sclerostin

Osteocytes are the most abundant bone cell type and play a central role in bone modeling and remodeling, regulating the bone biomechanical response to loading and the capacity to repair microcracks (i.e., fracture initiators). The role of osteocytes in diabetic bone disease is often overlooked, and yet to be fully clarified. Bone expression of sclerostin (encoded by *SOST*) and dickkopf-related protein 1, two major inhibitors of bone formation via inhibition of Wnt−β-catenin signaling, were increased in rat models of T1DM and T2DM (Hie et al., 2011; Kim et al., 2013; Nuche-Berenguer et al., 2010). Sclerostin levels were also found to be higher in patients with diabetes, either type 1 or type 2, than in healthy individuals (Gennari et al., 2012; Neumann et al., 2014). In T2DM, this increase was associated with a decrease in markers of bone formation (Gaudio et al., 2012), further suggesting that sclerostin inhibits bone turnover in diabetic states.

While increased circulating levels of sclerostin were associated with vertebral fractures in postmenopausal women with T2DM (Yamamoto et al., 2013), suggesting that sclerostin could be a useful clinical tool for fracture risk assessment in patients with T2DM, T1DM patients with the highest sclerostin levels had an 81% decreased risk of fracture compared with those with the lowest levels (Starup-Linde et al., 2016a).

Treatment of bone fragility in diabetes

Anti-osteoporosis drugs appear to be as effective in diabetic as in nondiabetic individuals, although the number of studies is limited. In a post hoc analysis of the Fracture Intervention Trial, alendronate 5−10 mg for 3 years increased aBMD at the spine and hip and reduced bone remodeling indices comparably in diabetic and nondiabetic postmenopausal women (Keegan et al., 2004). A population-based study that assessed the efficacy of antiresorptive drugs for fracture prevention found no difference in the anti-fracture efficacy between patients with diabetes and nondiabetic controls or between patients with T1DM and those with T2DM (Vestergaard et al., 2011). Efficacy in reducing nonvertebral fractures, increasing BMD, and decreasing back pain was reported with the osteoanabolic agent teriparatide independent of diabetes status in the Direct Assessment of Nonvertebral Fractures in Community Experience (DANCE) observational study (Schwartz et al., 2016). Data from pooled observational studies indicate that treatment with teriparatide for more than 6 months significantly reduces risk of clinical fractures. Interestingly, the efficacy of the medication on fracture risk was superior in diabetics compared with nondiabetics (Langdahl et al., 2018).

General conclusions

- Both T1DM and T2DM are associated with higher incidence of fractures, although the risk is far greater for T1DM. The increased fracture incidence in T1DM is more pronounced than could be explained by the relatively small BMD deficit.
- T2DM is characterized by higher risk of nonvertebral fracture and normal or higher areal and volumetric BMD. The role of cortical porosity, which appears to be increased in T2DM patients, is still controversial. Insulin deficiency may explain, at least in part, bone fragility in T1DM and in the last stages of T2DM. Insulin stimulates growth and bone formation in vitro and in vivo through its receptors on the bone cells. However, absence of IR expression in bone does not cause diabetic bone disease, indicating that the effect of insulin deficiency on bone is largely if not completely indirect.
- Fracture risk increases with diabetes duration and is higher among individuals with diabetes complications and limited physical capabilities; the higher incidence of falls in diabetic individuals is probably an important mediator.
- Glucotoxicity, increased oxidative stress, and inflammation are common findings in diabetics, but their impact on bone fragility is not known.
- Bone strength is clearly impaired in T1DM and T2DM. Diabetes-induced changes in the collagenous matrix are related to its biomechanical properties. These include reduced enzymatic collagen cross-links but increased glycosylated collagen (AGEs).
- Data from histology and bone markers indicate that diabetes is accompanied by low bone remodeling (both formation and resorption), a condition that may affect bone quality. Strong evidence indicates elevated sclerostin levels in T2DM, indicating a possible dysfunction of the Wnt osteoanabolic pathway in T2DM.

- Antidiabetic medications should be used wisely in diabetic patients, avoiding those that may affect bone strength (TZDs) or increase the risk of hypoglycemic events (sulfonylureas). Target HbA1c should not be too stringent, according to the most recent guidelines.
- Antiosteoporotic medications have been proved equally effective and safe in diabetics.

Key points

- Patients with type 1 diabetes mellitus or type 2 diabetes mellitus (T2DM) have an increased risk of fractures; bone mineral density underestimates this risk in individuals with T2DM, making risk assessment challenging.
- Patients with diabetes mellitus with long-term disease, poor glycemic control, β-cell failure and who receive insulin treatment are at the highest risk of fractures.
- Low bone turnover, accumulation of advanced glycation end products, micro- and macroarchitecture alterations, and tissue material damage lead to abnormal biomechanical properties and impair bone strength.
- Other determinants of bone fragility include inflammation, oxidative stress, adipokine alterations, Wnt dysregulation, and increased marrow fat.
- Complications of diabetes mellitus, such as neuropathy, poor balance, sarcopenia, vision impairment, and frequent hypoglycemic events, increase the risk of falls and risk of fracture; preventive measures are advised, especially in patients taking insulin.
- Use of thiazolidinediones, or some SGLT-2 inhibitors might contribute to increased fracture risk; antidiabetic medications with good bone safety profiles such as metformin, glucagon-like peptide 1 analogs, or dipeptidyl peptidase-4 inhibitors are preferred.

Chapter 41

Androgen receptor expression and steroid action in bone

Venkatesh Krishnan

Lilly Research Laboratories, Eli Lilly & Company, Lilly Corporate Center, Indianapolis, United States

Chapter outline

Introduction

Androgens and estrogens belong to the steroid hormone superfamily that binds to nuclear receptors that mediate their canonical actions in specific reproductive and endocrine tissues (Tsai and O'Malley, 1994). Estrogen mediates its action through two cognate receptors termed estrogen receptor alpha (ESR1) and estrogen receptor beta (ESR2)—also known as NR3A1: ERalpha and NR3A2: ERbeta (Nilsson et al., 2001). Androgen signals through the only known cognate receptor, termed androgen receptor (AR, also referred to as NR3C4) (Simental et al., 1991). Previous studies have shown that loss of estrogen following surgical removal of ovaries or an aging-related decrease in estrogen production (defined earlier as menopause) can lead to bone loss in women ((see Fig. 41.2) Albright, 1940). In a prospective study among prostate cancer patients seeking androgen-deprivation therapy (ADT) compared with age-matched patients not seeking ADT, it was shown that the absence of circulating androgens results in an increased rate of bone turnover and a loss in bone mineral density (BMD) over 2 years (Prostate Cancer, 2002). The ADT regimen included an LHRH agonist leuprolide along with concomitant administration of flutamide or bicalutamide, which are specific antagonists of AR. Therefore, both estrogen and androgen deprivation can lead to bone loss in women and men, respectively. Furthermore, surgical gonadectomy of sexually mature men resulted in bone loss as evidenced by a rapid decline in BMD and an increase in bone turnover markers (Stepan et al., 1989). Therefore, this provided a simple model that suggested a prominent role for androgen in maintaining healthy bone mass in men. However, in a landmark mechanistic study conducted by Khosla et al. in 1998, it was shown that estrogen (but not androgen) supplementation was both necessary and sufficient to recover the bone loss initiated by ADT. These results have challenged the dogma that androgens and other AR agonists are exclusive in imparting favorable skeletal effects in men. A subsequent study has corroborated this finding by exploring (Finkelstein et al., 2016) a different study design involving pharmacological induction of hypogonadism in men followed by graded doses of testosterone replacement with or without an aromatase inhibitor. Similar to the earlier study described by Khosla et al., changes in bone resorption and formation markers were predominantly regulated by estrogen and not androgen in these men. Moreover, testosterone, in the absence of aromatization to estrogen (aromatase inhibitor arm), was unable to

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00041-5

prevent decreases in BMD at multiple sites. Collectively, these two and additional interventional studies (Khosla et al., 2015), using variations of the approaches used in the studies just described, now provide compelling evidence in humans that in both women and men, estrogen is the dominant sex steroid regulating bone metabolism. While these mechanistic studies have employed the use of testosterone and its aromatase enzyme catalyzed conversion to estrogen, in the presence/absence of aromatase inhibitors, they do not address the direct consequences of androgen ligands in bone. These can be primarily achieved by the use of nonaromatizable androgens that may be represented by a wide array of selective androgen–receptor modulators (SARMs) (Narayanan et al., 2018). Unfortunately, most clinical development deploying these SARMs carries unknown long-term risks that have yet to warrant their use as therapeutic options in long-term disease contexts (treatment duration >2 years) other than exigent diseases such as cancer. Therefore, the field lacks access to published data describing carefully designed long-term efficacy studies with SARMs that could allow one to measure the effects of such specific AR ligands in the context of human bone health. In contrast, there is ample evidence that antiandrogens, by way of their use in prostate cancer and other benign prostate diseases, do result in loss of bone health that predisposes patients to a higher risk of fractures (Cheung et al., 2013).

The subsequent sections of the review will now explore the role of AR in affecting male bone health. It will contrast both loss-in-function and gain-in-function paradigms to help ascribe a holistic view on this topic. It is now evident that rodent models that reflect loss of function (LoF), either by way of a whole body knockout of these genes from early development or by way of tissue-specific knockout mice using tissue-specific promoters that drive *Cre* recombinase, provide useful ways to assess the importance of AR in rodent bone health. This review will capture our current understanding of these genetically modified animal models and help reconcile it with the LoF observations in man that may or may not align with these rodent observations. In addition, this article will summarize the numerous gain-in-function paradigms ranging from the use of steroidal testosterone replacement to the emerging discovery and development of SARMs as they impact bone health.

Loss-of-function evidence from rare human variants

The importance of ESR1 in male human skeleton was exemplified by a rare LoF homozygous deletion of ER-alpha in a male individual that rendered him with osteopenia and a spine BMD more than two standard deviations below the age-matched normal for 15-year-old boys (Smith et al., 1994). However, when carefully evaluating the iliac crest biopsy obtained from this rare ER-alpha-null male, it was reported to reflect reduced cancellous bone volume and cortical width at this site. It is conceivable that this is due to the absence of the direct beneficial effect of ER-alpha on strain-dependent bone formation indices, as suggested by Lanyon et al. (Lee et al., 2003). Aligned with this report were two reports of loss of hormone that was realized through a homozygous deletion of the aromatase gene that is crucial for converting circulating testosterone to estrogen, the ligand that targets the receptors ESR1 and ESR2. In both these individuals who lacked adequate circulating estrogen levels, the skeletal phenotype was near identical to that described earlier for the ER-alpha-null human (Carani et al., 1997; Bilezekian et al., 1998). Collectively, these findings, albeit rare, provide a prominent role for estrogens and ESR1 in affecting the peak bone mass in young adolescent males.

The enzyme 5-alpha reductase (type 1 and type 2) catalyzes the reduction of testosterone to the nonaromatizable and potent AR ligand dihydrotestosterone (DHT) (see Fig. 41.1), which can bind AR with greater affinity than testosterone and mediate the biological effects of testosterone as an active metabolite. Patients with mutations of 5-alpha reductase type 2 have been reported to have normal BMD (Sobel et al., 2006). These individuals have low circulating levels of DHT. Treatment of adult men with the 5-alpha reductase inhibitor finasteride does not affect BMD (Matsumoto et al., 2002). However, finasteride is a weak inhibitor of the type 2 isoform of 5-alpha reductase and does not affect the constitutively active prevalent type 1 isoform. Thus, although DHT levels are lower in finasteride-treated men than in healthy untreated controls, they are still in the low normal range in many treated men. More recent studies in dutasteride-treated patients, which is a potent inhibitor of both type 1 and type 2 isoforms of 5-alpha reductase, also have failed to elicit a significant reduction in BMD in men (Amory et al., 2008). These observations of normal bone health in light of reduced conversion of testosterone to its potent metabolite DHT further guide our conclusion for the relative importance of ESR versus AR ligands in maintaining bone mass in males.

The 3-beta hydroxysteroid dehydrogenase 2 (HSD3B2) gene is located on chromosome 1q13.1, and encodes for the human type II (3b-HSD2) isoenzyme, which is only expressed in the adrenal cortex and in steroidogenic cells within the gonads. It is an essential enzyme for the synthesis of testosterone along with cortisol and aldosterone (see Fig. 41.1). An individual who presented at birth with a salt-wasting syndrome as a result of this rare insufficiency variant, which represented an LoF for this enzyme, was rescued with cortisol treatments. This male achieved normal puberty and had the expected developmental defects in his sexual organs associated with androgen insufficiency. However, in spite of low

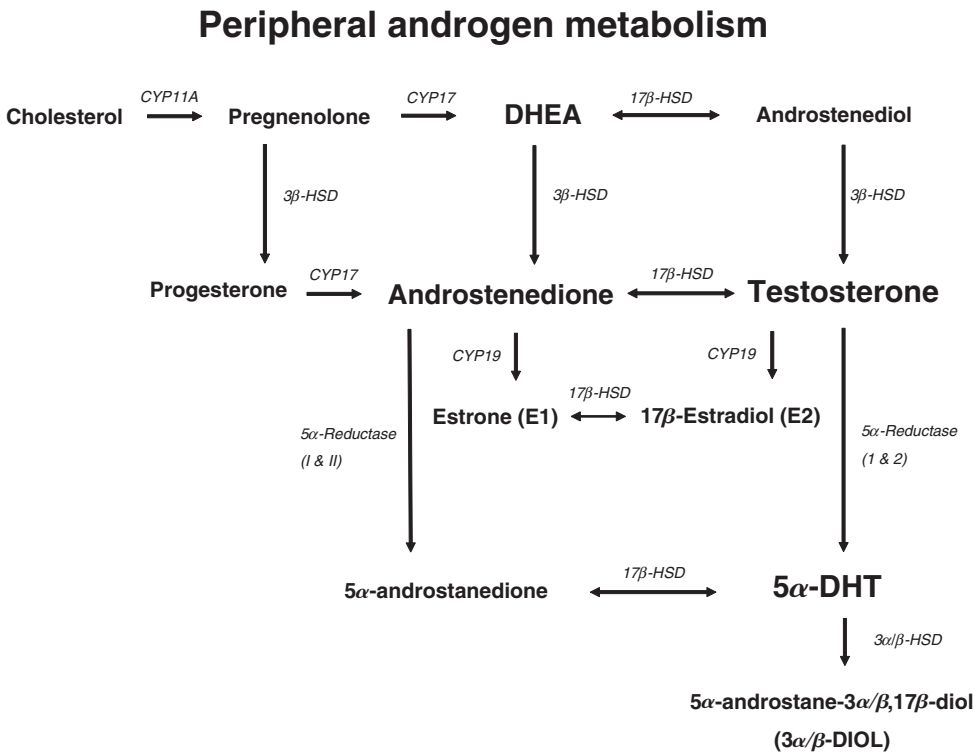

FIGURE 41.1 An outline of the steroidal synthesis of androgen and its metabolism has been provided. Of importance are the roles played by 5alpha-Reductase in converting Testosterone to 5alpha-Dihydrotestosterone, and the conversion of androstenedione to testosterone by 17 Beta HSD.

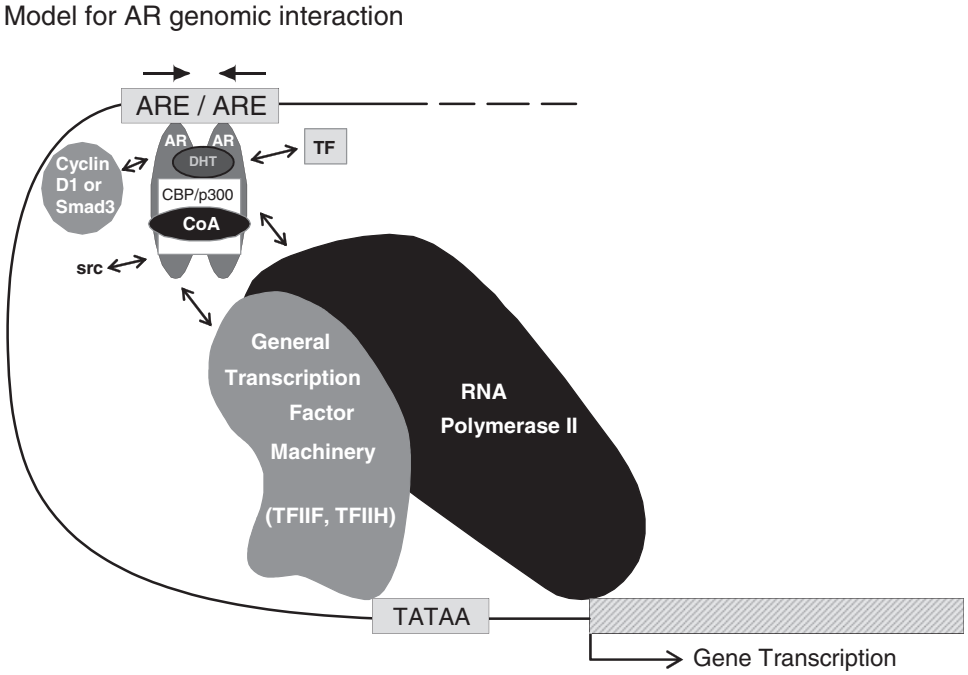

FIGURE 41.2 The molecular action of transcriptional activation by the AR homodimer acting on cis-regulatory elements identified on androgen-regulated genes is shown along with the coactivators that may influence tissue specific androgen-induced gene expression.

circulating testosterone levels (~13.8 nmol/L compared with normal range if 20−40 nmol/L), which is an expected consequence of this rare LoF variant, the patient showed a normal BMD. His bone density measured at approximately 19 years of age was normal with a femoral T-score of (+2.8 s.d.) and vertebral T-score of (+1.9 s.d.), suggestive of an absence of an obvious deleterious effect on BMD in spite of insufficient androgen levels (Bruno et al., 2018). Collectively, the rare occurrences of human LoF variants point to a prominent role for estrogen/ESR1 in maintaining male skeletal health and less so for the hormone testosterone and related androgens such as dihydrotestosterone. However, the absence of well-annotated AR LoF individuals makes it challenging to offer a comparative assessment of androgens (vs. estrogens) and their role in human bone health relying on this approach of rare LoF genetic variants.

Gain-of-function evidence from human trials

Placebo-controlled studies using various approved formulations of testosterone have been limited and often report conflicting results (Snyder et al., 1999; Kenny et al., 2001; Tenover, 1992). Some component of this discrepancy could be attributed to the study design within these trials. In the study conducted by Snyder et al., 108 men over 65 years of age were randomized to receive a testosterone or placebo patch for 36 months (Snyder et al., 1999). The majority of these subjects were neither osteoporotic by current WHO criteria, nor were they hypogonadal (mean testosterone level >350 ng/dL). The primary end point was the measure of vBMD as measured using dual-absorption X-ray absorptiometry (DEXA) measured at 6-month intervals over the 3-year period. The testosterone patch did not show significant improvement in the primary end point of *v*BMD compared with the placebo group, except for the final measure of spine BMD by DEXA at 36 months. In a posthoc analysis using secondary linear regression, it was reported that by stratifying subjects based on their pretreatment serum testosterone concentration, one could clearly show favorable effects of the testosterone patch arm compared with placebo arm on lumbar spine bone density in overtly hypogonadal patients. In contrast to the previous study of nonosteoporotic, eugonadal men, Amory et al. studied hypogonadal men ($T \leq 300$ ng/dL) over age 65, randomly assigned to placebo or testosterone, bimonthly 200 mg intramuscular injections ± finasteride, for 3 years (Amory et al., 2004). Their inclusion criteria for these elderly men used baseline mean T-scores ranging from −0.3 to −0.53, and therefore these hypogonadal men were not deemed osteoporotic. Their peak serum total testosterone levels were at the high normal serum range for the testosterone-only group, with a mean peak value for the group being 35.9 ± 12.1 nmol/L (mean ± sd). In contrast to the Snyder et al. study described above, BMD at a variety of sites including lumbar spine, total hip, and trochanter (femur site) were all increased with the testosterone ± finasteride arms at 12 months and remained significantly increased for the 3-year period compared with the results for placebo injections. It is noteworthy that the magnitude of the increases in lumbar spine BMD seen with intramuscular testosterone at 12 months were comparable to those observed in men with osteoporosis using daily injections of teriparatide, a strong well-known bone anabolic agent (Orwoll et al., 2003). However, this study could not account for these effects as being specific to the increase in serum testosterone, as testosterone could have been aromatized to estrogen in specific tissues. Consistent with this caveat, the authors measured an increase in serum estradiol throughout this 3-year period. Notably, these gains in lumbar BMD over 36 months were positively correlated with the magnitude of increase in serum total testosterone (r^2 0.44; $P \leq .001$), bioavailable testosterone (r^2 0.45 and $P \leq .009$), and serum estradiol (r^2 0.45; $P \leq .0006$). Therefore, in spite of encouraging changes in lumbar BMD comparable to those seen with anabolic agents such as teriparatide, one needs to cautiously ascribe direct beneficial effects in improving BMD for male subjects with androgens. It is important to note, however, that selective modulators of ESR1 and ESR2 ligands such as raloxifene do not provide such a robust change in lumbar spine BMD as seen with intramuscular testosterone after 12 months in patients receiving gonadotropin-releasing hormone (GnRH) agonists for prostate cancer. The mean (BMD ± SE) BMD of the posterior−anterior lumbar spine increased by 1.0 ± 0.9% in the men treated with raloxifene plus GnRH agonist and decreased by 1.0 ± 0.6% in the men who did not receive raloxifene but were taking GnRH agonist ($P = .07$) (Smith et al., 2004). It is not clear if the full complement of ESR1- and ESR2-related bone changes ascribed to estrogen-mediated action can be recapitulated by a selective ligand like raloxifene in the context of a GnRH agonist.

The use of intramuscular testosterone enanthate or cypionate, 100 mg/week, in patients with acquired hypogonadism as reported by Katznelson et al. had the most definitive gain seen in vertebral BMD (14% after 18 months) but is confounded by the fact that these were younger adults (average age 53) with lower vertebral BMD as a result of diminished peak bone mass caused by their central hypogonadism, which could have included changes in the growth hormone/IGF-1 axis. Most recently, Snyder et al. published the most extensive 1-year study in elderly (>65 years of age) hypogonadal men (serum $T < 275$ ng/dL), when approximately 790 men were randomized to placebo or a testosterone gel. However, the authors did not measure BMD or biomarkers of turnover such as CTX or P1NP (Snyder et al., 2016). In summary, while a few gain-of-function (GoF) studies have been conducted in elderly hypogonadal men, which included approximately 90 men

for a 1-year treatment duration and provided a 90% power to reliably detect vBMD changes based on the average 9% gain in vertebral BMD at 1 year as measured by Katznelson et al. (1996) using individuals with acquired hypogonadism, these results do not provide a compelling reason to ascribe this benefit in men. The primary reason to maintain a cautious position is that while all these studies provide a vignette or two of benefit in increasing BMD, in order to balance any perceived target-related risk, such as prostate and cardiovascular health, one needs larger, well-controlled, and longer-duration studies (>2 years) to provide a balanced view of the benefit−risk profile of androgen replacement to address issues with male skeletal health. In lieu of the robust efficacy of non-AR binding pharmaceuticals such as antiresorptives and anabolic agents in male patients, this data set will be challenging to seek from such well-controlled studies (Snyder et al., 2014).

Can we reliably measure androgen gain of function in bone health using end points such as bone mineral density?

It is now well established that bone quality is a measure that encompasses BMD plus aspects of bone strength that are difficult to measure using objective preestablished criteria such as bone geometry, microarchitecture, and bone tissue properties (Fonseca et al., 2014). The limitations for exclusive reliance on BMD are highlighted by the significant differences in trabecular connectivity with unit areas from subjects matched for bone volume (Recker, 1993). Also, in numerous interventional studies with antiresorptives, significant and clinically relevant reductions in fracture risk are associated with modest changes in BMD (Sarkar et al., 2002; Delmas and Seeman, 2004). Therefore, it is conceivable that clinical end points related to bone microarchitecture and other structural parameters as assessed by high-resolution computer tomography, magnetic resonance imaging, bone mineral strength by microindentation, etc. may provide valuable insight into bone quality that could supplement our experience with BMD to arrive at a holistic view of the benefits of androgen-related effects on bone quality. These alternate end points reflecting the changes in microarchitecture of bone in response to androgens are proposed due to the well-known observations related to striking changes seen in the mass, structure, and geometry of the male versus female skeleton (Bruzek, 2002).

Gender-specific differences in bone geometry and architecture

Higher peak bone mass in males compared with females would posit higher fracture risk for males (compared with females) as they progressively lose bone mass due to aging for a given BMD, because these males have a greater absolute reduction from their peak density. Yet, studies have shown that for a given DXA BMD score, the fracture risk between genders is indistinguishable (Selby et al., 2000). Characteristic differences in bone architecture between males (larger bone area) and females (smaller bone area) perhaps offer a potential advantage to males that may explain their reduced susceptibility to fracture (Seeman, 1993). Therefore, the higher peak bone mass in males compared with age-matched females offers them a distinct advantage (Lambert et al., 2011). It is also well known that the cross-sectional diameters of vertebrae and femoral necks are larger in males and that this is associated with greater bone strength than that of age-matched females (Mosekilde et al., 1990) Decreased axial width along with reduced cross-sectional area, seen in elderly men (MINOS study) with a higher risk of fragility fractures, further underscores the importance of bone geometry as an independent determinant of fracture risk in addition to BMD (Szulc et al., 2006). It is also believed that through aging, women show greater reductions in periosteal thickness compared with men (Christiansen et al., 2011) Interestingly, the type of trabecular changes that occur with aging also differ between the sexes, as males tend to have trabecular thinning and females tend to lose trabecular connectivity (Lambert et al., 2011). Therefore, despite the fact that males will have a larger reduction for any given DXA BMD value, this does not seem to translate into an increased fracture risk, and is perhaps related to the protective benefit of their peak bone characteristics and different types of bone architectural properties compared with females. Consistent with these findings, the prevalence of osteoporosis is significantly greater for women than men when stratified across age groups through deciles (Kanis, 2007). This observation is also substantiated in male rats deficient in androgen and exposed to aromatase inhibitors, which fail to convert testosterone to estrogen and show specific decrement in certain geometric features of the proximal femur, suggesting that androgens may control peak bone mass in the male rat by relying on non-BMD measures (Vanderschueren et al., 1997). The mechanistic underpinnings for the sexually dimorphic nature of skeletal geometry were described recently by Sims et al. Recent studies implicate the regulation of corticalization by SOCS-3. They used a DMP-1−driven Cre to generate an osteocyte-specific knockout of SOCS-3 that allowed them to create a sexually divergent phenotype of corticalization. The nonaromatizable androgen (i.e., DHT) can inhibit the activity of delayed corticalization in Dmp-1−specific SOCS-3-null mice by targeting IL-6 (Cho et al., 2017). This provides us with a mechanistic basis for the increased corticalization seen in the male skeleton,

which may effectively contribute to reduced fracture risk. Therefore, androgen ligands that enhance cortical bone parameters may favorably affect fracture risk. However, if these androgens resulted in changes in bone architecture or geometry such as increased cross-sectional area as a result of increased cortical area, even in the context of increasing bone mineral content, it would only reflect as a minimal change in BMD. Therefore, when it comes to androgen-mediated impact on male bone health, it may be more prudent to look beyond BMD.

Gain-of-function studies with testosterone treatment and change in bone architecture

In a small clinical study (32 hypogonadal men) exploring the use of testosterone treatment in hypogonadal men (primary hypogonadism), Leifke et al. showed that intramuscular injection of testosterone enanthate (250 mg every 2 weeks over 3 years) resulted in a 30% gain in trabecular BMD and a 9% increase in cortical BMD at the lumbar spine as measured by quantitative computer tomography (Leifke et al., 1998). These improvements were seen in all patients independent of their leading cause for primary hypogonadism. In contrast to this smaller study, Khosla et al. have shown in 269 men that there is no correlation between microstructural parameters at the wrist bone as measured by high-resolution three-dimensional quantitative computer tomography and those of bioavailable testosterone. Therefore, it is important to recognize that there may be a threshold effect of testosterone on structural properties of bone that may only be evident in men with severe hypogonadism and is less evident in the broad eugonadal population. Also, the anatomical site (wrist vs. spine) may offer distinct responses to androgens. In another very limited study (10 hypogonadal men) explored by Benito et al., it was shown that magnetic resonance microimaging-based end points highlight the integrity of the trabecular network, which is compromised in hypogonadal men and improved with testosterone replacement. These patients showed an increase in the surface-to-curve ratio (+11% vs. baseline), defined earlier (Gomberg et al., 2000), which is the topologic representation of the ratio of trabecular plates to rods and suggests that testosterone replacement partially restored trabecular connectivity. These studies show that testosterone treatment results in improvements typically seen with anabolic agents on trabecular connectivity.

Loss of function using genetically modified mice

The effects of estrogen on bone are mediated by two related but distinct receptors, ESR1 (ER-alpha) and ESR2 (ER-beta) (Nilsson et al., 2001; Almeida et al., 2017). Sims et al. published the global knockout of ESR1, and as a result of alteration in the hypothalamic−pituitary−gonadal axis, these animals had supraphysiological levels of circulating estrogen and androgen levels in females and male knockout mice. Loss of ESR1 from birth resulted in a decrease in bone turnover and an increase in cancellous bone mass accompanied by a decrease in cortical thickness (Sims et al., 2002). A follow-up study reported by Callewaert et al. pursued a strategy of creating both single- and double-knockouts of ESR1 and AR in male mice by crossing these compound heterozygotes. Removal of ESR1 resulted in an unusual gain in trabecular bone volume; in contrast, removal of AR resulted in an opposite and dramatic reduction in trabecular bone volume when assessed using computer tomography of the distal femur. These results would imply that in the absence of hypothalamic−pituitary−gonadal axis-related suppression of circulating hormones mediated by ESR1, systemic increases in serum androgens may result in this surprising increase in bone volume in ESR1-null mice. In contrast, when both ESR1 and AR were knocked out, they observed complete loss of this gain in trabecular bone volume in the single-ESR1-null mice comparable to that of the single-AR-null mice (Callewaert et al., 2009). In addition, cortical area at the femoral site was reduced with the single-ESR1-null mice, which was further reduced with the single-AR-null mice, followed by the greatest reduction in cortical area in the double-null mice. Collectively, AR may be required for male mice to accrue peak trabecular bone mass and peak cortical area. These interpretations from global ESR1 knockout mice are confounded by significant alterations in circulating sex steroid levels. To avoid these dramatic changes in circulating sex steroids that may inadvertently reflect GoF for other steroid hormone receptors that function through these circulating hormones, the field has resorted to a tissue-specific expression of Cre recombinase that allows targeted deletion of ESRs and AR in specific tissues that retain activity off these targeted promoters.

Deletion of ESR1 and AR in osteoprogenitor cells, osteocytes, and osteoclasts (Ucer et al., 2016) reported by Ucer et al. provides the most thorough assessment of the roles of these steroid hormone receptors in developing mice. In these reports, the authors were careful in not realizing systemic supraphysiological increases in circulating hormones by deleting these receptors in specific cell types. They utilized a Prx-Cre mouse to target the osteoprogenitor cells throughout development. Analysis of these mice using computer tomography showed a decrease in cancellous BV/TV and trabecular number, and an increase in trabecular separation, compared with C57BL6 mice that retain AR expression in these cells. The effect of orchidectomy on cancellous bone in the wild-type mice was similar to the effects of AR deletion from Prx-Cre-driven

mesenchymal progenitors in androgen-sufficient mice. Therefore, the targeted AR deletion in mesenchymal progenitors is similar to that observed with orchidectomy-induced loss in circulating androgens. Surprisingly, the authors noted an absence of cortical bone changes in these Prx-Cre-driven osteoprogenitor AR-null mice. Furthermore, removal of AR from osteoclast precursors that are reflected in the LysM Cre mice show that AR function in mouse bone is not dependent on osteoclast expression of AR. The LysM gene is specifically expressed in cells of the monocyte/macrophage lineage and their descendants as well as in neutrophils (Clausen et al., 1999).

Role of estrogen receptor alpha in bone using genetically modified mice is equivocal

ESR1 may arguably contribute to changes in both cancellous and cortical bone as described by the use of ESR1-floxed mice crossed to Dmp1-Cre, and ESR1-floxed mice crossed to OCN-Cre mice, both of which result in measurable decreases in cancellous bone (Maatta et al., 2013; Kondoh et al., 2014). In contrast to these reports, others have shown that removal of ESR1 from osteoprogenitor cells or osteocytes does not affect cancellous bone mass. These studies have crossed ESR1-floxed mice to osteoprogenitor-specific Prx1-Cre (Ucer et al., 2016) or osteoblast-expressed Col1-Cre mice (Almeida et al., 2013), and finally osteocyte-specific Dmp1-Cre mice (Windahl et al., 2013). In all these reports, the impact on regulating cancellous bone mass is not very evident for ESR1. However, cortical bone parameters are modestly dependent on ESR1, as reported in findings made by Almeida et al. (2013).

Factors that may contribute to these equivocal observations may be (1) the use of distinct Cre promoters that may vary in tissue specificity that has yet to be determined, (2) the limitations of using the Cre-Lox system, which may yield variable levels of gene deletion (Manolagas et al., 2014), and (3) phenotypes that are quite modest, so that subtle variations over time during development may affect how these results are interpreted. Collectively, one could suggest that ESR1 deletion in osteoblast lineage cells may result in reductions in both cancellous and cortical bone mass in female mice and only cancellous bone mass in male mice. However, an important caveat to all of these studies is that the receptor deletion, although cell-specific, has been present since conception. Therefore, the skeletal findings largely reflect developmental effects of these receptors rather than their exclusive role in the adult skeleton.

Gain-of-function studies using selective androgen receptor modulators in sexually mature animal models

LoF of AR in osteoprogenitor cells (Ucer et al., 2016) or since conception globally (Callewaert et al., 2009) leads to decreases in trabecular bone mass, connectivity, and cortical area as reported earlier. However, the most compelling data set explores GoF paradigms using nonsteroidal, nonaromatizable SARMs and offers the best approach to fully understand the effects of AR ligands in the mature skeleton.

Earlier reports included suggestions of robust activity in male orchidectomized rat models offered by perspective summaries described earlier (Rosen et al., 2002) but these did not provide an opportunity for detailed analysis of the preclinical datasets. However, the most compelling preclinical evidence was offered by Kearbey et al., who showed a dose-dependent gain in trabecular bone mass in female ovariectomized mature rats that were treated with a distinct aryl propionamide SARM (S-4) (Gao et al., 2005a). They showed protection from ovariectomy-induced trabecular bone loss using the S-4 SARM as measured by lumbar spine BMD. This benefit offered by the SARM was dependent on AR signaling, as observed by the reversal of this protection of spine BMD in the arm that combined the S-4 SARM along with the AR antagonist bicalutamide. In addition, they observed enhancements in cortical bone parameters, including cortical width, cortical density, and periosteal circumference at peak doses of 1.0−3.0 mg/kg-day. Collectively, this report provided compelling evidence of the osteoprotective effects of a nonsteroidal SARM that functions as an AR agonist in bone when used immediately after ovariectomy in female SD rats (Kearbey et al., 2007). To further evaluate the potential for an anabolic response, the same group reported deployment of the S-4 SARM in a delayed rat male orchidectomy model. In this model, the orchidectomy induced an expected loss in total whole-body bone mineral content and BMD over the 12-week wasting period. This change in whole-body BMC and BMD was completely recovered after 8 weeks of treatment with S-4 SARM given daily at 10 mg/kg-day. However, there were some modest reductions in osteocalcin levels, which may point to a decrease in bone turnover in these animals (Gao et al., 2005b). It was not clear whether the authors measured favorable changes in markers such as P1NP, which reflect de novo bone formation as reflected by changes in the N-terminus-modified epitopes presented in serum with the synthesis of new collagen molecules placed onto bone (Eastell et al., 2006). Therefore, while these results are encouraging, it is not definitive whether the gains in total bone mineral content and BMD are due to SARM-mediated gains in bone formation. The most compelling report that showcases the direct anabolic action of SARMs was reported by Hanada et al., who utilized a −tetrahydroquinoline derivative to generate

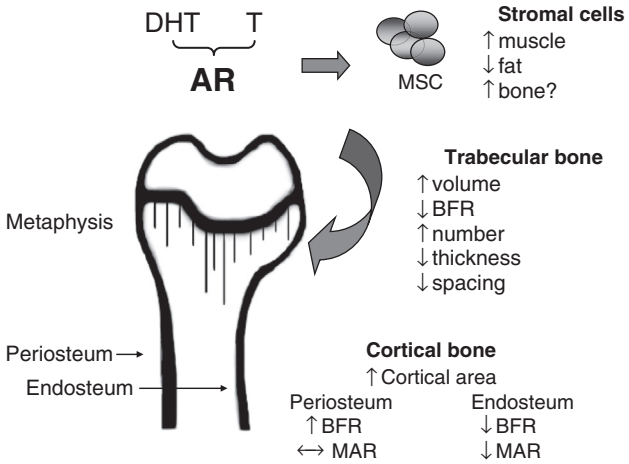

FIGURE 41.3 A summary of the expected changes in response to androgen action, at the various geometric sites associated with appendicular skeletal sites is shown.

an SARM, termed as S-40503 (Hanada et al., 2003). This molecule was shown to be very selective for AR and did not bind ESR1, ESR2, or other nuclear hormone receptors. In this report, they utilized a bilateral orchidectomized male rat that was treated with the S-40503 SARM for 4 weeks 1-day postgonadectomy. They showed increases in femoral BMD that were dose-dependent after the 4-week treatment period. To address direct anabolic action by SARM S-40503, they utilized an ovariectomized female rat model, wherein animals were allowed to lose bone mass for 4 weeks followed by 4 weeks of daily subcutaneous injections with SARM S-40503 (30 mg/kg-day), estrogen (20 μg/kg-day), or DHT (10 mg/kg-day). They measured distal femur cancellous BMD, which was most improved with estrogen followed by SARM S-40503 and DHT to a similar but qualitatively lesser extent. In contrast, they observed a robust increase in cortical BMD that was greater than intact nonovariectomized age-matched animals for both SARM S-40503 and DHT. This gain in cortical bone BMD was not apparent for the estrogen-only arm. Furthermore, they used calcein double-labeling to show direct evidence of an increased mineral apposition rate (MAR μm/day) in response to nonaromatizable DHT and SARM S-40503, which was in contrast to minimal apposition observed with estrogen (no change). Notably, the MAR observed for S-40503-treated animals was higher than for the intact nonovariectomized control, again suggesting direct anabolic action in response to this GoF paradigm using both a nonaromatizable androgen (i.e., DHT) and a nonsteroidal selective SARM, S-40503. Collectively, the use of structurally distinct nonsteroidal SARMs in preclinical models suggests a potential to directly and favorable impact bone mass in animals undergoing gonadectomy-induced bone loss (see Fig. 41.3). However, these preclinical findings have yet to translate to changes in improvements in bone mass or bone biomarkers in clinical studies exploring SARMs. This may be due to the positioning of these SARMs in diseases such as cancer cachexia and sarcopenia, which may require long-term use to determine such bone-related end points.

The muscle–bone interface and its potential impact on bone strength

Androgens in general are well known to be muscle anabolic and form the basis of numerous clinical reports on their ability to increase skeletal muscle mass (Bhasin et al., 1997). Changes in bone and muscle go hand-in-hand to affect the skeletal features of both men and women. Therefore, it is logical to expect the muscle–bone interface to provide favorable strain- or load-induced bone formation cues at these interfaces. The role played by the tendon that presents the collagen-enriched structural bridge between the muscle and bone interface is perhaps less understood for fully appreciating the impact of muscle and mobility on bone formation. The collagen fibrils, considered the fundamental force-transmitting unit of the tendon, are densely arranged within the extracellular matrix of specialized cells called tenocytes and are oriented parallel to the bone–muscle axis (Nourissat et al., 2015). Such an orientation provides a seamless transmission of the mechanical forces transduced by skeletal muscle contractions, which impinge on the enthesis within the bone–tendon interface. Evidence for such an impact was offered by Hamrick et al., who showed that gdf-8 knockout mice that had a dramatic increase in muscle weight and volume exhibited significant changes in cross-sectional area and bone mineral content in the proximal humerus and deltoid crest. These were consistent with areas closely representing sites of attachment of the muscle to the bone and further underscore the impact of muscle volume or mass on bone geometry (Hamrick et al., 2002).

Therefore, the muscle–bone relationship, expressed as the "bone–muscle unit," can be viewed as single coordinate structure that is strongly influenced by mobility-induced mechanical loading. Such differential strains imposed by increases or decreases in mechanical loading, as a result of disability or aging, can affect overall bone geometry and bone strength (Lang, 2011) (see Fig. 41.3). The close coupling between muscle and bone, and the gender differences in the relationship, are often viewed in the context of the mechanostat theory first elaborated by Frost (2000). The independent risk conferred by skeletal muscle was underscored in the Frost mechanostat review that highlighted falls as the largest "risk factor" for traumatic osteoporosis fractures, because without falls, the fractures caused by them would not occur regardless of whether some microscopic fatigue damage in bone increases the bone fragility associated with all osteopenias (Frost, 2003). However, fall risk accumulates as a result of multiple intrinsic and extrinsic risk factors such as changes in balance induced by medications or alcohol, loss in lower limb skeletal power with aging, poor vision, and a variety of environmental conditions. The independent risk factor of lower limb skeletal muscle strength and/or power was addressed by Becker et al. in the first-of-its-kind intervention on elderly weak fallers using an antimyostatin antibody (Becker et al., 2015). Results from this trial emphasized the importance of muscle power a feature of muscle strength over a fixed time period which is essential to how our body reacts to a displacement such as a fall. The intervention provided preliminary evidence that treatment with a muscle mass enhancing antibody that targets gdf-8 might improve functional measures of muscle power in elderly individuals prone to falls. Similar results have been published by Srinivas-Shankar et al., using transdermal testosterone gels for 6 months in elderly frail men with borderline low serum T levels. In this randomized controlled trial, they found that testosterone supplementation showed marked improvements in the primary outcome measure of isometric knee extension peak torque and isokinetic knee extension peak torque. Unfortunately, the study failed to measure markers of bone turnover to help inform the changes that could be affecting the muscle–bone unit. The study also did not measure the impact of testosterone gels to reduce the incidence of falls. In a separate study conducted by Bronwyn et al. in chronic glucocorticoid-treated patients, injectable testosterone esters given intramuscularly every 2 weeks for 12 months showed marked improvement in lumbar spine BMD ($+4.7\% \pm 1.1$) along with improvements in muscle strength as determined by knee flexion and extension using isokinetic dynamometry (Bronwyn et al., 2003).

Collectively, the impact of androgens on various functional parameters of skeletal muscle that impacts mobility may confer added benefit to measures of bone strength and/or geometry through the muscle–bone interface.

Future prospects for androgens and male skeletal health

The seminal findings made by Khosla et al. (1998) have provided some clarity on the importance of the ESR1–estrogen axis-mediated benefit conferred upon the male skeleton in the course of normal physiology. However, clinical interventions that address ESR1- and/or ESR2-mediated pathways to enhance skeletal health are relatively less prominent. The emergence of novel mechanisms of resistance to antagonists or inhibitors of the AR–testosterone axis as it pertains to prostate cancer (Watson et al., 2015) will naturally require better medicines that balance the benefit to the risk profiles of such agents. This will require us to be vigilant about the deleterious effects of androgen ablation as they become more prevalent and mainstream in their targeting of less severe patients suffering from PCa to help prevent the occurrence, or to add as maintenance regimens in patients undergoing remission to prevent the relapse of tumor burden. Recent advances in this approach have been seen with the development of such agents targeting distinct actions of estrogen and androgen action in breast cancer (Yu et al., 2017). Our ability to provide therapeutic options to balance cancer risk while maintaining skeletal health in these individuals would warrant more nuanced classes of agents in the future (Figs. 41.1–41.3).

SARMs offer a variety of chemical scaffolds that allow us to better design the benefit and risk profile of such interventions. However, as noted by recent reviews, the field has progressed slowly in large randomized controlled trials, querying bone-related end points as these novel agents posit risk in terms of their cardiovascular outcomes (Narayanan et al., 2018; Nique et al., 2012; Krishnan et al., 2018; Saeed et al., 2015). It is conceivable, as these agents receive prominence as they begin to discharge such risk in the clinic, that trials exploring their benefit on the muscle–bone interface will become more available for assessing the GoF paradigm with such agents. However, until such time, the use of AR ligands to better define such benefits shall remain elusive to the medical community.

Chapter 42

Growth hormone, insulin-like growth factors, and IGF binding proteins

Clifford J. Rosen[1] **and Shoshana Yakar**[2]

Chapter outline

Introduction

I has been 60 years since Salmon and Daughaday first reported the presence of a soluble factor induced by growth hormone (GH) that had insulin-like properties and mediated somatic growth. The subsequent identification of insulin-like growth factors (IGFs) has led to remarkable discoveries and therapeutic advances, particularly in relation to the skeleton. IGFs are 7 kDa peptides that are ubiquitous in nature and regulate cellular proliferation, differentiation, and death (Daughaday et al., 1972). The liver is the main source of circulating IGF-I; fat contributes about 10% and muscle about 5%. Although bone is a very minor contributor to circulating IGFs, it is one of the richest IGF tissues relative to the composition of other peptides

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00042-7

and growth factors (Finkelman et al., 1990). "Local"/bone tissue IGF pools play a predominant role in skeletal modeling and acquisition. IGFs are also highly conserved across species; hence, the physiology of these peptides can be studied in numerous animal models. Although GH has been recognized as the major determinant of liver-derived IGF-I, the balance between skeletal and serum IGF-I has also been clarified, particularly with the relatively recent introduction of targeted genomic engineering.

The importance of the GH/IGF system in aging has undergone intense scrutiny in the last 3 decades. Biological aging is a normal physiological process, part of the continuum from growth to death. Like other organ systems, skeletal homeostasis is maximized during the second and third decades of life, and IGFs are essential for that process. However, trabecular bone loss also begins by the third decade even though the mechanism is not clear. The hypothalamic–pituitary axis is profoundly affected by aging. GH secretion is reduced, resulting in lower levels of circulating IGF-I and IGF-II but higher levels of IGF binding proteins (IGFBPs) 1, 2, and 4 (Kelijman, 1991; Rudman et al., 1981). Early attempts to link age-related bone loss to a suppressed GH-IGF-I axis, or enhanced IGFBP expression, spawned considerable interest in GH and/or IGF-I as therapeutic tools for osteoporosis and sarcopenia. The advent of recombinant gene technology propelled synthetic growth factors into an ever-expanding therapeutic domain, particularly in regard to short stature. Another therapeutic venue for GH has been in its potential utility for the frail elderly. The paradigm that a "somatopause," or GH deficiency state with aging, produces discrete musculoskeletal changes, has never been firmly defined, nor has it been determined whether these changes can be reversed with GH. On the other hand, GH is indicated for individuals with pituitary insufficiency, and long-term studies suggest a major benefit for GH treatment in respect to bone mineral density (BMD) and quality of life. Regardless, more attention has focused on understanding the IGF regulatory system (i.e., IGFs, IGFBPs, Type I and II IGFRs, and proteases that cleave IGFBPs) in relation to bone acquisition and maintenance (Rudman et al., 1990). In this chapter, we will review the cellular and systemic actions of IGFs in order to more fully understand the functional integration of IGF regulatory components with other skeletal and systemic factors. As such, a thorough overview of the physiology of the IGF system, from GH to receptor signaling, is warranted.

Physiology of the GH/IGF/IGFBP system

Growth hormone releasing hormone

In order to appreciate the complexity and redundancy inherent in the IGF regulatory system in bone, an overview of the physiologic aspects of IGF-I regulation is required. Although IGF-I is regulated by genetic, nutritional, hormonal (insulin and thyroxine), and environmental factors, GH is the major regulator of IGF-I expression in tissues and dominates IGF-I

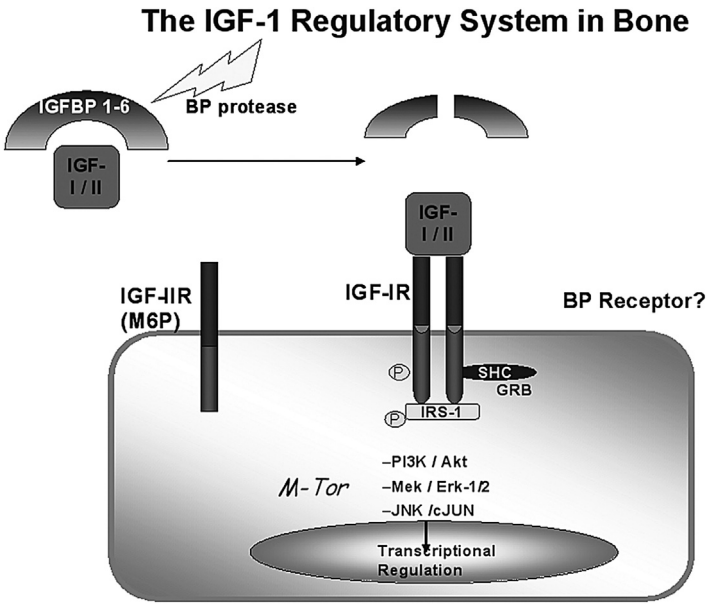

FIGURE 42.1 IGF-I is an endocrine and paracrine/autocrine growth factor. It is regulated by GH via hypothalamic GHRH. The primary source of circulating IGF-I is liver, although bone is a very rich source of IGF-I and IGF-II. Target tissues for IGF endocrine action include fat, muscle, and bone. IGF binding proteins (IGFBPs) circulate in excess of IGFs, but there is a ternary circulating IGF complex that includes the acid labile subunit (ALS) and IGFBP-3. GHBP is a growth hormone binding protein, a circulating GH receptor. The balance between circulating and skeletal IGF-I during growth and maintenance determines the overall effect of this peptide on bone.

levels in the circulation (Fig. 42.1). That process begins in the hypothalamus and ends at the tissue level. The regulation of GH secretion from the pituitary is complex and involves elaboration of discrete neurosecretory peptides from the hypothalamus. Growth hormone releasing hormone (GHRH) is a hypothalamic hormone essential for normal expansion of the somatotrope lineage during pituitary development (Frohman and Kineman, 2002). GHRH, via binding to GHRH receptor (GHRHR), acts on somatotropes to increase GH biosynthesis and secretion and is thought to cause somatotroph proliferation (Petersenn and Schulte, 2000). Release of GHRH is episodic, which accounts for the pulsatile release of GH from the pituitary. A decrease in GHRH is associated with somatotrope hypoplasia, whereas an increase in GHRH is associated with somatotrope hyperplasia (Frohman et al., 2000). Indeed, overexpression of human GHRH (hGHRH) (Mayo et al., 1998) in mice caused increased body size and skeletal gigantism. Excess in hGHRH led to systemic stimulation of endogenous GH and IGF-I, which in turn caused initial increase in bone mass (Tseng and Goldstein, 1998). However, with age, excess GH levels were associated with increases in bone resorption, thinning of the bone cortexes, and compromised mechanical properties. In contrast, a mutation in the mouse GHRH gene (lit/lit) resulted in growth retardation, where mice reached ~50%–60% of normal adult body size (Kasukawa et al., 2000). The blunted GHRH secretion inhibited GH release and IGF-I production in liver and other tissues, leading to significant decreases in BMD and reduced radial bone growth (periosteal circumference) (Kasukawa et al., 2000).

Growth hormone releasing hormone receptor

GHRHR is a G-protein-coupled receptor with seven hydrophobic transmembrane domains. The human GHRHR gene spans 15 kb and comprises 13 exons. The open reading frame was shown to extend 1269 bp and encode a protein of 423 amino acids with a predicted molecular weight of 47-kDa. After release from the hypothalamus, GHRH binds to the GHRHR predominantly located on the pituitary somatotrope (Lin-Su and Wajnrajch, 2002). GHRHR activation leads to the opening of a sodium channel in the somatotrope, which causes its depolarization. The resultant change in the intracellular voltage in turn opens a voltage-gated calcium channel, allowing for calcium influx, which directly causes the release of premade GH stored in secretory granules (Petersenn et al., 2000). The cAMP elevation stimulates protein kinase A, which phosphorylates and activates the transcription factor cAMP response element binding protein, which then stimulates de novo GH production (Petersenn et al., 2000; Muller et al., 1999; Mayo et al., 1995). Autosomal recessive mutations in the GHRHR can result in near total absence of GH and lead to short stature in humans as well as the little phenotype in mice with very low bone mass and reduced fat (Rosen and Donahue, 1998).

Somatostatin

Somatostatin (SMS) is a small (14-amino-acid) but ubiquitous polypeptide that inhibits GH synthesis and release. In concert with GHRH, SMS regulates GH secretion through a dual control system—one stimulatory, the other inhibitory. Several molecular forms of somatostatin, distinct from the native 14-amino-acid peptide, have been isolated. In addition to inhibition of GH release, SMS also inhibits secretion of thyrotropin as well as several pancreatic hormones, including glucagon and insulin. The SMS receptor has been localized to various cell types, especially those of neuroendocrine origin. Localization of this receptor suggests that SMS acts as an endocrine and a paracrine regulator in diverse tissues. A highly potent synthetic analog of SMS, octreotide, has been used therapeutically in acromegaly and diagnostically (in a radiolabeled form) for scintigraphic visualization of neuroendocrine tumors.

Growth hormone

Mechanism of growth hormone secretion

GH and its receptor belong to the cytokine superfamily of receptors and ligands. GH is an anabolic polypeptide hormone produced by the somatotropes of the anterior pituitary gland. GH is secreted under the influence of three hypothalamic hormones: (1) GHRH, which acts via the GHRHR; (2) GHS (also known as Ghrelin), which acts through the GHS receptor; and (3) somatostatin, SMS, which acts on the pituitary to suppress basal and stimulated GH secretion but is not believed to affect GH synthesis (Petersen et al., 2000; Lin-Su et al., 2002). GH secretion is pulsatile (due to the episodic release of GHRH) and circadian with the highest pulse amplitude occurring between 02:00 and 06:00 (Ho and Weissberger, 1990). Puberty has a dramatic effect on the amplitude of GH pulses due to changes in the hypothalamic milieu as a result of rising sex steroid concentrations (Jansson et al., 1985). Through binding directly to growth hormone receptor (GHR), GH has profound effects not only on somatic and bone growth but also on carbohydrate and lipid

homeostasis. GH antagonizes insulin action in muscle and fat. It activates lipase in adipose tissue and leads to mobilization of fatty acids from the adipose tissue (Liu et al., 2004; Heffernan et al., 2001). In liver, GH inhibits de novo lipid synthesis (Liu et al., 2016a,b,c).

Deletion of the GHR gene in mice (GHRKO) results in a 50%−60% reduction in body size associated with low serum and tissue IGF-I levels (Liu et al., 2004). Linear skeletal growth of GHRKO mice is severely inhibited and associated with premature growth plate contraction and reduced chondrocyte proliferation. Long bones of GHRKO mice show reductions in trabecular bone volume and all cortical bone traits (Sjogren et al., 2000). Likewise, bone turnover in the GHRKO mice severely reduced and periosteal bone apposition prematurely ceased. Gene inactivation of the GHR mediator, STAT5ab, in mice resulted in a 50% decrease in serum IGF-I levels, reduced linear growth due to abnormalities in the growth plate, and decreased cortical bone area and width.

Effects of gonadal status on the GH−IGF-I axis

Not surprisingly, the pattern of GH secretion in animals and humans depends highly on age and sex (Ho and Weissberger, 1990; Jansson et al., 1985). Both factors strongly influence the frequency and amplitude of GH pulses, which in turn determines GH basal secretory rates, and the levels of serum IGF-I. Characteristic changes during puberty in rats parallel pubertal changes in humans (Jansson et al., 1985). GH secretion in male and female rats is identical after birth but at puberty, a sexually differentiated pattern of secretion appears with male rats displaying high-amplitude, low-frequency pulses, and with female rats displaying pulses of high frequency but low amplitude (Jansson et al., 1985). In humans, sexual differences in GH secretion during puberty are less pronounced, even though administration of gonadal steroids to prepubertal children increases GH pulses and mimics the pubertal milieu of the hypothalamus. Various sampling techniques (profiles vs. stimulatory tests) and assays with different sensitivities have produced disparate findings. However, spontaneous and stimulated GH peaks in humans are enhanced during puberty. Matched for age and body mass index, young girls were found to have higher integrated GH concentrations than boys (Ho and Weissberger, 1990). Other secretory characteristics, including pulse amplitude, frequency, and the fraction of GH secreted as pulses were similar in both sexes of the same age. In one study, black adolescents (males and females) had higher GH secretory rates than age-matched white adolescents (Wright et al., 1995). Higher GH secretion rates in adolescent blacks could lead to a greater acquisition of bone mass.

Clinical and animal studies have shown that sex steroids can modulate GH secretion at the level of the pituitary, as well as GH's action in target tissues such as liver and bone (Meinhardt et al., 2006). GH levels correlate positively with estrogen and estrogen replacement therapy in postmenopausal women independent of serum IGF-I levels (Norman et al., 2013). Mean pulse amplitudes of GH are lower in older women than in premenopausal women. GH secretory indices in postmenopausal women correlate with serum estradiol but not with total serum androgen levels. During menopause, GH secretion is reduced (Ho and Weissberger, 1990). However, oral administration of estradiol (or conjugated equine estrogens) increases GH secretion as a result of reduced hepatic generation of IGF-I (Ho and Weissberger, 1990; Dawson-Hughes et al., 1986). On the other hand, transdermal administration of 17− estradiol increases serum IGF-I concentration, suggesting that suppression of IGF-I by oral estrogens is due to a "first-pass" hepatic effect. Impaired IGF-I generation in the liver removes a key component of negative feedback on the hypothalamus, resulting in increased GH release.

Effects of the GH/IGF-I/IGFBP system on the aging skeleton

GH exerts a multitude of biological effects on various tissues through the GHR. Regulation of GH bioactivity occurs at several pre- and postreceptor levels. Growth hormone binding protein (GHBP) is a plasma binding protein identical to the extracellular domain of the tissue GHR. GHBP binds exclusively to GH, and most if not all serum GH is bound to this carrier protein. Measurements of GHBP in serum are relatively stable and reflect the endogenous status of the GHR in responsive tissues (Baumann et al., 1989). With advanced age, GHBP concentrations increase substantially.

The GH-IGF-I axis undergoes changes over a life span so that elders have lower spontaneous GH secretion rates and serum IGF-I levels than in younger people (Kelijman, 1991; Rudman et al., 1981; Donahue et al., 1990). Most of these age-related differences are a function of an altered hypothalamic−pituitary set point due in part to changes in lifestyle and nutrition. The GH secretory responses to common stimuli, such as GHRH, clonidine, L-dopa, physostigmine, pyridostigmine, hypoglycemia, and met-enkephalin, but not arginine, reduced with aging. Somatotrope responsiveness to GHRH and arginine does not vary with age, implying that the maximal secretory capacity of somatotropic cells is preserved in elderly people (Corpas et al., 1993).

Age-dependent declines in GH/IGF-I signals have been causally linked to frailty in respect to musculoskeletal function. However, large cross-sectional studies have demonstrated only a weak association between diminished serum IGF-I and age-related bone loss, or between serum IGF-I and BMD (Rudman et al., 1981; Nicolas et al., 1994; Donahue et al., 1990; Corpas et al., 1993; Langlois et al., 1998). In one large cohort study, the lowest serum IGF-I quartile was associated with a significantly greater risk of hip fractures (Garnero et al., 2000). On the other hand, skeletal concentrations of IGF-I, IGF-II, and IGFBP-5 in femoral cortical and trabecular bone decline significantly with age, and these have been associated with low BMD (Rudman et al., 1981; Nicolas et al., 1994; Donahue et al., 1990; Corpas et al., 1993; Langlois et al., 1998). In contrast to the multitude of studies linking serum IGF-I to age-related frailty and muscle performance, differences in GH secretion are difficult to determine due to its normal pulsatility. There is one study in older postmenopausal women relating changes in 24-hour GH levels with BMD (Dennison et al., 2003), and a recent large and prospective study showed that GH replacement therapy in postmenopausal women had positive dose-dependent effects on BMD and sustained effects on reducing patient fracture risk, even 7 years after the GH treatment ceased (Krantz et al., 2015). Lastly, a clinical trial performed in which GH treatment was given to elderly patients with hip fractures and resulted in some positive outcomes (Yeo et al., 2003). Overall, clinical data suggest distinct and overlapping effects of the GH/IGF-I axis on the aging skeleton.

The IGF regulatory system and its relationship to the skeleton

IGF-I, IGF−II, IGFBPs, and IGF receptors

The IGFs are single-chain polypeptides. IGF-I consists of 70 amino-acid residues, and IGF-II has 67 amino acids (Fig. 42.2). They have B, C, and A domains similar to proinsulin as well as a D domain that is not found in proinsulin. This D domain may sterically hinder the interaction of IGFs with the insulin receptor (IR), leading to only weak ligand binding of IGFs to the IR. A number of posttranscriptional and posttranslational variants of IGFs have also been described (Slootweg et al., 1990). These IGFs have variable affinities for IGFBPs and IGF receptors (IGFRs). In vitro, these growth factors may have significantly greater activity than that of native IGF-I or IGF-II, especially those that exhibit weak binding to IGFBPs.

IGF-I and IGF-II differ in their abilities to promote tissue growth due in part to the presence of two distinct IGFRs, IGF-IR and IGF-IIR (Le Roith et al., 1997) (see Fig. 42.1). IGF-IR is a tetramer consisting of two identical extracellular

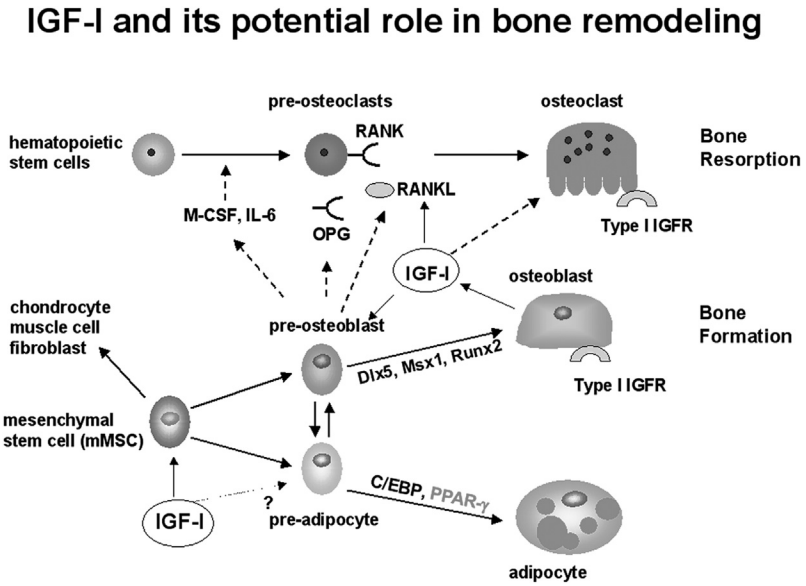

FIGURE 42.2 The IGF regulatory system contributes to bone formation through activation of the IGF type I receptor on osteoblasts. Downstream signaling is via three pathways: 1—PI3 kinase/Akt/mTor, 2—MAP kinase/ERK, and 3—JNK/Jun. PI3K/mTor regulates cell differentiation, while MAP/ERK and JNK/Jun impact cell growth. IGFBPs carry IGFs to the receptor; several proteases can cleave IGFs for binding to the type I receptor. The type II IGF receptor can bind IGF-II and generally is a clearance mechanism for IGF-II; it serves also as a mannose 6 phosphate binding site. Finally, IGFBP receptors have been theorized as possible IGF-independent signaling factors, but none have been proven. However, it is likely that IGFBPs could bind to other receptors (e.g., EGF) and affect cell growth and differentiation.

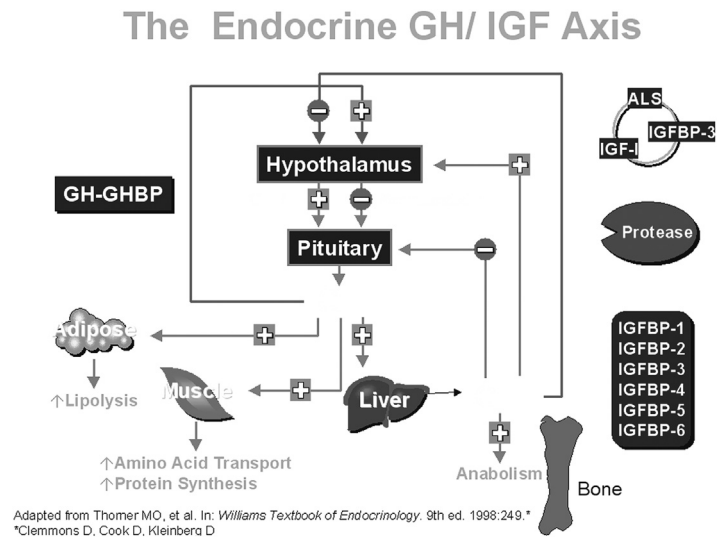

FIGURE 42.3 IGF-I serves as both a mitogen, albeit weak, and a differentiation factor for marrow stromal cells as they enter the osteoblast lineage. In addition, IGF-I can enhance osteoclast differentiation by stimulating RANKL production from stromal cells. There may be a direct effect of IGF-I on osteoclasts, because these cells express the type IGF-1 receptor and signal through IRS-2. IGF-I can also enhance adipocyte differentiation, and its role in promoting marrow adipogenesis is an area of recent investigations. Overall, IGF-I represents a coupling factor for bone remodeling.

αsubunits (conferring ligand-binding specificity) and two identical transmembrane β-subunits (possessing tyrosine kinase activity). IGF-IR resembles the IR and shares amino acid sequence homology (Zeslawski et al., 2001). IGF-II and insulin also bind to IGF-IR but with 2-fold or 15-fold to 1000-fold lower affinities, respectively (D'Ercole, 1996). It has an intrinsic tyrosine kinase activity critical for specific second message generation and indeed, ligand binding to the extracellular domain of IGF-IR results in autophosphorylation and tyrosine phosphorylation of IGF-IR substrates (Fig. 42.2). Tyrosine-phosphorylated insulin-receptor substrate-1 (IRS-1) and SHC bind different effector proteins involved in interconnecting pathways, including Ras/Raf-1/mitogen-activated protein kinase (MAPK, also known as extracellular signal-regulated kinase, or ERK) and phosphatidylinositol 3-kinase (PI3K)/phosphoinositide-dependent kinase-1 (PDK-1)/Akt (Maroni et al., 2004). Activation of the Ras/Raf-1/MAPK pathway is considered critical for cell proliferation, whereas the PI3K/PDK-1/Akt pathway is considered important for cell survival. The protein encoded by the phosphatase and tensin homologue gene deleted on chromosome 10 (PTEN) is a lipid phosphatase that decreases the activation of Akt by dephosphorylating phosphatidylinositol-3,4,5-triphosphate and phosphatidylinositol-3,4-biphosphate. Therefore, PTEN acts as an "off" switch for the PI3K/PDK-1/Akt pathway as well being a tumor suppressor. This tumor-suppressor gene is deleted or mutated in various types of human cancers (Zhao et al., 2004; Sansal and Sellers, 2004). On the other hand, the monomeric IGF type II receptor (IGF-IIR) does not bind insulin but does bind IGF-II, with a 500-fold increased affinity compared with IGF-I (Khandwala et al., 2000).

IGF-IIR exhibits no intrinsic kinase activity but is structurally very similar to the mannose 6-phosphate receptor, which is involved in targeting lysosomal enzymes intracellularly (Le Roith et al., 1997; Sell et al., 1995). Interestingly, it is now clear that in most tissues, except the hepatocytes in the liver, there are hybrid IGF-IR/IR receptors leading to significant cross-utilization between two rather distinct peptides. Hybrid receptors may also explain the growth-promoting activity of insulin, even in skeletal tissue, as well as the hypoglycemic effects of recombinant human IGF-I (rhIGF-I) when administered parenterally. However, there are little data on expression of hybrid receptors in bone.

IGFs stimulate cell proliferation and in some cases late differentiation. However, adequate nutrition is required for the full expression of IGF biologic activity in most tissues, particularly for linear growth. For example, during states of malnutrition, GH production increases but hepatic IGF-I generation is severely impaired. Resistance at the hepatic GHR reduces serum IGF-I and impairs GH bioactivity. The mechanism surrounding these nutrient-sensitive changes has not been clarified, although message stability is clearly reduced by undernutrition. For malnourished children, the result is cessation of linear growth. GH resistance, to lesser degrees, occurs in other conditions such as diabetes mellitus, acute catabolic stresses, and renal insufficiency.

IGFs are produced in virtually every tissue (Rosen et al., 1994). However, with new methods for conditional deletions of IGF-I in various tissues, it is clear that the main source of circulating IGF-I (>75%) is the liver. Other sources include

muscle and adipose tissue (Rosen et al., 1994; Mohan and Baylink, 1990). Together these three sites contribute more than 95% to the circulating IGF-I pool. With acute or chronic hepatic insufficiency, both serum IGF-I and IGF-II levels are decreased, and particularly in hepatic osteodystrophy bone formation, and cortical bone mass is impaired due to the low levels of circulating IGF-I (Liu et al., 2017).

In the circulation, IGFs are bound to six identified IGFBPs with a relatively small but detectable amount of "free" IGF-I, which also circulates but has a very short half-life. GH treatment increases total and free IGF-I levels in a dose-dependent manner. However, rhIGF-I increases "free" IGF-I considerably more than rhGH, likely due to inhibition of GH secretion and the GH-dependent production of the acid labile subunit (ALS) and IGFBP-3, the main carriers of IGF-I in serum. The clinical significance of increases in "free" IGF-I versus that bound to IGFBPs is still not clear. IGF-II also circulates in large concentrations bound to IGFBPs, and a small proportion is free. It generally is produced in much greater amounts during prenatal periods. Absence of IGF-II from genetic deletion in the embryo leads to transient but reversible growth retardation in the first 3 weeks of life that is restored by the secondary increases in endogenous IGF-I (Uchimura et al., 2017). In humans in contrast to mice, there is more circulating IGF-II than IGF-I, and this is true for the skeletal composition of IGFs.

The distribution of IGFs in the serum pool is determined by the relative saturation of IGFBPs. This may explain why treatment with IGF-I may have different tissue effects than treatment with GH. Infusions of IGF-I produce a transient rise in free IGF-I and the suppression of IGF-II, insulin, and endogenous GH (Ebeling et al., 1993). During the course of an IGF-I infusion, however, IGF-I is partitioned into several pools. This is due to the unsaturated nature of the lower molecular weight IGFBPs, and the presence of a large (150-kDa) circulating ternary IGF-binding complex. This complex, composed of IGF-I (or II), IGFBP-3 (or IGFBP-5), and an ALS, is the major circulatory reservoir for both IGFs. Normally, the majority of circulating IGF is bound to this saturated intravascular complex. However, with rapid IGF-I infusions, some IGF-I goes into the lower (50-kDa) unsaturated IGFBP fractions where transport into the extravascular space is possible. Partitioning of IGFs into various binding pools is critical to the biologic activity of GH and IGF-I.

Insulin-like growth factor binding proteins

In the circulation and in all tissues, there are six IGFBPs. IGFBPs 1−6 belong to the same gene family, and several features distinguish these known IGFBPs from one other (Rajaram et al., 1997) (Fig. 42.1). Just as IGFBPs serve important regulatory functions within the circulation, their role at the tissue level is also critical for the full biologic expression of IGFs. Binding of IGFBPs to IGFs normally blocks the interaction between IGFs and IGF-IR and consequently suppresses IGF actions (Kelley et al., 1996; Collett-Solberg and Cohen, 1996). Nevertheless, binding of IGFBPs to IGFs can also protect IGFs from proteolytic degradation and consequently enhances IGF actions by augmenting their bioavailability in local tissues (Kelley et al., 1996; Collett-Solberg and Cohen, 1996). Therefore, most IGFBPs function in a bipotential manner, and their impacts on IGFs depend to a large extent on the posttranslational modification of IGFBPs by phosphorylation and proteolysis (Kelley et al., 1996; Collett-Solberg and Cohen, 1996; Coverley and Baxter, 1997; Claussen et al., 1997). Some IGFBPs (IGFBP-3 and IGFBP-5) exhibit IGF-independent or partially independent effects (Kelley et al., 1996; Mohan et al., 1996, Xi et al., 2016).

The predominant binding protein in serum (and bone) is IGFBP-3, a 43-kDa glycosylated peptide. It is present in large concentrations in the serum and is easily measurable by radioimmunoassay (RIA). As noted earlier, IGFBP-3 is part of a larger saturated ternary complex including IGF-I (or II) and an 80-kDa ALS. The association of these three proteins requires the presence of either IGF-I or IGF-II. In turn, this complex prolongs the half-life of IGFs and provides a unique storage site. The levels of circulating IGFBP-3 are principally controlled by GH (Martin and Baxter, 1988). However, IGFBP-3 synthesis outside the liver is regulated by other endocrine and paracrine factors. At a cellular level, IGFBP-3 has stimulatory and inhibitory effects on IGF-I depending on the cell type and the physiologic milieu. IGFBP-3 action at the cell is characterized by its interaction with IGF-I or −II. In vitro, coincubation of IGFBP-3 with IGF-I can block IGF access to IGF-IR (Rosen et al., 1994; Conover, 1991). Conversely, preincubation of IGFBP-3 in certain cell systems facilitates receptor binding of the ligand by attaching to the cell membrane at a site remote from the receptor. In addition, IGFBP-3 may have IGF-independent actions on cell action. Although a putative IGFBP-3 receptor has not been cloned, IGFBP-3 has been shown to downregulate cell proliferation in certain cell lines and to enhance p53 production. Further regulation of IGF-I by IGFBP-3 can occur in the extracellular space if IGFBP-3 undergoes proteolysis. Enzymatic degradation of IGFBP-3 produces low-molecular-weight IGFBP-3 fragments that differ in their affinities for IGFs (Cohen et al., 1992; Mohan, 1993). There are numerous nonspecific IGFBP-3 proteases, which are produced by various cell types, that can be found in the intra- and extravascular space and are regulated by endocrine and paracrine factors. Prostate-

specific antigen (PSA) is a serine protease that cleaves IGFBP-3 and may be important in defining skeletal metastases with prostate cancer (Nunn et al., 1997).

IGFBPs 1−6 are also found in the circulation and may play both systemic and local roles in the regulation of IGF bioactivity at the tissue level. In contrast to IGFBP-3, these IGFBPs are not fully saturated, and they easily translocate from the circulation into the extracellular space. IGFBP-1 is a 30-kDa peptide produced primarily in the liver. Serum IGFBP-1 levels correlate inversely with circulating insulin, and in poorly controlled insulin-dependent diabetes mellitus (IDDM), serum IGFBP-1 levels are quite high (Brismar et al., 1988). Hepatic IGFBP-1 production is tightly regulated by insulin and substrate availability. However, unsaturated IGFBP-1 could also serve as a reservoir of binding activity for unbound IGF or as the initial binding site for cell-secreted IGF prior to transfer to the more stable GH-dependent 150-kDa complex. Shifts in the levels of IGFBP-1 may alter the distribution of IGFs among other IGFBPs and thus affect the relative distribution of IGFs between the intra- and extravascular space. This mechanism could be critical in controlling metabolic and mitogenic activities of IGFs (Arany et al., 1994). Indeed, mice overexpressing the hIGFBP-1 in hepatocytes (under the a1 antitrypsin promoter) show severe growth retardation (decreased linear growth) with mineralization defects and reduced BMD effects (Ben Lagha et al., 2006) that were likely mediated by sequestering IGF-I. Similarly, in vitro studies have shown that IGFBP-1 is synthesized by osteoblast and could inhibit IGF actions in bone during states of high IGFBP-1 production, such as starvation, and IDDM. In addition, Wang et al. have demonstrated that endocrine IGFBP-1 from the liver can regulate osteoclastogenesis and mediate the bone resorbing actions of fibroblast growth factor-21 (Wang et al., 2015).

Human IGFBP-2 is a 31-kDa protein that preferentially binds to IGF-II (Christiansen et al., 1991). It is found in high concentrations prenatally, and it is the major IGFBP in cerebrospinal fluid. IGFBP-2 is produced by most cells, but based on tissue-specific conditional genetic deletions, most circulating IGFBP-2 arises from the liver (DeMambro—personal communication). Insulin and dexamethasone have been shown to decrease the production of IGFBP-2 in rat osteoblasts (Schmid et al., 1992). Excess rhIGFBP-2 inhibits IGF-I−stimulated bone cell proliferation, bone collagen synthesis, and bone formation. Skeletal concentrations of IGFBP-2 are not nearly as high as the levels of IGFBPs 3−5. Interestingly, IGFBP-2 concentrations increase in puberty, with GH deficiency (GHD), and with malnutrition, as well as during aging. These changes are likely associated with circulating levels of GH and also IGF-I. Khosla et al. (1998) reported that pro-IGF-II coupled to IGFBP-2 is present in the circulation of patients with osteosclerosis due to hepatitis C infections, suggesting that IGFBP-2 may have a permissive role in enhancing skeletal turnover and in binding, through its heparin-binding domain, to extracellular matrices. In addition, animal studies using IGF-II and IGFBP-2 in a complex have demonstrated that this combination can prevent disuse- and ovariectomy-induced bone loss (Conover et al., 2002). Further support for that tenet comes from studies in the IGFBP-2-null mouse that have shown very low bone mass, particularly in males (Demambro, 2010). Importantly, Clemmons and colleagues reported that in appropriate concentrations, IGFBP-2 synergizes with IGF-I by binding to its own extracellular receptor RPTPb that inhibits PTEN activity and thereby enhances AKT-signaling from IGF-I (Xi et al., 2016). A small recombinant IGFBP-2 peptide fragment (HBD1) has also been shown to stimulate bone formation when pegylated and administered intermittently (Kawai et al., 2011).

IGFBP-4 is a glycosylated 24-kDa-binding protein. It is one IGFBP that is consistently inhibitory for IGFs in numerous cell systems. It was originally isolated from skeletal tissue and was found to inhibit IGF-mediated bone cell proliferation (Mohan et al., 1989b; Scharla et al., 1993). IGFBP-4 may serve as a reservoir for IGF-I and IGF-II in bone, and the relative proportions of IGF-I and IGFBP-4 are critical to define its function. Targeted overexpression of IGFBP-4 in osteoblasts under the osteocalcin promoter results in impaired overall postnatal skeletal growth, and reduced bone formation indices, likely via sequestration of IGF-I by IGFBP-4 and consequent impairment of IGF-I action in skeletal tissue (Zhang et al., 2003). The expression of IGFBP-4 in bone cells is regulated by cyclic adenosine monophosphate (AMP), parathyroid hormone (PTH), and 1,25-dihydroxyvitamin D. In addition, IGF-I stimulates IGFBP-4 proteolysis through the target enzyme, pregnancy-associated plasma protein-A (PAPP-A), thereby providing an autocrine/paracrine loop between the ligand and its binding protein (Durham et al., 1994). PAPP-A−deficient mice show growth retardation phenotype with reduced body size and low bone mass, suggesting a complex role for this autocrine−paracrine loop, particularly in the skeleton. Earlier studies showed that circulating IGFBP-4 was linked to hip fracture risk, although later studies have not validated this binding protein as a risk marker (Rosen et al. (1992). It is clear that there is an age-related increase in this binding protein, and in one case, a relatively strong correlation between PTH and IGFBP-4 (Honda et al., 1996)(Karasik et al., 2003).

More recently, it has been shown that global deletion of *Igfbp4* in mice resulted in sex-specific body composition and bone density phenotypes that have led to a reevaluation of the role of IGFBP-4 in peak bone acquisition. Maridas demonstrated that loss of *Igfbp4* affected mesenchymal stromal cell differentiation, regulated osteoclastogenesis, and influenced skeletal development and adult bone maintenance (Maridas et al., 2017a,b). Female *Igfbp4*-null mice had low trabecular and cortical bone mass, while male *Igfbp4* −/− were protected from changes in bone mass. In addition, fat mass

was reduced in both sexes, and IGFBP-4 was found to be essential for adipogenic differentiation and important for depot-specific changes (Maridas et al., 2017a,b).

IGFBP-5 is a nonglycosylated 31-kDa IGFBP produced by osteoblasts and numerous other cell types. It is found in relatively high concentrations in both bone and serum and can be measured by RIA (Nicolas et al., 1994). IGFBP-5 synthesis increased by PTH and other cyclic AMP analogs (Conover et al., 1993). IGFBP-5 is the only IGFBP shown to consistently stimulate osteoblast cell proliferation in vitro, thus increasing the number of osteoblasts. Recent studies suggest that the mitogenic effects of IGFBP-5 may in part be independent of IGFs and mediated through rhIGFBP-5's own signal transduction pathway (Mohan et al., 1995; Andress and Birnbaum, 1991; Schmid et al., 1996; Slootweg et al., 1996; Richman et al., 1999). IGFBP-5 is the most abundant IGFBP stored in the bone, where it is bound to hydroxyapatite and extracellular matrix proteins (Nicolas et al., 1995; Mohan et al., 1995). Intact IGFBP-5's major role in the skeleton may be as a storage component for IGFs, because both IGF-I and IGF-II have very low binding affinity for hydroxyapatite but bind avidly to IGFBP-5 (Rosen et al., 1994). During remodeling, resorption enhances proteolytic cleavage of IGFBP-5. In addition, during formation and mineralization, synthesis and release of IGFBP-5 by bone cells facilitates attachment of IGFs to the newly mineralized matrix (Koutsilieris and Polychronakos, 1992). Intact IGFBP-5 can also be found circulating in the extracellular space. In the circulation, IGFBP-5 can also bind ALS and IGF-I/IGF-II, providing an alternative ternary complex to the main complex ALS−IGFBP-3−IGF-I. In vitro, IGFBP-5 enhances IGF bioactivity, especially in bone. Yet, in vivo, IGFBP-5 action can be either inhibitory or stimulatory depending on the relative concentration of IGF-I and its mode of administration (Salih et al., 2005). Overexpression of IGFBP-5 ubiquitously in mice (under the CMV promoter) associates with reduced BMD in a gender- and an age-dependent manner, with males affected more severely (Salih et al., 2005). Expression of IGFBP-5 in osteoblasts (under the osteocalcin promoter) results in decreases in trabecular bone volume, impaired osteoblastic function, and osteopenia.

IGFBP-6 has been less well studied and slightly differs structurally from the other IGFBPs. Generally, IGFBPs are composed of three domains of approximately equal sizes (Baxter, 2000). The amino- and carboxyl-terminal domains are each internally disulfide-linked and share a high degree of sequence homology across the family (Neumann and Bach, 1999). However, little homology is exhibited among their central L-domains. The disulfide linkages of the amino-domain of IGFBP-6 differ from those of other IGFBPs, whereas the carboxyl-domain disulfides are the same for all IGFBPs so far studied (Neumann and Bach, 1999; Forbes et al., 1998; Chelius et al., 2001). IGFBP-6 differs functionally from other IGFBPs in binding IGF-II, with 20- to 100-fold higher affinity than IGF-I, whereas IGFBPs 1−5 do not have a marked IGF binding preference (Headey et al., 2004). Therefore, IGFBP-6 constitutes a relatively specific IGF-II inhibitor (Bach, 1999).

It is important to note that no mutations have been identified for any IGFBPs in humans. The importance of the ALS in keeping the IGF-I reservoir in serum was not appreciated for many years, until the generation of ALS-null mice (ALSKO) (Uekl et al., 2000) and the identification of several subjects with mutations in the *igfals* gene (Domene et al., 2004). The ALS plays fundamental roles in stabilizing two binary complexes of IGF-I with IGFBPs 3 and 5. Subjects with mutations in the *igfals* gene present with low levels of serum IGF-I, short stature, and reduced BMD (Domene et al., 2010). Similarly, ALSKO mice show ∼60% reductions in serum IGF-I levels; they are born at normal weight but show decreases in body size during early postnatal growth (3 weeks) and remain ∼20% smaller than controls throughout life (Courtland et al., 2010). Detailed morphology of the femurs by microCT revealed reduced total cross-sectional area, cortical bone area, polar moment of inertia, and reduced mechanical properties (by four-point bending assay).

Insulin-like growth factor binding protein proteases

IGF bioactivity is transcriptionally regulated by hormones and paracrine factors but also by their liberation from their respective binding proteins. Tissue-specific proteases provide another level of regulation of IGFs. Binding-protein-targeted proteases have been identified in serum and in various tissues including bone. These proteases alter the binding capacity of IGFs for IGFBPs, thereby freeing IGFs to bind to their respective IGFRs (Rosen et al., 1994). PSA and PAPP-A represent two of the most important circulating serine proteases that liberate IGFs from their IGFBPs, although these two enzymes are not specific for these binding proteins. Bone is a rich source of binding protein proteases. Proteases that cleave IGFBP play a pivotal role in determining the regulatory effects of IGFBPs on IGF actions. Three categories of known proteases proteolyze IGFBPs: (1) kallikreins; (2) neutral and acid-activated cathepsins; and (3) matrix metalloproteinases (MMPs) (Cohen et al., 1992, 1994; Conover et al., 1995; Fowlkes et al., 1994a). PSA is the first serine kallikrein IGFBP protease found to proteolyze both IGFBP-3 and IGFBP-5 into several lower molecular weight fragments and is regulated at least to some extent by testosterone and other androgens (Collett-Solberg and Cohen, 1996; Cohen et al., 1992; Koutsilieris et al., 1992). Its role in mediating the enhanced bone formation found in the lumbar spine of metastatic prostate cancer patients

remains to be determined. However, it is likely one of several mechanisms whereby IGFs stimulate the mitogenic activity of cancer and bone cells.

The concept of "soil and seed" implies that the inherent bioactivity of IGFs, whether bound or free, could stimulate growth of neoplastic tissue after homing of cancer cells to bone. A kallikrein-like IGFBP protease, 7S subunit nerve growth factor, is found to cleave both IGFBP 4 and 6. Cathepsin D is an acid-activated lysosomal protease that can cleave all six IGFBPs. MMPs are able to proteolyze a spectrum of IGFBPs including IGFBPs 2−5 (Collett-Solberg and Cohen, 1996; Fowlkes et al., 1994b; Rajah et al., 1996; Claussen et al., 1997; Marinaro et al., 1999; Braulke et al., 1995; Manes et al., 1999). PAPP-A, which is not specific for IGFBP-4, is activated by IGFs and found within skeletal tissue as well as other organs. Particularly for PAPP-A, it is clear that IGFs can regulate tissue-specific proteases, thereby establishing a complex regulatory loop in which the ligand (i.e., IGF) controls its own bioavailability through transcriptional and nontranscriptional means (Arany et al., 1994). Global deletions of PAPP-A result in smaller mice with reduced bone mass, while targeted transgenic overexpression of PAPP-A in muscle causes hypertrophy and increased body weight (BW). A human inactivating mutation in PAPA-2, a key protease of IGFBP-3 and IGFBP-5 protease, was reported in three subjects. These subjects presented with elevated serum IGF-I levels, elevated levels of IGFBPs 3 and 5, and increased levels of ALS, and showed growth failure and reduced BMD that were attributed to the inability to liberate IGF-I from its major binding proteins (IGFBPs 3 and 5) in the serum and the bone matrix (Dauber, 2016). IGF-I and IGF-II can regulate PAPP-A, but GH does not regulate PAPP-A or other proteases (Angelloz-Nicoud and Binoux, 1995; Skjaerbaek et al., 1998). Insulin and estrogen may also affect IGFBP protease activities (Bereket et al., 1995; Bang et al., 1998; Kudo et al., 1996).

Growth hormone/IGF actions on the intact skeleton

GH−IGF-I systemic effects on body size and longitudinal growth

Liu et al. (1993) were the first to report that newborn mice homozygous for a targeted disruption of Igf1 exhibit a growth deficiency of similar severity to that previously observed in viable Igf2-null mutants (i.e., 60% of normal birth weight). Depending on the genetic background, Liu found that some of the Igf1(−/−) dwarfs died shortly after birth, whereas others survived and reached adulthood (Liu et al., 1993). Conversely, null mutants for the Igf1R gene invariably die at birth of respiratory failure and exhibit a more severe growth deficiency (45% of normal size) compared with wild-type animals. In addition to generalized organ hypoplasia in IgfR(−/−) embryos, including the muscles and developmental delays in ossification, deviations from normalcy were found in the central nervous system and the epidermis. Igf1 −/−/Igf1R(−/−) double mutants did not differ in phenotype from Igf1R (−/−) single mutants, while in Igf 2(−)/Igf1R(−/−) and Igf1(−/−)/Igf 2(−) double mutants, which are phenotypically identical, dwarfism was further exacerbated (i.e., 30% of normal size).

To investigate the role of IGF-I in normal development, Powell-Braxton et al. generated mice with an inactive Igf1 gene. Heterozygous Igf1(±) mice are healthy and fertile; however, they are 10%−20% smaller than wild-type littermates and have lower levels of IGF-I (Powell-Braxton et al., 1993). The size reduction is attributable to a decrease in organ size and bone mass. This was also confirmed by the Kream laboratory, further describing a defect in osteoblast function as the major mechanism for reduced bone mass and size (He et al., 2006).

As previously noted, at birth homozygous mutant Igf1 (−/−) mice are less than 60% the BW of wild-type, and greater than 80% of the pups die perinatally. The survivors are sometimes compromised in terms of homeostatic processes, but the compensatory mechanisms in survivors are interesting. For example, Bikle et al. (2001) analyzed the structural properties of bone from mice rendered IGF-I deficient by homologous recombination. The knockout mice were 24% the size of their wild-type littermates at the time of study (4 months). The knockout tibias were 28%, and L1 vertebrae were 26% the size of wild-type bones. Bone formation rates (BFRs) of knockout tibias were 27% that of wild-type littermates (Bikle et al., 2001). The bones of mutant mice responded normally to GH (1.7-fold increase) and supranormally to IGF-I (5.2-fold increase) with respect to BFR. Cortical thickness of the proximal tibia was reduced 17% in the knockout mouse. However, trabecular bone volume (bone volume/total volume [BV/TV]) in knockout mice compared with wild-type controls was increased 23% in male mice and 88% in female mice as a result of increased connectivity, increased number, and decreased spacing of the trabeculae. Thus, absence of IGF-I causes a smaller bone that may be more compact, almost certainly due to reduced osteoclastic activity as noted earlier. The structural consequences of these bones in respect to fracture have not been studied.

As indicated previously, IGF-I acts in an endocrine (serum) and autocrine/paracrine fashion. Yakar et al. (1999) used the Cre/loxP recombination system whereby mice with loxP-flanked Igf1 gene were mated with albumin-Cre transgenic mice expressing the Cre recombinase exclusively in the liver. Liver-specific Igf1 gene-deletion (LID) mice were

macroscopically normal, suggesting that autocrine/paracrine IGF-I could support normal postnatal growth and development (Yakar et al., 1999). Nevertheless, more extensive developmental phenotyping of the LID mouse revealed a marked reduction in bone volume, periosteal circumference, and medial lateral width consistent with the hypothesis that circulating (endocrine) IGF-I had an important role in bone modeling (Yakar et al., 2002). Moreover, recent studies from Yakar et al. have shown that ALSKO mice also have reduced cortical thickness and enhanced trabecular bone, consistent with an endocrine effect of the circulating IGF complex on skeletal acquisition (Yakar et al., 2006). Finally, double-ALS and IGF-I knockout mice have a major growth phenotype as well as markedly reduced BMD despite normal expression of skeletal IGF-I (Yakar et al., 2006). Thus, it seems likely that both local and circulating IGF-I concentrations are essential for peak bone acquisition and maintenance.

GH has distinct IGF-I–independent effects on the skeleton in terms of linear growth and bone remodeling. However, due to the intimate relationship between these two hormones and their feedback loop regulatory system, it has been extremely difficult to ascertain their independent roles. Double-GH/IGF-I knockout mice exhibit significant growth retardation, suggesting that each of these two growth factors contributes distinctly to longitudinal growth (Lupu et al., 2001). Interestingly, in those studies only 17% of the growth in these mice could be attributed to non-GH and non-IGF-I determinants (Lupu et al., 2001). GH may have its own effect on linear growth independent of IGF-I. For example, GH stimulates longitudinal bone growth in normal rats, but rhIGF-I does not (Schmid and Ernst, 1991). Similarly, transgenic mice that overexpress GH grow to twice their normal size, even though administration of IGF-I to normal mice does not provoke a similar growth response. The presence of both GHR and IGFRs on bone cells complicates the interpretation of GH's action.

Longitudinal growth results from the activity of GH on the cartilaginous growth plate. In human bone, proliferating chondrocytes express IGF-IRs and are responsive to paracrine IGFs secreted by differentiated cartilage cells (Isaksson et al., 1987). The target for GH in the growth plate is the differentiated chondrocyte that synthesizes IGF-I in response to GH. Proliferating chondrocytes respond to locally produced IGF-I by differentiation, which in turn leads to cartilage expansion and linear growth. Thus, GH's stimulatory properties on the endochondral growth plate are mediated largely by induction of IGF-I. A detailed analysis of the growth plate of IGF-I–null mice showed that chondrocyte cell number and proliferation were preserved in IGF-I nulls despite significant (~35%) reductions in longitudinal growth, findings attributed to the high levels of GH in those mice (Wang et al., 1999). Further defects were found in chondrocyte hypertrophy, metabolism, and matrix production, suggesting that IGF-I plays a role in chondrocyte hypertrophy. In a separate study, the direct cellular targets for GH in the growth plate were mapped in normal, GH-deficient, and fasting mice and rats (Gevers, 2009). The authors confirmed that GH stimulated prechondrocytes and early chondrocytes but had no effect on hypertrophic chondrocytes. Chondrocyte-specific IGF-IR gene deletion using the type II collagen I (Col2a1)-driven Cre resulted in a more severe phenotype with shorter bones, disorganized chondrocyte columns, delayed ossification, and undermineralized skeletons (Wang et al., 2011). However, chondrocyte-specific IGF-I gene deletion using the same promoter (Col2a1) resulted in decreased body length, areal BMD, and bone mineral content, likely due to the compensatory effects of circulating IGF-I. Collectively, mouse studies strengthen the "dual effector hypothesis," which suggests that GH affects the resting cells of the growth plate, the perichondrium, and the groove of Ranvier to drive prechondrocytes at this region to proliferate, while locally produced IGF-I drives chondrocyte proliferation (clonal expansion at the proliferating zone) and possibly chondrocyte hypertrophy (Green et al., 1985).

Growth hormone and IGF-I effects on modeling and remodeling

Skeletal modeling during growth, and remodeling during maturation and aging, are the sum of several distinct events beginning with activation of lining cells, differentiation of osteoblast and osteocyte formation, and recruitment of osteoclasts. These processes engage multiple signaling pathways. Besides the large quantities of IGFs, there are other growth factors such as transforming growth factor-beta and fibroblast growth factors that are released during active resorption, ensuring that bone formation will be coupled to bone resorption (Mohan et al., 1991). IGFs also stimulate the differentiation and activation of osteoclasts, possibly in concert with cytokines such as receptor activator of nuclear factor Kappa β ligand (RANKL) and macrophage colony-stimulating factor (Slootweg et al., 1992; Mochizuki et al., 1992). Administration of IGF-I enhances bone formation and bone resorption to a similar degree (Ebeling et al., 1993). The acidic pH within the microenvironment of the osteoclast during active resorption permits activation of several proteases, including PAPP-A (Conover et al., 1994), that liberate IGFs from IGFBPs and allow for further recruitment of osteoblasts and osteoclasts to the remodeling site.

In vitro, GH, IGF-I, and IGF-II all have modest mitogenic effects on bone cell growth (Canalis et al., 1989; Mohan et al., 1988). This suggests that GH could act through IGFs to activate skeletal remodeling. Indeed, GH-induced cell

proliferation can be blocked by simultaneous addition of a specific monoclonal antibody to IGF-I (Mohan et al., 1991). IGF-II, on the other hand, stimulates mitogenesis independent of GH, and even if high doses of IGF-I are coadministered. This implies that IGF-II could regulate osteoblastic proliferation via IGF-IIR (Mohan et al., 1989a). In vitro, both IGF-I and IGF-II are mitogenic to rodent preosteoblasts, and both rapidly increase mRNA expression of the protooncogene, c-fos, 20- to 40-fold in less than 30 min (Merriman et al., 1990). IGFs also stimulate type I collagen synthesis, alkaline phosphatase activity, and osteocalcin in more differentiated human osteoblast-like cells (Mohan et al., 1989; Schmid et al., 1984). Taken together, IGFs are important for osteoblast activity, particularly in response to intermittent parathyroid hormone, but the effects are dose and time dependent.

Insulin-like growth factors, other transcription factors, and osteoblasts

The exact roles of IGFs in osteoblast and osteoclast differentiation are complex. In part this relates to the developmentally sensitive and finely orchestrated process that drives mesenchymal stromal cells (MSCs) into the osteogenic lineage. Not unexpectedly, this pathway involves multiple transcription factors and cytokines as well as IGFs. Hence, IGFs act directly on MSCs to drive cell growth and differentiation and also synergize with other growth factors (e.g., Wnts) and their signaling pathways (Akt, MAPK, p38, etc.) to promote osteogenesis.

Two critical transcription factors that control osteoblast fate are runt-related transcription factor 2 (Runx2) and osterix (Osx). Runx2, core binding factor 1/polyoma enhancer binding protein 2a, a transcription factor that belongs to the Runx family, is the subunit of a heterodimeric transcription factor, PEBP2/CBF, which is composed of α and β subunits (Ito, 1999). Runx2 is involved in osteoblast differentiation and bone formation. In particular, Runx2 is required for early commitment of mesenchymal stem cells into osteoprogenitors and also functions later in osteoblast differentiation to regulate the formation of the extracellular matrix (Ducy et al., 1999). IGF-I influences Runx2 expression through activation of PI3K, Pak1, and ERK (Xiao et al., 2000; Qiao et al., 2004).

Schnurri-3 (Shn3), a large zinc finger protein that functions as an adapter protein in the immune system (Oukka et al., 2002), has been shown to control the posttranslational protein expression level of Runx2 through promoting Runx2 degradation by recruitment of the WW domain containing E3 ubiquitin ligase1 to Runx2. Mice lacking Shn3 display adult-onset osteosclerosis with increased bone mass due to an augmented osteoblast activity (Jones et al., 2006). Glucose itself may also regulate Runx2 post translationally via Smurf1 that is regulated by AMP-activated protein kinase (AMPK) (Wei et al., 2015).

Osx (Sp7) is a master zinc-finger-containing transcription factor of osteoblast lineage progression that is highly specific to osteoblasts in vivo and acts downstream of bone morphogenetic protein (BMP)-2 Smad signaling (Xiao et al., 2000; Qiao et al., 2004; Nakashima et al., 2002). The Osx amino acid sequence predicts three C2H2-type zinc fingers with a high degree of identity to similar DNA-binding domains in the transcription factors Sp1, Sp3, and Sp4. The expression of Osx is more specific to osteoblasts than Runx2 (Nakashima and de Crombrugghe, 2003). Because no Osx transcripts are detected in the skeletal elements of Runx2-null mice, Osx must be downstream of Runx2 in the pathway of osteoblast differentiation (Nakashima et al., 2002). Both IGF-I and BMP-2 are shown to upregulate Osx expression during early osteoblast differentiation (Celil et al., 2005). In mesenchymal stem cells, it appears that both MAPK and PKD signaling pathways serve as points of convergence for mediating the IGF-I- and BMP-2-induced effects on Osx expression (Celil et al., 2005). IGF-I-mediated Osx expression required all three MAPK components (Erk, p38, and JNK), whereas BMP-2 required p38 and JNK signaling, and the synergistic interactions of BMP-2 and IGF-I were also disrupted by PKD inhibition (Celil et al., 2005).

It should be noted that Runx2-independent pathways of ossification also exist, including (1) the Wnt signaling pathway; (2) the Msx2-dependent vascular ossification pathway; and (3) Osx induction via Dlx5, a homeobox transcription factor, which acts downstream of BMP-2 (Kato et al., 2002; Cheng et al., 2003; Lee et al., 2003). These studies suggest additional pathways may act in parallel to, or independent of, Runx2 to regulate Osx expression during osteogenic lineage progression. Indeed, in the canonical Wnt signaling pathway, there is cross talk with the IGF pathway. For example, β-catenin binds to IRS-1 as well as other factors to enhance its transport from the cytoplasm into the nucleus where it can affect a whole series of downstream target genes.

In sum, IGFs enhance differentiation of mesenchymal stem cells. Targeted ablation of IGF-I in osteoblasts resulted in severe growth retardation and impaired bone mineralization. Reduced bone formation in Col1a2-IGF-IKO mice is attributed to decreased osteoblast function (Kesavan et al., 2011). Conditional deletion of IGF-IR in osteoblasts using the osteocalcin promoter-driven Cre recombinase led to low bone mass (Zhang et al., 2002; Wang et al., 2007). Histomorphometric indices demonstrated sufficient osteoblasts but reduced bone formation and mineralization rates, thereby implying that IGF-I must be important in late differentiation and mineralization (*See IGF actions on the skeleton*).

Moreover, IGF-I is essential for adipogenic differentiation and likely is downstream of peroxisome proliferator-activated receptor gamma (PPARγ) activation. Because mesenchymal stromal cells can enter several distinct lineages, the precise timing of IGF-I action and other factors, active in the marrow niche, some of them undefined, ultimately determine cell fate (Fig. 42.2).

Insulin-like growth factors and osteoclasts

In addition to regulating osteoblast function, several groups have shown that skeletal IGF-I can stimulate osteoclast recruitment and differentiation either directly through IGF-IR or via RANKL expression (Mochizuki et al., 1992; Rubin et al., 2002). This would place IGF-I in the category of a "coupler" for bone remodeling. Indeed, IGF-I-null mice are growth retarded, and most die after birth. Those that survive are very small and have developmental defects in brain, muscle, bone, and lung, and are infertile. However, their skeletal phenotype is particularly striking and is characterized by very little cortical bone but an increased trabecular bone volume fraction (Bikle et al., 2001, 2006). Recently, it has been demonstrated in vivo and in vitro that the absence of IGF-I impairs osteoclast recruitment and activity, although the exact mechanism is unknown (Wang et al., 2006).

Insulin-like growth factors and osteocytes

Osteocytes are terminally differentiated osteoblasts buried in the mineralized matrix and are the most abundant cells in bone. Osteocytes play fundamental roles in bone remodeling and bone response to mechanical loading. These cells are the first responders to crack or fracture and are responsible for sending signals to recruit osteoclasts to resorb and remodel the damaged site. The roles of GH or IGF-I in osteocytes function were partially elucidated recently. Using the DMP-1 promoter-driven cre, the GHR, IGF-IR, or IGF-I genes were inactivated in osteocytes. Ablation of GHR in osteocytes did not affect body weight, body length, body composition, or organ weights but led to slender bones with reduced total cross-sectional area and cortical bone area in both sexes. Likewise, Dmp-1-mediated *Igf-1 receptor (Igf-1r)* gene−deleted mice (DMP-IGF-IRKO) showed normal body and organ weights but exhibited significant reduction in cortical bone area and a reduced cortical bone thickness in both sexes. Notably, cortical bone area decreased by ∼20% while marrow area increased by 40%−50% compared with controls, suggesting that endosteal resorption increased following IGF-IR ablation in osteocytes. A similar approach was used to knock down IGF-I in bone (DMP-IGF-IKO mice) (Sheng et al., 2013). Skeletal characterization showed slender bones with reduced total cross-sectional area and reduced cortical bone area in both sexes of DMP-IGF-IKO mice. Collectively, inactivation of the GH/IGF-I axis in osteocytes leads to significant decreases in cortical bone with minimal (∼5%) effects on linear bone growth, suggesting that this axis regulates not only longitudinal growth but also radial bone growth via its actions on osteocytes.

As indicated above, osteocytes are the bone mechanosensors that initiate the anabolic response to loading or trigger the resorption process when damage occurs. In vitro and in vivo models of mechanical loading suggest that IGF-I mediates these processes. *Igf1* gene expression increases following mechanical stimulation (Lau, 2006; Reijnders et al., 2007). Mice with *Igf1* gene deletion in osteocytes showed blunted bone response to four-point bending, which was associated with significant decreases in the expression levels of cox2, c-fos, and *igf-1* (the early mechanosensitive genes) in bone and reduced Wnt signaling (Lau, 2013). Skeletal unloading, on the other hand, induced bone loss that was also shown to be dependent on IGF-I. Hind limb suspension in rats inhibited activation of IGF-IR signaling pathways and was associated with a reduced number of osteoblast progenitors, their differentiation, and reduced bone formation (Sakata et al., 2004).

Energy utilization by skeletal cells and the role of IGF-I

Both modeling and remodeling are energy requiring processes. Hence, understanding substrate utilization and ATP production, particularly by osteoblasts, is critical to defining the processes inherent in peak bone mass and maintenance. Glucose has long been known as a major nutrient for osteoblasts and other cells, and IGF-I can modulate glycolysis. Recent work with radiolabeled glucose analogs has confirmed a significant uptake of glucose by bone in the mouse (Wei, 2015; Zoch, 2016). The Glut transporters appear to be mainly responsible for glucose uptake in osteoblast lineage cells. Expression studies detected Glut1 and Glut3 in osteoblastic cell lines (Thomas et al., 1996; Zoidis et al., 2011). More recently, Glut1 was shown to be a major transporter in primary osteoblast cultures and modulates the post-translational modification of Runx2 by suppressing AMPK and blocking ubiquitination of Runx2 (Wei, 2015); selective deletion of Glut1 in osteoblast precursors suppressed osteoblast differentiation in vitro and in vivo. However, others have reported that Glut4 increases in neonatal calvarial osteoblast cultures in response to beta-glycerophosphate

and ascorbate, or insulin, even though genetic deletion of Glut4 does not cause an obvious skeletal phenotype (Li et al., 2016).

Recent work has linked the bone anabolic function of Wnts and IGFs with increased aerobic glycolysis in osteoblast-lineage cells (Esen et al., 2013; Lee et al., 2017). Both share common regulatory pathways, the former activating mTORC2 (mammalian target of rapamycin complex 2) and Akt that in turn acutely increase the protein abundance of a number of key glycolytic enzymes (e.g., Hk2, Pfk1, Pfkfb3 [6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase 3], and Ldha), the latter acting through IRS-1 and AKT. But IGF-I is also a major target of PTH's anabolic actions on osteoblasts. PTH has been shown by several investigators to increase glycolysis, and that is presumed to be the source of ATP for enhanced collagen synthesis and bone formation (Zoidis et al., 2011). Studies in MC3T3-E1 cells have uncovered that PTH stimulates aerobic glycolysis via activation of IGF signaling, which in turn activates the PI3K-mTORC2 cascade and upregulates metabolic enzymes such as Hk2, Ldha, and Pdk1 in a manner analogous to the Wnts. Importantly, genetic studies have demonstrated that deletion of either *Igf1* or *Igf1r* in osteoblasts essentially abolishes the bone anabolic effect of PTH in mice (Bikle et al., 2002; Wang et al., 2007). And blocking glycolysis with 2DG or other inhibitors completely prevents osteoblast differentiation. Hence, the mechanisms that allow IGFs to drive osteoblast function are multiple and include several fuel pathways. Undoubtedly, the major driver for osteoblast differentiation is glucose, but fatty acids and glutamine contribute in a temporal-specific manner (Lee et al., 2017).

Pathogenic role of GH/IGF/IGFBPs in osteoporosis

Effects of growth hormone deficiency on bone metabolism

GHD in childhood is associated with growth failure and short stature. However, the effects of GHD on BMD in prepubertal children have been more difficult to quantify, in part because of the mixed hypopituitary syndromes that often accompany GHD. Thus, there is a paucity of studies examining BMD status in GH-deficient children. By single-photon absorptiometry of the wrist, children with GHD have been found to have low BMD (Wuster et al., 1992). Serum concentrations of osteocalcin are also reduced in children with GHD, but the response of osteocalcin to GH administration does not correlate with linear growth (Delmas et al., 1986). In several cross-sectional studies of adults with GHD, lumbar spine BMD was reduced compared with that of age-matched controls (Wuster et al., 1991; Johansson et al., 1992; Hyer et al., 1992; Rosen et al., 1993; Bing-You et al., 1993; DeBoer et al., 1994). In one group of adult GHD patients, the lowest spinal BMD was found in people who were previously treated with rhGH during childhood (Wuster et al., 1991, 1993). This degree of osteopenia was not due to cortisone or thyroxine substitution, because the BMDs of patients on hormonal substitution did not differ from those without hormone replacement (Wuster et al., 1993). In that same study, Wuster et al. (1991) showed an increased prevalence of vertebral osteoporotic fractures among GH-deficient adults. Kaufman et al. (1992) confirmed low BMD in GHD adults with or without hormonal deficiencies. However, Kann et al. (1993) found no difference in the apparent phalangeal ultrasound transmission velocity of GHD patients compared with age- and sex-matched controls. De Boer et al. (1994) noted that low BMD was partly explained by reduced body height, but with correction for body mass index, BMD was still significantly reduced compared with age- and sex-matched controls (Wuster et al., 1992).

The cause of low BMD in adult GHD has been thought to be due to insufficient bone acquisition during the adolescent years (DeBoer et al., 1994). This hypothesis is supported by bone histomorphometry. In 36 men with GHD (primarily of juvenile onset), there were increased eroded surfaces, increased osteoid thickness and increased mineralization lag time, all indicative of delayed mineralization that was probably due to changes in the timing of puberty (DeBoer et al., 1994; Bravenboer et al., 1994). In support of those histomorphometric changes, low serum levels of osteocalcin have been detected in some adult GHD patients (Delmas et al., 1986). This is in sharp contrast to patients with normal GH secretion but multiple pituitary hormone deficiencies, where serum osteocalcin levels are normal but there is markedly increased urinary pyridinoline excretion (de la Piedra et al., 1988). Fracture rates are higher in individuals with GHD, and it is established that chronic GH treatment in GHD prevents further fractures, although interestingly it does not affect quality of life (Krantz, 2015).

Effects of growth hormone excess on bone mass and bone turnover

Chronic GH excess in adults (i.e., acromegaly) has been a surrogate model for studying the effects of GH on the skeleton. Acromegaly is a multisystem progressive disorder caused by uncontrolled secretion of GH, most commonly by a pituitary adenoma (Capatina et al., 2015). A major biochemical characteristic of acromegaly is the increased production of liver-derived IGF-I. In fact, most systemic complications associated with acromegaly can be attributed to the effects of

IGF-I, which mediates the somatic and some of the metabolic effects of GH (Capatina et al., 2015). Subsequently, the objectives of treatment are twofold—inhibition of tumor growth and controlling the secretion of IGF-I.

The effects of excess GH on the skeleton in acromegaly are complicated by GH-mediated changes in vitamin D metabolism in the kidney, secondary effects of GH on PTH production, and gonadotropin secretion (Ezzat et al., 1993; Bouillon, 1991). Increased bone turnover has been reported in acromegaly by biochemical markers and histomorphometric studies (de la Piedra et al., 1988; Ezzat et al., 1993). Studies reporting BMD in patients with acromegaly used different morphometric modalities, and the findings are inconsistent. However, several cross-sectional studies suggested that acromegaly associated with increased skeletal fragility, particularly increased vertebral fracture risk (Wassenaar et al., 2011; Mazziotti et al., 2008; Ueland et al., 2002; Kayath et al., 1997) that does not always correlate with decreased BMD. In one study, computed tomography (CT) measurements of the lumbar spine revealed that trabecular BMD was elevated in only 1 of 14 patients with active acromegaly (Ezzat et al., 1993). This may have been due to hypogonadism in the acromegalics. Wuster et al. (1993) recently studied five patients with active acromegaly treated with octreotide for 5 years. All had achieved normal IGF-I levels during therapy. Spinal BMD was initially decreased in all five patients but normalized in three of them with octreotide. All patients remained eugonadal throughout follow-up.

As noted earlier, biochemical markers of bone turnover are altered in acromegaly. Many of these changes can be related to alterations in gonadal status during disease and its treatment. However, changes in bone turnover with acromegaly reflect persistent coupling of the remodeling cycle with increased resorption and formation. Serum osteocalcin and skeletal alkaline phosphatase are increased in acromegaly, as are urinary calcium and hydroxyproline excretion (de la Piedra et al., 1988; Ezzat et al., 1993). Although serum calcium, total alkaline phosphatase, and phosphorus are usually normal, there may also be increased synthesis of 1,25-dihydroxyvitamin D. This results from significant intracellular phosphate shifts due in part to an increased circulating IGF-I.

Changes in the GH−IGF-I axis in patients with osteoporosis

For several years, attempts have been made to link GH secretory status with low BMD and osteoporosis. As noted previously, efforts to find a relationship between GH secretion and age-related bone loss have been conflicted at best. However, other investigators have examined the relationship of GH to BMD in the immediate menopausal period. These efforts gained prominence in the 1980s when it was reported that GH secretion in patients with osteoporosis was reduced even after stimulation with L-arginine. Low serum IGF-I, IGF-II, and IGFBP-3 levels (by RIA) were noted in 98 females with postmenopausal osteoporosis compared with 59 normal controls and 91 patients with osteoarthritis or degenerative bone disease (Wuster et al., 1993). In a cross-sectional study of a large cohort of older postmenopausal women from Framingham, Langlois et al. (1998) reported very strong correlations between the lowest quintile of IGF-I and BMD at the spine hip and radius. Bauer et al. reported that in the Study of Osteoporotic Fractures, women in the lowest quartile for serum IGF-I had a 60% greater likelihood of hip or spine fractures, even when controlling for BMD (Bauer et al., 1997). Gamero et al. (2000) noted that low serum levels of IGF-I were associated with a significantly greater risk of hip fractures among a large cohort of older postmenopausal women in France. In a study of 61 community-dwelling men over the age of 27, who were randomly selected from the Calgary cohort of 1000 subjects in the Canadian Multicentre Osteoporosis Study, IGF-I was found to be a significant predictor of BMD at the total hip, femoral neck, and femoral trochanter neck (p # 0.001). Szulc et al. (2004) evaluated the correlation of BMD with serum IGF-I in a large cohort of 721 men aged 19−85, considering age, BW, 17 b-estradiol, free testosterone, and PTH. Serum IGF-I decreased with age (r 5 20.44, p 5 0.0001). IGF-I correlated positively with BMD at the whole body and at the third lumbar vertebra. BMD of the total hip was 6% higher in men in the highest quartile of IGF-I than in men in the lowest quartile. However, others have not found a relationship between serum IGF-I and BMD in patients with fractures, in postmenopausal osteoporosis, or in otherwise healthy subjects (Kassem et al., 1994; Lloyd et al., 1996; Rudman and Mattson, 1994).

In male osteoporotic patients, serum IGF-I and IGFBP-3 concentrations are low and correlated with lumbar BMD (Ljunghall et al., 1992; Nakamura et al., 1992). Johannsen et al. (1994a,b) noted that among healthy males, IGFBP-3 was the best predictor of femoral BMD. (Kurland et al., 1997) reported that younger males with idiopathic osteoporosis had low serum levels of IGF-I in relation to age-matched controls. Similar results were noted in premenopausal women (Rubin et al., 2005). Moreover, those men also had low rates of bone turnover by histomorphometry but normal GH dynamics (Kurland et al., 1998), similar to women with idiopathic osteoporosis (Shane). Of potential pathophysiological importance is the observation that patients with osteoarthritis have higher concentrations of IGF-II than those of normal controls (Wuster et al., 1993; Mohan et al., 1991). Other studies have related serum IGFBP-4 and IGFBP-5 due to aging and low bone mass, although causality was not established (Karasik et al., 2002). Also, Dennison and colleagues reported that low

24-hour GH profiles were associated with low BMD of the lumbar spine in older British women (Dennison et al., 2003). Further longitudinal studies will be required to determine the precise relationship among IGFs, GH, and osteoporosis.

GH and IGF-I as treatments for skeletal disorders

Anabolic agents can directly stimulate bone formation and therefore might have great potential to decrease fractures. Therefore, there is an emerging interest in developing anabolic agents including PTH, PTHrp, GH, and IGF-I to treat osteoporosis (Rubin et al., 2002).

Growth hormone treatment for skeletal disorders

GH has direct and indirect effects on bone depending on age and skeletal maturity. Indirectly, GH can enhance bone mass through its effects on muscle mass and calcium transport in the gut through IGF-I—mediated increases in 1 alpha hydroxylase that generates active 1,25 vitamin D, as well as by suppressing adipocyte differentiation in different fat depots including bone marrow (Fleet et al., 1994; Bianda et al., 1998; Menagh et al., 2010). In addition, GH can directly stimulate bone remodeling and increase endochondral growth through its actions on the osteoblast. Overall, GH is considered essential for the growth and maintenance of skeletal mass. Moreover, it is established that for virtually all cohorts of GHD subjects, whether onset is in childhood or adulthood, male or female, there is reduced areal BMD. In some but not all studies, volumetric BMD, measured either by CT or areal-adjusted algorithms, was reduced in children with GHD (Baroncelli et al., 1998). In the largest observational trial of GHD subjects to date—i.e., KIMS—GHD was associated with a marked increase in fracture risk, particularly when compared with age-matched normal controls (Rosen et al., 1997; Wuster et al., 2001). Hence, there is a strong rationale to treat GHD in children.

Substantial differences between the direct and indirect (i.e., via IGF-I) effects of GH on the osteoblast, the marrow stromal cell precursor, and the osteocyte may partially explain changes in skeletal responsiveness to GH and IGF-I. For example, exogenous GH stimulates longitudinal growth in normal rats, but rhIGF-I does not (Schmid et al., 1991). Similarly, transgenic mice who overexpress GH grow to twice their normal size, whereas exogenous administration of IGF-I is far less efficient in stimulating long bone growth. Thus, despite the fact that GH induces IGF-I production in the skeleton and elsewhere, treatments with GH and with IGF-I are not equivalent. In general, skeletal responsiveness to GH and IGF-I depend on the species, GH status of the animal, and mode of administration. Systemic side effects of rhGH and rhIGF-I therapy may differ substantially.

Growth hormone treatment for children with insufficient GH secretion

Intermittent (daily or three times weekly) injections of rhGH to children with GHD resulted in a prolonged and sustained GH profile with resultant catch-up growth evident during the first year of treatment (Rappaport and Czernichow, 1993). This increase in skeletal growth was accompanied by a rise in serum levels of type I procollagen peptide. Although dosage schemes varied between the United States and Europe (0.1 mg/kg/tiw [USA] to 0.7 U/kg/week[Europe]), there was a strong dose-related growth response to rhGH (de Muinck Keizer-Schrama et al., 1992). Indeed, most studies of preadolescent GHD children have shown significant improvements in areal BMD with GH replacement. However, the skeletal response to GH depends on several factors including (1) GH secretory status; 2) pretreatment IGF-I levels; (3) pretreatment height velocity; and (4) GH dosage (de Muinck Keizer-Schrama et al., 1992). The rate of change in serum IGF-I (rather than the absolute level of IGF-I attained by GH treatment) is a relatively nonspecific predictor of growth, as are procollagen-I and osteocalcin concentrations (Delmas et al., 1986; de Muinck Keizer-Schrama et al., 1992). Serum procollagen III levels correlate with growth rates during GH treatment (Delmas et al., 1986).

Linear growth is a measurable response to exogenous GH, but changes in BMD in children are more difficult to quantify. In some studies, bone mineral content (BMC) is increased during GH treatment to a greater extent than expected for change in bone size (Inzucchi and Robbins, 1994). In one of the longest intervention trials to date, 26 GHD children were given rhGH (0.6 IU/kg per week) for 12 months (Saggese et al., 1993). Baseline radial BMC z scores (corrected for their chronological, statural, and bone ages) were significantly reduced, as were serum osteocalcin and procollagen peptide levels. Treatment with rhGH six times per week increased BMC and normalized the z scores of the radius in nearly 50% of the subjects. Serum levels of procollagen peptide during the first week of treatment were positively related to growth velocity at 6 and 12 months and radial BMC at 12 months. In another nonrandomized trial, 32 children with GHD aged 7—16 were treated for nearly 1 year with rhGH and found to have significant improvements in areal BMD and final adult

height (Saggese et al., 1996). In adolescent GHD subjects, GH replacement had more variable effects on peak bone acquisition. Even with higher rhGH doses, significant changes in volumetric BMD have not been found, nor has acceleration in skeletal maturation (Baroncelli et al., 2004; Mauras et al., 2000; Kamp et al., 2002). Controversy continues as to whether GH treatment impacts BMD in children with idiopathic short stature or children born small for gestational age (SGA). Arends et al. (2003) demonstrated that prepubertal SGA children given 33 ug/kg/d of rhGH for 3 years had significant increases in height, areal BMD, and areal adjusted spine BMD. However, rhGH administered to children with idiopathic short stature who had low volumetric BMD did not result in further increases in BMD despite significant changes in lean body mass and bone turnover indices (Hogler et al., 2005). In cerebral palsy children (aged 4−15 years), 18 months of rhGH (50 mg/day) in a randomized placebo-controlled trial RPCT, areal BMD increased significantly, as did height, IGF-I, IGFBP-3, and osteocalcin (Ali et al., 2007). In sum, rhGH improves adult height, and areal BMD in prepubertal GHD children treated for at least 1 year. These changes are accompanied by favorable effects on body composition, muscle strength, and overall quality of life. It is still uncertain, however, how beneficial these GH-induced effects are in late adolescent GHD subjects in non-GHD states, or whether true volumetric BMD is significantly improved by long-term GH therapy.

Growth hormone administration for healthy adults

Although there were striking differences between longitudinal growth in children and remodeling in adults, criteria that determine rhGH responsiveness in children still may be relevant for older individuals. It has already been established that biochemical and histomorphometric responses to rhGH in children may differ according to their GH secretory status. The same principle probably holds for adults treated with GH. Three adult populations have been studied before and after GH treatment in order to examine predictors of skeletal responsiveness: (1) healthy adults, 2) GHD adults, and (3) elderly men and women with/without osteoporosis.

Initial studies with rhGH in adults focused primarily on changes in body composition. Short-term treatment with rhGH leads to a decrease in adiposity and an increase in lean body mass (Crist et al., 1988). There is also a marked shift in extracellular water (Holloway et al., 1994). Detailed analysis of skeletal biomarkers during GH treatment (1990) was reported in 20 male volunteers (ages 22−31) given a relatively large dose (0.1 IU/kg) of rhGH twice daily for 7 days. Serum osteocalcin increased after 2 days of treatment and remained elevated for 6 months. Bone alkaline phosphatase decreased initially (during the 7 days of GH treatment) but then increased slightly over 6 months (Brixen et al., 1990). Serum calcium and phosphate increased but only during the 7-day treatment phase. Like bone formation indices, urinary markers of bone resorption (urinary Ca/Cr and hydroxyproline/creatinine) rose during treatment and remained elevated for up to 4 weeks after the discontinuation of therapy.

Treatment with rhGH stimulates bone remodeling. More importantly, the anabolic effect on bone may persist well beyond discontinuation of GH. Early (2-day) and late (2-week) osteocalcin responses imply that GH can stimulate existing osteoblasts and enhance recruitment of new osteoblasts. Still, it is uncertain whether those effects are mediated through IGF-I. For example, Brixen et al. (1990) were unable to find a significant correlation between the rise in serum IGF-I and an increase in osteocalcin or bone alkaline phosphatase. The absence of a significant correlation between bone formation markers and serum IGF-I, however, may be due to the relatively small changes in of serum IGF-I.

Growth hormone treatment for adult-onset GH deficiency

GHD can be diagnosed by insufficient GH secretion in serial measurements in response to provocative stimuli (GHRH, insulin, glucagon) and serial GH measurements. The majority of adult patients treated with rhGH have either idiopathic GHD or a history of previous central nervous system/pituitary-hypothalamic tumors. Early trials with rhGH replacement therapy examined changes in muscle mass, muscle strength, and body fat. Daily administration of subcutaneous rhGH to GHD patients produced a marked rise in serum IGF-I and an increase in muscle mass and basal metabolic rate (Jorgensen et al., 1991). Some of those anabolic changes were noted soon after the initiation of rhGH. For example, mean nitrogen retention during the first 15 days of rhGH treatment was as much as 2.8 g per day (approximately 20 g of muscle mass) (Valk et al., 1994). GH treatment can also increase the total cross-sectional area of thigh muscles and quadriceps as well as improve hip flexors and limb girdle strength (Jorgensen et al., 1991; Valk et al., 1994). At least one group has suggested that rhGH can increase the number of type II muscle fibers. Total fat mass, however, consistently decreases during rhGH treatment (Jorgensen et al., 1989, 1991).

Several biochemical parameters reflect the pharmacologic action of GH on the skeleton. Serum calcium, osteocalcin, and urinary hydroxyproline all increase, while PTH declines slightly during rhGH treatment. Newer and more sensitive

markers of bone turnover also reflect changes during rhGH treatment. Urinary deoxypyridinoline increases threefold, and the amino-terminal propeptide of type III procollagen doubles, during 4 months of daily rhGH (Christiansen et al., 1991; Johansen et al., 1990). After cessation of rhGH treatment, deoxypyridinoline excretion decreases, but type III procollagen levels remain higher than controls for several months (Johansen et al., 1990). Serum osteocalcin and procollagen 1 N-terminal propeptide markers of bone formation also increase significantly with rhGH therapy in adults, similar to the change noted in children.

If prolonged GHD in adults results in profound changes in the musculoskeletal system, then GH replacement would be expected to enhance muscle performance and subsequently BMD. When 0.25 IU/kg/week of rhGH was administered to 12 GHD adults for 1 year, there was a marked increase in trabecular BMD (measured by single- and dual-energy QCT of the spine) at 6 and 12 months. At 12 months proximal and distal forearm BMC increased, midthigh muscle area was greater, and fat cross-sectional area decreased. Because the rise in spine BMD was noted with both single- and dual-energy CT measurements of the spine, it is possible that the enhancement in BMD was significant and not related to a reduction in marrow fat.

Several groups have performed longer nonrandomized trials with rhGH in the GHD syndrome. Changes in BMD were not significant at 12 months; however by 24 and 36 months BMD has been reported to increase by as much as 5%−8% in the spine (Janssen et al., 1998; Baum et al., 1996; Papadakis et al., 1996). Krantz et al., in a randomized double-blinded control trial, demonstrated that 10 years of GH could reduce fractures (Krantz et al., 2015). In addition, other investigators have reported a concomitant increase in muscle strength after 2 years of rhGH treatment. It appears from those studies that individuals with earlier onset of GHD, as well as those with the lowest BMD, had the greatest likelihood of showing significant changes in BMD with rhGH. More recently, four randomized placebo-controlled trials have been conducted in adult GHD subjects treated with rhGH for at least 18 months. In one study of men only, BMD increased in the lumbar spine by 5.1% and the femoral neck by 2.4% (Baum et al., 1996). In another study of both men and women, there were no significant differences in BMD after 18 months between the group treated with rhGH and those taking placebo (Sneppen et al., 2002). In the third trial, men but not women showed increases in spine BMD after 24 months of rhGH compared with untreated controls. The most definitive and most recent study was a true randomized placebo-controlled trial using physiologic rather than pharmacologic doses of rhGH in GHD patients. In contrast to the three previous studies, changes in serum IGF-I were titrated within the normal range rather than to the supraphysiologic levels achieved with higher doses of rhGH. Interestingly, in that study of 67 men and women, spine BMD increased after 18 months by nearly 4% in men, which was statistically different from the placebo control but increased much less in women, and those changes were not statistically different from placebo (Snyder et al., 2007). Neither gender showed a significant change in hip BMD in response to rhGH in doses up to 12 ug/kg/day. In sum, there are clear sex- and dose-dependent effects of rhGH on BMD in GHD subjects treated for at least 18 months.

Growth hormone administration to elderly men and women

As previously noted, elderly people have lower GH secretory amplitudes and reduced serum levels of IGF-I and IGFBP-3 compared with younger adults (Kelijman, 1991; Rudman et al., 1981; Donahue et al., 1990). Moreover, the pulse frequency for GH is reduced in the elderly population. Based on these data, it was assumed that skeletal responsiveness to GH in elders would be identical to that seen in GHD patients. In elderly men, one group reported a blunted serum IGF-I response to 0.1 mg/kg GH (36% lower) compared with that in younger men or adults with GHD (Lieberman et al., 1994). However, Rosen et al. (1999) and others have noted that the generation of IGF-I after various doses of rhGH to frail elders was not associated with significant GH resistance. GH replacement for adult GHD or for pharmacologic treatment results in similar IGF-I responses independent of age. Side effects such as fluid retention, gynecomastia, and carpal tunnel appear to be more common in the elderly who are given rhGH compared with young adults who have GHD.

Rudman gave 21 men over age 65 0.03 mg/kg of rhGH three times per week (as a subcutaneous injection), or placebo, in a randomized controlled trial. Twelve men received rhGH while nine men served as observational controls. The men were selected on the basis of a low serum IGF-I concentration (Rudman et al., 1990). The rhGH produced a threefold rise in circulating IGF-I, an increase in lean body mass (as measured by 40K analysis), and a decline in total adipose mass. BMD of the lumbar vertebrae (L1−L4) as measured by dual-energy X-ray absorptiometry (DXA) increased 1.6% after 6 months in the treatment group, while no change was noted in controls. Biochemical markers of bone turnover were not examined, and no changes in BMD were detected in the mid or distal radius or three areas of the hip. Furthermore, the spinal BMD changes at 6 months were not sustained at 1 year.

Marcus et al. studied the effects of rhGH in 16 men and women over age 60 (Marcus et al., 1990). Daily doses of rhGH (0.03, 0.06, or 0.12 mg/kg BW/day) were randomly assigned to each subject and administered once daily for 7 days. Serum IGF-I, osteocalcin, PTH, and calcitriol concentrations all increased during treatment. In this short-term study, there was also a significant rise in urinary hydroxyproline and urinary calcium excretion with a concomitant decline in urinary sodium excretion.

Holloway et al. conducted a longer double-blind RPCT of daily rhGH for 1 year in 27 healthy elderly women, 8 of whom took a stable dose of estrogen throughout the study (Holloway et al., 1994). Thirteen women completed 6 months of treatment, and fourteen women completed 6 months in the placebo group. Side effects prompted a 50% reduction in the original dose of rhGH (from 0.043 mg/kg BW or approximately 0.3 mg rhGH/kg/week to 0.02 mg/kg/day) and led to several dropouts in the treatment group. Fat mass and percentage body fat declined in the treatment group, but there were no changes in BMD at the spine or hip at 6 or 12 months in other groups (Holloway et al., 1994). Although BMD did not change, there were changes in some biochemical parameters. In particular, urinary markers of bone resorption (e.g., hydroxyproline and pyridinoline) increased after 6 months of rhGH treatment. The response of bone formation markers was more variable. Osteocalcin increased, but type I procollagen peptide levels did not change. For women taking estrogen replacement therapy, indices of bone turnover (both formation and resorption) were blunted.

Rosen et al. (1999) reported that there was a dose-dependent decrease in total body BMD after 1 year of rhGH in frail elderly men and women. This occurred despite striking increases in osteocalcin and serum IGF-I with the highest doses of rhGH (0.01 mg/kg/day). In part, the absence of a GH effect on BMD is not surprising, because resorption is coupled to formation and GH activates the entire remodeling sequence. Moreover, the skeletal response was only measured after 1 year of treatment; this was probably inadequate to determine the true effect of rhGH on BMD as noted from earlier studies in GHD. Not surprisingly, in the same trial of 132 frail elderly subjects by Rosen and colleagues, urinary N-telopeptide and osteocalcin rose to the same extent, suggesting that total bone turnover, not just bone formation, was increased by rhGH therapy. The relatively high incidence of acute side effects (weight gain, carpal tunnel syndrome, edema, and glucose intolerance) in GH trials, especially in the frail elderly, has remained particularly troublesome even with titrating doses. Moreover, high serum IGF-I levels for long periods may predispose individuals to certain malignancies. Thus, there is limited enthusiasm for rhGH or rhGHRH treatments in the frail elderly.

Growth hormone treatment for osteoporotic patients

Short nonrandomized clinical trials with GH in osteoporosis were attempted well before GH replacement therapy was approved in pituitary insufficiency. As early as 1975, two patients with osteogenesis imperfecta and one patient with involutional osteoporosis were treated with GH. Histomorphometric parameters of increased bone formation and resorption were noted. Subsequent studies employed GH with and without antiresorptive agents. Aloia et al. (1987) administered between 2 and 6 U/day of GH for 12 months to patients with postmenopausal osteoporosis (the first 6 months of treatment featured low-dose GH; the last 6 months consisted of high-dose GH (6 U/day). Radial BMC dropped slightly, and histomorphometric parameters did not change during treatment. However, severity of back pain decreased considerably in several people. Daily GH injections (4 U/day) combined with alternating doses of calcitonin produced an increase in total body calcium (measured by neutron activation analysis) but a decline in radial bone mass after 16 months. In a separate trial, 14 postmenopausal women were given 2 months of GH, then 3 months of calcitonin, in a modified form of coherence therapy. Total body calcium increased 2.3%/year with few side effects, but there were no changes in BMD or histomorphometric indices. One study administered 16 U of rhGH every other day along with daily sodium fluoride to six women with postmenopausal osteoporosis. On histomorphometric analysis, there was a significant increase in the number of osteoblasts and osteoclasts, but BMD was unchanged.

Johansson et al. (1994) conducted a crossover double-blinded RPCT of rhGH and idiopathic osteoporosis. In this 7-day trial with rhGH 2 IU/m2, procollagen peptide and osteocalcin levels increased after treatment as did urinary markers of bone resorption. The changes in osteocalcin were relatively small and were not sustained after discontinuation of GH treatment. Thus, GH stimulates bone remodeling activity, thereby leaving open the possibility that GH can be coupled to antiresorptive agents. This thesis was tested in a 2-year randomized trial by Holloway and colleagues (Holloway et al., 1997). In that study, rhGH and nasal calcitonin increased spine BMD by approximately 2%. This, however, was not much different than the use of CT alone, and certainly less than what has been seen in very large randomized trials with antiresorptive agents. Once again, there were several side effects that produced limited enthusiasm for rhGH as a primary treatment for osteoporosis. In another combination trial that was larger and longer, 80 osteoporotic postmenopausal women on hormone replacement therapy (HRT) (estrogen with or without progestin) were administered rhGH 10 2.5 U/day or placebo for 18 months, and then open-label rhGH for another 18 months. These women were then followed for an

additional 24 months. Women given GH and HRT had a marked increase in total body and spine BMD compared with placebo, which was maintained to year 3 but disappeared by year 5 (Landin-Wilhelmsen et al., 2003). This trial suggested that combination therapy of an anabolic and an antiresorptive could be used in postmenopausal osteoporosis. A similar result was noted in a 7-year follow-up of 30 men and women who received rhGH for 4 years and then were treated with alendronate for an additional 3 years. BMD increased significantly versus a control group after 3 years, especially in the males, and the addition of alendronate further enhanced spine BMD at year 7 (Biermasz et al., 2004). Therefore, it is likely that GH may induce small changes in BMD that over an extended period could translate into fewer spine fractures as noted by Krantz et al.

Insulin-like growth factor I for the treatment of osteoporosis

Overview

In the late 1980s, clinical trials with rhIGF-I for diabetes mellitus were begun. The availability of this recombinant peptide and the absence of other treatments to stimulate bone formation accelerated animal and human studies of rhIGF-I in metabolic bone diseases. Theoretically, there are potential benefits for rhIGF-I compared with rhGH. These include (1) more direct stimulation of bone formation; (2) bypass of skeletal GH resistance; and (3) reduction in GH-induced side effects such as carpal tunnel and diabetes mellitus. There are, however, considerably fewer animal and human studies using rhIGF-I than those using rhGH. Therefore, these advantages have either yet to be fully realized or have not been validated.

IGF-I is not a potent mitogen in most tissues, and bone is no exception (see Chapter 8 by Canalis). There are high-affinity receptors for IGF-I expressed on osteoblasts, and IGF-I can stimulate preosteoblast replication and provoke resting cells to proceed through their growth cycles. IGF-I maintains the differentiated osteoblast phenotype, stimulates collagen synthesis, and prevents collagen degradation. Theoretically, therefore, despite its relatively weak mitogenic properties, IGF-I could potentially have significant anabolic activity on the skeleton.

Murine studies

In hypophysectomized rats, growth can be fully restored by administration of either GH or IGF-I but not IGF-II (Schoenle et al., 1985). A similar growth response occurs after rhIGF-I in streptozotocin-diabetic rats but not in sex-linked dwarf-mutant chickens (Schoenle et al., 1985; Tixier-Boichard et al., 1992). In normal rats, rhIGF-I administrated either systemically or locally (hind limb infusions) does not stimulate longitudinal bone growth. In the spontaneously diabetic BioBreeding (BB) rat, rhIGF-I treatment did not result in changes in epiphyseal width, osteoblast surfaces, or osteocalcin concentration (Verhaeghe et al., 1992).

The skeletal response to rhIGF-I is determined by the GH/IGF-I status of the animal. For example, IGF-I does not increase bone formation in normal rats, whereas it stimulates bone growth and normalizes type I procollagen mRNA levels in hypophysectomized rats (Schmid et al., 1989; Spencer et al., 1991; Tobias et al., 1992). Similarly, in the spontaneous mouse mutant (lit/lit), GHR absence results in very low levels of IGF-I and skeletal dwarfism. IGF-I treatment restores growth and increases total body water but does not enhance BMD in these mice (Donahue et al., 1993). These findings are somewhat similar to the effects of GH on the skeleton in GHD animals. However, rhIGF-I and rhGH differ in their actions on the circulatory IGF regulatory system. GH stimulates hepatic production of IGF-I, IGFBP-3, and ALS, while rhIGF-I administration increases the total circulating pool of IGF-I but suppresses hepatic production of IGFBP-3, primarily through feedback inhibition of GH secretion. It is conceivable that variations in IGF-I biological activity (between direct IGF-I administration and endogenously produced IGF-I as a result of GH treatment) may be due to the relative proportion of free versus bound IGF-I to IGFBP-3.

Several experimental paradigms have been employed to study the effects of IGF-I on bone turnover in animals. These include (1) oophorectomy, (2) diabetes mellitus (spontaneous or induced), and (3) immobilization. In oophorectomized rats, administration of rhIGF-I has variable effects on bone remodeling, BMD, and bone strength. In older oophorectomized rats, rhIGF-I increased midshaft tibial BMD and enhanced periosteal bone apposition (Ammann et al., 1996). Six weeks of rhIGF-I (delivery by mini-osmotic pump) to older rats caused a dose-dependent increase in BMD in the lumbar spine and proximal femur, although bone strength and stiffness did not change. Muller reported that subcutaneous administration of rhIGF-I to adult oophorectomized rats stimulated bone formation as evidenced by increased osteoid surfaces, osteoblast surfaces, and mineral apposition rates. At high doses of rhIGF-I, osteoclast surface and osteoclast number also increased. In contrast, Tobias et al. (1992) found that rhIGF-I (200 mg/kg) administered for 17 days to 15-week-old rats increased longitudinal and periosteal growth of the femur but suppressed trabecular bone formation in

oophorectomized and control rats. Bone resorption was also slightly suppressed during rhIGF-I treatment, although not to the extent that bone formation was inhibited.

T1DM (Type I diabetes mellitus) is associated with decreased cortical BMD. Although the pathophysiology of diabetic osteopenia remains unknown, it appears that the duration of diabetes, the extent of diabetic control, and the timing of disease onset are each associated with higher risks of low BMD (McNair, 1988). Numerous clinical studies report abnormalities in the GH/IGF-I axis in TIDM (Rasingani, 2017) including reductions in serum IGF-I due to portal insulinopenia and elevations in GH secretion (Hourd, 1991). Diminished insulin action in TIDM is associated with increased serum IGFBP-1 levels, which can sequester IGF-I, affect its bioavailability to the skeleton, and contribute to impaired bone acquisition. The cellular mechanism leading to low BMD in TIDM relates mainly to defects in osteoblastic function, as serum levels of osteocalcin, a marker of bone formation, are reduced in TIDM (Verhaeghe et al., 1992). Serum markers of bone formation are reduced in type I diabetics, suggesting a possible defect in osteoblastic activity (Verhaeghe et al., 1992). Serum IGF-I levels are either normal or low in IDDM but often are reduced in patients with poor diabetic control. In these same people, serum IGFBP-1 levels are quite high. This has led investigators to believe that changes in the IGF regulatory system during poor metabolic control contribute to impaired growth.

Spontaneously diabetic BB rats exhibit osteopenia and therefore provide a useful model for studying the effects of IGF-I on bone remodeling. Even though bone formation is lower in BB than in control rats (as measured by serum markers), administration of rhIGF-I does not increase bone epiphyseal width, osteoblast surfaces, or serum osteocalcin (Verhaeghe et al., 1992). Thus, despite evidence that circulating levels of IGF-I are reduced in some patients with type I IDDM, preliminary animal studies have failed to show that IGF-I administration can correct any inherent defect in bone formation. However, those studies did not include insulin treatment, so it is unclear whether IGF-I could have anabolic properties on bone in the presence of adequate insulin levels.

Alternate ways of exploiting the anabolic properties of IGF-I in bone have been proposed. IGF-I has been administered by intraarterial infusion or coupled to IGFBP-3. Infusion of rhIGF-I continuously into the arterial supply of the right hind limb of ambulatory rats for 14 days led to a 22% increase in cortical and trabecular bone formation in the infused limb (Spencer et al., 1991). By histomorphometry the number of osteoblasts, but not osteoclasts, was increased. Using an alternative model, Bagi et al. (1994) administered rhIGF-I or a complex of IGF-I-IGFBP-3 to 16-week-old oophorectomized rats. The IGF-I—IGFBP-3 complex (7.5 mg/kg/day) led to greater increases in bone formation than IGF-I alone, though both treatments increased longitudinal bone growth. The highest doses of rhIGF-I and rhIGF-I-GFBP-3 enhanced trabecular thickness in the lumbar vertebrae and femoral epiphyses, and increased bone resorption, but only in the femoral metaphysis. A similar study contrasting IGF-I with IGF-I-GFBP-3 was performed in 22-week-old oophorectomized rats (Brommage et al., 1993). BMD increased in both groups, but fewer than 10% of the rats treated with IGF-I—IGFBP-3 complex developed hypoglycemia, compared with nearly 50% of those treated with rhIGF-I alone.

Human studies of insulin-like growth factor I and bone mineral density

There is one published study of bone markers that employed rhIGF-I to healthy young postmenopausal women. Doses of rhIGF-I from 30 to 180 mg/kg/day were administered daily by subcutaneous injection for 6 days to older postmenopausal women without fractures and with normal BMD (Ebeling, 1993). Very significant dose-dependent increases in serum PICP, osteocalcin, and urinary deoxypyridinoline were reported. Although the rise in PICP was greater than the increase in collagen breakdown (measured by deoxypyridinoline), it is uncertain whether this meant that formation was stimulated more than resorption. For the two highest doses of rhIGF-I (120 and 180 mg/kg/day), orthostasis, weight gain, edema, tachycardia, and parotid discomfort were noted. At lower doses (30 and 60 mg/kg/day), fewer side effects were reported, but less discrete changes in PICP were noted.

One indication for rhIGF-I treatment, which has been approved in the United States, Sweden, and other countries, is the GH-resistant short stature syndrome (Laron dwarf), in which patients lack functional GHRs and thus do not respond to GH. Laron dwarfs show very low levels of IGF-I in serum with high levels of GH (due to a lack of negative feedback on GH by IGF-I) and are growth retarded (Bondy et al., 1994). Underwood treated one such boy (age 9) with 2 weeks of continuous intravenous rhIGF-I (Bondy et al., 1994). Urinary calcium excretion increased while urinary phosphate and sodium decreased. After a 2-week continuous infusion of rhIGF-I, the patient was treated with twice-daily SC rhIGF-I (120 mg/kg) for 2 years. Growth occurred at a rate of 10 cm/year, compared with 5 cm for the 3 years prior to treatment. Subsequently, Underwood and colleagues have treated eight patients in this manner without hypoglycemia, while Laron and his group have treated five children (Bondy et al., 1994; Laron et al., 1992). More recently, a child with an IGF-I deletion mutation in exon 5 has been reported. This patient had very short stature, mental retardation, and other abnormalities along with very low levels of circulating IGF-I (Woods et al., 1996). The rhIGF-I treatment led to a marked increase in linear growth and a

huge increase in spinal bone mass. However, when corrected for changes in size of the bone, the incremental changes in volumetric bone mass were much less impressive (Camacho-Hubner et al., 1999). Hypoglycemia was avoided in these cases by having children eat 3 to 4 hours after their IGF-I injection, although several children had selective growth of adenoidal tissue.

Two unique aspects of these IGF-I data challenge previous concepts about the role of GH in skeletal homeostasis. First, IGF-I can act as a classical endocrine hormone stimulating longitudinal growth independent of GH, although not to the same extent as GH; second, GH may not be absolutely essential for statural growth; i.e., the stimulatory effect of GH on chondrocytes that permits skeletal responsiveness to IGF-I may not be as critical as once perceived. In fact, crossing Laron dwarf mice (GHR-null mice, GHRKO) with mice expressing hepatic IGF-I transgene (HIT) restored IGF-I levels in serum (GHRKO-HIT mice) and was able to promote skeletal linear growth and BMD (Wu et al., 2013). However, despite restoration of serum IGF-I in the GHRKO-HIT mice, growth was not normalized due to compromised delivery of IGF-I to the tissues, the inability of endocrine IGF-I to restore bone tissue IGF-I levels, and IGF-I-independent effects of GH on linear and radial bone growth. Caution must be undertaken in examining the effects of rhIGF-I on BMD in children, because most changes in the skeleton relate to linear growth and periosteal enhancement, both of which can contribute to two-dimensional changes in BMD as measured by DXA, but the changes are less when corrected for size (Bachrach et al., 1998).

Idiopathic osteoporosis in men is an ill-defined syndrome of low bone mass and spinal fractures without associated hypogonadism. By histomorphometry, these men often have low bone turnover, suggesting a possible defect in bone formation. Several groups of investigators have suggested that this syndrome is related to low serum IGF-I levels (Ljunghall et al., 1992; Kurland et al., 1997, 1998, Rubin and Bilezikian, 2002). Because the therapeutic options in males with osteoporosis are somewhat limited, and treatment for low bone turnover states is generally frustrating, the therapeutic potential for anabolic agents like IGF-I in this condition should be quite high. In one male with idiopathic osteoporosis and low serum IGF-I, Johansson et al. (1994) administered rhIGF-I (160 mg/kg/day SC) for 7 days. Bone alkaline phosphatase, osteocalcin, and PICP all increased more than 40% over baseline. However, urinary calcium/creatinine and hydroxyproline excretion rose during treatment. In a recent trial of rhIGF-I (at a dose of 80 mg/kg/day) and rhGH (2 IU/m2/day) in 12 men, serum osteocalcin, serum procollagen peptide, and urinary deoxypyridinoline excretion all increased following 7 days of rhIGF-I treatment (Holloway et al., 1997). Although there were slight differences in the response of certain biochemical markers to IGF-I and GH, both forms of therapy produced significant increases in bone resorption.

Anorexia nervosa is a condition characterized by amenorrhea and profoundly low BMD (due to either low peak bone mass or rapid bone loss) as well as reduced body weight, low circulating IGF-I, resistance to GH, and a marked propensity for fractures. Hence, rhIGF-I might be considered an ideal therapeutic option for this group of adolescents and young adults with severe bone disease, particularly because oral contraceptive pills (OCPs) have virtually no effect on BMD in these patients. Grinspoon et al. (2003) studied 60 anorexic women with low BMD in an RPCT of 9-month duration using rhIGF-I 30 ug/kg/d with and without OCPs (Grinspoon, 1993). The group of women receiving rhIGF-I and OCPs had the greatest increase in spine BMD (11.8%); rhIGF-I alone also increased BMD (11.1%), while bone loss occurred in the group receiving placebo or OCPs alone. Interestingly, there were virtually no side effects in the anorexic women, and serum IGFBP-2 was inversely correlated with changes in hip BMD. Although the increase in BMD was relatively modest, considering the lack of other available therapies, these changes are encouraging and suggest that further studies are needed.

Clinical trials provide evidence that IGF-I acts by increasing the generation of new osteons, thereby promoting bone resorption and formation. This action might be ideal for older individuals, because one characteristic of age-related osteoporosis is suppressed bone formation. However, concerns about dosing and side effects have limited enthusiasm for this approach. Yet it is conceivable that low doses of rhIGF-I (,30 mg/kg/day) could differentially stimulate bone formation. In one trial, 16 healthy elderly women were given 60 ug/kg/day (high dose) and 15 mg/kg/day (low dose) of rhIGF-I and tested for 28 days. The high-dose rhIGF-I increased the markers of bone resorption and formation. However, low doses of rhIGF-I caused increases in serum osteocalcin and PICP but had no effect on total pyridinoline excretion (Ghiron et al., 1995). These data would support the thesis that low doses of rhIGF-I may directly increase osteoblastic function with only a minimal increase in bone resorption. However, further studies will be needed to assess the future therapeutic role of low doses of rhIGF-I in osteoporosis.

One strategy is to administer a bone-specific agent that stimulates bone mass, such as PTH. Intermittent hPTH increases trabecular bone by stimulating osteoblasts to synthesize IGF-I and other growth factors (Rosen and Donahue, 1998). Another strategy is to administer IGF-I along with an IGFBP. Bagi et al. (1994) previously reported that the IGF-I/IGFBP-3 complex could enhance bone mass in the metaphysis and epiphysis of rats. One small randomized placebo-controlled trial utilized subcutaneous infusions of IGF-I/IGFBP-3 in 24 older women with hip fractures. Bone loss in the contralateral hip was reduced considerably after 6 months (i.e., from 6% to 1.5%) in those subjects who were given complex

IGF-I/IGFBP-3 versus those receiving saline (Geusens et al., 1998; Boonen et al., 2002). Accompanying that change in BMD was also an increase in grip strength in those that received the active agent, with no significant side effects reported.

Limitations to the clinical use of recombinant human insulin-like growth factor I

IGF-I treatment has its limitations (Zofkova, 2003). The impacts of serious sequelae of long-term administration of IGF-I remain to be evaluated. During IGF-I treatment, undesirable metabolic manifestations may develop hypoglycemia (in particular after large intravenous doses) and hypophosphatemia with subsequent hypotension (Zofkova, 2003). A more frequent incidence of gynecomastia was also observed. The use of IGF-I/IGFBP-3 complex seems to be very useful and safe in women who are older and who have a recent hip fracture (Agnusdei and Gentilella, 2005). Furthermore, the combination of an anabolic agent with an antiresorptive drug (such as calcitonin or alendronate) could be more potent than either agent alone. However, the therapeutic effects of such a combined approach on BMD at different skeletal sites have been controversial (Agnusdei et al., 2005).

Summary

Several lines of evidence point to the importance of local IGF-I in skeletal turnover. Systemic IGF-I, regulated by GH, IGFBPs, and several proteases as well as IGFRs, also must be important for full linear growth and peak skeletal acquisition. Recent work suggests that recombinant growth factors may be anabolic for the skeletal remodeling unit. First, both GH and IGF-I stimulate osteoblastic differentiation. In vivo models using targeted deletion or overexpression of IGFs or IGF-IR support a critical role for this regulatory circuit in peak bone acquisition. In respect to growth hormone, rhGH treatment increases bone mass but must continue for several years, and outcomes should be measured for several years thereafter (as the skeletal response cannot be detected shortly after treatment). Skeletal response to rhGH is greater in men than in women, and the potential long-term risks of elevated IGF-I, as well as the availability of other less expensive therapies (such as bisphosphonates, teriparatide and abaloparatide), precludes more vigorous development of these peptides. Third, in GHD children, both rhGH and rhIGF-I can enhance trabecular and cortical BMD, and certainly recombinant GH is part of current recommendations for this condition. Therefore, unless more favorable responses in properly controlled clinical trials are seen with rhGH or rhIGF-I, these drugs are not recommended for the treatment of postmenopausal osteoporosis.

Chapter outline

Introduction

Periodontal bone and subsequent tooth loss are a major health problem affecting over 60% of the United States population over 60 years of age. The regenerating of periodontal ligaments (PDL) has shown some limited success using PDL cells, with accomplishments in cell homing techniques and in vivo growth factors such as GDF5 and BMPs (Dangaria et al., 2011; Kim et al., 2010; Emerton et al., 2011). Understanding the complex differentiation process of periodontal stem/progenitor cells (PSCs) with these three tissues, alveolar bone, PDL, and the associated attachments to bone and tooth root surface by formation of cementum is beginning to show progress, with a combination of lineage studies in mice, new genetic mouse models, and in vitro mechanistic studies.

Periodontal stem/progenitor cells

A variety of studies over the years have identified ectomesenchyme-derived progenitor cells from the dental follicle (DF) and periodontium region of shed teeth that exhibit many properties of progenitor and stem cells with high CD146 and STRO-1 expression (Seo et al., 2004; Xu et al., 2009; Ivanovski et al., 2006). DF progenitors are fairly heterogeneous in their capacity to differentiate toward components of the periodontium and may involve mechanisms of Hertwig's epithelial root sheath during periodontium formation (Luan et al., 2006; Jung et al., 2011). In vivo αSMA+ cells, surrounding capillaries (pericytes) in the periodontium and a classical marker of the DF stem/progenitor cell population, are good candidates for a major class of stemlike cells that form alveolar bone, PDL fibroblast−PDL, and cellular cementum within the periodontium (San Miguel et al., 2010). Using lineage tracing techniques, the PSCs for alveolar bone, cellular cementum, and PDL have been identified as a αSMA+ cell population within the cervical and apical regions of the periodontium (Roguljic et al., 2013). The PDL cells were identified by scleraxis-GFP transgene, a marker of periodontal fibroblasts overlaid with the αSMA-CreERt2-dependent tdTomato signal (see chapter on lineage tracing; Kalajzic et al.). The mineralizing cementum and alveolar bone cells were identified by overlay of Col1a1-GFP signals (osteoblasts) with αSMA-CreERt2-dependent tdTomato signal. αSMA+ cells in the bone marrow are, also by lineage tracing, capable of

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00043-9

differentiating into osteoblasts and osteocytes (Grcevic et al., 2012). These αSMA+ cells are the progenitor/stem cells for fracture healing tissue (both chondrocytes and osteoblasts) as well as after damage to the PDL (Roguljic et al., 2013; Matthews et al., 2014). Recent studies have also shown that αSMA+ cells in the tendons are progenitors for mature mid-substance tenocytes and are the main progenitors recruited from the paratendon during a tendon injury repair model (Dyment et al., 2014). In the periodontium, αSMA+ cells are the progenitors of PDL fibroblasts, which have many properties of gene regulation similar to tendon and ligaments.

An excellent marker for mesoderm-derived progenitor cells of the periodontium (excluding the gingiva-epithelium) is the Osterix+ cells. By lineage tracing, Osterix+ cells are expressed slightly later than αSMA+ cells, and these cells have major effects on tooth root formation and cementogenesis (Cao et al., 2012). αSMA+ cells are minimally expressed in the tooth pulp, but do play a role in reparative dentinogenesis (Vidovic et al., 2017). By lineage tracing studies in long bones, Osterix+ cells overlap with αSMA+ cells as well as progress to mature osteoblasts (Chan et al., 2018). Recently, data also show that Osterix+ cells surrounding the small capillaries in the bone marrow contribute to the link of angiogenesis to osteogenesis (Kusumbe et al., 2014; Mizoguchi et al., 2014). In fact, Osterix has been shown to directly bind to the VegfA gene promoter and regulate VegfA expression (Tang et al., 2012). Osterix expression is dependent on Bmp2 signaling in long bones and in the alveolar bone and the tooth pulp (Yang et al., 2012; Yang et al., 2013; Rakian et al. 2013).

Other candidate periodontal stem/progenitor cells

Recent data demonstrate that cathepsin-K-CD200+ cells are a major population of periosteal stem cells that can self-renew and selectively form intramembranous bone (Debnath et al., 2018). The CD200+ marker alone in the context of the DF stem cell population of the periodontium marks both early cells and highly differentiated matrix-producing osteoblasts (Takahashi et al., 2018). In the mature skeleton of 4-month-old mice, leptin receptor−expressing cells have all the properties of self-renewing skeletal stem cells (Zhou et al., 2014). Leptin receptor+ cells also are a major contributor to myelofibrosis in bone marrow (Decker et al., 2017). However, in the case of the periodontium that develops early in mouse postnatal development, leptin receptor+ cells may be of less importance. Likewise, αSMA+ cells may be less important as a stem/progenitor cell population under normal homeostatic conditions at these later stages except under fracture repair or in the case of reparative regeneration as in the pulp and after PDL damage (Roguljic et al., 2013; Vidovic et al., 2017).

A new set of markers has been suggested for skeletal stem cells and bone and cartilage progenitors that in some degree overlaps with previous studies, as in CD146 and other pericyte markers such as NG2 (Cspg4) (Chan et al., 2018). One proposed marker for skeletal stem cells in this study (Chan et al., 2018) is podoplanin Pdpn, aka E11 or GP38), a general marker found in osteocytes and almost any cell with long filopodia or dendritic processes, such as osteocytes and many neural cells and lung fibroblasts (Zhang et al., 2006). The authors discuss a collection of other markers that define these skeletal stem cells, such as PDPN+, CD73, and CD164. CD164 expression is very high in PSCs, as is αSMA and Sca1. All three markers decrease expression as PSCs differentiate into mineralizing tissue (Harris SE, unpublished).

Hedgehog signaling in bone and periodontium

Another class of osteoprogenitors have been identified with a Gli1-CreERt2 model by lineage tracing and are also involved in fracture repair (Guo et al., 2018). These Gli1+ stem cells highly expressed CD146, αSMA, and leptin receptor but expressed low levels of Sca1 and NG2. In addition, the conditional removal of the smoothened receptor with Gli1-CreERt2, the key signaling receptor for hedgehog signaling (hh), decreased trabecular bone formation. Also, deletion of β-catenin with this Gli1-CreERt2 model decreased bone formation, indicating that this pool of stem cells is regulated by Wnt signaling. As related to the periodontium, Zhao et al. demonstrated that sonic hedgehog from the neurovascular bundle niche supports mesenchymal stem cell (MSC) differentiation in and around the mouse incisor (Zhao et al., 2014). Recently, these Gli+ cells have also been shown to be the key driver of bone marrow fibrosis in various pathological, hematological, and nonhematological conditions, similar to leptin receptor+ cells (Kramann et al., 2015).

In the periodontium, a critical target associated with periodontitis is the loss of attachment of PDLs to the cementum on the tooth surface and alveolar bone. This enthesis region of the periodontium has many of the same properties as the tendon/ligament attachment to bone and its biology. As discussed above, GDF5 treatment in a primate model has been shown to regenerate not only the bone but also healthy PDLs (Emerton et al., 2011). Gdf5-positive progenitors in the tendon−bone interface give rise to fibrocartilage that mineralizes by hh signaling to form the enthesis (Dyment et al., 2015). Similar mechanisms with hh are suggested to play a key role in enthesis formation in the periodontium. Analysis of the enthesis region in the periodontium has shown selective enrichment of CD31 endothelial cells with attached CD146 stem cells. As the CD146 cells migrate from the vascular niche, they increase the expression of the pericyte NG2 marker

near the bone−PDL enthesis region. GDF5 is likely to play a key role in this process as in tendon−bone enthesis biology (Lee et al., 2015).

A key role is played by hh in fracture repair and most likely in periodontium healing. During stress fracture healing, mice were given a selective hh pathway inhibitor, vismodegib. A reduction in both woven bone and later-stage lamellar bone formation and vascularization, with a major decrease in Ibsp and other osteoblast markers during healing, was observed (Kazmers et al., 2015). Follow-up studies demonstrate that activation of the hh pathway by systemic agonist, Hh-Ag1.5, during fracture healing in 18-month old female mice, accelerated the fracture repair process (McKenzie et al., 2018). Little is known about hh in the periodontium, except for its role in incisor stem cell biology. However, Ibsp, a key downstream gene, is critical for cementum-enthesis formation, likely regulated by hh, and worth further investigation (Foster et al., 2013a). Previous in vitro cell experiments suggest that hh signaling and Gli2 transcription factors play a role in regulating Bmp2 gene transcription in response to hh signaling (Zhao and el al., 2006). Whether this mechanism plays a role in vivo is unknown.

Parathyroid hormone/parathyroid hormone−related protein role in long bones and periodontium

Parathyroid hormone (PTH) is produced by the parathyroid gland, regulates calcium homeostasis, and has anabolic and catabolic effects on bone (Poole and Reeve, 2005). PTH1 receptor is expressed in osteocytes, early skeletal stem cells, and Osterix+ cells in long bones and many cell types in the periodontium including DFs that contain the stem cells for much of root, cementum, and PDL formation (Takahashi et al., 2018; Ono et al., 2016). As well, PTH1 receptor expression in the periodontium is maintained in later mature cells of the periodontium and suggests that PTH signaling plays a role in homeostatic maintenance later in life (Ono et al., 2016).

A strong anabolic effect of PTH is seen at low intermittent doses in which the activation of osteoclastogenesis and bone resorption is linked to a stronger anabolic bone-formation effect. PTH results in enhanced recruitment, proliferation, and differentiation, as well as decreased apoptosis of osteoblasts (Ishizuya et al., 1997; Jilka et al., 1999). PTH and PTH-related protein (PTHrP) (selectively expressed in early chondrocytes and highly expressed locally in DF cells of the developing periodontium) create their effects through interactions with many different cellular pathways and mechanisms. PTH/PTHrP increases the commitment of MSC precursors to an osteoblast cell fate (Baron and Hesse, 2012). PTH/PTHrP binds to PTH1 receptor, a G-protein-coupled receptor that stimulates phospholipase C, cAMP-dependent protein kinase A, and protein kinase C. The overall effect is an increase in bone formation. The PTH1 receptor is able to activate the Wnt pathway in the absence of Wnt by forming a complex with LRP5/6 after PTH binding (Wan et al., 2008). This allows for the phosphorylation and stabilization of β-catenin, permitting the Wnt signaling pathway to proceed (Guo et al., 2010). The PTH1 receptor is highly expressed on osteocytes. PTH indirectly activates the Wnt pathway in osteoblast progenitor cells by inhibiting secretion from osteocytes of SOST and Dkk1 (Prideaux et al., 2015). This interaction of the Sost gene product, Sclerostin, and PTH signaling previously demonstrated that bone formation induced by PTH is decreased in mice that overexpress Sclerostin (Kramer et al., 2010). Additionally, mice deficient in the PTH1 receptor in osteocytes show an osteogenic phenotype with increased Sclerostin expression and decreased Wnt signaling (Powell et al., 2011). Therapeutic use of PTH analogs has focused on teriparatide and related analogs. Teriparatide and related analogs have been in use for many years for the anabolic treatment of osteoporosis (Neer et al., 2001; Papapoulos, 2015).

As related to the periodontium, mechanistic and mouse models have clarified that PTH/PTHrP are critical signaling molecules in determining the fate and lineage progression of various stem/progenitor cells in the developing periodontium after birth. Osterix, a key Bmp signaling dependent-and-induced transcription factor, plays a major role in PDL and cementum formation as discussed previously (Cao et al., 2012). Osterix is highly expressed in the DF, containing stem/progenitor cells that also express PTHrP and PTH1 receptor. Osterix is also expressed in dental papilla cells that form odontoblasts and develop the dentin of the crown and roots of the tooth. Deletion of the PTH1 receptor in these Osterix+ cells leads to major failure of tooth root formation, PDL formation and redirection of acellular cementoblasts to cellular cementocytes on the root surface, and failure in primary tooth eruption (Ono et al., 2016). Many DF cells and cells on the tooth root surface express PTHrP and are likely a local autocrine-paracrine signaling mechanism. Markers of the PDL, such as periostin, are also decreased, and PDL almost disappears in these PTH1 receptor−conditional KO mice. After deletion of the PTH1 receptor, major defects in the capacity of DF cells to proliferate was demonstrated using EdU-labeling methods with overlap of a red tdTomato signal from the initial Osterix-Cre event. Histone deacetylase 4 (HDAC4), a downstream target of PTH/PTHrP signaling, is thought to play a contributing factor, and deletion of HDAC4 in Osterix+ cells leads to a major root phenotype.

Further studies enlighten our mechanistic understanding of PTH/PTHrP signaling in DF and DP stem/progenitor cells (Takahashi et al., 2018). As stated earlier, PTHrP is produced locally in the DF, DP, and other cells of the periodontium. Using a PTHrP promoter-driving mCherry reporter, these cells were isolated from the mandible and subjected to single-cell transcriptome analysis. A large fraction of these cells coexpress PTHrP and PTH1 receptor. Of eight clusters, DF cells were identified by high levels of αSMA+ cells and with Spon1 and Mkx expression (Takahashi et al., 2018). Other clusters of PTHrP cells were epithelial, DP, fibroblast-like (potential PDL), and cycling and transition cells between epithelial and mesenchymal. By lineage tracing with tdTomato and the use of a PTHrP-creERt2 model, these PTHrP+ cells differentiate into alveolar osteoblasts, PDL fibroblasts, and coronal cementoblasts. Deletion of the PTH1 receptor in PTHrP+ cells at day 3 resulted in excessive formation of cellular cementum at the expense of reduced acellular cementum by day 11−22. Proliferation by day 11 was decreased, suggesting an exhaustion of the progenitor cell pool in the absence of the PTH1 receptor. PDL formation massively decreased in this model as demonstrated by the reduction of periostin expression. As well, the molars were significantly unerupted, similar to the human condition with PTH1 receptor mutations in which there is a primary failure in tooth eruption. RNA-seq analysis of Het and cKO cells suggests the Mef2c transcription factor, a target of HDAC4, as a key node in the DF differentiation program.

The use of PTH signaling, using teriparatide in modulating periodontal disease and other bone loss in the oral cavity, has started to yield promising results. Several animal studies indicate promise with respect to the use of teriparatide in treating alveolar bone loss and the attachment loss of PDL associated with periodontitis. Periodontal defects around dental implants in dogs were treated with guided bone regeneration that included teriparatide bound to a synthetic matrix, and this demonstrated accelerated and increased osseointegration (Valderrama et al., 2010). Using a fenestration defect model created in the buccal plate in rats demonstrated enhanced new bone formation, reduced defect size, and increased newly formed cementum-like tissue after intermittent treatment with teriparatide (Vasconcelos et al., 2014). A clinical trial evaluated the effect of teriparatide on patients with severe chronic periodontitis. After periodontal surgery, patients received teriparatide injections daily for 6 weeks. Significant improvements were observed in measured periodontal parameters, with gains in linear bone around the teeth, gains in attachment, and reduction in probing depth (measure of PDL attachment to the tooth) in the teriparatide-treated group compared with controls (Bashutski et al., 2010). An overall assessment of the use of tripeptide and other agents, such as FGF2, suggests that these approaches need further evaluation; however, they show promise for periodontal regeneration (Rios et al., 2015). Since this report, mechanisms of PTH signaling in the periodontium have greatly improved, as discussed earlier, and hopefully will lead to better clinical approaches.

Wnt signaling in the periodontium and the role of the sost gene

The canonical Wnt pathway plays a fundamental role in PSC specification and differentiation (Lim et al., 2014). Axin2 (a negative regulator of Wnt signaling but a readout of cells experiencing Wnt activation-like ptch1 for hh and noggin for Bmp signaling) lacZ mice were used with a conditional KO, osteocalcin-Cre, of the Wnt-less gene (which controls processing and presentation to Frizzled receptors and blocks Wnt signaling). The mice had reduced alveolar bone and a major disruption of PDL formation. Using an Lrp5 high-bone-mass mutation mouse, in which Wnt signaling is constitutively active, a large increase in alveolar bone around the teeth and a narrow PDL space were demonstrated (Lim et al., 2015). These early studies suggest that Wnt signaling in early stem/progenitor cells in the periodontium can be "jump-started" and activated to regenerate components of the periodontium including the teeth (Yin et al., 2015).

Studies now support the view that in osteoporotic conditions, the jaw bone and surrounding tissues are a target for canonical Wnt signaling. In this study of an ovariectomized mouse, major atrophy of the PDL was shown with a reduction of the number of stem/progenitor cells in the PDL that differentiate into the alveolar bone and cementum (Arioka et al., 2019). Some implant procedures may remove the tooth and immediately place an implant into the socket. Recently, studies in mice show that if PDL cells are left on one side of the socket and PDL is removed on the other, the side with the PDL cells remaining shows accelerated bone formation, reduced osteocyte death, an increase in osteogenic gene expression, and accelerated osseointegration (Yuan et al., 2018). This demonstrates that a liposomal L-Wnt3a mixture applied to both the buccal (with PDL cells) and palatal (without PDL cells) socket side results in expanded new Wnt3a-responsive cells on the PDL buccal side, decreased bone resorption signals (tartrate-resistant acid phosphatase), and much better bone−implant contact. Even on the palatal side with few PDL cells, better bone−implant contact is observed. In the case of human patients with severe periodontal PDL and bone loss, the inflammatory aspects would need to be controlled and have some level of PDL regeneration that might make this Wnt3a approach viable for the clinic.

The PDL and its attachment to the bone and cementum is an enthesis. The normally quiescent PDL can be activated by tooth movement, as in orthodontic treatment, and the PDL is mechanically responsive to mastication. In mice, eating a soft

or liquid diet leads to major changes in collagen fiber−PDL orientation and integration into the cementum and a decrease in PDL proliferative cells (Huang et al., 2016). In the case of tooth movement, massive reorientation and integration into the cementum occurs, with increases in Runx2 and Osterix expression. Mastication has been shown to lead to a burst of Wnt-responsive cell proliferation, and if a mouse is fed a soft diet from weaning, this burst in load-mastication phenomena is reduced (Zhang et al., 2019). The alveolar bone and PDL undergo atrophy on this unloaded soft diet protocol.

A secreted and negative regulator of Wnt signaling, the Sost gene product sclerostin protein, is produced primarily by osteocytes and cementocytes (Jager et al., 2010). Sclerostin selectively binds to LRP5/6 receptors and blocks canonical Wnt signaling (Li et al., 2005). Deletion of the Sost gene in mice and in Van Buchem syndrome (human mutation in Sost leading to sclerosis) has major effects on bone composition and periodontium homeostasis (Kuchler et al., 2014; Hassler et al., 2014). In the periodontium, alveolar bone formation is accelerated and cementogenesis increases in the periodontium (Kuchler et al., 2014). Bone composition is also altered in Sost knockout gene homozygote (SostKO) mice and humans with Sost mutations, with an increased ratio of proteoglycans to calcium matrix (Hassler et al., 2014).

Expression of sclerostin is also influenced by mechanical loading. Increased mechanical loading in vivo has been shown to downregulate the SOST gene, resulting in increased bone deposition (Robling et al., 2008). In the presence of decreased load, the SOST gene is upregulated, causing bone resorption (Morse et al., 2018). Also, data now show that even in the SostKO mouse model, mechanical loading can further increase bone formation, especially in young mice (Spatz et al., 2015).

Two published studies have demonstrated alveolar bone regeneration in experimental periodontitis when the sclerostin antibody (Scl-Ab) was administerd (Taut et al., 2013; Chen et al., 2015). In ligature-induced periodontitis in ovariectomized rats, systemically administered Scl-Ab treated rats had a greater increase in regeneration of the alveolar bone around the teeth. Bone formation markers including PINP and osteocalcin in the Scl-Ab group were similar to those of the periodontal healthy group at 6 weeks (Chen et al., 2015). Dickoff1 (Dkk1) is also a potent inhibitor of Wnt signaling by binding the LRP5/6 signaling complex. New studies using a single and combination treatment with antibody to sclerostin and/or Dkk1 in a rat ovariectomized mouse model of chronic maxillary molar extraction show preserved and augmented alveolar bone volume and architecture (Liu et al., 2018). Of interest, the mandibular molar tooth across from the extracted maxilla molar tooth experiences no occlusal loading. These mandibles with unloaded teeth show massive loss of alveolar bone. This loss was prevented in the unloaded mandibles by treatment with either Scl-Ab or the combination of Scl and Dkk1 antibodies.

Periostin is a key protein expressed by primarily PDL cells in the periodontium; deletion of periostin leads to a variety of phenotypes including severe loss of PDL, cementum, and alveolar bone (Tsuji et al., 2006). Crossing periostin KO mice with SostKO mice or treating the mice with sclerostin antibody rescues these defects in the periodontium (Ren et al., 2015). Osteocyte number and connectivity in the alveolar bone of the periostin KO are greatly disrupted; however, treatment of these mice with the sclerostin antibody brings back normal and highly connected osteocyte dendritic structure. This disruption in osteocyte connectivity and orientation is correlated to poor quality of bone architecture, but the mechanisms are poorly understood. Fig. 43.1 shows how the alveolar ridge increases, bone porosity decreases, and normal osteocyte morphology is restored in periostin KO mice treated with sclerostin antibody or crossed with the SostKO mouse.

Bmp2 gene function in the periodontium

Early studies of Bmp2 (bone morphogenetic protein 2) regulation in primary and other cell models demonstrated that of all the Bmps, Bmp2 mRNA expression was sensitive to a variety of signaling molecules, such as TGFβ and Bmp itself. Bmp2 showed dynamic changes in expression in osteoblasts at different times and states of differentiation. The first conditional knockout of the Bmp2 gene, with Prx-Cre in middle stages of embryonic development, showed dramatic changes in postnatal long bones that were very narrow as well as dramatic changes in chondrogenesis. These mice developed extensive bone fractures that would not heal (Tsuji et al., 2006). Bone graft materials and techniques are critical for the periodontist to treat periodontitis and the loss of bone around the teeth. If bone graft material was from a Bmp2 cKO mouse, the bone grafts failed to incorporate into the healing process, indicating that at least one key material in bone graft material is the Bmp2 protein (Chappuis et al., 2012). Further studies of conditional KO of Bmp2 and Bmp4 demonstrate that the Bmp2 gene is critical for chondrogenesis (Shu et al., 2011). However, earlier studies of conditional Bmp4 KO with the Col1a1-3.6-Cre model indicate that Bmp4 plays a key role in development of the tooth root and periodontium and potentially an indirect role in amelogenesis (Gluhak-Heinrich et al., 2010). In these studies, deletion of the Bmp4 gene led to a dramatic decrease in Bmp2 expression. Therefore, the interacting roles of Bmp2 and Bmp4 in the periodontium, as well as in long bones needs further investigation.

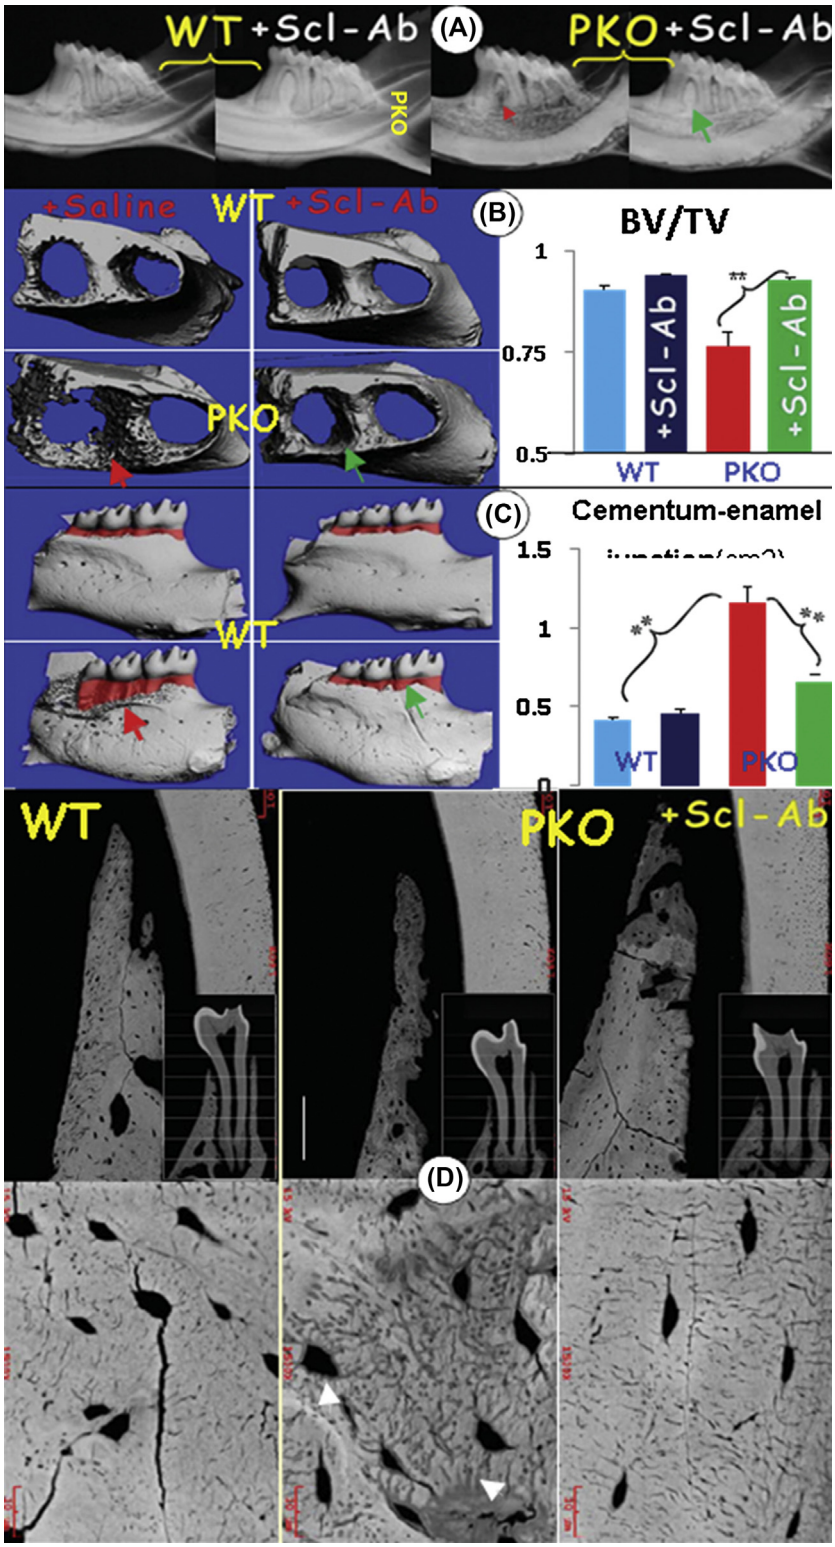

FIGURE 43.1 Restoration of bone loss, defective CEJ area (cementum-enamel junction), and defective osteocyte morphology (5 months, after 2-month Scl-Ab treatment, 25 ug/gm 2x per week) in the periostin KO (PKO) mouse model. (A) X-ray showing correction of alveolar bone loss with Scl-Ab treatment in PKO (periostin knockout) mice (3−5 month treatment, 2x per week). (B) uCT showing loss of alveolar bone in PKO mice and correction with Scl-Ab treatment. (C) uCT analysis around the CEJ region (buccal), and loss of alveolar bone ridge and correction with Scl-Ab treatment as above. Note large quanitative increase bone ridge around teeth with Scl-Ab treatment (marked cememtum). (D) Backscatter SEM shows loss of Ca++ signal in alveolar bone matrix in PKO (bone quality) and regain of bright white signal in PKO mice treated with Scl-Ab. Note the more elliptical osteocytes in control and Scl-Ab treated Periostin KO mice, and the disorganized dendritic processes in the Periostin KO, generally a reflection of poor quality of the bone matrix. Scl-Ab treatment of the Periostin KO rescues this disordered dendritic osteocyte structure. (From Ren et al, 2015, with permission from FASEB J)

The deletion of the Bmp2 gene in Osterix+ cells, with the use of an Osterix-GFP-Cre mouse model, resulted in a dramatic phenotype in the development of tooth roots as well as in major defects in cellular cementogenesis, PDL formation, and alveolar bone formation around the teeth (Rakian et al. 2013). In these mice, there were decreases in periostin, a marker for PDL; Nfic, a critical transcription factor for root and PDL formation; and VegfA, a critical factor for vascular formation produced by periodontal fibroblast, osteoblast, and odontoblast. There were also reduced CD31+ endothelial cells on capillaries and associated CD146+ and αSMA+ pericytes. This again shows the link of Bmp2-regulated VegfA production and the creation of the vascular niche for stem/progenitor cells. Also, this is demonstrated in long bones with Bmp2 cKO with the Col1a1-Cre model (Yang et al., 2013). Vascular endothelial cells make very little Bmp2, but the associated pericytes can be activated to begin production of Bmp2 in a paracrine manner from the more mature cells that produce high levels of endogenous Bmp2 protein.

Because Osterix+ cells are in both the PDL region and pulp, and deletion of Bmp2 affects both structures, separating the indirect effects on root, PDL, and cementum formation has been difficult. The αSMA-CreERt2 model was used to address these separate issues because αSMA+ cells are very low in dental pulp but highly expressed in the PDL region where these stem/progenitor cells reside. As stated earlier, αSMA+ cells, by lineage tracing, have been shown in vivo to be stem/progenitor cells in both long bones and the periodontium, at least during the first couple months of life (Roguljic et al., 2013; Grcevic et al., 2012). Lineage tracing studies with αSMA-CreERt2 with td Tomato as a marker follows the fate of these αSMA+ stem/progenitor cells. In the presence of Bmp2 cKO, with the aSMA-CreERt2 model (TAM at 6 days) in these cells, demonstrate that the Bmp2 gene is required for their lineage progression to mature PDL, as marked by colocalization of the red td Tomato+ cells and the antibody periostin. This is shown in Fig. 43.2.

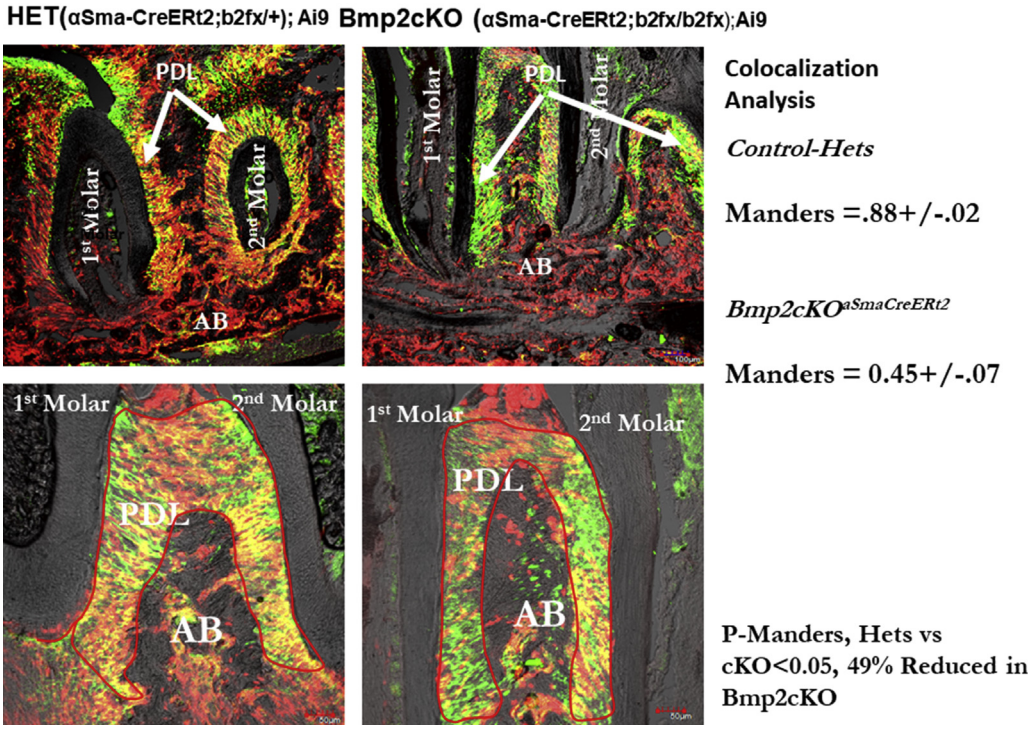

FIGURE 43.2 Deletion of the Bmp2 gene in αSMA+ cells decreases the capacity of these stem/progenitor cells to differentiate into periostin+ periodontal ligament fibroblasts. (A) Section through first and second molar (10× confocal) of heterozygous mice with αSMA-CreERt2- Bmp2 fx/+ and Rosa26-stop-tdTomato allele (Ai9). Note the high concentration of red and green colocalized in the PDL region (*yellow cells or white to light gray in the printed version*). (B) Section through the first and second molar of Bmp2 conditional knockout, αSMA-CreERt2-Bmp2fx/fx, and Rosa26-stop-tdTomato allele. Note the reduced colocalization of red and green pixels in the PDL fibroblasts. (C) Higher magnification (20×) of A. HET, with the red line defining the area quantified by the Coloc 2 program. (D) Higher magnification (20×) of B. (Bmp2 cKO), with the red outline region used for quantification. Mice were 1 month old, and the 50% reduction of periostin-tdTomato signal in the Bmp2 cKO was quantified using the Fiji ImageJ Coloc 2 program. The Manders coefficient shown on the right is a measure of threshold red and green pixel overlap. Note in A and B, the reduced tdTomato+ cells in the alveolar basal bone in the Bmp2cKO compared with the heterozygote, and no green periostin signal, reflecting the relative periodontal specificity of the periostin marker for PDL. The Manders coefficient is a quantitative measure of the true overlap of the green and red signal, thresholded using the coloc2 program in Fiji.

Lineage tracing with other markers, such as Dmp1 and Ibsp (Bsp), demonstrate that the Bmp2 gene is required for differentiation to both acellular and cellular cementoblasts and cementocytes and alveolar bone osteocytes (Rakian et al., 2019).

Since the Bmp2 gene and its endogenous expression appear to be a critical node downstream of a variety of signaling pathways, understanding how this gene is regulated at various levels has been of interest for the past 25 years. For example, statins were identified as positive regulators of Bmp2 transcription, Bmp2 protein production, and increasing bone mass in various in vivo models (Mundy et al., 1999). However, statin side effects on muscle in some individuals have limited the use of statins as an anabolic bone agent in humans. Other methods that appear promising to activate the endogenous Bmp2 gene include Wnt signaling molecules. For example, in vivo activation of the Wnt pathway with Axin2 cKO in chondrogenic models increases both Bmp2 and Bmp4 expression (Yan et al., 2009). Studies now show that Bmp2 transcription and mRNA expression are dependent on Wnt3a and B-catenin activity (Zhang et al., 2013). Blocking Wnt activity with Dkk1, sFRP4 or β-TrCP, ICAT, or delta TCF4 decreases transcription of the Bmp2 promoter-enhancer 5′ region. Site-directed mutagenesis of a Wnt/TCF response region in this Bmp2 promoter-enhancer region blocked Wnt3a activity on the Bmp2 gene. Using an immortalized mouse limb bud cell model in which the endogenous Bmp2 gene is inhibited by siRNA, studies demonstrated that the key transcription factors Osterix and alkaline phosphatase were dramatically inhibited at the basal level. Bone marrow stromal cells (BMSCs) were prepared from Bmp2fx/fx mice, and the endogenous Bmp2 gene was deleted with Ad-CMV-Cre. Recombinant Bmp2 can still stimulate Osterix expression in these in vitro Bmp2-deleted cells, but Wnt3a has now lost the ability to stimulate Osterix, alkaline phosphatase, and Col1a1. Wnt3a-stimulated mineral matrix is greatly reduced in Bmp2 KO cells. Thus, the transition to a Runx2/Osterix+ cell requires the Bmp2 gene and cannot be compensated for by canonical Wnt signaling (Salazar et al., 2016). These data support the hypothesis that the endogenous Bmp2 gene is a critical downstream node of canonical Wnt signaling in bone biology. In support of this hypothesis, the coumarin-like compound from Chinese herbs, osthole, stimulates bone formation in ovariectomized mice and calvarial assays by stimulating both β-catenin signaling and Bmp2 expression (Tang et al., 2010). Deletion of the Bmp2 gene in vitro blocks osthole-induced osteoblast differentiation through the β-catenin pathway. Osthole also decreases inflammation profiles, suppresses bone resorption, and increases osteogenic differentiation in periodontal stem cells by epigenetically increasing the positive H3K9ac states associated with increased β-catenin. This suggests that osthole can be used to treat periodontitis (Sun et al., 2017). Recent studies also show that in the presence of the SostKO model, increased canonical Wnt signaling in vivo cannot rescue the loss of bone and defective periodontium defects seen in the Bmp2 cKO with either the αSMA-CreERt2 model or the Osterix-CreERt2 model. Fig. 43.3 shows X-rays that demonstrate that in the presence of SostKO and increased canonical Wnt signaling, bone loss in both long bones and periodontium due to the absence of Bmp2 gene in these stem/progenitor cell populations cannot be rescued in the presumed presence of elevated Wnt signaling, as can be rescued in the periostin KO model.

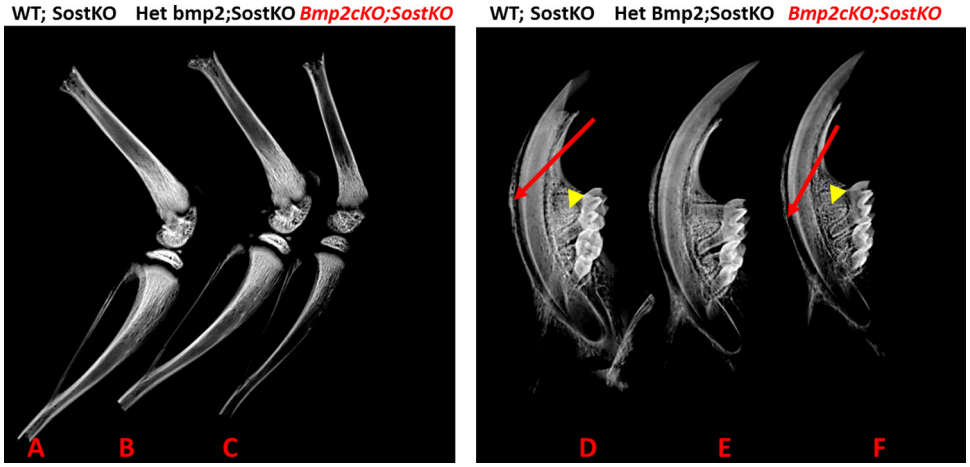

FIGURE 43.3 Decreased trabecular and cortical bone in long bones and decreased alveolar bone in the mandibles of Bmp2 cKO with the αSMA-CreERt2 model cannot be rescued by Sost knockout gene homozygotes (SostKOs). Compare A and B with C for long bones and D and E with F for mandibles. A. Wild-type for Bmp2 and SostKO. B. Heterozygote for Bmp2 gene and SostKO. C. Bmp2 cKO with SostKO—long bones. D. Wild-type for Bmp2 and SostKO. E. Heterozygote for Bmp2 gene and SostKO. F. Bmp2 cKO with SostKO—mandibles, 1-month animal at sacrifice. Tamoxifen at 100 ug/gm given at days 4, 12, and 21. In D and E, note the thinner and less radiopacity in the alveolar bone (*arrowheads*) and basal bone surrounding the incisor (*arrows*).

Also, excess Wnt signaling using a constitutively active β-catenin driven by the Dmp1 promoter causes major destruction of the PDL's fibrous nature (enthesis), excess cellular cementum formation, and ankylosis and fusion of the bone to the root of the teeth (Wu et al., 2018). Most likely, excess activation of the Bmp2 gene and other unknown genes contributes to activated mineralization programs, alveolar bone, and cellular cementum. In the clinic, the use of rBmp2 in periodontal regeneration results in the destruction of the PDL and ankylosis of teeth to the bone. This reminds us that many of these pathways, having so many feed-forward and feedback loops, are constantly searching for the optimal signal levels at a given time, what is referred to as the "goldilocks effect," or having just the right amount of a given signal for a given cell at a given time interval.

The words are heard so often at the end of various studies and presentation: "and target gene expression." What this means is that for the future, the set of target genes, and how they integrate into the biology of what is being studied, will give a better and deeper understanding of that biology. Using the new tools of epigenomics, transcriptomics of single cells, and CrispR-Cas9-selective modulations of the genome, will provide a greater depth of knowledge of these complex biological processes, especially for bone and periodontium biology. For example, the complete list of all Runx2 binding sites used during the MC3T3 osteoblast model has been defined (Meyer et al., 2014; Tai et al., 2017). These resources can be utilized for various select studies in which a deeper understanding of over 5000 Runx2 sites and interactions with other transcription factors, such as members of the C/EBP family and Sp7 (Osterix), can be investigated in the context of other individual studies. Epigenomic changes, active enhancer maps with H3K27ac, repressor maps with H3K27 and 9me3, and promoters with H3K4me3 chip-seq studies have been carried out at various stages of αSMA+ progenitor cell differentiation up to a highly mineralizing state (Wu et al., 2017). Work on defining the Osterix binding sites on a genome-wide basis, in collaboration with Dlx5 and the genes that Osterix-Dlx5 regulates during MC3T3 osteoblast differentiation and in primary calvarial osteoblasts, is a powerful resource for studying and developing gene network models for osteoblast differentiation and comparing with periodontium biology (Hojo et al., 2016).

The gene, epigenomic, and transcription network of PSCs that differentiate into three major components of the periodontium has great promise to develop specific methods and therapeutics for regeneration of the complete periodontium including alveolar bone and crest height and healthy PDLs with good attachment to both bone and cementum. The transcriptome at four different stages of differentiation of αSMA+ PSC, with and without the endogenous Bmp2 gene, has been determined on a genome-wide basis (Rakian et al., 2019). Deletion of the endogenous Bmp2 gene in this in vitro system demonstrates that the endogenous gene is critical for differentiation of PSCs to the three major cell types of the periodontium. Osterix is decreased over fivefold without the endogenous Bmp2 gene. Of the 576 genes reduced in expression, over 51 histone genes and other growth-related genes were reduced 2- to 50-fold. These studies reinforce the concept that the endogenous gene is critical not only for differentiation but also for fundamental growth and expansion of these stem/progenitor cells from their niche, in many cases the capillaries. These in vitro observations were validated in vivo using EdU-labeled animals and demonstrated that αSMA+ cells have reduced capacity to proliferate and expand in the absence of the endogenous Bmp2 gene in these PSCs (Rakian et al., 2019).

The growth-promoting activity of the Bmp2 gene may depend on the Bmp2 ligand and select receptor patterns on the cell at a given stage or time (Chapter 48, by Vicki Rosen et al, titled Bone morphogenetic proteins). Over 2500 genes change expression between the undifferentiated and mineralizing state, with many gene ontologies supporting this differentiation gene set. The major gene expression changes occur during differentiation without the addition of rBmp2. However, many of these differentiation-associated gene expression changes do not occur when endogenous Bmp2 is deleted and can only be partially rescued by the addition of rBmp2. The extent of rescue is dependent on the added rBmp2 ligand levels.

For many years, small regions of the Bmp2 gene have been studied to determine how the gene is regulated and if methods could be discovered to increase its transcription, leading to increased endogenous Bmp2 production and possible new bone formation. As discussed, there are Wnt response regions in the 3 kb enhancer-promoter region of the Bmp2 gene and Bmp2 mRNA and protein that are a critical node downstream of canonical Wnt activity. Estrogen response elements in the Bmp2 regulatory regions have also been found in vitro in osteoblast cell line studies (Zhou et al., 2003). Estrogens including tamoxifen and genistein can directly activate Bmp2 transcription through an ERE or estrogen DNA response element. A variety of studies have shown that various phytoestrogens have positive in vivo roles as traditional suppressors of osteoclastogenesis and anabolic bone-formation agents. Studies of these phytoestrogens and their mechanism of action with in vitro cell models have demonstrated that many osteogenic genes are activated including the Bmp2 gene. Quercetin stimulates matrix mineralization and the proliferation of primary osteoblasts and increases Bmp2 expression twofold through the estrogen receptor−mediated pathway (Pang et al., 2018). Another example is Icariin phytoestrogen, which stimulates osteoblast differentiation and inhibits adipocyte differentiation through an estrogen-mediated pathway (Li et al., 2018). Estrogens play an important role in bone formation and resorption in both men and women, and have been

extensively reviewed (Khosla and Monroe, 2018). Further studies on the role and action of estrogen in the presence and absence of the Bmp2 gene on both the periodontium and long bones will be of interest.

The decapentaplegic gene (dpp) in fruit flies is equivalent to the Bmp2/4 genes in mammals. Studies of the regulation of this gene in leg and wing formation found that many of the regulatory elements in the genome are 3′ and hundreds of thousands of base-pairs away from the dpp promoter region (Blackman et al., 1991). Likewise, the Bmp2 gene lies in a "genomic desert" with no other major coding gene within one million base pairs of the promoter. The part of the Bmp2 gene that has been studied for so long is like the "tip of an iceberg." If one looks at the enhancers in the Bmp2 gene in a variety of in vivo and many in vitro cell models using simple tools in NCBI, it becomes apparent that the 5′ 2-3 Kb region upstream of the transcription start side is loaded with enhancer marks, such as the H3K27ac site and open chromatin domains. However, downstream of the gene body are massive candidate-enhancer regions that are to some extent cell or tissue specific. Also, much data is available on the "connectome" of the Bmp2 gene region, distal regions of the Bmp2 gene region up to 1 Mb away that connect—loop in 3-D genomic space—with the Bmp2 promoter-enhancer region. Therefore, to understand transcription regulation and upstream pathways, this larger region of the Bmp2 gene area needs investigation. Using various epigenomic tools, enhancers in the Bmp2 area up to 1 Mb from the gene body have been studied in αSMA+ osteoblast differentiation (Wu et al., 2017), and one can now overlay with enhancer maps at various stages of αSMA+ PSCs differentiation (Rakian et al., 2019). Also, open chromatin domains activated during differentiation of PSCs have been defined, with over 30,000 ATAC-seq peaks induced 2- to 30-fold over the undifferentiated state. Motif analysis found over 5000 new Runx2 sites and 10,000 AP-1/Atf3-4 sites. Specifically in the 1 Mb region 3′ from the 10 KB Bmp2 gene body, 25 new open chromatin domains were increased on differentiation, and motif analysis again found enrichment of Runx2 sites, candidate Sp7 sites, and AP-1 sites (Rakian et al., 2019). Fig. 43.4 shows an example of this analysis for the Bmp2 gene at several stages of PSC differentiation in over the 1 Mb 3′ region with the 25 or so enhancers marked with H3K27ac peaks and overlaid with the open chromatin domains defined by ATAC-seq analysis.

Much of the genome is organized into topological-associated domains (TADs). These 3-D structures define sets of genes insulated from the regulatory regions of genes in adjacent cis regions or across chromosomes in trans within the genome. The Bmp2 gene body and 3′ 1 Mb region lie in a unique TAD as marked by the red line. Some RNA-seq data with many long-coding RNAs are associated with enhancers and likely play an enhancer RNA role. Overlaid are also maps of enhancer regions in αSMA+ BMSCs at three stages, and demonstrate that many of these enhancer regions are used in both long bone osteoblasts and the periodontal PSC differentiation program. Future studies of the interacting role of these osteoblast and PSC enhancers will lead to a deeper appreciation of the complexity of gene regulation the Bmp2 gene and hopefully new approaches to activate endogenous Bmp2 production.

Key regulators of mineral metabolism and the periodontium

Many markers we use to study BMP2- and Wnt-regulated genes control enthesis formation and mineralization and play key roles in periodontal biology. Loss-of-function mutations in the gene *ALPL* in the inherited disease hypophosphatasia (HPP; OMIM# 241500, 241510, 146300) cause reduced tissue-nonspecific alkaline phosphate (TNAP) activity and increased levels of inorganic pyrophosphate (PP_i), a potent inhibitor of mineralization (Bowden and Foster, 2018; Millan and Whyte, 2016). While severe skeletal defects, including rickets, can accompany the most severe cases of HPP, premature primary tooth loss is nearly universal among affected individuals across the disease spectrum. The cause of premature tooth loss is the reduction, absence, or hypomineralization of acellular cementum resulting in weakened or absent periodontal attachment (Fig. 43.5A) (Bruckner et al., 1962; Foster et al., 2014), Bruckner et al., 1962; Foster et al., 2014). HPP is also associated with mineralization defects in enamel, dentin, and alveolar bone, with periodontal disease demonstrated in some case reports and in global and conditional *Alpl* knockout mouse models of HPP (Fig. 43.5B) (Foster et al., 2017; Foster et al., 2013b; Hu et al., 2000; Luder, 2015; Reibel et al., 2009; van den Bos et al., 2005; Yadav et al., 2012).

While TNAP activity reduces PP_i levels, additional factors work in opposition. Ectonucleotide pyrophosphatase phosphodiesterase 1 (ENPP1) and progressive ankylosis protein (ANKH in humans/ANK in mice) both increase extracellular PP_i, and are thought to prevent ectopic calcification at distinct sites throughout the body. Loss of function of either ANK or ENPP1 in mice causes dramatically increased acellular cementum growth, while not substantially affecting enamel or dentin and only modestly affecting cellular cementum and alveolar bone (Fig. 43.5C, D) (Ao et al., 2017; Foster et al., 2012; Thumbigere-Math et al., 2018). While the effects of *ANKH* mutations on cementum in humans have yet to be demonstrated, loss of function of *ENPP1* has a similarly dramatic effect on human acellular cementum in a GACI subject (Fig. 43.5E, F) (Thumbigere-Math et al., 2018). Based on evidence from humans and mice, "tuning" of cementogenesis by PP_i appears to be a powerful evolutionarily conserved mechanism.

FIGURE 43.4 Example of transcriptome and epigenomic analysis of the Bmp2 gene region of 1.44 million base pairs. Note the turquoise regions that mark the 10 kb transcription gene body and over one million base pairs away on the 3′ side, the Hao1 gene body in turquoise. This area including the Bmp2 5′ promoter-enhancer region to almost the Hao1 gene body is of key interest because of all the regulatory regions discovered and modulated during PSC differentiation as well as long bone osteoblast BMSC differentiation. The CM6 clonal cell model is used to study the process of stem cell to cementoblast and cementocytes in the cellular cementum, and the SW3 clonal cell model is used to study the process of osteoblastogenesis, all the way to osteocytes. In all cell models, Cd1 is control at day 1—one day past confluency, Bd1-d22 are rBmp2 treated (50 ng/mL) at days 1, 5, 10, 14, 16, and 22 as indicated. In PSCs and BMSC primary cells, by day 14 a complex mineralizing culture has formed with early expression of Dmp1, osteocalcin, and Ibsp (Bsp). The double-lined box defines the Bmp2 transcription unit (turquoise) and local surrounding region, with strong overlap of ATAC peaks (open chromatin domains) with active enhancer H3K27ac chip-seq peaks in primary PSCs and BMSCs in published data on αSMA+ Bmsc (Wu et al., 2017), with a twofold to fivefold increase of both enhancer-promoter and open chromatin regions. Red boxes at the CTCF insulator marks (indirect repeats) show about a 3′ 1 Mb region that defines a TAD for the Bmp2 gene region in mouse and humans in many cell and tissues, forming a large chromatin 3-D structural loop. Light blue boxes (RNA-seq data-lower part of figure), show Bmp2 expression that increases 20-fold to 70-fold in the various models, with differentiation—i.e., Cd1 to Bd5 in the PSC, by Bd14 in long bone osteoblast BMSCs, by Bd10 in CM6 cells, and by Bd22 in SW3 cells. Light green boxes A, B, and C show overlap of ATAC-seq open chromatin domain, overlaps with enhancer regions, increased changes associated with differentiation, and associated Sp7 (Osterix), Dlx5, and Runx2 chip-seq peaks from published data in αSMA+ osteoblast models. These regions are about A. 350,000; B. 800,000; and C. 900,000 bp from the Bmp2 5′ promoter-enhancer region studied for so many years. Orange boxes in this 1 Mb 3′ region of the Bmp2 gene show areas of increased expression of long-noncoding RNAs during differentiation in these enhancer areas, overlap in the different cell models, and a subset that intersects with ATAC and H3K27ac peaks. BMSC d0 and d21 for H3K27ac and CTCF are from GEO GSE76074 (Wu et al., 2017); Sp7 and Dlx5 are from GEO GSE76187 (Hojo et al., 2016); and Runx2 are from GSE41920 (Meyer et al., 2014). Orange arrow, near the Bmp2 transcription unit, defines a Wnt/b-catenin-TCF response region.

Disorders of inorganic phosphate (P_i) metabolism can strongly affect periodontal mineralization. These include acquired conditions such as vitamin D deficiency and inherited disorders such as X-linked hypophosphatemia (XLH; OMIM# 307800; mutations in the *PHEX* gene) and autosomal recessive hypophosphatemic rickets (ARHR1; OMIM# 241520; mutations in the *DMP1* gene) (Foster et al., 2014; Biosse Duplan et al., 2016; Coyac et al., 2017; Fong et al., 2009; Ye et al., 2008). Defects in cementum and alveolar bone, and enamel and dentin, may arise from the direct effects of insufficient phosphate for mineralization as well as from disturbances in vitamin D signaling, FGF23 signaling, and local levels of ECM proteins.

Cementum and alveolar bone have significant overlap in their ECM constituents including BSP and OPN, members of the small integrin-binding ligand N-linked glycoprotein (SIBLING) family and two of the most commonly used markers for osteoblasts and cementoblasts (MacNeil et al., 1995a; MacNeil et al., 1995b; McKee et al., 1996). In vitro and in silico studies suggest that BSP promotes hydroxyapatite crystal growth (Harris et al., 2000). Genetic ablation of the *Ibsp* gene (Bsp protein) in mice results in a decrease or an absence of acellular cementum, causing periodontal detachment and breakdown (Fig. 43.5G) (Foster et al., 2013a; Soenjaya et al., 2015). Lack of BSP also causes delayed mineralization of

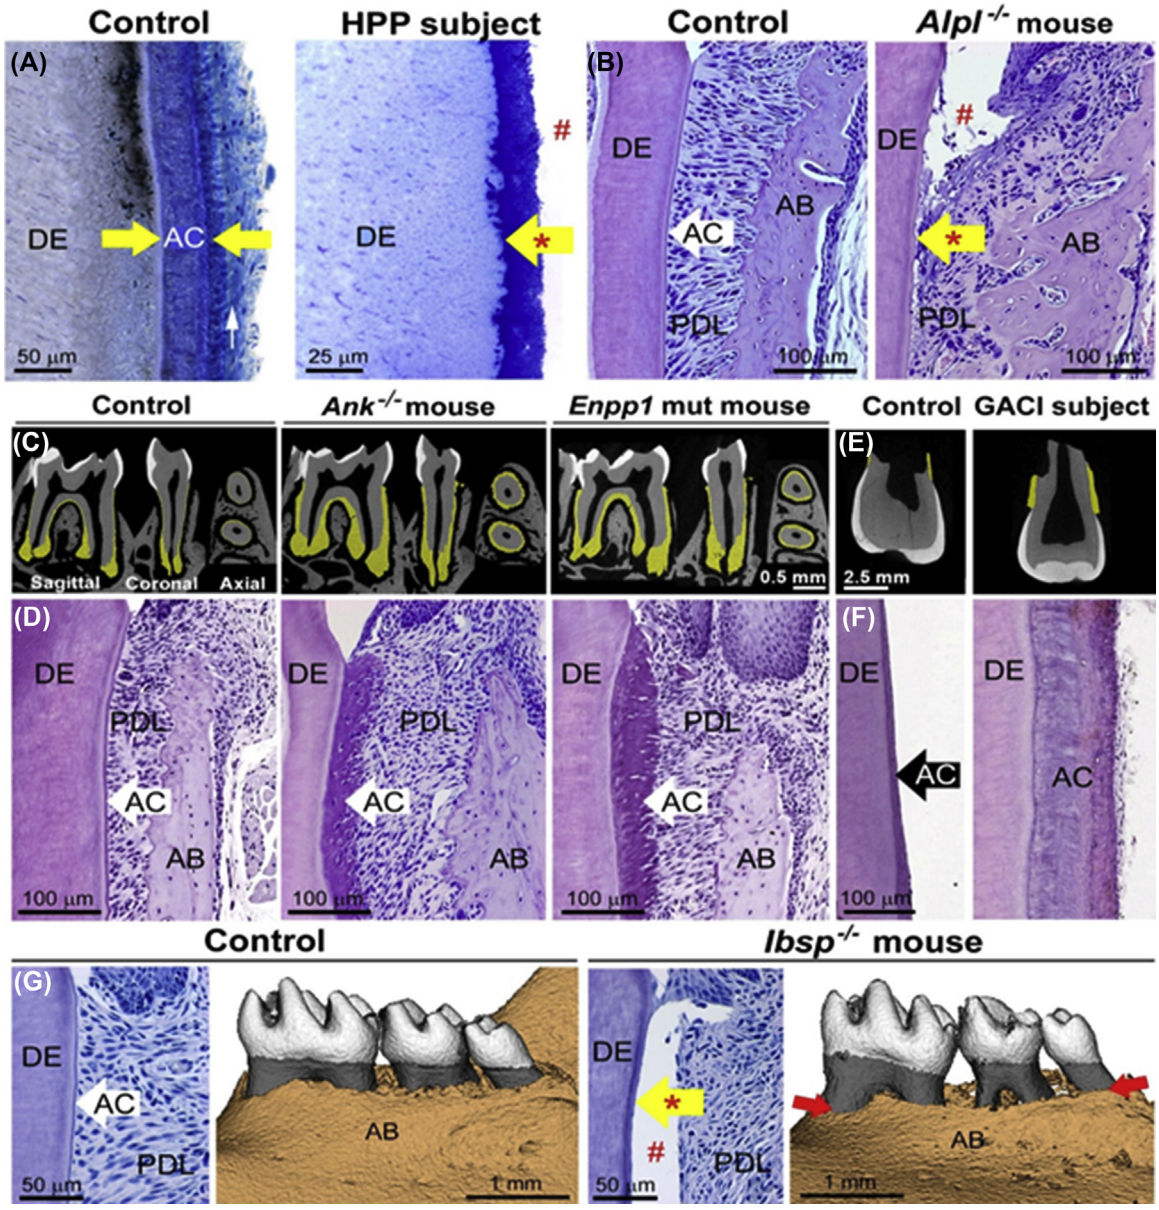

FIGURE 43.5 Key regulators of mineral metabolism and the periodontium. (A) Compared with the well-developed acellular cementum (AC) on the root dentin (DE) surface in a healthy control tooth, HPP (hypophosphatemia) inhibits AC formation, allowing bacterial invasion and formation of dental plaque (P). (B) Compared with the functional periodontium in control mice, molars from *Alpl*$^{-/-}$ mice exhibit deficient AC (*red**) (light grey in print versions), periodontal ligament (PDL) detachment (#), and accumulation of osteoid at the alveolar bone (AB) surface. (C) Compared with normal control mice, microcomputed tomography reveals that molars from *Ank*$^{-/-}$ and *Enpp1* mutant mice feature dramatically increased AC (*highlighted yellow*) (white arrowhead in print versions). (D) Histology images of H&E stained sections show increased AC in *Ank*$^{-/-}$ and *Enpp1* mutant mice compared with controls. (E) Compared with an exfoliated primary incisor from a healthy control subject, microcomputed tomography reveals that the primary incisor from an individual with GACI (loss-of-function mutations in *ENPP1*) exhibits increased AC (*highlighted yellow*). (F) H&E stained histology sections from a control and GACI subject reveal the dramatically expanded AC from loss of ENPP1 function. (G) Compared with H&E stained sections of control mouse molars, *Ibsp*$^{-/-}$ mice feature reduced or absent AC (*red* *) and PDL detachment (#). Microcomputed tomography scans of mandibles show reduced AB (*red arrows*) around roots of *Ibsp*$^{-/-}$ mouse molars. *Panel A images adapted from Luder,* Front Physiol *6:307, 2015, and reproduced with permission under the terms of the Creative Commons Attribution License (CC BY). Panel B images adapted from Bowden and Foster,* Drug Des Devel Ther *12:3147–3161, 2018. cellular cementum and alveolar bone, with no substantial effects in dentin or enamel. By contrast, the closely related protein OPN (osteopontin or Spp1) regulates or inhibits mineralization (Boskey et al., 2002). Genetic ablation of *Spp1* did not substantially affect cementogenesis; however, there was increased volume and mineralization of alveolar bone and dentin (Foster et al., 2018). BSP, OPN, and other SIBLINGs have been increasingly linked to P_i/PP_i metabolism. OPN expression is tied to expression of *Alpl*, *Ank*, and *Enpp1*, and these work in concert to direct the P_i/PP_i ratio and mineralization milieu (Harmey et al., 2004; Harmey et al., 2006). Genetic ablation of the *Ibsp* gene resulted in perturbation of some P_i/PP_i regulators, and ablation of ANK in the absence of BSP (lowering PP_i levels) reestablished acellular cementum formation and periodontal function (Ao et al., 2017). However, genetically decreasing PP_i levels did not completely overcome the absence of BSP, confirming that BSP does not function solely through P_i/PP_i-related mechanisms and is likely exerting effects through one or more of its functional domains.

Temporal expression of Ibsp, Spp1, TNAP, ANK, and Enpp1 genes is dynamic during differentiation of osteoblasts or periodontal stem cell differentiation, and most are regulated by BMP signaling at some level as shown in Bmp2 conditional knockout studies in bone and periodontium. BMP2 gene expression and action is in part downstream of Wnt-PTH/PTHrP and hh pathways, as discussed. These observations in humans and mouse studies demonstrate the importance of Ibsp, Spp1, TNAP, and Enpp1 genes in regulating extracellular and highly organized mineralized matrix formation in both bone and the periodontium, where tight regulation of these processes is necessary for maintaining a healthy, tendon-like enthesis between the alveolar bone and cementum as well as controlled rates of spatially determined mineralization.

Periodontal stem/progenitor regeneration and methods to control inflammation in periodontal disease

As stated, PDL tissues are derived from the DF (Woodfin et al., 2011) region, which originates from the cranial neural crest during tooth development (Miletich and Sharpe, 2004; Chai et al., 2000). The DF is a condensation of the ectomesenchymal tissue (Grant and Bernick, 1972). PSCs isolated from the PDL have been shown to have MSC characteristics including in vitro trilineage differentiation potential (Gay et al., 2007). Numerous studies have reported PSCs expressing pericyte markers including CD146 and STRO-1 (Xu et al., 2009; Iwasaki et al., 2013; Nagatoma et al., 2006), which is consistent with Bruno Péault's group suggesting that MSCs originate from the perivasculature (Crisan et al., 2008; Corselli et al., 2010). PSCs isolated from the PDL using colony selection and STRO-1/CD146 developed into cementoblast-like cells and adipocytes in vitro. In vivo transplantation showed that in vitro expanded PSCs generate a cementum/PDL-like complex characterized by a layer of aligned cementum-like tissues and clearly associated PDL-like tissues. They also showed the capacity to form collagen fibers, similar to Sharpey's fibers, connecting to the cementum-like tissue (Seo et al., 2004). This study demonstrates that a large fraction of PSCs are derived from a population of perivascular cells and may be an effective target for periodontal regenerative therapy. αSMA+ cells on the capillaries are classified as pericytes (Alarcon-Martinez et al., 2018). In an in vitro study, PSCs possessed the capacity to adhere to endothelial cell capillary networks in coculture experiments, mimicking pericyte-like localization in vitro, and expressed pericyte markers NG2+ and CD146+ on the cell surface, also suggesting that these cultured PSCs originated from perivascular cells and function as pericytes (Iwasaki et al., 2013). Chen et al. also showed that STRO-1/CD146 were expressed around blood vessels in the PDL (Chen et al., 2006) Lin et al. demonstrated that regenerating periodontal tissue obtained from guided tissue regeneration procedures contained cells that express the MSC-associated markers STRO-1, CD146, and CD44 and had the capacity to form mineral deposits and fat cells in vitro (Lin et al., 2008). In another study, PSCs expressed the perivascular cell markers NG2, α-SMA, PDGFR-β, and CD146 and formed vessel-like structures in vivo (Bae et al., 2017).

Periodontitis is a chronic osteolytic inflammatory disease of bacterial etiology. The sustained microbial challenge and dysbiosis is due to a failure of endogenous resolution of inflammation pathways that results in host-mediated destruction of the hard and soft tissues of the periodontium (Taubman et al., 2007; Graves et al., 2008; Fredman et al., 2011; McCauley and Nohutcu, 2002; Van Dyke, 2011). Resolution of inflammation is an active and highly coordinated response modulated by specialized proresolving lipid mediators (SPMs) (Hasturk et al., 2007; Serhan et al., 2007) that include lipoxins (LXs), resolvins (Rvs), protectins, and maresins. SPMs are physiologic mediators and pharmacologic agonists that stimulate the resolution of inflammation and infection (Serhan, 2017). SPMs exhibit multipronged actions that improve the outcome of inflammation-related pathologies in experimental models and clinical trials (Serhan, 2007; Colas RA et al., 2014; Van Dyke et al., 2015; Cianci et al., 2016).

In periodontitis, SPMs have been shown to directly improve bone healing and regeneration (Hasturk et al., 2006, 2007). Resolvin E1 (RvE1) downregulates inflammation in vivo in periodontitis at molecular and histological levels (Hasturk et al., 2006; Bannenberg et al., 2005) and stimulates the resolution of inflammation and bone formation by directly

modulating both osteoclast and osteoblast functions (Zhu et al., 2013). RvE1 exhibits receptor-mediated control of osteoclasts and inhibits mature osteoclast formation and bone resorption in vitro (Zhu et al., 2013; Herrera et al., 2008; Gao et al., 2013). RvE1 specifically targets and downregulates the pivotal fusion protein DC-STAMP in osteoclasts and decreases DNA binding activity of the transcription factor NFATc1, leading to decreased cell fusion and attenuated bone resorption (Zhu et al., 2013). In osteoblasts, RvE1 increases the OPG/RANKL secretion ratio, favoring bone formation through a pathway that includes phosphorylation of AKT, rS6, and mTOR. In osteoclasts, RvE1 inhibits AKT pathways with activation of caspase 9 and increases apoptosis, reducing osteoclast numbers and proliferation (El Kholy et al., 2018; Papathanasiou et al., 2016).

PSCs hold great promise in periodontal tissue regeneration. Human PSCs have been able to produce cementum and PDL Sharpey's fibers (Seo et al., 2004; Trubiani et al., 2008), and participate in the process of periodontal tissue repair in immune-compromised rats (Seo et al., 2004). Human PSCs release SPMs including LXs and D-series Rvs to regulate immunomodulatory and prohealing properties (Cianci et al., 2016). Human PSCs also express the ALX/FPR2 receptor that recognizes lipoxin A_4 (LXA_4), RvE1, and annexin-A1, all of which have antiinflammatory and proresolution functions (Krishnamoorthy et al., 2010). Activation of ALX/FPR2 by LXA_4 significantly enhances the proliferation, migration, and wound-healing capacity of human PSCs in vitro (Cianci et al., 2016) through an LXA_4-driven, receptor-mediated mechanism. In an experimental periodontitis miniature pig model, the use of autologous periodontal ligament stem cells regenerated periodontal tissues including alveolar bone, cementum, and PDLs (Liu et al., 2008). In addition, the use of nanoproresolving medicines containing a novel LX analog (benzo-LXA_4, or $bLXA_4$) promoted the regeneration of hard and soft tissues that had been irreversibly lost to periodontitis in the miniature pig (Van Dyke et al., 2015). Therefore, periodontal tissue regeneration mediated by human PSCs may have potential as a stem cell–based strategy for human oral and craniofacial tissue regeneration. Treatments that activate the creation of new vascular-associated pericytes/PSCs have the potential to regenerate a healthy periodontium.

Role and mechanism of the junctional epithelium in periodontium function

Most of this chapter has focused on a few pathways that have some in vivo mouse studies and in vitro cell models of regulation of PSC differentiation to the mesenchymal components of the periodontium. However, in the oral cavity around the teeth are several key epithelial tissues that play roles in protecting the teeth and surrounding the PDL and alveolar bone from the constant onslaught of bacteria present in the oral cavity. Over 700 different species of bacteria reside close to and on the gingiva and tooth surface (Aas et al., 2005). This population of bacteria can change with increases in gram-negative species that have potent LPS antigens and can lead to severe periodontitis (Tanner et al., 1979). Because of this, it is important to understand the role, for example, of the junctional epithelium (JE) and how the JE serves as a primary barrier and protection against bacteria and mechanical insult for the progression of gingival inflammation into the underlying periodontal tissues. Thereby, epithelial integrity facilitates gingival and periodontal health. When epithelial integrity is overruled, inflammation expands into connective tissue attachment and PDL, manifesting in periodontitis.

Periodontal tissues attach to the tooth via epithelial and connective tissues. Insults to these structures can lead to inflammation, detachment, and destruction of periodontium and finally tooth loss. The epithelial tissue forming a seal on the tooth is the JE and is directly exposed to the oral cavity by virtue of its close location to the base of the gingival sulcus. Oral microbiota organized in a biofilm and their metabolic products can initiate inflammation in the gingiva, with the JE being exposed at the base of the gingival sulcus. Therefore, the JE is the first barrier for gingival inflammation. It consists of a squamous, nonkeratinizing epithelium of 3–20 cell layers. Developmentally, the JE is formed at tooth eruption upon contact between reduced enamel epithelium and oral epithelium.

The JE forms two basal laminae: the internal basal lamina facilitates the attachment to the tooth surface, while the external basal lamina is anchored to the connective tissue (Listgarten, 1966; Loe and Karring, 1969). The internal basal lamina consists of two components, the lamina lucida facing the JE and the lamina densa facing the tooth. The JE forms hemidesmosomes interacting with the lamina lucida. Lamina lucida, lamina densa, and hemidesmosome are connected by fine filaments conceived as a functional unit and containing glycoproteins (Kobayashi et al., 1976, 1977). The integrity of the seal between the enamel surface and the JE is maintained by hemidesmosomes and a basal lamina. Hemidesmosomes establish adhesion by connecting keratin intermediate filaments with the extracellular matrix. Their function is to maintain integrity and homeostasis in the JE. They contain bullous pemphigoid antigen (BPAG1) isoform e (= BP230, *DST* gene), BPAG2 (= BP180, collagen XVII, *COL17A1*), and plectin (= HD1, *PLEC* gene), consistent with type I hemidesmosomes (Hormia et al., 2001). Integrins are transmembrane receptors of hemidesmosomes consisting of alpha and beta subunits encoded by separate genes. As heterodimers, integrin α6β4 interacts together with CD151 and laminin-332 in the extracellular matrix. Integrin alpha6 interacts with BPAG2, and integrin β4 interacts with BPAG1e and plectin and

connects to keratins of the cytoskeleton (Walko et al., 2015). Kindlin1 binds to beta integrin cytoplasmic tails to facilitate binding to the extracellular matrix and cytoskeleton organization (Larjava et al., 2014). Laminin 332 is found in the internal and external basal laminae of the JE; collagen type IV is found in the external basal lamina but is lacking from the internal basal lamina (Sawada et al., 1990). Further, collagen type VII, perlecan, and laminin-111 are absent from the internal basal lamina (Hormia et al., 2001).

Mutations in genes contributing to the hemidesmosome cause epidermolysis bullosa, with blister formation within the skin or epithelium, and periodontal disease (Albandar et al., 2018; Wright, 2010). In families with mutations in the hemidesmosome-related genes *CD151* and *KIND1* (Kindler syndrome) (OMIM #173650), severe periodontal disease with tooth exfoliation has been reported (Vahidnezhad et al., 2018; Wiebe et al., 1996).

Recently, additional extracellular matrix molecules were localized to the internal basal lamina, namely amelotin, odontogenic ameloblast-associated protein (ODAM, also termed APin), and SCPP-proline/glutamine-rich-1 (Iwasaki et al., 2005; Moffatt et al., 2008, 2014; Kawasaki, 2009). The integrity of the attachment of JE is compromised in the absence of

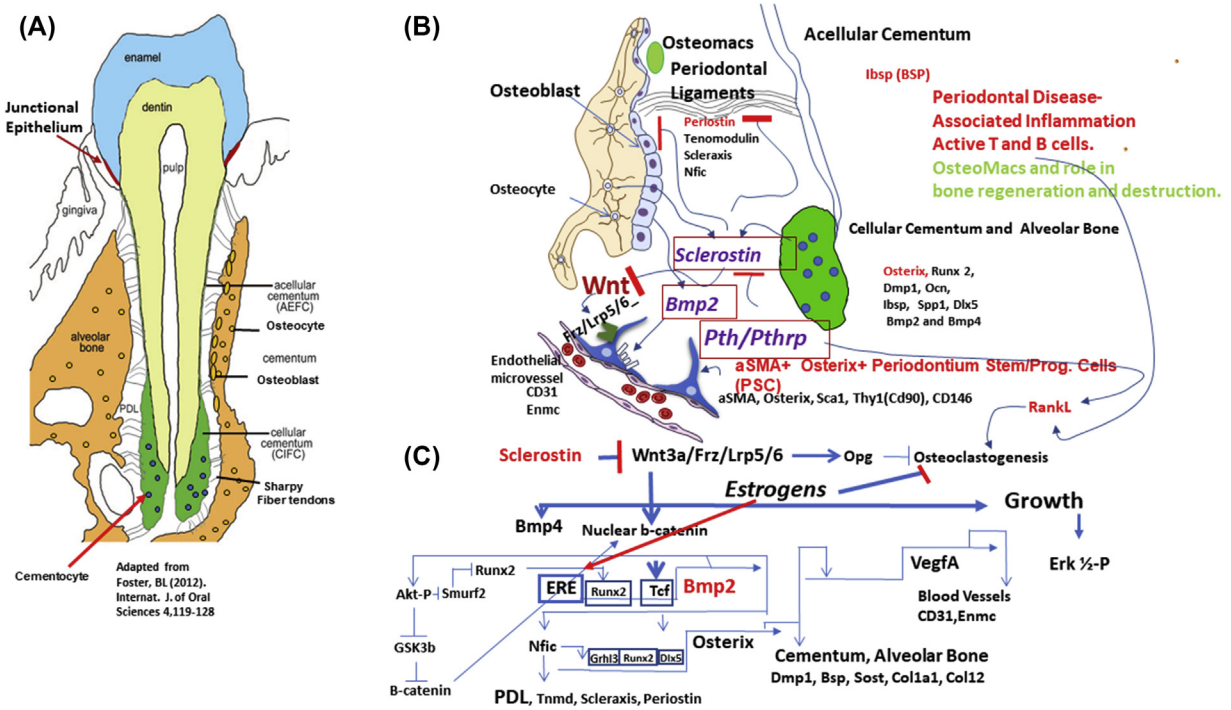

FIGURE 43.6 Overall model of the interactions of the PTH/PTHrP, Wnt, hedgehog, and Bmp2 pathways in periodontal biology. (A) Diagrammatic view of the periodontium with enamel in *blue* (grey in print versions), dentin in *light brown* (dark grey in print versions), alveolar bone in orange with marked osteoblasts and osteocytes, cellular cementum in green with cementocytes, acellular cementum along the root surface in light brown (dark grey in print versions), and junctional epithelium in maroon opposing the tooth crown. (B) Diagram of alveolar bone, periodontal ligament, and acellular and cellular cementums with markers used to study these components of the periodontium—i.e., Ibsp for acellular cementum; Runx2, Osterix, Bmp2 and Bmp4, and osteocalcin for cellular cementum; and alveolar bone, scleraxis, tenomodulin, and periostin for PDL fibroblasts. Osteomacs and T and B cells play a major role in the inflammatory process in periodontal disease but were not discussed in this chapter. The main summary in B is the interaction of PTH/PTHrP contribution to not only RankL production and bone resorption, in many cases stimulated by activated T and B cells, but the pronounced effect of PTH/PTHrP on the suppression of Sost expression from osteocytes that then leads to activated Wnt signaling. In turn, Wnt activates Opg to suppress bone resorption and activate bone formation by increasing Bmp2 expression. The emphasis is on Wnt signaling of stem progenitor cells (CD146, αSMA, Sca1, Thy1) on the small capillaries in the PDL region and alveolar bone marrow region. Wnt signaling stimulates these stem cells to begin differentiation to PDL, alveolar bone, and cementum. (C) Potential pathways for Wnt/Bmp2 signaling and downstream genes in the context of the periodontium. Canonical Wnt signaling activates both the Bmp4 and the Bmp2 genes in several systems but has not been rigorously tested in the context of the periodontium. We do know or hypothesize that without the Bmp2 gene, Wnt signaling is severely compromised in osteoblast models. Bmp2 transcription is also modulated by a variety of estrogens through at least one ERE in the promoter-enhancer region. Other EREs have been found in 3′ open chromatin domains but not characterized. Bmp2 and other Bmps are potent activators of Osterix expression in a Dlx5-Runx2-dependent manner, and the Bmp2 gene is required in the periodontium for the activation of Nfic, for PDL fibroblast differentiation, and for root formation. Bmp2-induced Osterix is a key regulator of VegfA production and links the Bmp2−Osterix−VegfA axis that connects alveolar bone formation to the creation of a new vascular−capillary stem/progenitor cells niche. Bmp signaling can also increase Akt and GSKB phosphorylation, releasing more active b-catenin in a simple feed-forward loop. Degradation of Runx2 is modulated by Smurf2 ubiquitin ligase. How Bmp2 controls growth in long bone and the periodontium is not known.

ODAM (Wazen et al., 2015). Amelotin-null mice did not have apparent defects in the JE and periodontium (Nakayama et al., 2015). In gingival inflammation, the expression of amelotin and ODAM may be altered and spread from the JE to adjacent gingiva.

In addition to its structural barrier functions, JE allows the presence and passage of antimicrobial peptides and neutrophils originating from adjacent tissues through enlarged intercellular spaces to the gingival sulcus (Hashimoto et al., 1986; Greer et al., 2013). The antimicrobial peptides in the JE belong to the family of defensins (alpha-, beta-) and cathelicidins (LL-37). Their mechanism of action is to exert pore formation on microbial membranes (Otto, 2009) and kill gram-negative bacteria associated with periodontal disease (Miyasaki et al., 1990). In addition to antimicrobial activity at homeostasis, the expression of antimicrobial molecules increases in response to periodontal disease (Gorr, 2012; Vardar-Sengul et al., 2007; Puklo et al., 2008). The JE itself does not express antimicrobial peptides but instead recruits neutrophils containing alpha-defensins and LL-37 to release them upon degranulation. Beta-defensin is produced by cells of the spinous layer of the gingiva and sulcular epithelium (Dale and Fredericks, 2005). En route to the oral cavity via intercellular spaces of the JE and gingival, the antimicrobial peptides join the gingival crevicular fluid and are exposed to periodontal microbiota.

The attachment of the JE presents a seal for mechanical insults and microbiota of the oral cavity to penetrate along the root into underlying connective tissues and PDLs via an internal basal lamina and hemidesmosomes. At the same time, the JE is permeable for neutrophils, antimicrobial peptides, and gingival crevicular fluid to assist in tissue homeostasis. When these defense mechanisms of the epithelial attachment are overwhelmed, the periodontal connective attachment apparatus succumbs to breakdown, with a clinical diagnosis of periodontal disease.

Conclusion

We have tried to integrate and connect many of the pathways that regulate the complex differentiation of PSCs to alveolar bone, PDLs, and the cellular and acellular cementum of the enthesis. Understanding the ways to regenerate this PDL and maintain a healthy JE are prime efforts in the clinic. In Fig. 43.6, we have brought together the data supporting the interacting roles of PTH, Sost, canonical Wnt signaling, and the Bmp2 and Bmp4 genes. Many of the "target" genes for these pathways are indicated, such as *Bsp, Ank, Spp1, Enpp1, and Alpl or TNAP*. We have discussed the role of the JE in the periodontium as a key initial barrier to infection in the health of the periodontium and oral cavity in general.

In particular, we have also brought together evidence that elements of estrogen action, part Sost-cWnt function, part PTH/PTHrP action, in terms of the anabolic bone formation axis, are upstream of Bmp2 action and signaling. Future studies will focus on Bmp2 and Bmp4 enhancer and repressor functions in a single-cell analysis pipeline, and complex gene network (i.e., all the genes regulated by Osterix, Runx2, AP-1, etc.) transcription factors, and how they are linked together and change over time. New approaches of single-cell sequencing and single-cell ATAC-seq will hopefully be a beginning of this effort to integrate gene networks that will predict the most effective nodes to modulate and regenerate new tissue and conserve bone mass and periodontium function as we age.

Chapter 44

Notch and its ligands

Stefano Zanotti and Ernesto Canalis

Departments of Orthopaedic Surgery and Medicine, and the UConn Musculoskeletal Institute, UConn Health, Farmington, CT, United States

Chapter outline

Introduction

The Notch signaling pathway is a mechanism of communication between neighboring cells that has important functions in the development of metazoans, and was first identified by genetic analysis in *Drosophila melanogaster* (Morgan and Bridges, 1916). Whereas *Drosophila* expresses one Notch receptor and two ligands, termed Serrate and Delta, mice and humans express four Notch receptors, two Serrate homologues termed Jagged (JAG) 1 and 2, and three Delta homologues named Delta-like (DLL) 1, 3, and 4 (Lindsell et al., 1996). Interactions of receptors expressed by a signal-receiving cell with ligands from adjacent cells lead to a series of proteolytic cleavages that result in the release of the Notch intracellular domain (NICD) from the cellular membrane (Schroeter et al., 1998). The NICD translocates to the nucleus, where it forms an active transcriptional complex with the DNA-associated protein recombination signal-binding protein for immunoglobulin of kappa J region (RBPJ) to regulate the transcription of target genes (Kovall, 2008). The NICD does not bind to DNA directly but interacts with various nuclear proteins to form a transcriptional complex that is essential for cellular response to the activation of Notch receptors. Although these signal transduction events are shared by the four receptors, each paralog has distinct functions (Groot et al., 2014).

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00044-0

Notch signaling from all receptors is governed by multiple mechanisms, such as posttranslational modifications and endocytosis, that determine the function of the receptor, ligands, and the several nuclear proteins that mediate the transcriptional effects of Notch (Kovall et al., 2017; Kopan and Ilagan, 2009). The importance of these regulatory mechanisms is attested by the remarkable number of diseases associated with genetic defects that cause gain- or loss-of-function of the core and ancillary components of the Notch signaling pathway (Zanotti and Canalis, 2016). The role played by Notch receptors and cognate ligands in the skeleton was established by work in genetically engineered mice and by the characterization of congenital human diseases. These studies revealed that Notch signaling regulates chondrocytic, osteoblastic, and osteoclastic differentiation and function, demonstrating that Notch receptors and ligands are critical for skeletal development, bone remodeling, and fracture healing. Efforts to reproduce disease-associated Notch mutations in mice have provided new insight into the pathogenesis of rare diseases affecting the skeleton and reaffirmed the importance of Notch receptors in skeletal biology.

Notch receptors

Structure

Notch are four single-pass transmembrane receptors characterized by a variable number of extracellular epidermal growth factor (EGF)-like tandem repeats: 36 in NOTCH1 and NOTCH2, 34 in NOTCH3, and 29 in NOTCH4 (Kovall et al., 2017; Kopan and Ilagan, 2009). Binding of calcium ions to selected EGF-like repeats determines the structure of the extracellular region and affinity of receptors for individual ligands (Weisshuhn et al., 2015a, 2015b, 2016). The EGF-like repeats forming the interface between NOTCH1 and JAG1 are distinct from those responsible for binding to DLL4. In addition, the contact area between NOTCH1 and JAG1 is larger than that between NOTCH1 and DLL4, possibly explaining the higher affinity of NOTCH1 for JAG1 than for DLL4 (Luca et al., 2015, 2017).

Notch receptors are translated as monomeric precursors that are cleaved by furin-like proprotein convertases in the Golgi compartment, and this process results in the creation of extracellular and transmembrane monomers that form a heterodimeric receptor. The C-terminus of the extracellular peptide interacts with the N-terminus of the transmembrane peptide via noncovalent bonds that occur within the heterodimerization domain (HD). The C-terminus of the extracellular monomer contains three Lin12/Notch repeats that together with the HD form the negative regulatory region (NRR), which prevents Notch activation in the absence of ligands (Sanchez-Irizarry et al., 2004; Gordon et al., 2007). The importance of the NRR is exemplified by the fact that point mutations in the HD of *NOTCH1* activate the receptor in the absence of ligands and lead to NOTCH1 gain-of-function, which is associated with over 50% of cases of T-cell acute lymphoblastic leukemias (Malecki et al., 2006). Analogous mutations in *NOTCH2* are not as common and are found in a small percentage of marginal zone B-cell lymphomas (Kiel et al., 2012). The NRR of NOTCH3 may be a less effective inhibitor of ligand-independent activation than the NRR of NOTCH1 and NOTCH2, since NOTCH3 exhibits a higher degree of basal activation than NOTCH1 and NOTCH2 (Xu et al., 2015). Limited information is available about the NRR of NOTCH4, and its three-dimensional structure has not been described. The transmembrane domain is located immediately downstream of the HD and contains three cleavage sites recognized by disintegrin and metalloprotease domain (ADAM) proteases as well as the γ-secretase complex. These sites are critical for signal activation and are not accessible to proteases in the absence of ligands because of the structural conformation of the NRR in the unbound receptors (Gordon et al., 2007).

The intracellular domain of NOTCH1, NOTCH2, and NOTCH3 consists of an RBPJ-association module (RAM) domain, a nuclear localization sequence (NLS), seven ankyrin repeats, and two additional NLS in close association. The NICD of NOTCH4 has a distinct organization and lacks the tandem NLS. A transactivation domain located downstream of this region is the most variable among the four Notch paralogs; it displays a defined spatial organization in NOTCH1 and NOTCH2 but does not appear to form an organized structure in NOTCH3 and NOTCH4. A proline (P)-, glutamic acid (E)-, serine (S)-, threonine (T)-rich motif (PEST) domain is present at the C-terminus of all Notch receptors and is recognized by ubiquitin ligases that target Notch for proteasomal degradation (Fig. 44.1A) (Kovall et al., 2017; Kopan and Ilagan, 2009).

Function

Despite their structural similarities, the functions of NOTCH1 and NOTCH2 are not redundant; the deletion of *Notch1* is developmentally lethal due to vascular malformations, whereas mice harboring a hypomorphic *Notch2* allele die perinatally because of renal and vascular defects (Swiatek et al., 1994; McCright et al., 2001). These differences may be related to the specific temporal and cellular expression patterns of the individual receptors and to variations in NOTCH1 and NOTCH2

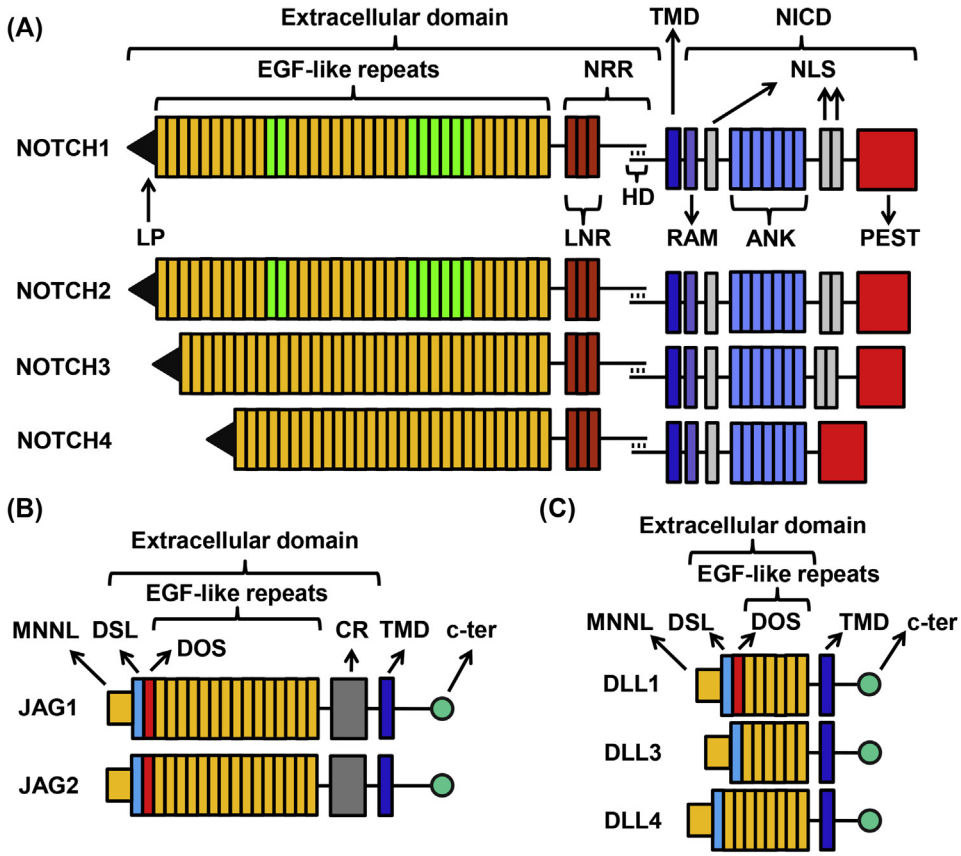

FIGURE 44.1 Domains of Notch receptors and cognate ligands. (A) Notch receptors. Extracellular domain containing a leader peptide, multiple epidermal growth factor (EGF)-like tandem repeats (36 in NOTCH1 and NOTCH2; 34 in NOTCH3 and 29 in NOTCH4), Lin12-Notch repeats (LNR) and the heterodimerization domain (HD). Negative regulatory region (NRR) formed by the LNR and HD, followed by a transmembrane domain (TMD). Intracellular domain (NICD) containing an RBPJ-association module (RAM), nuclear localization sequences (NLS; three in NOTCH1, NOTCH2, and NOTCH3, one in NOTCH4), ankyrin repeats and a proline (P)-, glutamic acid (E)-, serine (S)-, threonine (T)-rich (PEST) domain. EGF-like repeats in green are required for binding of NOTCH1 and NOTCH2 to cognate Jagged and Delta ligands. (B) Jagged ligands. Extracellular domain containing the modulus at the N-terminus of Notch ligands (MNNL), Delta/Serrate/Lag2 (DSL) and Delta and OSM11-like (DOS) domains, 15 EGF-like tandem repeats and a cysteine-rich domain, followed by the TMD and intracellular conserved c-terminus (c-ter). (C) Delta ligands. Extracellular domain containing the MNNL, DSL, DOS (only in DLL1), and EGF-like tandem repeats (six in DLL1 and DLL3, eight in DLL4), followed by a TMD and intracellular conserved c-ter. *Adapted from Zanotti, S., Canalis, E., 2016. Notch signaling and the skeleton. Endocr. Rev. 37 (3), 223–253, with permission.*

affinity for their cognate ligands. Paralog-specific functions of the NICDs may also contribute to the distinct phenotypes of *Notch1* and *Notch2*-null mice, even though their NICDs appear to have equivalent functions in various cellular contexts (Liu et al., 2013, 2015a; Yuan et al., 2012). The structure and activation mechanics of NOTCH3 diverge from those of NOTCH1 and NOTCH2, as NOTCH3 possesses fewer EGF-like repeats, displays a higher level of basal activity in the absence of ligands, and has a shorter intracellular domain (Kovall et al., 2017; Kopan and Ilagan, 2009; Xu et al., 2015). The deletion of *Notch3* causes vascular abnormalities, and *NOTCH3* mutations are found in individuals afflicted by cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy syndrome (Domenga et al., 2004; Joutel, 2011; Krebs et al., 2003). NOTCH4, like NOTCH3, is dispensable for embryonic development, although some of its functions overlap with those of NOTCH1 (Krebs et al., 2000). Mice that overexpress the NOTCH4 NICD in endothelial cells display brain arteriovenous malformations, attesting to the importance of signaling from all Notch receptors for the development of the vascular system (Murphy et al., 2008, 2014).

Regulatory mechanisms

The expression of individual Notch receptors is cell-specific, restricting receptor activation to selected cell types and providing initial levels of signal regulation (Wu and Bresnick, 2007). More complex regulatory mechanisms are mediated by posttranslational modifications of the extracellular and intracellular regions of Notch. The EGF-like repeats are

subjected to fucosylation and glycosylation events that regulate the specificity and binding affinity for cognate ligands. The *O*-fucosyltransferase POFUT1 is responsible for the addition of the fucosyl residues that are the site of initiation of glycosaminoglycan chains (Rampal et al., 2005). Fucosylation also facilitates folding of the nascent Notch receptors and is required for their trafficking to the cellular membrane (Stahl et al., 2008). The importance of this posttranslational modification is demonstrated by the observation that *Pofut1*-null mice die in utero and phenocopy the individual deletion of *Notch1* and *Notch2* (Shi and Stanley, 2003; Schuster-Gossler et al., 2009). In mice and humans, the *O*-fucose residues in the Notch EGF-like repeats provide the substrate for the β-1,3-*N*-acetylglucosaminyltransferases lunatic fringe (LFNG), manic fringe (MFNG), and radical fringe (RFNG). These enzymes elongate glycosaminoglycan chains of selected EGF-like repeats, promoting interaction of Notch receptors with DLL1 while hindering interactions with JAG1 (Visan et al., 2006; Stanley, 2007). The functions of the three fringe enzymes are not redundant, and the EGF-like repeats targeted by MFNG and LFNG are different from those recognized by RFNG (Kakuda and Haltiwanger, 2017).

Glycosylation of Notch receptors is carried out by protein *O*-glucosyltransferase (POGLUT)1 and is necessary for the activation of NOTCH1 and NOTCH2, since *Poglut1*-null mice die during embryonic development with a phenotype that overlaps with that of the individual deletions of *Notch1* or *Notch2* (Fernandez-Valdivia et al., 2011). A hypomorphic *POGLUT1* mutation that attenuates Notch signaling was identified in a family afflicted by muscular dystrophy, attesting to the importance of the posttranslational regulation of Notch receptor activity (Servian-Morilla et al., 2016). Selected *O*-glucose residues may be extended by GXYLT1/2 and XXYLT1, which are type II-membrane proteins with xylosyltransferase activity (Sethi et al., 2010a). In contrast to the general effects of acetylglucosamine modification, studies in *Drosophila* indicate that the addition of the xylose residues may inhibit Notch-ligand interactions, but the function of xylosylation remains to be determined (Lee et al., 2017).

The levels of Notch receptors at the cell surface are tightly regulated by posttranslational mechanisms such as endocytosis and lysosomal degradation (Nichols et al., 2007; Le et al., 2005). NOTCH1, in its unbound state, is ubiquitinated and targeted for lysosomal degradation by the sequential activities of the really interesting new gene (Ring)-finger E3 ubiquitin ligase CBL and of the itchy E3 ubiquitin protein ligase (ITCH) (Jehn et al., 2002; Chastagner et al., 2008). *Itch*-null mice exhibit enhanced NOTCH1 activity and proliferation of hematopoietic stem cells (Rathinam et al., 2011). The activity of another ring-finger protein termed deltex E3 ubiquitin ligase (DTX)1, which in itself is encoded by a Notch target gene, may direct the receptors to the recycling endosome and allow their reexposure at the cell surface (Mukherjee et al., 2005). However, the mechanisms that determine the fate of ubiquitinated Notch receptors are poorly defined (Fig. 44.2).

Notch cognate ligands

Structure and function

Notch are four single-pass transmembrane proteins that interact with Notch receptors. The interaction occurs at a conserved extracellular region containing the modulus at the N-terminus of Notch ligands domain and a Delta/Serrate/Lag2 (DSL) motif as well as the DLL and OSM11-like protein domains, which are two specialized tandem EGF-like repeats (D'Souza et al., 2010). The C-terminal domain of each ligand consistently mediates interactions with the cytoskeleton (Fig. 44.1B and C) (Pintar et al., 2007). Mice null for *Jag1, Jag2, Dll1,* or *Dll4* exhibit developmental defects and die in utero (Jiang et al., 1998; Xue et al., 1999; Hrabe de et al., 1997; Gale et al., 2004). Global *Jag1, Jag2, Dll1*-null mutants display a less severe phenotype that may be explained by the potential role of DLL3 as a mild inhibitor of Notch receptors (Kusumi et al., 1998; Ladi et al., 2005). Additional mechanisms that do not require Notch−ligand interactions, such as shear stress generated by blood flow at the surface of endothelial cells, may be capable of activating the receptors in the absence of protein ligands (Theodoris et al., 2015).

Other proteins are known to act as ligands of Notch receptors and to modulate signaling, although the nature of these interactions is not clearly defined. Delta/Notch-like EGF-related receptor (DNER) and Delta-like homolog (DLK)1, also termed PREF1, are related to Dll ligands although they lack a DSL domain. DNER induces DTX1 in the developing nervous system and mirrors Dll/Notch interactions, whereas DLK1 inhibits Notch signaling (Baladron et al., 2005; Eiraku et al., 2005). F3 and NB3 are glycosyl phosphatidylinositol-tethered proteins capable of inducing Notch signaling through DTX1-dependent mechanisms that are similar to those utilized by DNER (Hu et al., 2003; Cui et al., 2004). At least three soluble proteins have been reported as potential Notch ligands, namely microfibril-associated glycoproteins (MAGP) 1 and 2 and nephroblastoma overexpressed (NOV). The cellular context determines the effects of these ligands on Notch signaling, and both stimulatory and inhibitory effects of Notch activation have been reported for MAGP1, MAGP2, and NOV (Miyamoto et al., 2006; Albig et al., 2008; Sakamoto et al., 2002; Rydziel et al., 2007; Minamizato et al., 2007).

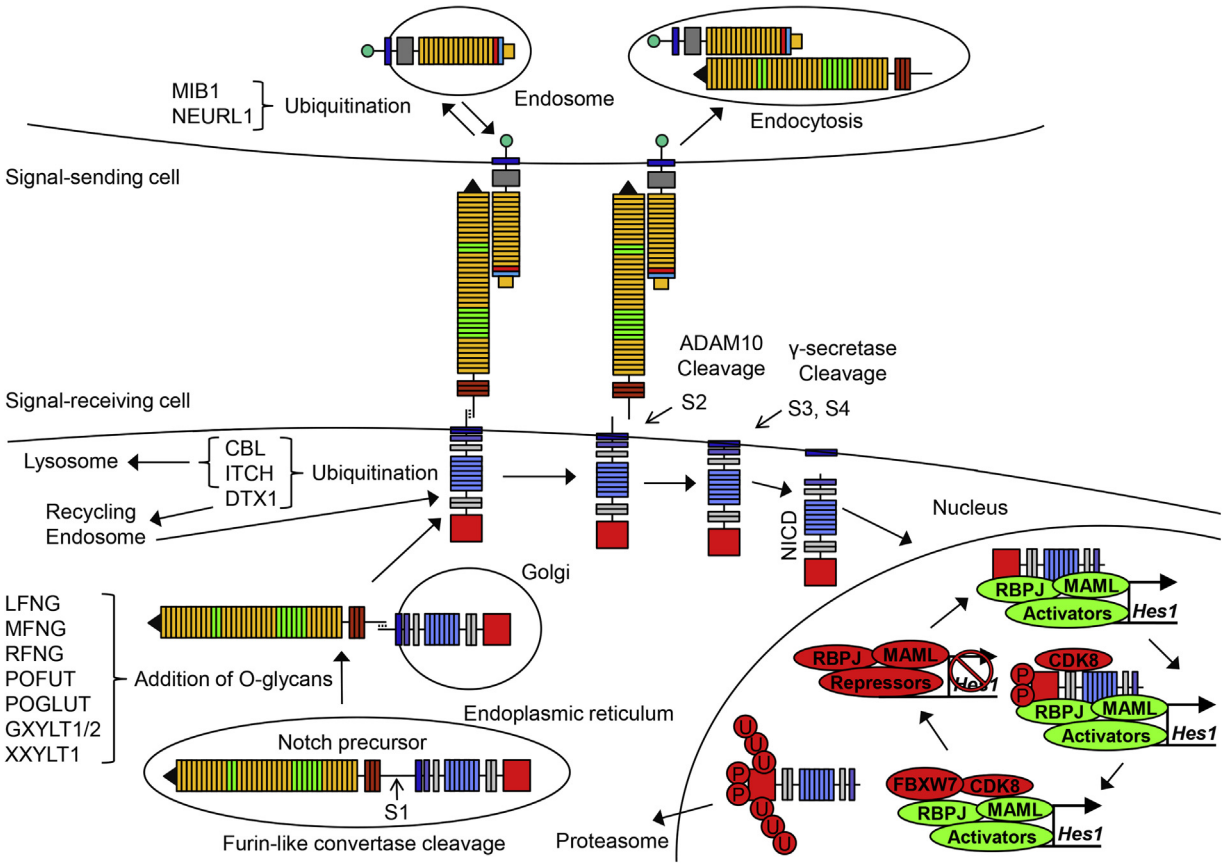

FIGURE 44.2 Regulation of Notch signaling. From the lower left corner, clockwise. The Notch precursor synthesized by the signal receiving cell is cleaved at the S1 site by a furin-like convertase in the endoplasmic reticulum, generating a mature heterodimeric receptor. O-Glycans are added by the actions of selected glycosyl-, fucosyl- and xylosyl-transferases as Notch transits through the Golgi. The receptor in its unbound state may be ubiquitinated by CBL, ITCH, and DTX1 and either directed to the lysosome for degradation or to the recycling endosome for reexpression at the cell membrane. A cognate ligand (Jag protein in diagram) expressed by a signal-sending cell must be ubiquitinated by MIB1 or NEURL1 and processed into the endosome prior to engaging a Notch receptor at the surface of the signal-receiving cell. The ligand bound to the extracellular domain of Notch is internalized by the signal-sending cell, allowing cleavage of the S2 site by ADAM10 and of the intramembranous S3 and S4 sites by the γ-secretase complex. The Notch intracellular domain (NICD) is released into the cytoplasm and translocates into the nucleus where it forms a ternary complex with RBPJ and MAML proteins. Transcriptional repressors associated with RBPJ in the absence of NICD are displaced by transcriptional activators that induce the expression of Notch target genes, such as *Hes1*. CDK8 associates with MAML and phosphorylates the PEST domain of the NICD, leading to ubiquitination by FBXW7 and targeting of the NICD for proteasomal degradation. The ternary complex is disassembled and transcriptional repression of Notch target genes is reinstituted.

Regulatory mechanisms of notch ligands

Cellular trafficking regulates the function of Notch receptors and the ability of ligand proteins to induce signaling. Ubiquitination of the intracellular portion of ligand proteins leads to endocytosis and recycling to the cellular membrane, and these processes are required for the ligands to develop sufficient affinity for Notch receptors (D'Souza et al., 2008; Heuss et al., 2008). In mammals, JAG1 and DLL1 are substrates of the ring family E3 ubiquitin ligases mind bomb (MIB)1 and neuralized E3 ubiquitin protein ligase (NEURL)1, whereas the ubiquitin ligases that act on the remaining ligand paralogs have not been identified (Fig. 44.2) (Koo et al., 2005; Koutelou et al., 2008). The deletion of *Mib1* leads to developmental defects similar to those observed in *Notch1* and *Notch2*-null mutants, whereas the deletion of *Neurl1* is compatible with life, indicating that MIB1 is necessary for signaling from NOTCH1 and NOTCH2 and might compensate for the loss of NEURL1 (Koo et al., 2005; Ruan et al., 2001). Hypomorphic *MIB1* mutations in humans are associated with suppressed Notch signaling and cardiomyopathy, documenting the importance of posttranslational modifications of Notch ligands (Luxan et al., 2013).

Mechanisms of Notch activation

Generation of the Notch intracellular domain

Proteolysis is a critical mechanism of Notch maturation and activation. Notch receptors are subjected to four cleavage events occurring at specific sites within the HD and transmembrane domains; these are sequentially termed S1 to S4 (Kovall et al., 2017; Kopan and Ilagan, 2009). Initially, the monomeric Notch precursor is cleaved in the Golgi compartment by furin-like proprotein convertases that act on the S1 site, leading to the formation of a heterodimeric receptor (Blaumueller et al., 1997). Interactions of mature receptors with ligands generate pulling forces in the order of piconewton that cause dissociation of the heterodimer and a subsequent internalization of the ligand bound to the extracellular monomer of Notch by the ligand-expressing cell (Gordon et al., 2015). This process, termed *trans-endocytosis*, unravels the NRR and exposes the S2 site to the action of ADAM10 (Kovall et al., 2017). Cleavage of the S2 site generates an unstable peptide consisting of the transmembrane and intracellular regions of Notch, and it is a substrate of the transmembrane proteases presenilin (PSEN) 1 and 2 that are the catalytic units of the γ-secretase complex and cleave the S3 and S4 sites of Notch (Sato et al., 2007). Several accessory proteins, such as nicastrin, presenilin enhancer 2, and anterior pharynx defective 1 associate with PSENs to form the γ-secretase complex (Duggan and McCarthy, 2016). PSEN1, but not PSEN2, is necessary for Notch activation, as *Psen1*-null mice die during embryonic development due to severe abnormalities of the skeleton and central nervous system, whereas *Psen2* inactivation does not lead to an appreciable phenotype (Herreman et al., 1999; Shen et al., 1997). Cleavage of the S3 and S4 sites is the final event in the generation of the NICD (Song et al., 1999).

Formation of an active transcriptional complex

The NICD translocates to the nucleus where it forms a ternary complex with the DNA binding protein RBPJ and mastermind-like (MAML). Formation of this complex results in the recruitment of transcriptional coactivators that displace transcriptional repressors associated with RBPJ, leading to the expression of Notch target genes (Kovall, 2007). RBPJ is constitutively bound to DNA to repress transcription, although increased occupancy of *Rbpj* consensus sequences by RBPJ following activation of Notch signaling was reported (Hass et al., 2015; Wang et al., 2014). RBPJ consists of N-terminal and β-trefoil domains that bind to the DNA and a C-terminal region that, in conjunction with the β-trefoil domain, interacts with the RAM domain of the NICD and with the N-terminus of MAML proteins (Kovall and Hendrickson, 2004; Nam et al., 2006). The intracellular domains of NOTCH1 (N1ICD) and NOTCH2 (N2ICD) regulate transcription by interacting with distinct regions of RBPJ. Paralog-specific NICD interactions with RBPJ and the structure of the target gene promoter may lead to differences between the transcriptional output of distinct receptors (Yuan et al., 2012). In addition, the orientation and distribution of *Rbpj* consensus sequences appears to influence the cellular response to Notch induction (Kovall et al., 2017). Humans and mice harbor a single copy of *Rbpj*, and its deletion in mice is lethal during early embryonic development due to vascular abnormalities that phenocopy the inactivation of *Notch1* and *Notch2* (Krebs et al., 2004). Although the deletion of *Rbpj* precludes the ability of NICD to induce a transcriptional response, it also relieves the transcriptional repression of DNA regulatory elements that harbor *Rbpj* consensus sequences. In addition, RBPJ has Notch-independent functions during pancreatic development (Nakhai et al., 2008; Fujikura et al., 2006, 2007).

Maml is a family of nuclear proteins consisting of an N-terminal region, which mediates binding to RBPJ and NICD, and a C-terminal region that interacts with CBP/p300, a histone acetylase that creates the necessary conditions for the core transcriptional machinery to access the targeted gene/enhancer (Wu et al., 2000; Nam et al., 2003; Fryer et al., 2002). Humans and mice harbor three homologous *Maml* genes that display a certain level of functional redundancy. *Maml1*, like *Notch2*, is required for selected aspects of lymphocyte development, as its deletion prevents the formation of the B-cell marginal zone in the spleen (Witt et al., 2003; Oyama et al., 2007). The deletion of *Maml3* has no appreciable phenotype, whereas the consequences of global *Maml2* inactivation have not been reported. Dual *Maml1*/*Maml3* deletion phenocopies the systemic loss of Notch signaling and demonstrates that both paralogs are necessary for the formation of the NICD/RBPJMAML/ complex (Oyama et al., 2011). MAML proteins also determine the duration of transcriptional response by recruiting cyclin dependent kinases (CDKs), such as CDK8, that phosphorylate the PEST domain of the NICD and lead to

the disassembly of the ternary complex (Fryer et al., 2004). The phosphorylated NICD is subsequently ubiquitinated by ubiquitin ligases, such as E3 ubiquitin-ligase F-box and WD repeat domain-containing (FBXW)7, and targeted for proteasomal degradation (Fig. 44.2) (Thompson et al., 2007).

Notch target genes

Some of the better characterized Notch transcriptional targets are the genes encoding for the hairy and enhancer of split (HES) and Hes-related with YRPW motif (HEY) transcription factors (Ohtsuka et al., 1999; Iso et al., 2001). Mice and humans express seven HES proteins, termed HES1 through HES7, and three HEY paralogs named HEY1, HEY2, and HEYL; all but HES2 and HES3 are induced by RBPJ-mediated Notch signaling (Iso et al., 2003). HES and HEY are characterized by the presence of a basic helix-loop-helix (bHLH) domain and display a high level of structural homology. The bHLH domain allows homo- or heterodimerization with other proteins containing bHLH domains (Leimeister et al., 2000). The formation of homo- or heterodimers defines the binding specificity of the transcription factor to DNA and provides an additional level of regulation of the cellular response to Notch activation (Fischer and Gessler, 2007). HES paralogs can be distinguished from HEY proteins by the presence of a proline instead of a glycine at a conserved site within the bHLH domain and by the presence of a WRPW instead of a YRPW C-terminal tetrapeptide motif (Iso et al., 2001). The bHLH domain confers HES and HEY proteins the ability to suppress transcription by allowing the recruitment of histone deacetylases to target gene promoters and by mediating interactions with other bHLH-containing nuclear factors and the core transcriptional machinery (Fischer and Gessler, 2007). The WRPW motif is required for interactions of HES1 with transducin-like enhancer of split factors and for the consequent formation of a transcriptional repressor complex (Grbavec and Stifani, 1996). Although HES and HEY are fundamentally inhibitors of gene transcription, HES paralogs may activate transcription under certain conditions (Ju et al., 2004).

HES and HEY mediate functions of Notch signaling during development and at the early stages of cell differentiation programs in tissues with high cellular turnover. HES1, HES3, and HES5 are necessary to preserve the undifferentiated state of precursor cells throughout life (Kageyama et al., 2007). HES7 governs somite segmentation and acts in part by regulating the expression of *Lfng* (Bessho et al., 2001). HES6 suppresses HES1 function and contributes to the development of the central nervous system (Bae et al., 2000). In agreement with the role of Notch in the development of the cardiovascular system, mice harboring a systemic *Hey2* deletion or a dual *Hey1*/*HeyL* inactivation display impaired vascular development, whereas dual *Hey1*/*Hey2*-null mice recapitulate the vascular phenotype of the *Notch1* global deletion (Fischer and Gessler, 2007; Xin et al., 2007; Fischer et al., 2004, 2007; Kokubo et al., 2005).

Notch receptors and ligands in chondrocytes

Role of Notch signaling in endochondral bone formation

Early investigations in mouse embryos demonstrated that NOTCH1 is expressed by chondrocytes in the proliferative zone of the growth plate, and studies addressing the function of DLL1 in embryonic chicken limbs suggested a potential inhibitory role of Notch signaling in chondrogenesis (Crowe et al., 1999; Watanabe et al., 2003). Subsequent work in mice where the N1ICD was expressed under the control of the *Prx1* or *Col2a1* promoter to induce Notch signaling in the limb bud or in chondrocytes, respectively, revealed that NOTCH1 activation suppresses endochondral bone formation (Tables 44.1 and 44.2). N1ICD expression in the limb bud impairs the development of the cartilaginous precursors of appendicular bones, whereas its induction in chondrocytes disorganizes the growth plate, with both phenotypes leading to embryonic death (Dong et al., 2010; Mead and Yutzey, 2009). Accordingly, conditional *Psen1* deletion in *Prx1*-expressing cells in a null *Psen2* genetic composition, or dual *Notch1*/*Notch2* inactivation in the limb bud, causes an accumulation of hypertrophic chondrocytes and subsequent postnatal elongation of the cancellous bone compartment. This phenotype is recapitulated by the conditional deletion of *Notch2* but not of *Notch1* (Hilton et al., 2008). Consistent with this observation, linear femoral growth is delayed in mice harboring a systemic *Notch2* gain-of-function, indicating that among Notch receptors, NOTCH2 is the predominant regulator of bone growth (Canalis et al., 2016; Zanotti et al., 2017). Elongation of the trabecular bone compartment is noted also in tibiae of skeletally mature mice harboring a *Jag1* deletion in *Prx1*-expressing cells, possibly identifying JAG1 as the ligand responsible for the activation of Notch signaling in cells of the limb bud (Lawal et al., 2017).

Mechanisms of notch action in endochondral bone formation

The effects of Notch signaling during skeletal development are mediated by RBPJ-dependent mechanisms, since the deletion of *Rbpj* precludes the actions of the N1ICD in the limb bud and chondrocytes (Dong et al., 2010; Kohn et al., 2012; Chen et al., 2013). Accordingly, downregulation of *Hes1* in *Prx1*-expressing cells in the context of the individual *Hes5* or the dual *Hes3*/*Hes5* global inactivation accelerates chondrogenesis and increases femoral length, whereas the overexpression of HES1 in the limb bud has opposite effects (Rutkowski et al., 2016; Zanotti et al., 2011a). Dual *Hey1*/*HeyL* global deletion has no impact on endochondral bone formation, suggesting that HES1, HES3, and HES5, but not HEY1 or HEYL, act downstream of RBPJ to mediate the effects of Notch signaling in this developmental context (Rutkowski et al., 2016). The conditional inactivation of *Hes1* in *Col2a1*-expressing cells, either in the presence or absence of *Hes5*, has no skeletal effects (Karlsson et al., 2010; Sugita et al., 2015). This indicates that other HES paralogs can compensate for the loss of *Hes1* and *Hes5* in mature chondrocytes, or that both genes are required for early chondrogenesis but dispensable in differentiated chondrocytes.

In vitro studies reveal that Notch activation inhibits chondrogenesis by suppressing the expression of *Sox9*, *Col2a1,* and *Acan* genes encoding for factors that are critical for chondrocyte differentiation and function (Olsen et al., 2000; Zanotti and Canalis, 2013b,c). Potential mechanisms for the inhibitory effect on *Sox9* are a direct suppression of promoter activity by NICD/RBPJ interactions or an indirect transcriptional action mediated by HES5 but not HES1 (Chen et al., 2013; Rutkowski et al., 2016). Although suppression of *Sox9* in the context of Notch activation might be fully accountable for the inhibition of *Col2a1*, HES1 may contribute to this effect by binding to N-boxes found in proximity of *Sox9* consensus sequences in the *Col2a1* promoter (Grogan et al., 2008). It is of interest that downregulation of *Acan* is mediated by IL6, a molecule associated with inflammatory response. However, it is not clear whether this mechanism is operational during skeletal development or active only in articular chondrocytes in the context of degenerative joint diseases (Zanotti and Canalis, 2013b; Liu et al., 2015b).

Notch receptors and ligands in osteoblasts

Role of notch signaling in osteoblasts

Initial studies in osteoblasts revealed a potential role of Notch signaling in osteoblastogenesis. Constitutive activation of Notch receptors suppressed the capacity for osteoblastic differentiation of multiple cell lines, although the transient induction of Notch signaling had the opposite effect (Nofziger et al., 1999; Deregowski et al., 2006; Sciaudone et al., 2003; Tezuka et al., 2002; Nobta et al., 2005; Ugarte et al., 2009). These results suggested that the length of exposure to activated

Notch receptors and the cellular context determine the consequences of the signaling event on osteoblastic differentiation and function. The availability of genetically modified mice made it possible to establish the cellular response to Notch signaling in cells of the osteoblast lineage at various stages of maturation (Tables 44.1 and 44.2). Early studies in transgenic mice expressing the N1ICD under the direction of a 3.6 kb fragment of the *Col1a1* promoter revealed that NOTCH1 activation in immature osteoblasts reduces osteoblast number and activity, thereby causing osteopenia (Zanotti et al., 2008). Accordingly, mice where the N1ICD is induced in *Sp7*-or *BGLAP*-expressing osteoblasts display defective bone formation and severe osteopenia, confirming that NOTCH1 inhibits osteoblastic function (Canalis et al., 2013b). Cortical bone in these mice has an embryonic appearance characterized by the absence of a compact shell, suggesting that NOTCH1 activation in osteoblasts delays cortical bone development (Sharir et al., 2011). It is of interest that work using a tamoxifen-inducible model concluded that NOTCH1 is potentially anabolic in skeletally mature mice, although an independent effect of tamoxifen on bone remodeling was not excluded and could have caused the increased bone mass ascribed to NOTCH1 activation (Liu et al., 2016; Shevde et al., 2000).

Studies of *Notch2* misexpression in mice demonstrated that NOTCH2 shares with NOTCH1 the ability to suppress osteoblast function. Mice harboring systemic or osteoblast-specific *Notch2* gain-of-function mutations are osteopenic because of enhanced bone resorption that does not trigger a bone-forming response, indicating reduced osteoblast function (Canalis et al., 2016; Zanotti et al., 2017). Accordingly, the inactivation of *Notch2* in *Runx2*-expressing cells increases cancellous bone volume by increasing osteoblast number and bone formation (Yorgan et al., 2016). In agreement with results from individual NOTCH1 or NOTCH2 gain-of-function models, dual *Notch1*/*Notch2* deletion in immature *Prx1*-or *Sp7*-expressing osteoblasts increases cancellous bone volume, providing further evidence of the inhibitory functions of both receptors on bone formation (Hilton et al., 2008; Zanotti and Canalis, 2014).

The role of NOTCH1 evolves as osteoblast differentiation progresses, and NOTCH1 induction in mature osteoblasts expressing the 2.3 kb fragment of the *Col1a1* promoter causes osteosclerosis secondary to an accumulation of dysfunctional cells that fail to deposit a mineralized matrix (Engin et al., 2008). Transgenic overexpression of DLL1 in mature osteoblasts leads to an osteosclerotic phenotype similar to the one reported for the activation of NOTCH1 in osteocytes (Muguruma et al., 2017). The conditional inactivation of *Jag1* governed by the 2.3 kb fragment of the *Col1a1* promoter causes marginal changes in bone microarchitecture, indicating that the expression of JAG1 in mature osteoblasts is dispensable for bone homeostasis (Youngstrom et al., 2016).

Mechanisms of notch action in osteoblasts

The inactivation of *Rbpj* in *Prx1*-expressing cells enhances bone formation, and its deletion in osteoblasts prevents the effects of N1ICD, suggesting that genes under the control of RBPJ, such as *Hes* and *Hey*, are accountable for the osteoblastic response to Notch signaling (Tao et al., 2010; Tu et al., 2012). The N1ICD also interacts with RUNX2 and suppresses its transcriptional activity, suggesting the existence of RBPJ-independent effects (Engin et al., 2008). Studies of osteoblast-specific gene misexpression reveal that HES1 and HEY2 suppress osteoblast function and reduce bone mass (Zanotti et al., 2011a; Zanotti and Canalis, 2013a). In contrast, the global misexpression of HEY1 has a modest effect on osteoblastic function, and HEYL is dispensable for bone homeostasis (Tu et al., 2012; Salie et al., 2010; Canalis and Zanotti, 2017). Importantly, findings from studies of systemic HEY1 misexpression must be interpreted with caution due to the potential nonskeletal effects of the genetic alterations. Collectively, the reported results suggest that HES1, HEY2, and possibly HEY1 contribute to the inhibitory actions of Notch signaling on osteoblast function. HES1 and HEY1 reduce the expression of osteoblastic gene markers by inhibiting transactivation of RUNX2 (McLarren et al., 2000; Shen and Christakos, 2005; Suh et al., 2008; Zhang et al., 2009; Zamurovic et al., 2004). The skeletal phenotypes associated with inactivation of *Hes* and *Hey* in osteoblasts are milder than those observed in the context of *Notch1* and *Notch2* deletion in the same cells, suggesting that additional factors contribute to the effects of Notch receptors in osteoblasts (Fig. 44.3 and 44.4).

Activation of Notch signaling inhibits the differentiation of immature osteoblasts by suppressing cytosolic β-catenin levels and favoring proliferation of dysfunctional osteoblasts by upregulating the expression of cyclins and KI67 (Zanotti et al., 2008; Engin et al., 2008; Muguruma et al., 2017). Notch also regulates the expression of nuclear factor of activated T-cells (NFATc), and NFATc1 and NFATc2 compete with RBPJ for binding to DNA and prevent RBPJ-mediated transcriptional responses (Zanotti et al., 2011b, 2013). These observations indicate that Notch receptors are part of a signaling network that regulates osteoblastogenesis. Notch signaling is subjected to endocrine regulation, and PTH induces JAG1 but suppresses NOTCH1 and NOTCH2 activity by altering RBPJ/DNA interactions (Zanotti and Canalis, 2017; Calvi et al., 2003). These observations indicate that suppression of Notch signaling may contribute to the stimulatory effects of PTH on osteoblast function and bone formation.

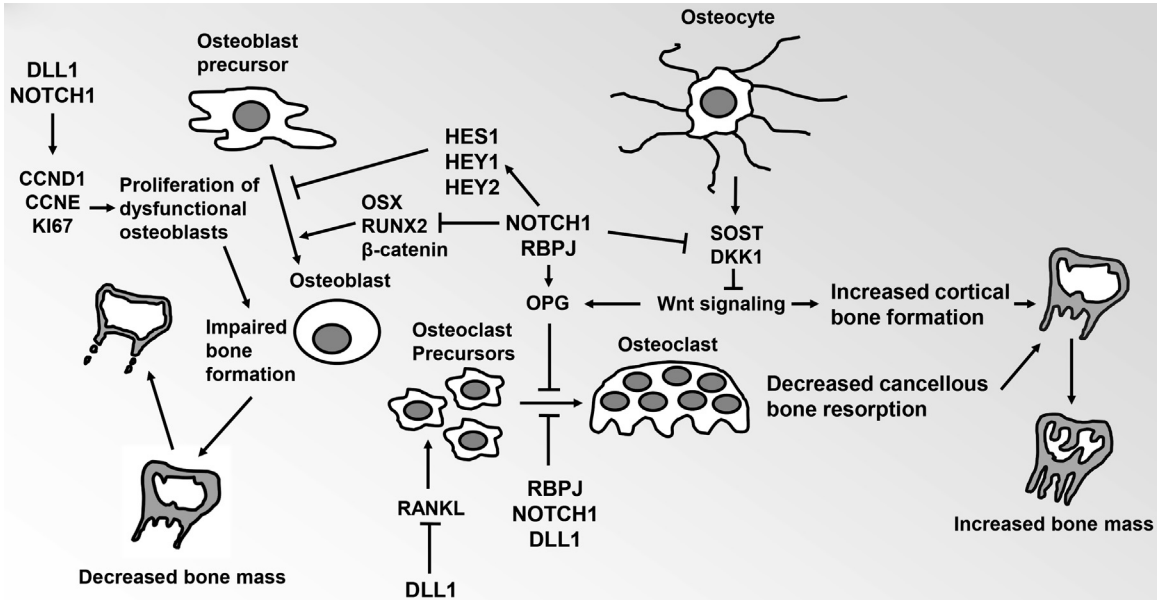

FIGURE 44.3 Regulation of bone remodeling by NOTCH1 and DLL1. NOTCH1 and DLL1 induce CCND1, CCNE, and KI67 leading to proliferation of dysfunctional osteoblasts and impaired bone formation. Activation of NOTCH1 in osteoblast precursors inhibits the function of SP7 and RUNX2 and the levels of cytosolic β-catenin by RBPJ-dependent mechanisms, thereby suppressing bone formation. Parallel induction of HES1, HEY1, and HEY2 contributes to inhibition of osteoblast function. Collectively, these events lead to a decrease in bone mass (left). NOTCH1 activation in osteocytes suppresses SOST as well as DKK1, thereby enhancing Wnt signaling and increasing cortical bone formation. In osteoblastic cells, NOTCH1 induces OPG, whereas DLL1 suppresses RANKL, and direct actions of NOTCH1 and DLL1 in osteoclast precursors inhibit osteoclastogenesis and bone resorption. The effects of NOTCH1 are mediated by RBPJ. Enhanced cortical bone formation and the inhibition of bone resorption lead to an increase in bone mass (right). *Adapted from Zanotti, S., Canalis, E., 2016. Notch signaling and the skeleton. Endocr. Rev. 37 (3), 223–253, with permission.*

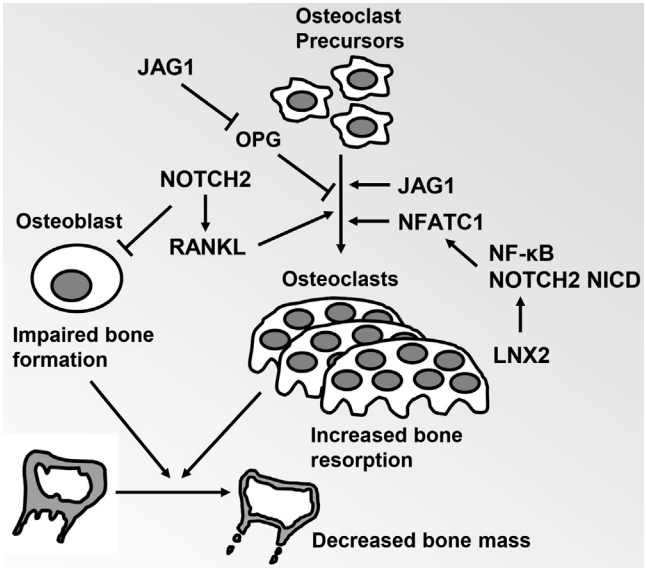

FIGURE 44.4 Regulation of bone remodeling by NOTCH2 and JAG1. Activation of NOTCH2 in osteoblasts suppresses bone formation and induces RANKL expression, thereby enhancing bone resorption. NOTCH2 activation in osteoclasts and exposure of osteoclast precursors to JAG1 enhances osteoclastogenesis and bone resorption. Interactions of nuclear factor-κB (NF-κB) with the NOTCH2 intracellular domain (N2ICD) in osteoclast precursors that lead to the induction of NFATC1 contribute to the stimulatory effects of NOTCH2 in osteoclasts. LNX2 enhances the stability of the N2ICD, thereby stimulating osteoclastogenesis. Suppressed osteoblastic function and increased bone resorption lead to a decrease in bone mass (right). *Adapted from Zanotti, S., Canalis, E., 2016. Notch signaling and the skeleton. Endocr. Rev. 37 (3), 223–253, with permission.*

Notch receptors and ligands in osteocytes

Role of Notch signaling in osteocytes

The function of Notch signaling in osteocytes was investigated in transgenic mice, where Cre expression is governed by a 9.6 kb fragment of the dentin matrix protein (*Dmp)1* promoter. *Dmp1* is expressed selectively in osteocytes but also in mature osteoblasts and in endosteal lining cells (Tables 44.1 and 44.2) (Lu et al., 2007; Xiong et al., 2015). NOTCH1 induction in *Dmp1*-expressing cells causes osteopetrosis by inducing osteoprotegerin and suppressing cancellous bone resorption. Activation of Notch in osteocytes increases cortical bone formation, although the cortex is porous and has the appearance of trabecular bone (Canalis et al., 2013a,b). The induction of N1ICD in *Sp7*-expressing cells causes a phenotype that evolves with age to resemble the effects of NOTCH1 activation in osteocytes, and this is consistent with lineage tracing studies demonstrating that *Sp7*-expressing cells have the potential to differentiate into osteocytes (Canalis et al., 2013b; Maes et al., 2010). The dual *Notch1*/*Notch2* deletion in osteocytes has minimal impact on cortical and cancellous bone remodeling and structure (Canalis et al., 2013a, 2017). The mild phenotype of the dual *Notch1*/*Notch2* deletion may be due to compensatory actions of *Notch3*, and this is consistent with the observation that *Notch3* is preferentially expressed in osteocytes (Zanotti and Canalis, 2017).

Mechanisms of Notch action in osteocytes

The conditional deletion of *Rbpj* prevents the effects of NOTCH1 activation in osteocytes, as it does in osteoblasts, supporting the notion that RBPJ carries out the functions of Notch signaling in the osteoblastic lineage (Canalis et al., 2015). In contrast to its effects in osteoblasts, activation of NOTCH1 in osteocytes suppresses the Wnt antagonists *Dkk1* and *Sost,* and as a consequence it enhances Wnt/β-catenin signaling (Canalis et al., 2013, 2015). Activation of β-catenin governed by the *Dmp1* promoter induces the expression of Notch receptors, adding a layer of complexity to the interactions of Notch and Wnt signaling in osteocytes (Tu et al., 2015). Based on this evidence, one can speculate the existence of a positive-feedback loop where Wnt enhances Notch activation, thereby leading to downregulation of *Sost* and a consequent increase in Wnt activity that sustains signaling from Notch receptors in osteocytes. Analogous mechanisms are not operational in osteoblasts, possibly because expression of *Sost* is negligible in these cells, and further downregulation by Notch would have no appreciable effect on the levels of cytosolic β-catenin (Nioi et al., 2015). It is not known whether the N1ICD/RBPJ complex inhibits *Dkk1* and *Sost* directly or whether the effect is secondary to transcriptional repressor activity of HES and HEY. JAG1 is the only Notch cognate ligand expressed in osteocytes, although it is not clear whether JAG1/Notch interactions are possible in this cellular context (Zanotti and Canalis, 2017). This is because osteocytes communicate within the confines of a canalicular network that restricts the membrane surface available for Notch receptor-ligand interactions between neighboring cells. Mechanical forces may be responsible for the induction of Notch in osteocytes (Fig. 44.3 and 44.4) (Robling et al., 2008).

Notch receptors and ligands in osteoclasts

The functions of Notch receptors in osteoclast progenitors were investigated in cultures of osteoclast precursors and conditional mouse models of gene misexpression in cells of the myeloid lineage (Clausen et al., 1999). The activation of NOTCH1 in osteoclast precursors suppresses osteoclastogenesis in vitro, and the induction of N1ICD in *Lyz2*-expressing cells inhibits bone resorption in mice exposed to tumor necrosis factor (Tables 44.1 and 44.2) (Bai et al., 2008; Zhao et al., 2012). Accordingly, myeloid-specific conditional *Notch1*/*Notch2* deletion in a *Notch3*-null genetic composition enhances osteoclastogenesis and the stimulatory effects of receptor activator of NF-kb-ligand (RANKL) on bone resorption (Bai et al., 2008). The inactivation of *Rbpj* in cultures of myeloid cells enhances osteoclastogenesis, suggesting that NOTCH1 suppresses osteoclastic differentiation with an RBPJ-dependent mechanism (Swarnkar et al., 2015). In contrast to NOTCH1, activation of NOTCH2 in osteoclast precursors induces osteoclastogenesis in vitro (Canalis et al., 2016; Fukushima et al., 2008; Jin et al., 2016; Zhou et al., 2015). However, neither the activation nor deletion of NOTCH2 in *Lyz2*-expressing cells affects osteoclastogenesis (Zanotti et al., 2017; Yorgan et al., 2016).

The identity of the ligand responsible for Notch activation in osteoclasts may influence the response to Notch signaling. Bone marrow mononuclear precursors cultured in the presence of JAG1 display enhanced Notch signaling and a capacity for osteoclastic differentiation in response to RANKL, whereas exposure to DLL1 suppresses osteoclastogenesis in vitro (Muguruma et al., 2017; Ashley et al., 2015; Nakao et al., 2009; Yamada et al., 2003). Direct stimulation of osteoclastogenesis by JAG1 was verified in vivo, since JAG1 expressed by metastatic breast cancer cells engages Notch receptors

in osteoclast precursors and contributes to the formation of lytic bone lesions (Sethi et al., 2011). However, the ligands responsible for activation of Notch receptors in osteoclasts under conditions of physiological bone remodeling remain to be determined.

Notch signaling also governs osteoclastogenesis via indirect effects on osteoblasts that lead to the regulation of *Tnfrsf11b*, the gene encoding for OPG, and *Tnfsf11*, which encodes for RANKL (Lacey et al., 1998). By downregulating *Tnfsf11*, transgenic DLL1 expression in osteoblasts inhibits osteoclastogenesis and leads to a high bone mass phenotype (Muguruma et al., 2017). In contrast to the inhibitory effects of NOTCH1 and DLL1 on osteoclast differentiation, activation of NOTCH2 in osteoblasts enhances osteoclastogenesis and bone resorption by inducing RANKL (Canalis et al., 2016; Zanotti et al., 2017). The deletion of *Jag1* in osteoblast precursors inhibits bone resorption RANKL (Lawal et al., 2017). Although JAG1 and NOTCH2 promote osteoclast differentiation through the regulation of osteoblast-derived signals, it is not clear whether JAG1 is the ligand responsible for NOTCH2 activation in this context. These observations demonstrate that NOTCH1 and DLL1 are inhibitors, whereas NOTCH2 and JAG1 are enhancers, of osteoclastogenesis, confirming that the identity of Notch receptors and cognate ligands determines the response to Notch signaling (Fig. 44.3 and 44.4).

Fracture repair and Notch signaling

Bone has a remarkable ability to regenerate following a fracture. The repair process involves complex interactions between cells of different lineages and is characterized by an initial inflammatory response and by neovascularization. Subsequently, bone tissue is regenerated either by intramembranous or endochondral ossification processes, depending on whether the fractured bone is stable or unstable (Thompson et al., 2002). Work attempting to characterize Notch expression during fracture repair has reported both upregulation and downregulation of Notch receptors and ligands, and the contradictory results may be related to experimental differences (Matthews et al., 2014; Dishowitz et al., 2012). Studies in genetically modified mice reveal that Notch signaling plays a critical role during fracture repair. Induction of a dominant negative MAML1 mutant in *Mx1*-expressing cells, and consequent inhibition of Notch signaling, prolongs the inflammatory response during fracture and delays the endochondral bone formation process (Dishowitz et al., 2013). The *Mx1* promoter is active in immune and vascular cells, so that these findings are consistent with the roles of Notch in the inflammatory response and vascularization of long bones (Ramasamy et al., 2014; Gridley, 2010; Benedito and Hellstrom, 2013). The requirement of Notch signaling for fracture healing was demonstrated by findings revealing that the *Rbpj* deletion in *Prx1*-expressing cells results in nonunion fractures. Conversely, the deletion of *Rbpj* in *Acan*-expressing cells or osteoblasts does not alter the repair process, indicating that Notch signaling is required during the early phases of cell differentiation since *Prx1* is expressed in chondroprogenitors, whereas *Acan* is expressed in mature chondrocytes (Wang et al., 2016). These findings are not congruent with the inhibitory effects of Notch on the differentiation of mesenchymal precursors, chondrocytes, and osteoblasts, and indicate that the endochondral ossification events that drive fracture repair are distinct from those that determine skeletal development (Dong et al., 2010; Mead and Yutzey, 2009; Kohn et al., 2012). Studies where *Rbpj* is conditionally deleted should be interpreted with caution, as this approach may affect the expression of genes not directly regulated by Notch signaling. It is of interest that the administration of a γ-secretase inhibitor accelerates healing in a murine model of tibial midshaft fracture (Wang et al., 2015). However, it is possible that the reported effect is secondary to downregulation of other signaling pathways affected by the broad actions of γ-secretase inhibitors (Duggan and McCarthy, 2016).

Congenital skeletal diseases caused by Notch loss of function

Alagille syndrome

Alagille syndrome is a multiorgan disease characterized by cardiovascular defects including tetralogy of Fallot, cholestatic liver disease due to bile duct atresia, and kidney anomalies that can result in renal failure (Alagille et al., 1987). Alagille syndrome is associated with mutations in either *JAG1,* or rarely, *NOTCH2*. Affected subjects present with craniofacial developmental abnormalities including craniosynostosis and distinctive facial features such as broad nasal bridge, deep set eyes, pointed chin, prominent forehead, and triangular facies. Skeletal defects extend to the spine, where vertebrae fail to fuse ventrally during development and assume a characteristic "butterfly" appearance in radiographic images. Short stature, digit abnormalities, and osteoporosis are common symptoms, although the latter is considered secondary to liver failure and subsequent malnutrition (Emerick et al., 1999). Alagille syndrome is associated with inherited loss-of-function mutations of *JAG1* such as total gene ablation, insertions that lead to protein truncations, short deletions, and nonsense mutations (Bauer et al., 2010; Crosnier et al., 1999; Morrissette et al., 2001; Boyer-Di Ponio et al., 2007). Defects are

distributed across the length of the gene and interfere with the processing of JAG1, leading to accumulation of the protein, and as a consequence, impaired Notch signaling (Morrissette et al., 2001). De novo and inherited mutations have been reported, and the disease is transmitted with an autosomal dominant pattern, suggesting that *JAG1* is haploinsufficient (Boyer-Di Ponio et al., 2007). Sporadically, patients with Alagille syndrome harbor *NOTCH2* loss-of-function mutations, either in isolation or associated with *JAG1* mutations. These subjects present with hypoplastic kidneys and renal insufficiency, which is consistent with the role of NOTCH2 in renal development (Kamath et al., 2012; McDaniell et al., 2006). Mice heterozygous for both a *Jag1*-null and a hypomorphic *Notch2* allele recapitulate selected features of Alagille syndrome, while the conditional deletion of *Jag1* in cells of the neural crest phenocopies the craniofacial abnormalities associated with the disease (McCright et al., 2002; Humphreys et al., 2012). These findings suggest that Alagille syndrome is caused by mutations in *JAG1* and *NOTCH2* resulting in loss of function.

Spondylocostal and spondylothoracic dysostosis

Spondylocostal and spondylothoracic dysostosis are diseases of defective somitogenesis that cause abnormalities in vertebral segmentation and rib structure (Turnpenny et al., 2003). These disorders are associated with dominant or recessive mutations in genes encoding components of the Notch signaling pathway, namely *DLL3*, *LFNG*, *HES7,* and mutant mesoderm posterior bHLH transcription factor (*MESP*)*2*. The mutations can occur de novo or be inherited (Zanotti and Canalis, 2012). The most frequent mutations associated with spondylocostal dysostosis, found in 20%−25% of affected individuals, occur within the coding region of *DLL3* and lead to the translation of a truncated or misfolded protein (Kusumi et al., 1998; Dunwoodie et al., 2002). Accordingly, the systemic deletion of *Dll3* in mice phenocopies the manifestations of spondylocostal dysostosis, although it remains to be determined whether these genetic defects lead to suppressed Notch signaling (Kusumi et al., 1998; Ladi et al., 2005). Homozygous missense loss-of-function mutations in *LFNG* and *HES7* are found in individuals affected by spondylocostal dysostosis, albeit with less frequency than *DLL3* mutations, and inactivation of *Lfng* or *Hes7* in mice impairs the development of the spine and rib cage (Bessho et al., 2001; Okubo et al., 2012; Sparrow et al., 2006, 2008, 2010). Spondylothoracic dysostosis is observed primarily in people of Puerto Rican descent and is associated with *MESP2* mutations, although sporadic cases in subjects homozygous for *MESP2* nonsense mutations have been reported (Cornier et al., 2008; Whittock et al., 2004). *MESP2* is a Notch transcriptional target that encodes for a bHLH transcription factor similar to HES1, as well as HEY1, and vertebral development is impaired in *Mesp2*-null mice, reaffirming the role of Notch signaling and bHLH proteins in the development of the axial skeleton (Saga, 2012; Saga et al., 1997).

Adams Oliver syndrome

Adams Oliver syndrome (AOS), a disease characterized by aplasia cutis congenita and limb defects, is associated with mutations in *NOTCH1*, *RBPJ*, *DLL4*, and *EOGT*, which encodes for EGF-domain-specific O-linked *N*-acetylglucosamine transferase (O-GlcNAc). Subjects with AOS exhibit significant phenotypic variations, with distal limb abnormalities including transverse amputations, oligodactyly, syndactyly, and hypoplastic nails (Snape et al., 2009; Adams and Oliver, 1945). AOS also presents with ventricular septal defects, tetralogy of Fallot, and anomalies of arteries and cardiac valves consistent with the role of Notch signaling in the cardiovascular system. Symptoms of peripheral vessel dysfunction, such as retinal hypovascularization and cutis marmorata telangiectatica congenita, are observed.

The mutations of *NOTCH1* associated with AOS are distributed across the length of the receptor but are more prevalent in EGF-like repeats and lead to structural changes that result in loss-of-NOTCH1 function (Stittrich et al., 2014). These mutations are associated with a higher incidence of transverse limb defects, which may be caused by developmental small vessel abnormalities and thrombosis leading to vascular obstruction rather than direct effects on mesenchymal cell differentiation (Stittrich et al., 2014; Southgate et al., 2015; Hoyme et al., 1982; Swartz et al., 1999). Two families with AOS were found to harbor heterozygous loss-of-function mutations that impair binding of RBPJ to regulatory regions of Notch target genes without interfering with RBPJ/NICD interactions (Hassed et al., 2012). Only a few AOS subjects that carry *DLL4* mutations present with cardiovascular defects, despite the fact that DLL4 is expressed in arteries and is necessary for vascular development (Gridley, 2007). Mutations of *DLL4* occur throughout the coding sequence, disrupt the structure of all known domains of DLL4, and are predicted to cause loss of function (Meester et al., 2015). Recessive mutations in *EOGT* impair O-GlcNAc activity and possibly cause defects in the glycosylation of the EGF-like domain of NOTCH1, disrupting its interactions with cognate ligands and leading to loss of function (Shaheen et al., 2013; Cohen et al., 2014; Ogawa et al., 2015).

Congenital skeletal diseases caused by Notch gain of function

Hajdu Cheney syndrome

Hajdu Cheney syndrome (HCS) is a rare disorder characterized by prominent skeletal features and phenotypical manifestations that evolve with age (Brennan and Pauli, 2001; Cheney, 1965; Currarino, 2009; Descartes et al., 2014; Gray et al., 2012; Hajdu and Kauntze, 1948; Silverman et al., 1974). Platybasia and basilar invagination are observed frequently and can result in severe neurological complications, such as hydrocephalus and central respiratory arrest with sudden death. Some subjects present with renal cysts, polycystic kidneys, or cardiovascular defects, including septal and valve abnormalities (Kaler et al., 1990; Sargin et al., 2013). The facial appearance is distinctive, with micrognathia, flattening of the midface, and abnormal dental eruptions as well as premature tooth decay and loss. Kyphosis, scoliosis, and long bone deformities, including serpentine fibula, have been reported, indicating involvement of both the axial and appendicular skeleton (Currarino, 2009; Gray et al., 2012). Focal lysis of the distal phalanxes leads to short and broad digits; histopathology is characterized by neovascularization or inflammation, and fibrosis can present with pain and swelling (Elias et al., 1978; Nunziata et al., 1990; Udell et al., 1986). Generalized osteoporosis affects most subjects, and increased bone resorption was documented in iliac crest biopsies of selected cases (Sakka et al., 2017). A recent report of an HCS patient with increased RANKL serum levels suggests that enhanced osteoclastogenesis and bone resorption are a possible mechanism for the bone loss (Adami et al., 2016).

HCS cases are frequently sporadic, although familial transmission via an autosomal dominant mechanism is possible. HCS is associated with point mutations or small deletions/insertions in exon 34 of *NOTCH2* that lead to the creation of a premature stop codon upstream of sequences coding for the PEST domain and downstream of the domains required for N2ICD/RBPJ interactions (Isidor et al., 2011; Majewski et al., 2011; Simpson et al., 2011; Zhao et al., 2013). Mutant transcripts are predicted to translate a truncated and stable NOTCH2, since the PEST domain is necessary for proteasomal degradation. This may lead to gain of function, as the sequences required to induce a transcriptional response are preserved. Pedigree analysis in affected families indicates that penetrance of the mutation is complete, whereas its expressivity is variable, as clinical manifestations of HCS can differ significantly between affected individuals. It is of interest that analogous somatic *NOTCH2* mutations increasing Notch activity are found in splenic marginal zone B-cell lymphoma (Kiel et al., 2012; Lee et al., 2009; Rossi et al., 2012; Zhang et al., 2014). Although splenomegaly has been reported in one case, there is no apparent increase in the incidence of B-cell lymphoma in HCS subjects (Adami et al., 2016).

Work in mutant mice harboring a truncating *Notch2* mutation that replicates the one found in an HCS subject demonstrates that NOTCH2 gain-of-function is the mechanism responsible for the bone loss (Canalis et al., 2016). The mutant (MGI symbol *Notch2*$^{tm1.1Ecan}$) exhibits osteopenia secondary to increased bone resorption associated with increased RANKL expression. There is no corresponding enhancement of bone formation, indicative of an inhibitory effect of the mutation on osteoblastic function. Further work in a conditional model of HCS demonstrated that deletion of the NOTCH2 PEST domain in osteoblasts, but not in myeloid cells, reproduced the osteopenic phenotype of *Notch2*$^{tm1.1Ecan}$ mutants; the mechanism was increased RANKL in *Bglap*-expressing cells (Zanotti et al., 2017). These initial reports were corroborated by another model of HCS, termed here *Notch2HCS*$^{(Yorgan)}$, that displays generalized bone loss and increased RANKL expression (Vollersen et al., 2017). This particular *NOTCH2* mutant triggers a bone-forming response and enhanced bone remodeling, indicating variations in the skeletal phenotype of the HCS mutation in mice.

Lateral meningocele syndrome

Lateral meningocele syndrome (LMS), also known as Lehman syndrome, is a rare disorder characterized by hypotonia and meningocele associated with neurological dysfunction (Lehman et al., 1977). Clinical features include empty sella and craniofacial abnormalities that lead to distinctive facies with hypertelorism, high arched eyebrows, ptosis and low set eyes, a cleft, high and narrow palate, and mandibular hypoplasia. LMS subjects have developmental delay, intellectual disability, hypotonia, decreased muscle mass, and syringomyelia as well as cardiac valve defects. There are prominent skeletal manifestations, such as short stature, scoliosis, pectus excavatum, thick calvariae, wormian bones, and high density of the base of the skull (Gripp et al., 1997). A generalized increase in bone remodeling and osteopenia are present.

Whole-exome sequencing in affected families demonstrated that LMS is associated with point mutations or deletions of up to 80 bases in exon 33 of *NOTCH3*, upstream of the PEST domain but downstream of sequences required for N3ICD/RBPJ interactions (Gripp et al., 2015; Ejaz et al., 2016). The resulting mutant NOTCH3 is truncated and presumably stable due to the absence of the PEST domain, possibly leading to enhanced Notch signaling. The etiology is analogous to the one proposed for HCS, and there is a certain degree of overlap in the clinical manifestations of both conditions (Gripp, 2011).

However, acroosteolysis, a defining feature of HCS, is not reported in LMS. Most documented cases of LMS are associated with de novo heterozygous truncating mutations in exon 33 of *NOTCH3,* and the mode of inheritance is not established, although a dominant mechanism is suspected (Gripp et al., 1997).

Brachydactyly

Brachydactylies are a group of diverse congenital disorders often associated with dysregulated bone morphogenetic protein and hedgehog signaling pathways. Genetic analysis in a Jordanian family afflicted by symmetric bilateral preaxial brachydactyly, short stature, micrognathia, and learning disabilities identified a recessive nonsense mutation in chondroitin sulfate synthase (*CHSY)1* as the potentially causative genetic defect (Tian et al., 2010). In zebrafish, downregulation of *Chsy1* results in enhanced Notch signaling and impairs skeletal development; moreover, cultured fibroblasts from individuals affected by brachydactyly exhibit upregulation of *JAG1* and enhanced Notch activity (Tian et al., 2010). Although these observations suggest that gain-of-Notch function drives the disease, the *Chsy1* inactivation in mice does not affect the expression of genes coding for components of the Notch signaling pathway, suggesting that murine CHSY1 does not regulate Notch activity. *Chsy1*-null mice display skeletal defects compatible with brachydactyly and osteopenia that are ascribed to reduced chondroitin sulfation, a shift in cellular orientation, and induction of growth differentiation factor 5, a member of the bone morphogenetic family of proteins (Wilson et al., 2012). A recent study in humans identified several distinct *CHSY1* loss-of-function mutations in brachydactyly but no abnormalities in parameters of Notch activity, questioning whether brachydactyly is a disease of enhanced Notch signaling (Li et al., 2010).

Notch and skeletal malignancies

Osteosarcoma

Osteosarcoma is the most common primary malignancy affecting bone tissue. The tumor is of osteoblastic origin, and the molecular events that determine the onset of the cancerous lesion and drive the evolution of the disease remain poorly understood. Enhanced Notch signaling was demonstrated in human and canine osteosarcoma (Tanaka et al., 2009; Dailey et al., 2013). Analysis of gene expression in biopsies from subjects with osteosarcoma has demonstrated frequent upregulation of *NOTCH1*, *NOTCH2,* and *JAG1* as well as sporadic enhanced expression of *DLL1* (Dailey et al., 2013; Engin et al., 2009). In addition, induction of *HEY1* and *HEY2* was reported, verifying increased RBPJ-mediated Notch signaling in osteosarcoma, and this may be responsible for the proliferation of tumor cells (Tanaka et al., 2009). Notch signaling promotes tumor invasiveness, and *NOTCH1*, *NOTCH2*, *DLL1,* and *HES1* are highly expressed in osteosarcoma cell lines with the ability to metastasize (Hughes, 2009). These observations are corroborated by a study where the induction of the N1ICD in murine osteoblasts leads to the development of osteosarcoma in vivo (Tao et al., 2014). The mechanism of Notch action is *Rbpj*-dependent, as its inactivation prevents the effects of N1ICD overexpression, and the process is accelerated by loss of p53. Collectively, findings in humans, dogs, and mice suggest that somatic gain-of-function mutations affecting the Notch signaling pathway play a role in the initiation and invasive potential of osteosarcoma.

Multiple myeloma

Multiple myeloma is a primary tumor affecting the bone marrow and characterized by the expansion of monoclonal plasma cells. This malignancy is associated frequently with lytic bone lesions caused by interactions of tumor cells with osteoblasts and osteocytes that induce RANKL expression. Cocultures of multiple myeloma cells and osteocytes induce Notch signaling in both cell types. Cell contact is required for this effect, suggesting that bidirectional Notch induction occurs between multiple myeloma cells and osteocytes. NOTCH3 appears to mediate these interactions, as osteocytes induce Notch target genes only in multiple myeloma cells with high *NOTCH3* expression irrespective of *NOTCH1* and *NOTCH2* transcript levels (Delgado-Calle et al., 2016). Osteocytes in contact with myeloma cells exhibit increased expression of *Sost*, and this effect contributes to the establishment of the lytic lesions in mice (Delgado-Calle et al., 2017). It is not clear whether *Sost* induction is mediated by engagement of osteocytic Notch receptors by myeloma cells, as under physiological conditions Notch inhibits *Sost* expression in osteocytes (Canalis et al., 2013a, 2015).

Metastatic carcinoma of the breast and prostate

Carcinoma of the breast frequently metastasizes to bone, and Notch signaling appears to mediate interactions between osteoblasts and carcinoma cells. Human osteoblasts residing in bone marrow are capable of inducing *NOTCH3* and *JAG1* and

to promote the formation of colonies by human breast carcinoma cell lines. Cardiac inoculation or direct injection of carcinoma cells into the bone marrow of athymic mice causes osteolytic bone metastases, while downregulation of *NOTCH3* in tumor cells reduced their metastatic potential, suggesting that NOTCH3 contributes to the invasiveness of breast cancer (Zhang et al., 2010). Accordingly, *JAG1* expression in mammary cancer cells correlates with tumor load and metastatic potential of breast cancer in mice (Sethi et al., 2011). JAG1 expressed by the tumor engages osteoblastic Notch receptors, leading to induction of IL6, enhanced osteoclastogenesis, and ultimately formation of osteolytic metastases. As bone is resorbed, transforming growth factor β is released from the matrix, upregulates *JAG1*, and induces Notch activation, establishing a positive-feedback loop that contributes to the metastatic potential of the tumor. Downregulation of *JAG1* by RNA interference or administration of γ-secretase inhibitors decreases the formation of osteolytic metastasis, confirming that Notch activity is important for the localization of tumor cells to bone in a murine model of breast carcinoma.

Bone metastases are a serious complication of prostate carcinoma and characterized by excessive production of osteoblastic woven bone associated with variable levels of osteoclastic bone resorption (Koutsilieris, 1993). Expression of *NOTCH1* and *JAG1* in carcinoma of the prostate is associated with metastatic potential and tumor recurrence, suggesting that dysregulated Notch activity may be accountable for the progression of metastatic prostate carcinoma (Zayzafoon et al., 2004; Santagata et al., 2004). This is consistent with the observation that downregulation of *NOTCH1* by RNA interference in human prostate cancer cells decreased tumor invasiveness by suppressing the expression of matrix metalloprotease 9 and of urokinase plasminogen activator receptor (Bin Hafeez et al., 2009). Expression of *NOTCH1* and of molecular markers of the epithelial−mesenchymal transition (EMT), a cellular event that occurs during cancer progression and tumor invasiveness, can be observed in metastatic carcinoma of the prostate by immunohistochemical analysis (Emadi Baygi et al., 2010; Sethi et al., 2010b). Thus, Notch may contribute to tumor aggressiveness by favoring the EMT and the metastatic potential of prostate cancer.

Conclusions

Over the past decade, work in genetically modified mice demonstrated that Notch signaling in mesenchymal precursors and in the chondrocytic, osteoblastic, and osteoclastic lineages must be tightly regulated to preserve bone homeostasis. The effects of Notch are determined by the cellular context, and distinct skeletal outcomes are observed when Notch activity is perturbed in immature or mature chondrocytes and osteoblasts. NOTCH1 and NOTCH2 in immature and differentiated osteoblasts act as inhibitors of bone formation, whereas Notch activation in more mature osteoblasts or in osteocytes leads to osteosclerosis. Notch signaling is integrated with the signaling network that governs the osteoblast differentiation program, and Notch receptors engage in complex interactions with local regulators of cell function. Investigations on the individual effects of NOTCH1, NOTCH2, JAG1, and DLL1 misexpression in osteoblasts and osteoclasts demonstrate that different Notch receptors and cognate ligands have distinct skeletal functions. Because of this, studies addressing the role of individual Notch receptors, cognate ligands and associated proteins should lead to a more accurate understanding of the role of Notch signaling in skeletal remodeling. The importance of Notch signaling in skeletal health is underscored by the fact that Notch activity is necessary for fracture healing. Clinical studies have established a strong association between gain- and loss-of-Notch-function mutations and congenital diseases with severe skeletal manifestations. Somatic mutations in Notch receptors as well as Jag ligands are a common occurrence in osteosarcoma and may enhance the metastatic potential of breast and prostate carcinoma.

In conclusion, Notch receptors and ligands play critical roles in skeletal development, in the regulation of bone remodeling, and during fracture repair; the genetic defects affecting the various components of Notch signaling have serious consequences on skeletal development.

Abbreviations

ADAM A disintegrin and metalloprotease domain
AOS Adams Oliver syndrome
ANK Ankyrin repeat
bHLH Basic helix-loop-helix
BAC Bacterial artificial chromosome
c-ter c-terminus
CADASIL Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy
CHSY Chondroitin sulfate synthase
CreER^{T2} Cre recombinase/estrogen receptor fusion protein
CDK Cyclin dependent kinases

CR Cysteine-rich
DLL Delta-like
DLK Delta-like homolog
DNER Delta/Notch-like EGF related receptor
DOS Delta and OSM11-like
DSL Delta/Serrate/Lag2
DMP Dentin matrix protein
DTX Deltex E3 ubiquitin ligase
EGF Epidermal growth factor
EMT Epithelial mesenchymal transition
FBXW7 F-box and WD repeat domain-containing
HCS Hajdu Cheney syndrome
HES Hairy and enhancer of split
HEY Hes-related with YRPW motif
HD Heterodimerization
ITCH Itchy E3 ubiquitin protein ligase
JAG Jagged
LMS Lateral meningocele syndrome
LP Leader peptide
LNR Lin12-Notch repeats
LFNG Lunatic fringe
MFNG Manic fringe
MAML Mastermind-like
MESP Mesoderm posterior bHLH transcription factor
MAGP Microfibril-associated glycoproteins
MGI Mouse Genome Informatics
MIB Mind bomb
MNNL Modulus at the N-terminus of Notch ligands
NRR Negative regulatory region
NOV Nephroblastoma overexpression
NEURL Neuralized E3 ubiquitin protein ligase
NICD Notch intracellular domain
N1ICD NOTCH1 intracellular domain
N2ICD NOTCH2 notch intracellular domain
Nf Nuclear factor
NFAT Nuclear factor of activated T cells
NLS Nuclear localization sequences
O-GlcNAc O-linked *N*-acetylglucosamine transferase
PSEN Presenilin
PEST Proline (P)-, glutamic acid (E)-, serine (S)-, threonine (T)-rich motif
POGLUT Protein *O*-glucosyltransferase
RFNG Radical fringe
RANKL Receptor activation of NF-kb-ligand
RBPJ Recombination signal-binding protein for immunoglobulin of kappa region
RAM RBPJ-association module
Ring Really interesting new gene
TMD Transmembrane domain.

Chapter outline

Fibroblast growth factor production and regulation in bone

Fibroblast growth factors (FGFs) are a family of polypeptides found in metazoan organisms ranging from nematodes to humans (Gospadorowicz et al., 1974; Itoh et al., 2007; Fon Tacer et al., 2010). There are 22 members of the human/rodent FGF gene family (FGFs 1−23), of which FGF15 is the mouse ortholog of human FGF19. Based on sequence homology and phylogeny, the mouse and human FGF families are divided into seven subfamilies: FGFs 1 and 2 are members of the FGF1 subfamily; FGFs 4, 5, and 6 belong to the FGF4 subfamily; FGFs 3, 7, 10, and 22 are comprised in the FGF7 subfamily; the FGF8 subfamily consists of FGFs 8, 17, and 18; the FGF9 subfamily includes FGFs 9, 16, and 20; the FGF11 subfamily consists of FGFs 11−14; and the endocrine/hormonal FGF15/19 subfamily consists of FGFs 15/19, 21, and 23 (Itoh and Ornitz, 2004, 2008; Ornitz and Marie, 2015; Ornitz and Itoh, 2015). Members of the FGF family of ligands have important roles in the regulation of osteogenesis, osteoclastogenesis, and bone and mineral homeostasis, and there is evidence of the mRNA expression of some but not all FGF ligands in bones. Among the *Fgf* mRNAs expressed in rodent bones are *Fgf1, Fgf2, Fgf6, Fgf7, Fgf18,* and *Fgf23* (Fon Taser et al., 2010). Expression profiling of *Fgf* gene expression during rat calvarial osteoblast differentiation demonstrated low levels of expression of *Fgf2, Fgf4, Fgf7, Fgf18*,

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00045-2

and *Fgf20* throughout the culture period, although there was a progressive increase in Fgf9 and Fgf23 during the late differentiation stages (Takei et al., 2015).

FGF1, also known as acidic FGF, is a 155-amino-acid-long nonglycosylated polypeptide produced by bone (Hauechka et al., 1986). FGF1 is not released from cells under normal physiological conditions, but is secreted in response to stress conditions such as heat shock, hypoxia (Carreira et al., 2001; Jackson et al., 1992), serum starvation (Shin et al., 1996), and exposure to low-density lipoproteins (Ananyeva et al., 1997). FGF2, like FGF1, is stored in the bone matrix (Hauschka et al., 1986), with FGF2 levels being 10-fold higher than than those of FGF1 (Seyedin et al., 1985). FGF2 is produced by osteoblasts (Globus et al., 1989). In cultures of mouse osteoblastic MC3T3-E1 cells, exogenous FGF2 increases its own mRNA (Hurley et al., 1994). Transforming growth factor beta (TGF-β) also increases Fgf2 mRNA and protein in MC3T3-E1 cells (Hurley et al., 1994). However, there was no measurable FGF2 in the conditioned medium. The significance of TGF-β regulation of FGF2 in osteoblasts is not clear. Amplification of the responses to both FGF and TGF-β could occur from an increase in endogenous FGF2. Other regulators of FGF2 expression include parathyroid hormone (PTH) (Hurley et al., 1999) and prostaglandins (Sabbieti et al., 1999) that increase *Fgf2* mRNA and protein levels in osteoblasts, suggesting that anabolic factors for bone may act in part by stimulating endogenous FGF2 in osteoblasts. Interestingly, FGF2 is an immediate-early gene induced by mechanical stress in osteoblasts, an effect that results in activation of the protein kinase A (PKA) and MAP kinases ERK1/2 pathways, suggesting that FGF2 may mediate some osteogenic effects induced by mechanical forces (Li and Hughes-Fulford, 2016). FGF8 is expressed in chondrocytes, perichondrium and calvarial osteoblasts, and the growth plate of developing bones. FGF8 also regulates osteoblast and chondrocyte differentiation (Xu et al., 1999; Ornitz and Marie, 2002, 2015). *Fgf8* knockout in mice resulted in embryonic lethality; therefore, there are limited data on its role in bone homeostasis (Sun et al., 1999). FGF9 has an important role in skeletal development and repair. It is expressed in multiple tissues including the perichondrium/periosteum, chondrocytes, and primary spongiosa (Garafolo et al., 1999; Colvin et al., 1999; Hung et al., 2007). *Fgf9* knockout in mice resulted in lethality at the neonatal stage (Colvin et al., 2001). *Fgf9* knockout mice also have shortening of the proximal skeletal elements (Hung et al., 2007). In addition, knockout of *Fgf9* results in osteoclast deficiency (Hung et al., 2007). These data imply that FGF9 positively regulates osteogenesis and osteoclastogenesis. FGF18 is expressed in osteoprogenitor cells, differentiated osteoblasts, perichondrium, joints, and growth plates of long bones (Lazarus et al., 2007; Liu et al., 2007; Obayashi et al., 2002). Mice with global *Fgf18* knockout die perinatally and display expansion of proliferating chondrocyte (PC) and hypertrophic chondrocyte (HC) zones consistent with a negative regulatory role of FGF18 on chondrogenesis. FGF18 also contributes to bone development by its effects to induce vascularization of bone and recruitment of osteoclast progenitors during bone development (Liu et al., 2007). In vitro, *Fgf18* expression is upregulated by Wnt signaling in chondrocytes (Kapadia et al., 2005) and by Runx2 in cooperation with Wnt signaling (Reinhold and Naski, 2007), suggesting a link between Wnt signaling and FGF signaling during endochondral bone development. To date, there are no data on regulators of FGF18 expression in bone in vivo.

FGF23 functions as an endocrine hormone that interacts with FGF tyrosine kinase receptors and FGF alpha-Klotho coreceptor to regulate phosphate homeostasis and vitamin D metabolism (Quarles et al., 2012). Although FGF23 is expressed in many tissues (Yamashita et al., 2000), it is mainly secreted by differentiated osteoblasts and osteocytes (Liu et al., 2003, 2006; Yoshiko et al., 2007) and may locally control the differentiation of bone marrow stromal cells (Li et al., 2013). In addition to osteoblasts and osteocytes, mesenchymal tumors (Shimada et al., 2001) and osteogenic cells in fibrous dysplastic lesions (Riminucci et al., 2003) also increases FGF23 production. The regulation of FGF23 expression is quite complex. Studies have demonstrated that systemic factors including ions such as calcium, phosphate, and iron, as well as hormones such as PTH and 1,25-dihydroxyvitamin D, in combination with local factors such as FGFs, highly regulate bone FGF23 production, intracellular processing, and function (Quarles 2012; Larsson et al., 2003; Stubbs et al., 2012; Clinkenbeard and White., 2016). Reduced serum iron is associated with increased serum FGF23 in autosomal dominant hypophosphatemic rickets (ADHR) subjects (Imel et al., 2011), and C-terminal FGF23 is negatively correlated with ferritin (Durham et al., 2007; Clinkenbeard et al., 2014; Farrow et al., 2011). Iron chelation in vitro results in significantly increased Fgf23 mRNA via increased MAPK signaling (Farrow et al., 2011). The expression of FGF23 in osteoblasts and osteocytes is in part controlled by signaling from fibroblast growth factor receptor (FGFR) 1 (Martin et al., 2011). Conditional deletion of *Fgfr1* in osteocytes of Hyp mice, a mouse model of ADHR, reduced FGF23 production and partially rescued the abnormal phenotype in these mice (Xiao et al., 2014). Moreover, pharmacological FGFR inhibition ameliorates FGF23-mediated ADHR (Wohrle et al., 2013) whereas pharmacological activation of FGFR1 in osteoblasts leads to increased FGF23 secretion and hypophosphatemia in adult mice (Wu et al., 2013).

Novel studies have demonstrated FGF2 isoform−mediated regulation of FGF23 production in bone (Xiao et al., 2010a). The low-molecular-weight isoform of FGF2 (LMW 18kD) signals via cell-surface FGFRs, but high-molecular-weight isoforms (HMWFGF2) interact with intranuclear FGFR1 to activate integrative nuclear FGFR1 signaling

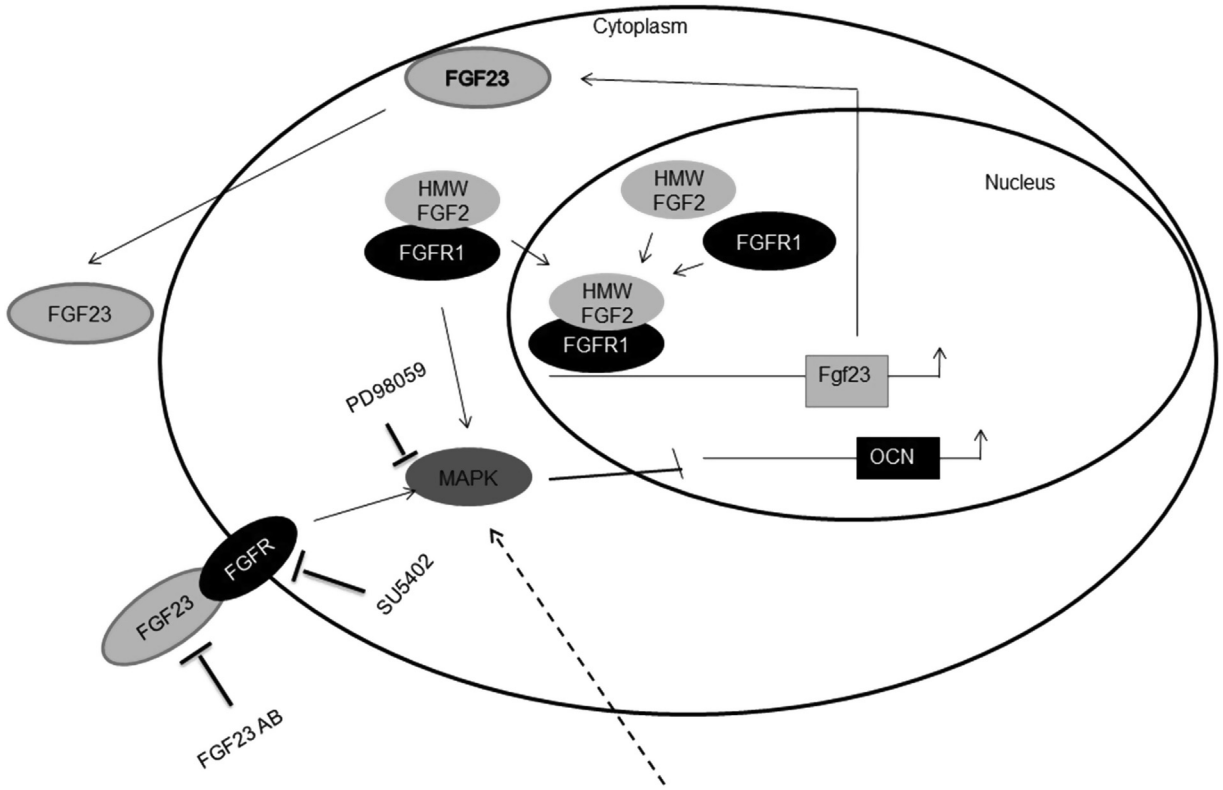

FIGURE 45.1 A schematic model depicting how high-molecular-weight (HMW) isoforms regulate bone formation. HMW isoforms, which have nuclear targeting sequences, translocate to the nucleus to upregulate FGF23 expression. FGF23 is secreted into the media and activates the tyrosine kinase domain of FGFR on the cell surface, triggering the downstream ERK signaling pathway. *Reprinted from Xiao L, Esliger A, Hurley MM., 2013. Nuclear fibroblast growth factor 2 (FGF2) isoforms inhibit bone marrow stromal cell mineralization through FGF23/FGFR/MAPK in vitro. J. Bone Miner. Res. 28, 35–45, with permission.*

(Clinkenbeard and White, 2016). Importantly, overexpression of nuclear HMWFGF2 in osteoblast lineage cells increased FGF23 production and induced an ADHR phenotype in mice (Xiao et al., 2010a). FGF23 production was increased by bone marrow stromal cell cultures from HMWFGF2 transgenic mice, and an intrinsic defect in mineralization was rescued by an FGF23-neutralizing antibody, an MAPK inhibitor, and an FGFR tyrosine kinase inhibitor (Xiao et al., 2013). In contrast, ablation of HMWFGF2 resulted in mice with high BMD versus wild-type littermates with increased osteoblastic activity (Homer-Bouthiette et al., 2014) associated with reduced *Fgf23* mRNA in the HMWFGF2-KO mice. These data suggest that HMWFGF2 isoforms may affect bone homeostasis through regulation of FGF23 production (Fig. 45.1). Conditional knockout of HMWFGF2 should clarify their role in FGF23 production and phosphate homeostasis.

Fibroblast growth factor receptor expression in bone

The FGF family comprises 18 secreted proteins that bind to 4 receptor tyrosine kinase FGFRs (Ornitz and Itoh, 2015). FGFRs 1, 2, and 3 undergo alternative splicing to produce variants that have distinct ligand-binding specificities and are differentially expressed. FGFRb splice variants bind FGF7 and FGF10 in mesenchymal tissues. FGFRc splice variants in mesenchymal tissues bind FGF ligands in epithelial and mesenchymal tissues. During skeletal development, *Fgfs* and *Fgfrs* are expressed in a time- and space-dependent manner in the condensing mesenchyme and intramembranous bone (Ornitz and Marie, 2002). In the distal limb bud mesenchyme, *Fgfr1* and *Fgfr2*, but not *Fgfr3* and *Fgfr4*, are expressed at the precondensation stage (Sheeba et al., 2010). At a later stage in the condensing mesenchyme, *Fgfr2* expression increases (Eswarakumar et al., 2002; Sheeba et al., 2010). Conditional inactivation of *Fgfr1* and *Fgfr2* in limb bud mesenchyme (using *Prx1-Cre)* or inactivation of *Fgfr1* in all mesenchyme (using *T(brachyury)-Cre)* causes severe skeletal hypoplasia (Verheyden et al., 2005; Yu and Ornitz, 2008), whereas inactivation of *Fgfr1* or *Fgfr2* in distal limb bud mesenchyme (using *AP2-Cre*) causes only a mild skeletal phenotype (Coumoul et al., 2005; Li et al., 2005), suggesting redundancy between FGFRs 1 and 2 in distal limb mesenchyme. During early stages of intramembranous bone formation, *Fgfs 2, 4, 9,*

and *18* and *Fgfrs 1, 2,* and *3* are coexpressed (Rice et al., 2000; Britto et al., 2001; Liu et al., 2002; Ohbayashi et al., 2002; Quarto et al., 2009; Marie et al., 2010). The FGFR2c splice variant expressed in early mesenchymal condensations and in sites of intramembranous ossification interacts with FGF18 (Eswarakumar et al., 2002). At later stages of cranial bone development, *Fgf18* is expressed in mesenchymal cells and differentiating osteoblasts (Ohbayashi et al., 2002; Reinhold and Naski, 2007), whereas *Fgf9* is expressed during mid to late stages of development in calvarial mesenchyme (Kim et al., 1998). Mice lacking both *Fgf9* and *Fgf18* have severely deficient cranial bone formation (Hung et al., 2016), as these FGFs interact with *Fgfr1* and *Fgfr2* expressed in preosteoblasts and osteoblasts in the developing membranous bone (Rice et al., 2003). *Fgfr1* and *Fgfr2* are also expressed in the periphery of mesenchyme condensations that will form the perichondrium and periosteum (Eswarakumar et al., 2002). At later stages in the perichondrium and trabecular bone, FGFR1 is expressed in mesenchymal progenitors, and FGFR2 in differentiating osteoblasts (Ohbayashi et al., 2002; Jacob et al., 2006; Coutu et al., 2011). *Fgfr3* expression occurs when condensed mesenchyme differentiates into chondrocytes, while *Fgfr2* expression decreases (Purcell et al., 2009). *Fgfr3* expression decreases when central chondrocytes begin to hypertrophy, while *Fgfr1* expression is increased (Jacob et al., 2006; Karolak et al., 2015). Thereafter, FGFR1 and FGFR3 are both expressed in mouse and human articular chondrocytes (Yan et al., 2011; Weng et al., 2012).

Fibroblast growth factor and FGF receptor signaling

Binding of FGF ligands to FGFRs induces dimerization and juxtaposition of the tyrosine kinase domains, leading to transphosphorylation of six tyrosine residues (Furdui et al., 2006; Goetz and Mohammadi, 2013), followed by phosphorylation of FGFR substrate 2α (FRS2α), a docked adaptor protein, and binding of other adaptor proteins including phospholipase Cγ (PLCγ) and signal transducer and activator of transcriptions (STATs) 1, 3, and 5 (Ornitz and Itoh, 2015). The phosphorylation of FRS2α leads to the recruitment of another adaptor protein, GRB2, which activates MAPKs through SOS and the PI3K−AKT pathway through GAB1 (Kouhara et al., 1997; Lamothe et al., 2004). FGF binding to FGFR1/2 can activate several MAP kinases including ERK1/2, JNK, and p38 (Tsang and Dawid, 2004; House et al., 2005; Liao et al., 2007; Kanazawa et al., 2010). FGFR intracellular signaling is downregulated by GRB2, which blocks PLCγ binding to FGFRs, and Sprouty (Spry), which interacts with GRB2 to block MAPK and PI3K signaling (Hanafusa et al., 2002; Timsah et al., 2014). Downstream of these events, SEF (similar expression to FGF) antagonizes the MAPK pathway by interacting with MEK (Torii et al., 2004) and DUSP6 (dual-specificity phosphatase 6), which reduces MAPK signaling through ERK1/2 dephosphorylation (Camps et al., 1998). Furthermore, GRB14, an adaptor protein, binds to FGFR phosphotyrosine 766 and interferes with phosphorylation and activation of PLCγ (Browaeys-Poly et al., 2010). Extracellularly, the biological activity of FGFs is tightly regulated by sulfated polysaccharides (Shimokawa et al., 2011; Ornitz and Itoh, 2015). Notably, heparan sulfate proteoglycans (HSPGs) such as syndecans bind to diffusible FGFs and thereby control the affinity of FGF to FGFR and receptor activation (Belov and Mohammadi, 2013; Xu and Esko, 2014; Ornitz and Itoh, 2015).

Fibroblast growth factor and FGF receptor signaling in chondrogenesis

Initiation of chondrogenesis

The differentiation of cells in the mesenchymal condensation to chondrocytes is regulated in part by FGF signaling (Kumar and Lassar, 2014; Mariani et al., 2008; Murakami et al., 2000; Ten Berge et al., 2008; Yu and Ornitz, 2008). In cooperation with Wnt signals, FGF signaling maintains mesenchymal progenitor cells in an undifferentiated and proliferative state, in part through the inhibition of Sox9 expression (Ten Berge et al., 2008). In the absence of Wnt signaling, FGF signaling increases Sox9 expression in mesenchymal progenitor cells and chondrocytes (Kumar and Lassar, 2014; Murakami et al., 2000; Shung et al., 2012; Ten Berge et al., 2008). Once cells are committed to the chondrogenic lineage, Sox9 directly increases expression of the *Fgfr3* gene, and FGFR3 signaling promotes Sox9 expression, forming a potential feed-forward loop (Murakami et al., 2000; Oh et al., 2014). These cells downregulate expression of FGFR2; however, the mechanisms regulating this are not known. This is consistent with the lack of an effect of FGFR2 on growth plate function and chondrocyte proliferation (Yu et al., 2003). In the definitive growth plate, *Fgfr3* is maintained at high levels in PC- and prehypertrophic chondrocytes (PHCs)-zone chondrocytes, and *Fgfr1* is expressed in HCs (Delezoide et al., 1998; Eswarakumar et al., 2002; Hamada et al., 1999; Jacob et al., 2006; Karolak et al., 2015; Karuppaiah et al., 2016; Lazarus et al., 2007; Ornitz and Marie, 2002; Peters et al., 1993; Yu et al., 2003). FGFR3 is a key regulator of chondrogenesis. In early embryonic stages of skeletal development during establishment of the growth plate, FGFR3 promotes chondrocyte proliferation and is most likely activated by FGF9 and FGF18 signals that arise from adjacent mesenchyme in the

perichondrium (Havens et al., 2008; Hung et al., 2007; Iwata et al. 2000, 2001; Liu et al. 2002, 2007; Ohbayashi et al., 2002). However, in the mature growth plate (after formation of the secondary ossification center), FGFR3 signaling potently inhibits chondrogenesis, primarily acting on PCs and their differentiation into PHCs and HCs (Colvin et al., 1996; Deng et al., 1996). The mechanisms that regulate this change in the response of chondrocytes to FGFR3 during development are not known. Recent data indicate that FGF signaling regulates autophagy during bone growth (Cinque et al., 2015). Postnatal induction of chondrocyte autophagy is mediated by FGF18 through FGFR4 and is suppressed in growth plates from *Fgf18−/−* embryos, indicating that FGF signaling acts as a crucial regulator of autophagy in chondrocytes.

Regulation of fibroblast growth factor receptor 3 expression

Several signaling pathways regulate growth plate chondrocytes, in part through the regulation of FGFR3 expression. Thyroid hormone inhibits chondrocyte proliferation and promotes chondrocyte hypertrophy, similar to signaling through FGFR3. In cultured chondrocytes, thyroid hormone increased *Fgfr3* expression, and mice lacking thyroid hormone receptor have low levels of *Fgfr3* in growth plate chondrocytes (Barnard et al., 2005). Signaling through the PTH receptor PTH1R directly suppressed *Fgfr3* expression through a cAMP- and PKA-dependent regulatory element in the *Fgfr3* promoter (McEwen et al., 1999). Treatment of mice with PTH suppressed *Fgfr3* expression and partially rescued dwarfism phenotypes in a mouse model for thanatophoric dysplasia, where *Fgfr3* has an activating mutation, and in other mouse models in which *Fgfr3* is overexpressed (Karuppaiah et al., 2016; Xie et al., 2012). Interestingly, in bladder cancer cells, *Fgfr3* expression was induced by hypoxia in an HIF-1α−dependent manner (Blick et al., 2013). Because growth plate chondrocytes are avascular and functionally hypoxic, it will be interesting to determine whether *Fgfr3* expression in chondrocytes is also regulated by hypoxia.

Fibroblast growth factor receptor 3 signaling in growth plate chondrocytes

In the mature growth plate, FGFR3 suppresses chondrocyte proliferation and differentiation through the activation of several downstream signaling pathways (Fig. 45.2). These include activation of STAT1, ERK1/2, and p38, decreased AKT phosphorylation, increased protein phosphatase 2a (PP2a), dephosphorylation (activation) of p107 and p130, and increased expression of the cell cycle inhibitor $p21^{Waf1/Cip1}$ (Aikawa et al., 2001; Chapman et al., 2017; Cobrinik et al., 1996; Dailey

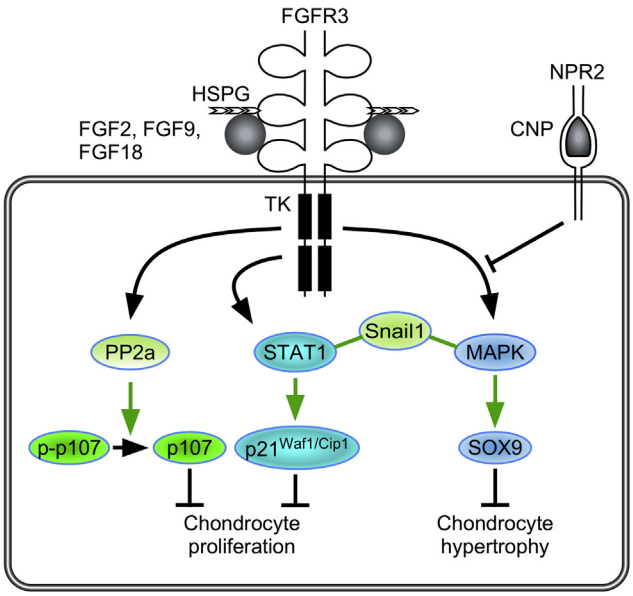

FIGURE 45.2 FGF/FGFR signaling in growth plate chondrocytes. FGF9 and FGF18 bind to heparan sulfate proteoglycans (HSPGs) and FGFR3 to activate the FGFR3 tyrosine kinase (TK) domain. This leads to activation of downstream signals, PP2a and STAT1, activating p107 and $p21^{Waf1/Cip1}$, respectively, which function to suppress chondrocyte proliferation. Activation of the MAPKs, ERK1 and ERK2, regulate Sox9 expression, which functions to suppress chondrocyte terminal differentiation and endochondral ossification. C-natriuretic peptide (CNP) signals through natriuretic peptide receptor 2 (NPR2) and inhibits the MAPK signaling pathway downstream of FGFR3, resulting in increased chondrocyte hypertrophy and increased longitudinal bone growth.

et al., 2003; de Frutos et al., 2007; Kolupaeva et al. 2008, 2013; Kurimchak et al., 2013; Laplantine et al., 2002; Legeai-Mallet et al., 2004; Priore et al., 2006; Raucci et al., 2004; Su et al., 1997). In a recent phosphoproteomic analysis of FGF signaling in chondrocytes, FGF activation of GSK3β (and degradation of β-catenin) was necessary for the inhibition of chondrocyte proliferation, identifying a potential role for Wnt/β-catenin signaling in regulating chondrogenesis (Chapman et al., 2017).

Regulation of chondrogenesis by FGFR3 may involve *Snail1,* a transcriptional repressor that is expressed in PHCs and induced in thanatophoric dysplasia bone tissue and mouse models that activate FGFR3 (see later) (de Frutos et al., 2007; Karuppaiah et al., 2016; Seki et al., 2003). At late embryonic stages, ectopic activation of SNAIL1 resulted in an achondroplasia-like phenotype in mice, with decreased chondrocyte proliferation and decreased longitudinal bone growth (de Frutos et al., 2007). This phenotype required activation of STAT1 (which increases $p21^{Waf1/Cip1}$ expression) and MAPK downstream of FGFR3 (de Frutos et al., 2007). Interestingly, conditional inactivation of both *Snail1* and *Snail2* in limb bud mesenchyme also resulted in increased $p21^{Waf1/Cip1}$ and decreased chondrocyte proliferation in embryonic bone (Chen and Gridley, 2013). Mechanistically, SNAIL1 may regulate the nuclear localization of p-ERK, and ERK2 activation directly phosphorylates SNAIL1, leading to nuclear accumulation and increased protein stability (Smith et al., 2014; Zhang et al., 2013). In cancer cells, GSK3β binds and phosphorylates Snail, leading to its degradation (Zhou et al., 2004). Future studies will be required to determine the relationship between FGFR3, GSK3β, and Snail in chondrocytes.

Requirements for STAT1 regulation of chondrocyte proliferation comes from in vivo experiments in which inactivation of *Stat1* partially rescues chondrocyte proliferation in mice with activating mutations in FGFR3 (Murakami et al., 2004). However, inactivation of *Stat1* did not rescue the defect in chondrocyte hypertrophy in these mice, which is under the control of MAPK signaling (Murakami et al., 2004). Mechanistically, activated FGFR3 signaling and increased p-ERK may stabilize SOX9 in PHCs and suppress hypertrophic differentiation (Murakami et al., 2000; Shung et al., 2012; Zhou et al., 2015).

Further support for a role for STAT1 suppression of chondrocyte proliferation, and MAPK regulation of chondrocyte differentiation, comes from interactions between FGFR3 and the c-natriuretic peptide (CNP) signaling pathways. The CNP signaling pathway increases bone growth through increased extracellular matrix production as well as hypertrophic differentiation in chondrocytes through the inhibition of MAPK signaling (Yasoda et al., 2004) (Fig. 45.2). The CNP signaling pathway did not affect STAT1 activity or chondrocyte proliferation (Yasoda et al., 2004). CNP analogues are currently in clinical trials for achondroplasia (Legeai-Mallet, 2016; Lorget et al., 2012; Ornitz and Legeai-Mallet, 2017).

FGFR3 also regulates chondrogenesis through interactions with BMP, Wnt, IHH, and PTHLH/PTH1R signaling pathways. In chondrocyte cultures, FGF signaling activates Wnt/β-catenin signaling through phosphorylation of LRP6 and suppression of hypertrophic differentiation (Buchtova et al., 2015; Krejci et al., 2012). FGFR3 signaling suppresses the expression of *Bmp4, BMPR1a, Ihh*, and *Pth1r* in the postnatal growth plate (Chen et al., 2001; Naski et al., 1998; Qi et al., 2014). Additionally, in a chondrocyte cell line, overexpression of FGFR3 suppresses the expression of both *Pthlh* and its receptor, *Pth1r* (Li et al., 2010).

Fibroblast growth factor receptor 1 signaling in hypertrophic chondrocytes

Fgfr1 is expressed in PHCs, HCs, and surrounding perichondrial and periosteal tissue. Although FGFR1 signaling appears to have only small effects on chondrogenesis, it has been difficult to distinguish direct effects on HCs from indirect effects resulting from gene inactivation in surrounding tissue. Inactivation of *Fgfr1* in limb bud mesenchyme using *Dermo1(Twist2)-Cre* impairs chondrocyte hypertrophy (Hung et al., 2007). In contrast, inactivation of *Fgfr1* at later stages of development with *Col2a1-Cre* or *Osx-Cre* results in an expanded HC zone (Jacob et al., 2006; Karuppaiah et al., 2016). Both *Dermo1-Cre* and *Col2a1-Cre* efficiently target chondrocytes, but they also target the osteoblast lineage (Ford-Hutchinson et al., 2007; Jacob et al., 2006; Ono et al., 2014; Wang et al., 2011; Yu et al., 2003). In contrast, Osx-Cre is more specific for osteoblasts (Karuppaiah et al., 2016). These studies suggest that FGFR1 signaling in osteoblast development could indirectly affect chondrogenesis (Jacob et al., 2006; Karolak et al., 2015; Karuppaiah et al., 2016). A definitive assessment of FGFR1 function in HCs will require more precise gene targeting.

Fibroblast growth factor receptors and chondrodysplasia syndromes

Genetic mapping studies identified a missense mutation in *Fgfr3* that accounts for almost all cases of achondroplasia, the most common form of dwarfism in humans (Shiang et al., 1994; Shiang et al., 1994). Subsequent to this initial discovery, additional mutations have been identified in FGFRs 1, 2, and 3 that cause skeletal dwarfism, craniosynostosis, and skeletal overgrowth. The clinical and genetic features of these diseases have been extensively reviewed (Vajo et al., 2000; Ornitz

and Marie, 2002; Chen and Deng, 2005; Ornitz, 2005; Melville et al., 2010; Johnson and Wilkie, 2011; Foldynova-Trantirkova et al., 2012; Krejci, 2014; Xie et al., 2014; Yeung Tsang et al., 2014; Narayana and Horton, 2015; Ornitz and Itoh, 2015; Ornitz and Legeai-Mallet, 2017; Pauli, 2019; Rosello-Diez and Joyner, 2015).

Mutations in fibroblast growth factor receptor 3 and fibroblast growth factor 9

The *FGFR3* G380R autosomal dominant missense mutation accounts for over 97% of cases of achondroplasia (Rousseau et al., 1994; Shiang et al., 1994; Vajo et al., 2000; Wilkin et al., 1998). Related autosomal dominant chondrodysplasia syndromes include thanatophoric dysplasia types I and II, which are caused by mutations in K650E or R248C mutations in *FGFR,* and hypochondroplasia, which is caused by an N540K or K650N mutation in *FGFR3* (Bellus et al. 1995, 2000; Bonaventure et al., 1996; Tavormina et al., 1995). SADDAN syndrome (severe achondroplasia with developmental delay and acanthosis nigricans) (Bellus et al., 1999; Tavormina et al., 1999) and platyspondylic lethal skeletal dysplasia, San Diego type (Brodie et al., 1999), are both caused by a K650M mutation in *FGFR3*. These mutations in FGFR3 cause disproportional (rhizomelic) short stature.

Mutations in FGFR3 associated with dwarfism activate the receptor in proportion to disease severity (Krejci et al., 2008; Naski et al., 1996). Hypochondroplasia is associated with a weak gain-of-function mutation, whereas achondroplasia and thanatophoric dysplasia result from progressively stronger activating mutations. Activation of FGFR3 in growth plate chondrocytes results in decreased chondrocyte proliferation, impaired hypertrophic differentiation, and increased apoptosis (Legeai-Mallet et al. 1998, 2004; Naski et al., 1998; Wang et al. 1999, 2001; Krejci et al., 2008; Pannier et al., 2009; Xie et al., 2014; Yeung Tsang et al., 2014; Narayana and Horton, 2015; Rosello-Diez and Joyner, 2015; Ornitz and Legeai-Mallet, 2017). A dominant mutation (M528I) in *FGFR3* had been identified that causes proportionate short stature (Kant et al., 2015). Functional studies suggest that this mutation also activates FGFR3 signaling; however, the mechanisms that determine proportionate versus rhizomelic limb shortening are not known.

Mutations in *FGF9* have also been identified in mice and humans and are generally associated with defects in joint development. Elbow knee synostosis in mice is caused by an N143T mutation in *Fgf9,* and multiple synostosis syndrome is cause by *S99N, S99D*, or *R62G* mutations in *FGF9* in humans (Harada et al., 2009; Wu et al., 2009; Rodriguez-Zabala et al., 2017; Tang et al., 2017). Mechanistically, *Fgf9* N143T and R62G mutations reduce homodimerization and the affinity of FGF9 for heparin and FGFR3, and increase FGF9 diffusion through developing joint tissue (Harada et al., 2009; Rodriguez-Zabala et al., 2017). In contrast, the *S99N* mutation increases the affinity of FGF9 for heparin and decreases its affinity for FGFR3c (Tang et al., 2017).

Skeletal overgrowth and CATSHL syndrome

Inactivation of FGFR3 in mice results in skeletal overgrowth (Colvin et al., 1996; Deng et al., 1996; Eswarakumar and Schlessinger, 2007). In mice lacking *Fgfr3*, bones of the appendicular and axial skeleton were disproportionally long, resulting in an abnormal gait and scoliosis. *Mi*ce lacking *Fgfr3* also have defects in inner ear development that result in deafness (Colvin et al., 1996). These phenotypes suggested that loss-of-function mutations in *FGFR3* in humans could also result in skeletal overgrowth and hearing loss and lead to the identification of humans with dominantly inherited camptodactyly, tall stature, and hearing loss (CATSHL) with missense mutations (R621H, T546K) in *FGFR3* (Toydemir et al., 2006; Makrythanasis et al., 2014; Escobar et al., 2016). A recessive mutation in FGFR3 (V700E) in sheep results in spider lamb syndrome, with phenotypes similar to those of CATSHL patients (Beever et al., 2006; Smith et al., 2006).

Fibroblast growth factor and FGF receptor signaling in bone formation and repair

Fibroblast growth factor and FGF receptor signaling in osteoblasts

The signaling mechanisms induced by FGF/FGFR in osteogenic cells are complex (Marie, 2003, 2012). After FGFR activation by FGF ligands, several signaling pathways are activated depending on the stage of osteogenic cell differentiation (Dailey et al., 2005; Marie et al., 2005), resulting in a fine modulation of osteogenic cell proliferation and differentiation (Fig. 45.3). At an early stage, activation of FGFR1/FGFR2 by FGF2 in osteoblast precursors leads to increased ERK1/2 MAPK, causing increased cell proliferation (Xiao et al., 2002; Kim et al., 2003; Shimoaka et al., 2002; Choi et al., 2008; Miraoui et al., 2009). FGF2 or FGR2 activation may also activate PKC signaling in osteogenic cells, which is involved in growth response (Hurley et al., 1996), increased fibronectin expression (Hurley et al., 1996; Tang et al., 2007), and differentiation marker expression in osteoblasts (Debiais et al., 2001, Lemonnier et al., 2001a)(. At later stages,

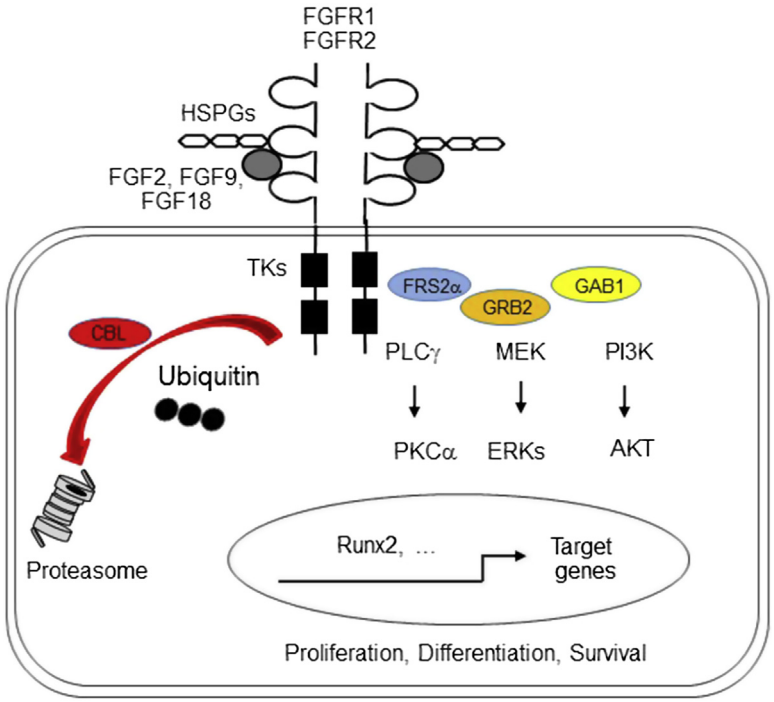

FIGURE 45.3 FGF/FGFR signaling in osteogenic cells. FGF2, FGF9, and FGF18 bind to heparan sulfate proteoglycans (HSPGs) and FGFR1 or FGFR2 to activate tyrosine kinases (TKs). This leads to the recruitment of substrates and activation of various kinases, such as PLCγ, PKCα, ERK MAPKs, and PI3K/AKT, which results in the expression of transcription factors controlling cell proliferation, differentiation, or survival. FGFR activation also leads to c-CBL recruitment, resulting in FGFR ubiquitination and downregulation by proteasome degradation.

ERK1/2 activation by FGF2 induces RUNX2 acetylation and stabilization (Xiao et al., 2002; Park et al., 2010; Yoon et al., 2014). FGFR1/FGFR2 activation by FGF18 also leads to ERK1/2-mediated increased *Runx2* expression in osteoblast precursor cells, resulting in osteoblast differentiation (Hamidouche et al., 2010). *Runx*2 expression is also increased by PKC activation induced by FGF/FGFR (Kim et al., 2003; Niger et al., 2013). In cells of the perichondrium, a positive loop involves RUNX2-mediated increased expression of *Fgfr2*, *Fgf18*, and proteoglycans, which in turn control FGF signaling (Hinoi et al., 2006; Reinhold and Naski, 2007; Teplyuk et al., 2009). At a later stage of differentiation, FGF2-mediated ERK1/2 activation in an osteocyte cell line increases the expression of *Dmp1*, a marker of osteocytes, indicating that FGF/ERK/1/2 signaling also regulates osteocyte differentiation (Kyono et al., 2012).

Several positive interactions between FGF signaling and other pathways have been described. FGF1 and FGF2 increase the production of TGF-β in vitro and in vivo (Noda and Vogel, 1989), and TGF-β and FGF1 or FGF2 interact to modulate their mitogenic effects (Globus et al., 1989). In human calvaria osteoblasts, FGF2 decreases TGF-β2 production in immature cells but increases TGF-β2 synthesis by more differentiated cells (Debiais et al., 1998). In addition, FGF2 increases vascular endothelial cell growth factor (VEGF) (Saadeh et al., 2000) and hepatocyte growth factor expression in cultured osteoblasts (Takai et al., 2007; Blanquaert et al., 1999). FGF18 also promotes VEGF expression and subsequent neovascularization (Liu et al., 2007) that may mediate part of the effects of FGF on osteogenesis. On the other hand, FGF2 enhances canonical BMP2 signaling in osteoblastic cells by promoting phospho-SMAD1/5/8 and RUNX2 transactivation (Agas et al., 2013). Functionally, FGF2 isoforms directly modulate BMP2 function (Sabbieti et al., 2013), whereas FGF2, FGF9, and FGF18 positively control BMP function through inhibition of the BMP antagonist noggin (Warren et al., 2003; Reinhold et al., 2004; Fakhry et al., 2005). In vivo, FGF2 stimulates *Bmp2* expression in osteoblasts during cranial bone ossification (Choi et al., 2005; Fakhry et al., 2005), and BMP2 expression is reduced in bones of *Fgf2*-null mice (Naganawa et al., 2008), further indicating that FGF and BMP signaling cooperates to modulate osteogenesis (Nakamura et al., 2005; Kuhn et al., 2013).

FGF signaling interacts negatively or positively with Wnt/β-catenin signaling, depending on the stage of cell differentiation (Dailey et al., 2005; Miraoui and Marie, 2010). In early osteoprogenitors, FGF2 antagonizes WNT/β-catenin signaling (Mansukhani et al., 2005; Ambrosetti et al., 2008). However, *Fgf2−/−* mice show decreased Wnt genes expression in osteoblasts, and FGF2 promoted canonical Wnt/β-catenin signaling and rescued osteoblast differentiation in

Fgf2−/− mice, indicating that FGF signaling positively cooperates with Wnt/β-catenin signaling to promote osteoblast differentiation in vivo (Fei et al., 2011). Conversely, FGF18 is positively regulated by canonical Wnt signaling in osteogenic cells (Kapadia et al., 2005; Reinhold and Naski, 2007). PTH also cooperates with FGF signaling by increasing *Fgf2*, *Fgfr1*, and *Fgfr2* expression in osteoblastic cells (Hurley et al., 1999). In vitro, FGF2 is required for the positive PTH effects on osteoblast proliferation and differentiation. In vivo, the anabolic effect of intermittent PTH is impaired in *Fgf2*-null and heterozygous mice (Hurley et al., 1999), indicating that FGF signaling is part of the anabolic PTH effect on osteogenesis (Sabbieti et al., 2009).

After activation, FGFR signaling is downregulated by several negative feedback mechanisms. Spry2 acts as a negative regulator of FGFR signaling. Consistently, a dominant-negative mutant of Spry2 (Y55A-Spry2) promotes FGF2-induced ERK activation in murine osteoblastic cells, resulting in increased *Runx2* expression and osteoblastogenesis (Sanui et al., 2015). In addition, activated FGFR interacts with the ubiquitin ligase c-CBL, leading to FGFR ubiquitination and its subsequent degradation by the proteasome (Lemmon and Schlessinger, 2010; Sévère et al., 2013). In osteoblasts, FGFR2 ubiquitination by c-CBL leads to FGFR2 downregulation and results in decreased osteogenic differentiation (Kaabeche, 2004). Consistently, inhibition of c-CBL interaction with FGFR2 promotes osteoblast differentiation and survival through increased ERK1/2 and PI3K signaling (Sévère et al., 2011). FGFR2 activation also leads to increased c-CBL interaction with PI3K in osteoblasts, leading to PI3K ubiquitination and degradation and decreased osteoblast survival (Dufour et al., 2008). Overall, these data illustrate the complexity of the regulation of FGF/FGFR signaling in positively or negatively controlling osteogenic cells (Fig. 45.3).

Fibroblast growth factor regulation of bone formation

The regulation of bone formation by FGF/FGFR signaling depends on the stage of osteoblast lineage differentiation, FGF/FGFR expression, and low-affinity coreceptors in the bone microenvironment. In osteoprogenitor cells, FGFR1/2 inhibit cell senescence and thereby maintain mesenchymal cell stemness (Coutu et al., 2011; Di Maggio et al., 2012). In immature osteoblasts, FGF2 signaling increases cell proliferation (Debiais et al., 1998; Shimoaka et al., 2002; Ignelzi et al., 2003; Fakhry et al., 2005), although the mitogenic effect of FGF2 on rat calvaria cells decreases with age (Tanaka et al., 1999). FGF18 also stimulates the proliferation of cultured osteoblasts through activation of ERK signaling (Shimoaka et al., 2002). These effects lead to expand the pool of osteoblast precursor cells (Fakhry et al., 2005), and consistently blocking FGF2 biological activity reduces osteogenesis in vivo (Moore et al., 2002). In cultured osteoblastic cells, FGF2 inhibits collagen synthesis transcriptionally (Hurley et al., 1994) but stimulates fibronectin expression through PLCγ, PKCα, c-Src, NF-κB, and p300 pathways (Tang et al., 2007), as well as affecting osteocalcin transcription in mouse calvaria cells (Boudreaux et al., 1996; Newberry et al., 1996). The effect of FGF/FGFR signaling on osteoblast apoptosis also depends on the stage of cell maturation. In osteoblast precursor cells, FGF2 reduces apoptosis through activated PI3K/AKT signaling (Debiais et al., 1998), and FGFR1 increases the Bcl2/Bax ratio (Agas et al., 2008), which contributes to enhance the pool of osteoprogenitors. In more mature osteoblasts, FGF treatment or overexpression of FGF2 in transgenic mice induces osteoblast apoptosis (Mansukhani et al., 2000; Ignelzi et al., 2003), which contributes to reduce the pool of more mature cells. The control of osteogenesis by FGF/FGFR signaling also depends on the type and level of FGFs expressed. Mice lacking *Fgf2* show decreased bone formation due to altered osteoblast differentiation (Montero et al., 2000; Xiao et al., 2010b). *Fgf18*-deficient mice display reduced osteogenic mesenchymal cell proliferation, decreased osteoblast differentiation, and delayed ossification (Liu et al., 2002; Ohbayashi et al., 2002). Consistently, FGF18 is an autocrine-positive regulator of osteogenic differentiation (Jeon et al., 2012) through FGFR1/FGFR2-mediated activation of ERK1/2 and PI3K signaling (Hamidouche et al., 2010).

In addition to FGFs, FGFR expression controls osteoblastogenesis in a complex manner. Elevated *Fgfr1/Fgfr2* expression is associated with a high FGF2-mediated proliferative response (Cowan et al., 2003; Haupt et al., 2009). In contrast, decreased expression of *Fgfr1* and increased expression of *Fgfrs 2, 3,* and *4* in more mature osteoblasts is associated with reduced FGF2 responsiveness (Haupt et al., 2009). Inactivation of *Fgfr1* in differentiated osteoblasts accelerates differentiation, possibly through increased expression of FGFR3 (Jacob et al., 2006). In older mice inactivation of Fgfr1 results in increased bone formation and osteocyte death (McKenzie et al., 2019). In mice conditionally lacking *Fgfr2* or harboring a mutation in *Fgfr2c*, *Runx2* expression and bone mineral density are decreased due to defective proliferation of osteoprogenitor cells and function of mature osteoblasts, suggesting that *Fgfr2* positively regulates osteoblast maturation (Eswarakumar et al., 2002; Yu et al., 2003). Consistently, constitutive *Fgfr2* activation enhances ERK1/2 and PKCα signaling and *Runx2* expression, resulting in increased osteoblast differentiation (Miraoui et al. 2009, 2010b). FGFR3 may also play a role in postnatal bone formation, since young adult *Fgfr3*-null mice show decreased osteoblast maturation and trabecular bone mineralization (Valverde-Franco et al., 2004).

The effects of FGF/FGFR on osteogenesis are also tightly controlled by the local expression of HSPGs (Eswarakumar et al., 2005; Ornitz and Itoh, 2015). This includes both cell surface and secreted HSPGs, such as syndecans, which serve as coreceptors for FGFs and can promote FGF/FGFR signaling in osteogenic cells (Jackson et al., 2007). During development, syndecan-1 is expressed in limb bud and affects bone cell differentiation (Dhodapkar et al., 1998). Syndecan-2 is expressed in the perichondrium and periosteum at the onset of osteogenesis (Molténi et al., 1999a), whereas syndecan-3 is expressed in mesenchymal cells during limb bud formation (Gould et al., 1992). Syndecan-4 is expressed in calvaria osteoblasts (Molténi et al., 1999a) and is upregulated by FGF2 (Song et al., 2007). Rat calvaria osteoblasts coexpress syndecans 1, 2, and 4 with FGFR1 and FGFR2, indicating that syndecans locally interact at the cell surface with FGFRs to control FGF actions during osteogenesis (Molténi et al., 1999a, 1999b; Jackson et al., 2007). Notably, syndecan-2, whose expression increases during osteoblast differentiation, enhances the osteoblast response to FGF2 during in vitro osteogenesis (Molténi et al., 1999a; Mansouri et al., 2015). The expression of both FGFRs and syndecans is positively controlled by *Runx2* in osteoblasts, suggesting a positive mechanism controlling osteoblastogenesis (Fromigué et al., 2004; Teplyuk et al., 2009). Another HSPG, glypican-3, is essential for *Runx2* expression and osteoblast differentiation in vitro (Haupt et al., 2009).

Fibroblast growth factor and FGF receptor signaling in bone repair

FGF/FGFR signaling plays important roles during fracture repair (Marie, 2000; Du et al., 2012; Fei et al., 2013; Charoenlaro et al., 2017). During fracture repair in mice, *Fgfs 2, 5, 6,* and *9*, as well as *Fgfrs,* are upregulated distinctly depending on the stage of healing (Schmid and Ornitz, 2009). There is evidence that the exogenous application of FGFs can accelerate bone healing (Charoenlarp et al., 2017). In various models of bone defects, the local delivery of FGF2 or LMWFGF2 can promote bone healing (Kodama et al., 2009; Kawaguchi et al., 2010; Kwan et al., 2011; Hurley et al., 2016), although the effects depend on the dose and duration of treatment (Du et al., 2012; Fei et al., 2013; Charoenlarp et al., 2017). The positive effect on bone healing by FGF2 results in part from expansion of the osteoblast precursor cell pool which subsequently differentiates into osteoblasts (Nakamura et al., 1998; Nakajima et al., 2007). In addition, FGF2 and FGF9 can promote bone repair through activation of angiogenesis via increased *Vegf* expression by osteoblasts (Takai et al., 2007; Behr et al., 2010). Mice overexpressing the LMW isoform of FGF2 in mature osteoblasts show accelerated fracture healing associated with increased expression of factors involved in osteoblast differentiation and vascular invasion (Hurley et al., 2016). A functional link between FGF9 and VEGF is provided by the finding that $Fgf9^{-/+}$ mice show delayed cortical bone repair, reduced *Vegf* expression, and impaired neovascularization associated with decreased osteoblast proliferation and differentiation, a phenotype which can be rescued by exogenous FGF9 (Behr et al., 2010). VEGF by itself can promote bone healing by enhancing mesenchymal stem cell differentiation into osteoblasts (Liu and Olsen, 2014), and consistently, both angiogenesis and osteogenesis are promoted by VEGF alone (Behr et al., 2012). Although $Fgf18^{-/+}$ mice show reduced cortical bone healing, this is due only to decreased osteoblast differentiation, indicating that FGF18 is not required for angiogenesis during bone repair (Behr et al., 2011). When injected locally, FGF18 increased peri-implant bone formation in $Fgfr3^{+/+}$ and $Fgfr3^{-/-}$ mice, indicating that FGF18 promotes bone repair through activation of FGFR1 and/or FGFR2 (Carli et al., 2012). The cross talk between osteoblasts and endothelial cells during bone fracture repair is in part mediated by DJ-1, which stimulates human mesenchymal cell differentiation to osteoblasts and induces angiogenesis through FGFR1 activation, resulting in enhanced bone regeneration (Kim et al., 2012). Overall, current data indicate that FGF/FGFR signaling plays an important role in bone repair through activation of angiogenesis and osteogenesis, which may have therapeutic implications for promoting bone regeneration.

Fibroblast growth factor and FGF receptor signaling in bone resorption

Several studies have demonstrated a role for FGFR/FGF ligand signaling in the regulation of osteoclast production and bone resorption. Of the four FGF tyrosine kinase receptors, only *Fgfr1* was produced by osteoclasts (Chikazu et al., 2000). FGFR1 was shown to regulate the differentiation and activation of osteoclasts via the ERK1/2 pathway. In addition, conditional deletion of *Fgfr1* in osteoclasts leads to reduced osteoclast formation and activity (Lu et al., 2009). Further analysis showed that osteoclasts with *Fgfr1* deficiency exhibited downregulated expression of genes related to osteoclastic activity including tartrate-resistant acid phosphatase (TRAP) and matrix metalloproteinase-9. The phosphorylation of ERK1/2 MAP kinase was also decreased. These results suggest that FGFR1 is indispensable for complete differentiation and activation of osteoclasts in mice (Lu et al., 2009).

Among FGF ligands, FGF2 has previously been shown to induce osteoclast formation in murine bone marrow cultures (Hurley et al., 1998) and to stimulate resorption of mature osteoclasts through activation of ERK1/2 MAP kinase

(Chikazu et al., 2000). The importance of endogenous FGF2 in osteoclast formation and bone resorption is demonstrated by reduced osteoclast formation in *Fgf2* KO mice and impaired osteoclast formation in response to PTH, interleukin 11, and receptor activator of NF−B ligand (RANKL) (Okada et al., 2003). Modulation of suppressors of cytokine signaling (SOCS) may also be important in FGF2 regulation of RANKL. Interestingly, *Fgf2* expression was shown to be increased in Paget's disease of bone and human Pagetic mononuclear cells, and FGF2 modulated SOCS signaling to induce RANKL expression in PDB. Furthermore, siRNA inhibition of *Stat-1* suppresses FGF2-increased *Socs-1/3* expression in Pagetic osteoclasts (Sundaram et al., 2009).

FGF6 has also been shown to enhance osteoclast formation and promote absorption (Bosetti et al., 2010). To study FGF6 activity on osteoclast differentiation, human bone marrow cells were used, and TRAP-positive multinucleated cells together with actin filaments arrangements were quantified. Human primary mature osteoclasts were used to evaluate the effect of FGF6 on osteoclast reabsorbing activity by reabsorbed pit measurements. FGF6 increased the formation of TRAP-positive multinucleated cells in a dose-dependent manner, and a greater percentage of TRAP-positive cells formed typical osteoclast sealing zones. Mature osteoclasts cultured on dentine slice increased the area of reabsorption with a dose-dependent maximal effect of FGF6.

A role for FGF8 in osteoclastogenesis has also been reported. Studies by Lin et al. (2009) examined the isoforms of FGF8 on osteoclast formation. FGF8a, unlike FGF8b, inhibited osteoclastogenesis in mouse bone marrow cultures in an RANKL/osteoprotegerin (OPG)-independent manner. However, FGF8a did not affect osteoclastogenesis in RAW 264.7 cells (a macrophage cell line devoid of stromal cells) exogenously stimulated by RANKL, nor did it affect mature osteoclast function as assessed in rat calvarial organ cultures and isolated mature osteoclasts.

FGF11, also known as FGF homologous factor 3, belongs to the family of intracellular nonsecreted FGFs that resides in the nucleus and does not bind either the classical FGFR or HSPGs and are thought to bind target proteins distinct from those of the classical FGFs (Olsen et al., 2003). Intriguingly, studies by Knowles (2017) investigated the effects of FGF11 on osteoclast function. FGF11 was induced by both hypoxia and inhibition of the HIF-regulating prolyl hydroxylase enzyme in osteoclasts. Isoform-specific siRNA demonstrated that the induction of *Fgf11* mRNA expression by hypoxia is HIF-1α−dependent. Hypoxic stimulation of bone resorption was inhibited in osteoclasts treated with siRNA targeting *Fgf11*. This was at least partially due to reduced secretion of an unidentified proresorptive factor downstream of FGF11. FGF11 expression within hypoxic, resorbing osteoclasts was colocalized with microtubule-associated alpha-tubulin. *Fgf11* was also abundantly expressed in osteoclasts within the rheumatoid synovium and in giant cell tumor of bone. There is a gap in knowledge about whether other intranuclear FGFs, specifically FGF12, FGF13, and FGF14, also modulate osteoclastogenesis.

FGF18 is important in bone development and has been shown to be necessary in recruitment and formation of osteoclasts in developing long bone (Liu et al., 2007). In addition, Shimoaka et al., (2002) studied the action of FGF18 on bone resorption. FGF18 induced osteoclast formation through RANKL and cyclooxygenase-2 and also stimulated osteoclast function to form resorbed pits on a dentine slice in the mouse coculture system.

FGF21's role in osteoclastogenesis is controversial. FGF21 was reported to stimulate osteoclastogenesis and bone resorption by activation of PPARγ and to change of the ratio of RANKL/OPG (Wei et al., 2012). Furthermore, studies by Wang et al. (2015) proposed that a liver−bone endocrine relay by IGFBP1 promotes osteoclastogenesis and mediates FGF21-induced bone resorption. Mechanistically, IGFBP1 functioned via its RGD domain to bind to its receptor integrin β1 on osteoclast precursors, thereby potentiating RANKL-stimulated ERK phosphorylation and NFATc1 activation. Consequently, osteoclastic integrin β1 deletion conferred resistance to the resorption-enhancing effects of both IGFBP1 and FGF21. In contrast to these reports, recent studies in which mice with high-fat-diet-induced obesity were administered vehicle or recombinant human FGF21 failed to demonstrate a role for FGF21 in bone turnover (Li et al., 2017). There was no evidence of bone loss or changes in bone resorption markers, histologic bone resorption indices, or *Rankl/Opg* mRNA expression. Furthermore, in contrast to the studies of Wei et al. (2012), FGF21 knockout mice did not show a high bone mass phenotype (Li et al., 2017). Further studies are warranted to clarify the role of FGF21 in bone homeostasis.

There are limited studies on the direct effect of FGF23 on osteoclast biology, and studies from mouse models of ADHR with increased FGF23 have reported decreased osteoclast number in the Hyp mouse (Hayashibara et al., 2007) and in a transgenic murine model overexpressing FGF23, and while there were no significant modifications of the osteoclast number as compared with WT mice, there was a trend toward a decreased ratio of osteoclast volume to bone volume on histomorphometric values (Holberg et al., 2008). In studies of the direct effect of FGF23 on osteoclast formation and function, Allard et al. (2015) used human monocytes differentiated by MCSF and RANKL to demonstrate a biphasic effect of FGF23 on human osteoclast metabolism, with an inhibition of osteoclast differentiation at the early stages and a moderate albeit significant stimulation of osteoclast activity. This effect of FGF23 appears to be mediated by FGFR/AKT/

ERK signaling independent of Klotho. FGF23 also upregulated the mRNA expression of osteoclastogenic factors (e.g., *Mcsf, Mcp-1, Il-6*, and *Tnf-α*), and bone-resorption regulators (*Rankl* and *Opg*) in UMR-106 cells (Teerapornpuntakit et al., 2016).

Fibroblast growth factor receptors and craniosynostosis

Skeletal phenotype

Several mutations in *FGFRs 1* to *3* cause cranial dysplasias, called craniosynostosis, in Apert, Crouzon, and other syndromes, characterized by premature fusion of one or more cranial sutures (Ornitz and Marie, 2002; Johnson and Wilkie, 2011). Mutations in *FGFR2* may also induce bent bone dysplasia, a dysmorphology of the appendicular skeleton (Merrill et al., 2012). The molecular mechanisms involved in these syndromes induced by *FGFR* mutations include ligand-independent or ligand-dependent FGFR activation, loss of function, and altered FGFR trafficking (Yu et al., 2000; Ibrahimi et al., 2001; Yu and Ornitz, 2001; Neben et al., 2014). The skeletal abnormalities induced by gain-of-function *FGFR* mutations have been extensively studied (Hajihosseini, 2008; Marie et al., 2008; Senarath-Yapa et al., 2012). The phenotype induced by FGFR mutations in mice and humans is variable due to distinct environmental factors or genetic background, although the resulting effect is premature suture fusion induced by increased osteogenesis (Marie et al., 2005; Wilkie, 2005). In Apert syndrome, *FGFR2* mutations induce abnormal mesodermal progenitor cell proliferation, differentiation, and cell fate in cranial sutures. Conditional expression of the Apert *FGFR2* (S252W) mutation in cells derived from mesoderm is sufficient to cause coronal craniosynostosis (Heuze et al., 2014). However, the cellular abnormalities caused by this mutation are variable, depending on the affected suture and the stage of cell differentiation (Wang et al., 2005; Holmes et al., 2009; Heuze et al., 2014; Motch Perrine et al., 2014). In mice, osteoprogenitor cell proliferation is unchanged (Chen et al., 2003) or is transiently and slightly increased by activating Apert and Crouzon *FGFR2* mutations in cranial sutures at an early stage of development (Mansukhani et al., 2000, 2005), whereas at a later stage, osteoblast maturation is increased (Eswarakumar et al., 2004; Yang et al., 2008; Yin et al., 2008; Holmes et al., 2009; Yeh et al., 2012; Liu et al., 2013a, 2013b; Morita et al., 2014). In mice, gain-of-function mutations in *FGFR1*, *FGFR2,* or *FGFR2c* cause increased expression of *Runx2* (Zhou et al., 2000; Baroni et al., 2005; Eswarakumar et al., 2004). In humans, Apert and Crouzon *FGFR2* mutations promote *Runx2* expression and osteoblast maturation and function in postnatal suture development (Lomri et al., 1998; Lemonnier et al., 2001b; Tanimoto et al., 2004; Baroni et al., 2005; Guénou et al., 2005). In mice, disruption of *FGFR2IIIc*, the mesenchymal splice variant of *FGFR2*, decreases *Runx2* transcription and thereby retards ossification (Eswarakumar et al., 2002). *FGFR2*-activating mutations also increase *Sox2* expression in murine osteoblasts and reduce Wnt target genes (Mansukhani et al., 2005), although the role of these genes in craniosynostosis remains unclear. In bent bone dysplasia syndrome, *FGFR2* mutations (M391R or Y381D) reduce ligand-dependent receptor activation, which leads to increased nucleolar activity of the mutant FGFR2, resulting in increased proliferation and decreased differentiation of osteoprogenitor cells (Merrill et al., 2012; Neben et al. 2014, 2017). In humans and mice, *FGFR2* mutations are associated with increased osteoblast apoptosis in fused sutures (Lemonnier et al., 2001a; Lomri et al., 2001; Kaabeche et al., 2005; Mansukhani et al., 2005; Chen et al., 2014), which may in part be mediated by increased IL-1 expression (Lomri et al., 2001) and may occur as a consequence of the premature osteoblast maturation (Holmes et al., 2009) (Fig. 45.3). Activating *FGFR3* mutations was also found to cause partial premature fusion of the coronal sutures in mice (Twigg et al., 2009; Di Rocco et al., 2014). In the growth plate, chondrocyte-specific activation of *Fgfr3* was reported to induce premature suture closure indirectly through activation of MAPK and BMP signaling, leading to increased osteoblast differentiation (Matsushita et al., 2009b). In long bones, activating *FGFR3* mutations in chondrocytes led to increased osteoclast recruitment and decreased trabecular bone mass (Su et al., 2010; Mugniery et al., 2012). In contrast, conditional knockout of *Fgfr3* in chondrocytes indirectly leads to increased bone mass due to reduced osteoclast number and increased osteoblast number and bone formation by upregulating the expression of *Ihh*, *Bmp2*, *Bmp4*, *Bmp7*, *Wnt4*, and *Tgf-β1* (Wen et al., 2016).

Fibroblast growth factor receptor signaling in craniosynostosis

The premature suture fusion induced by *FGFR* mutations occurs subsequently to the activation of several signaling pathways (Miraoui and Marie, 2010; Su et al., 2014; Marie, 2015). In mice, gain-of-function *FGFR2* mutations activate ERK1/2 and p38 MAPKs, AKT and PLCγ, in osteogenic cells (Chen et al., 2003; Kim et al., 2003; Shukla et al., 2007; Yin et al., 2008; Wang et al., 2010; Suzuki et al., 2012; Pfaff et al., 2016). Reduced expression of ERF, an inhibitory ETS transcription factor directly bound by ERK1/2, causes craniosynostosis in humans and mice, indicating a role of ERF and

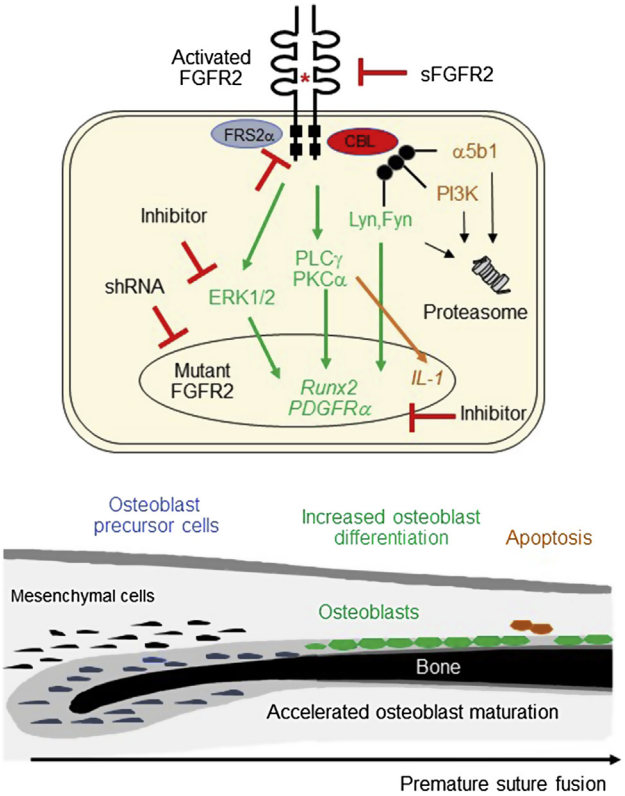

FIGURE 45.4 FGFR signaling in craniosynostosis. Gain-of-function *FGFR2* mutations induce constitutive activation of FGFR2, resulting in activation of PKCα, downregulation of the SRC proteins LYN and FYN, and increased PDGFRα expression, all leading to increased *Runx2* expression and premature osteoblast maturation and suture fusion. FGFR2 activation also leads to increased *IL-1* expression and α5β1 integrin proteasome degradation, resulting in increased apoptosis of more mature osteoblasts. Potential therapeutic strategies to attenuate the aberrant FGFR2 signaling in craniosynostosis include uncoupling of FRS2α with the mutant FGFR2c (1), targeting the mutant FGFR2 with a small hairpin RNA (2), inhibition of ERK1/2 MAPK (3) or PDGFRα (4), or the use of a soluble mutant form of FGFR2 (4).

ERK signaling in cranial suture ossification (Twigg et al., 2013). In human cranial osteoblasts, Apert *FGFR2* (S252W) mutation induces PLCɣ and PKCα activation (Lemonnier et al., 2001b), resulting in increased *Runx2* expression. This effect leads to increased osteoblast gene expression and premature fusion of cranial sutures in both mice and humans (Zhou et al., 2000; Eswarakumar et al., 2002; Tanimoto et al., 2004; Baroni et al., 2005; Guénou et al., 2005). In human cranial sutures, Apert *FGFR2* (S252W) mutation increases the expression of platelet-derived growth factor receptor α (*PDGFRα*) and epidermal growth factor receptor via activation of PKCα-mediated AP-1 transcription, which contributes to the premature suture ossification (Miraoui et al., 2010a). Consistently, conditional expression of activated *PDGFRα* in neural crest cells causes premature cranial fusion at early postnatal stages in mice (Moenning et al., 2009). Downregulation of regulatory molecules induced by activated *FGFR2* mutations may also contribute to craniosynostosis. In both mice and humans, the Apert *FGFR2* (S252W) mutation induces c-CBL–mediated ubiquitination and degradation of FGFR2 (Kaabeche et al., 2004; Holmes et al., 2009). In addition, activated FGFR2 leads to c-CBL–mediated ubiquitination of the SRC family members LYN and FYN (Kaabeche et al., 2004), α5β1 integrin (Kaabeche et al., 2005), and PI3K (Dufour et al., 2008), and the attenuation of these signals contributes to enhance osteoblast differentiation and apoptosis in human mutant osteoblasts. Increased binding of activated FGFR2 to the adaptor protein FRS2α also contributes to the negative feedback mechanism induced by FGFR activation in murine Crouzon-like craniosynostosis (Eswarakumar et al., 2006). These data emphasize the complexity of the aberrant signaling pathways induced by gain-of-function *FGFR* mutations in cells of the osteoblast lineage (Fig. 45.4).

Potential therapeutic approaches

Several potential therapeutic strategies targeting the aberrant cellular signaling induced by *FGFR* mutations have been proposed (Wilkie, 2007; Melville et al., 2010). In vitro, Apert and Crouzon FGFR2 signaling can be attenuated using either

specific glycosaminoglycans (McDowell et al., 2006), inhibitors of FGFR or tyrosine kinase (Perlyn et al., 2006), or a dominant negative FGFR2 (Tanimoto et al., 2004). In mice, activated FGFR2c signaling can be attenuated by selective uncoupling of the docking protein FRS2α and the mutant FGFR2c (Eswarakumar et al., 2006). Other therapeutic strategies include treatments with a small hairpin RNA targeting the Apert *FGFR2 (*S252W*)* mutation, an ERK1/2 MAPK inhibitor (Shukla et al., 2007), or a soluble mutant form of FGFR2 (Morita et al., 2014; Yokota et al., 2014). Since activated FGFR2 cooperates with other signaling pathways, such as PDGFRα (Moenning et al., 2009; Miraoui et al., 2010a), targeting these pathways may attenuate the aberrant signals induced by *FGFR* mutations in osteogenic cells (Miraoui and Marie, 2010). Furthers studies are needed to determine whether these strategies may correct the abnormal osteoblast phenotype and premature suture fusion in craniosynostosis.

Conclusion

During the last decade, novel cellular, molecular, and genetic studies have led to a better understanding of the role of FGF/FGFR signaling in chondrogenesis, bone formation and resorption, bone remodeling, and repair. The pathways and mechanisms induced by FGF/FGFR signaling that regulate chondrogenesis and osteogenesis are now better understood. The role of FGFs in the regulation of bone and other tissues has also been clarified. The analysis of human skeletal dysplasias and the use of genetic mouse models has improved our knowledge of the pathogenesis of chondrodysplasias and craniosynostosis induced by *FGFR* mutations. Genetic and functional studies have also allowed for the identification of some key pathways altered by *FGFR* mutations, which may in turn be targeted to reduce their impact on skeletal development and remodeling. Further genetic studies in mice are needed to identify more precisely the role of the various FGFs and FGFRs in skeletal cells at specific stages of development in order to generate safe and efficient targeted therapeutic interventions in skeletal dysplasias associated with *FGFR* mutations.

Chapter outline

Introduction

It has been long established that a functional vascular system is crucial for skeletal development and homeostasis (Trueta and Morgan, 1960; Trueta and Amato, 1960). Skeletal blood vessels not only supply oxygen and nutrients to ensure proper functioning of bone-forming and bone-resorbing cells but also deliver calcium and phosphate to sites of active bone mineralization, together with hormones and growth factors that regulate the function of skeletal cells (Marenzana and Arnett, 2013). Moreover, the bone marrow vasculature provides a niche for skeletal stem and progenitor cells next to blood-forming hematopoietic stem cells (HSCs) (Gomez-Gaviro et al., 2012). Particular to the skeleton is that in contrast to the highly vascularized bone tissue, the cartilaginous part is avascular. The intimate connection of the vascular system with bone cells occurs not only during development (Stegen and Carmeliet, 2018) but also during bone repair (Trueta, 1974; Stegen et al., 2015), indicating that a better understanding of the mechanisms that couple bone and blood vessels may provide new therapeutic options for skeletal pathologies.

Recent work using transgenic mouse models and technical advances in bone imaging have substantially improved our knowledge about the role, molecular regulation, and cellular interplay of skeletal vascularization processes during bone development, homeostasis, and repair. In this edition, we first discuss the current understanding of the vascular organization and structure in bone and the interplay of blood vessels and skeletal cells. We specifically focus on the coupling of angiogenesis and osteogenesis by vascular endothelial growth factor (VEGF), the prime angiogenic mediator. Only a brief overview will be given on VEGF molecular biology, and the reader is referred to earlier editions of this volume and excellent recent reviews (Bilzikian et al., 2002; Simons et al., 2016; Chung and Ferrara, 2011; Potente et al., 2011; Towler, 2008). In the final part, we will briefly discuss the therapeutic potential of VEGF modulation during fracture healing.

Bone development and the skeletal vascular system

Bone is formed through either intramembranous or endochondral ossification (Harada and Rodan, 2003; Long, 2011). During intramembranous bone formation, mesenchymal cells condense at the site of the future bone and differentiate directly into bone-forming osteoblasts. These osteoblasts synthesize a collagenous bone matrix, which later becomes mineralized. Intramembranous ossification primarily forms the flat craniofacial bones and part of the clavicle. Endochondral bone formation, on the other hand, regulates especially the development of the long bones of the axial and appendicular skeleton. Typical for this bone formation process is the conversion of cartilage into bone, which mainly happens at three different stages. The first time is when the primary ossification center (POC) is formed. This process encompasses several consecutive steps including condensation of mesenchymal cells, followed by differentiation of the centrally localized cells into chondrocytes to form a cartilage template, and finally replacement of this anlage by bone tissue through the coordinated action of invading blood vessels, osteoprogenitors, and osteoclasts. The second site is the chondro−osseous junction between growth plate and bone metaphysis, where hypertrophic chondrocytes and cartilage matrix are continuously being replaced by trabecular bone. This process is crucial for bone lengthening. The third stage is the conversion of the epiphyseal cartilage into the secondary ossification center (SOC); this process is comparable, but not identical, to the formation of the POC.

Both intramembranous and endochondral bone formation are closely associated with angiogenesis, ultimately giving rise to bone tissue that is highly vascularized. The blood supply of long bones is partially provided by nutrient arteries that enter the diaphyseal cortex, link to capillaries in the bone marrow and then connect to the venous tree, characterized by a central sinus, which finally exits the bone (Marenzana and Arnett, 2013). Recent evidence shows, however, that most of the blood circulation enters and leaves the bone by hundreds of transcortical vessels expressing arterial or venous markers (Grüneboom et al., 2019). How these vessels connect with the blood vessels in the bone marrow is still unknown.

Skeletal blood vessels in the bone marrow of long bones are thus highly heterogeneous and functionally specialized. Typical for the bone vascular system is that the connection between arterial and venous systems is formed by a serial organization of two capillary systems, each of which displays specific morphological and physiological features, and together they form the majority of medullary vessels (Stegen and Carmeliet, 2018). Blood from the arteries first flows to capillaries at the endosteum and chondro−osseous junction. These highly organized capillary vessels, especially in the metaphysis, display a columnar structure, are interconnected by distal loops or arches (Ramasamy et al., 2016), and are called type H vessels because of their high expression of the endothelial cell markers CD31 and endomucin (Kusumbe et al., 2014). Type H vessels then connect to the dense, highly branched capillary network in the bone marrow cavity of the diaphysis, which corresponds to the sinusoidal vasculature described previously. These vessels express lower levels of CD31 and endomucin, and are therefore called type L vessels (Kusumbe et al., 2014). Thus, blood from arteries first flows into type H vessels and subsequently enters the type L sinusoidal network and finally drains into the large central vein (Kusumbe et al., 2014). An important feature of type H capillaries is the close association with Osterix (Osx)-expressing osteoprogenitor cells that are involved in the maintenance of trabecular bone mass. Indeed, endothelial cells from type H vessels express relatively high levels of proosteogenic factors, which may explain the coupling of angiogenesis and osteogenesis at the molecular level (Kusumbe et al., 2014; Ramasamy et al., 2014). In contrast, type L vessels lack perivascular Osx-positive cells and are instead surrounded by cells from the hematopoietic system. The distinct structural and functional properties of type H and L endothelium likely also affect the local microenvironment and the function of associated cells. For example, the bone marrow diaphysis is suggested to be more hypoxic than the metaphyseal and endosteal regions (Kusumbe et al., 2014; Spencer et al., 2014), which may be related to the serial organization of the two capillary systems and the potential reduced delivery of oxygen by the type L vessels or sinusoids to the diaphysis. Moreover, the relatively higher blood flow and shear rate in arteriolar capillaries, compared with sinusoids, are suggested to be involved in the regulation of osteoprogenitor function (Ramasamy et al., 2016). On the other hand, HSCs mainly reside near endosteal capillaries, which display a tight endothelial blood−bone marrow barrier, whereas highly permeable sinusoids serve as a site for cell trafficking (Itkin et al., 2016).

Taken together, despite recent advances, the mechanisms that govern the establishment, growth, and maintenance of the bone vascular system are not yet fully understood and require further investigation. However, several studies have provided more insight on the molecular regulation of skeletal angiogenesis by VEGF, which will be further discussed below. We will primarily focus on findings evidenced by in vivo experiments and less on those only supported by in vitro analyses.

Vascular endothelial growth factor, a crucial angiogenic factor

In recent years, several molecular factors that control bone vascularization have been identified. Some of these stimulate angiogenesis directly by inducing neoangiogenesis and include factors such as VEGF, placental growth factor (PlGF),

fibroblast growth factor (FGF), and members of the transforming growth factor β (TGF-β) family. Others primarily regulate the production of angiogenic molecules; examples are bone morphogenetic proteins (BMPs), angiopoietin, platelet-derived growth factor, and insulin-like growth factor family members.

The most extensively studied group of angiogenic growth factors in bone is the VEGF family, which includes VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and PlGF (Ferrara et al., 2003; Tjwa et al., 2003). Skeletal cells, including chondrocytes, osteoblasts, osteocytes, and osteoclasts, mainly express VEGF-A, although additional roles for PlGF, VEGF-C, and VEGF-D have been recently proposed in osteolineage cells (Hominick et al., 2018; Deckers et al., 2000; Orlandini et al., 2006; Maes et al., 2006; Coenegrachts et al., 2010). VEGF-A, hereafter referred to as VEGF, controls angiogenesis and vascular function at multiple levels. First, as a mitogen for endothelial cells derived from arteries, veins, and lymphatics, VEGF induces sprouting angiogenesis and new blood vessel formation. Second, it functions as a survival factor for endothelial cells. Third, VEGF controls hemodynamics by inducing vasodilatation and enhancing vascular permeability (Potente et al., 2011; Stegen and Carmeliet, 2018). The requirement for VEGF signaling in early vasculogenesis is underscored by the phenotypic lethality of mice lacking even a single VEGF allele (Carmeliet et al., 1996; Ferrara et al., 1996). Moreover, pharmacological inactivation of VEGF signaling in neonatal mice results in stunted growth and increased apoptosis of endothelial cells (Gerber et al., 1999).

The human *VEGF* gene, encoded on chromosome 6, is organized as eight exons separated by seven introns. Alternative splicing results in several protein isoforms, including VEGF121, VEGF165, VEGF189, and VEGF206 as the most predominantly expressed, with different matrix-binding affinities (Ferrara et al., 2003). VEGF121 freely diffuses throughout the extracellular matrix (ECM) because it lacks heparin-binding properties, whereas VEGF198 and VEGF206 are almost completely sequestered in the ECM. VEGF165 has intermediary properties—it is secreted, but a significant fraction remains bound to the cell surface and ECM (Fig. 46.1A). Only three isoforms have been identified in mice (VEGF120, VEGF164, and VEGF188), with similar heparin-binding affinities as their respective human isoforms (Ferrara et al., 2003; Tjwa et al., 2003). In murine bone, VEGF164 is the most expressed isoform, followed by VEGF120 and VEGF188 (Maes et al., 2002).

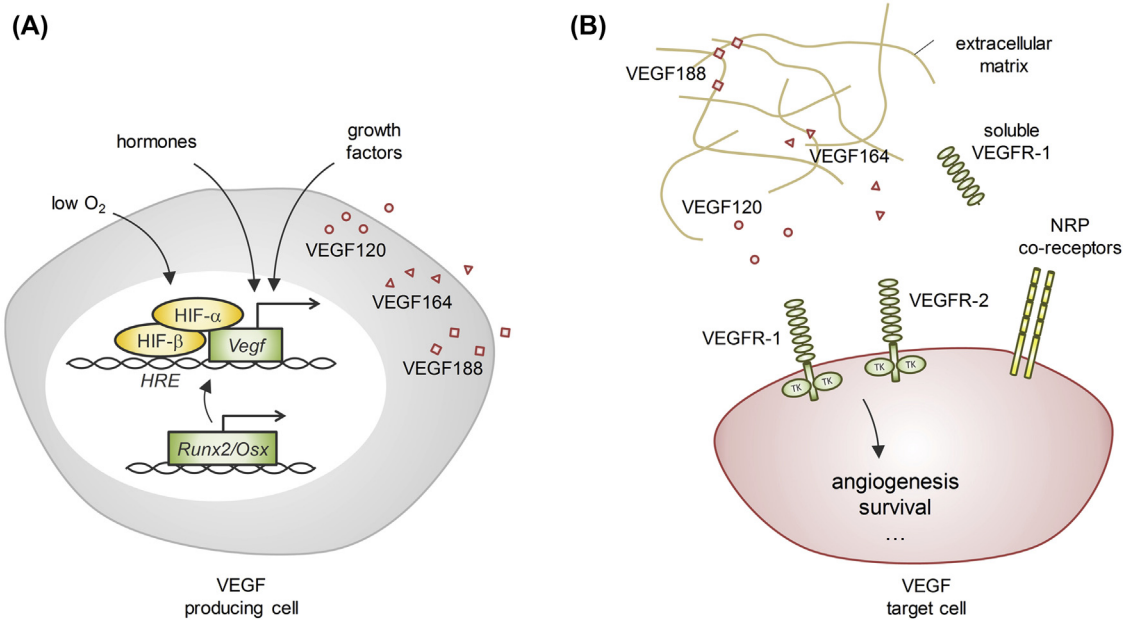

FIGURE 46.1 Regulation and signaling of VEGF in skeletal cells. (A) During bone development, vascular endothelial growth factor (VEGF) is mainly expressed by osteochondroprogenitors and hypertrophic chondrocytes. Bone-specific transcription factors like Runx2 and Osterix (Osx) regulate VEGF expression, which is further controlled by hormones and growth factors. At several stages, skeletal cells become hypoxic because of blood vessel scarcity. In response to the resulting decrease in oxygen tension, the hypoxia-inducible factor HIF-α is stabilized, forms a heterodimer with HIF-β and induces VEGF expression through binding to the hypoxia response element (HRE). The combined secretion of three VEGF isoforms (VEGF120, VEGF164 and VEGF188) results in a VEGF gradient that controls guided angiogenesis. (B) The VEGF isoforms differ in matrix-binding properties, with VEGF120 being the most diffusible isoform and VEGF188 the isoform that is most sequestered in the extracellular matrix. VEGF binds to VEGFR2, which is the main angiogenic receptor. Neuropilin (NRP) co-receptors of VEGFR2 increase VEGF signaling. VEGFR1, and certainly soluble VEGFR1, may act as a sink by sequestering VEGF. *TK*, tyrosine kinase.

To exert its proangiogenic function, VEGF binds to and activates two tyrosine kinase receptors, VEGF receptor 1 (VEGFR-1, also known as fms-like tyrosine kinase/Flt-1) and VEGFR-2 (also known as kinase domain region/KDR or Flk-1) (Fig. 46.1B). Both receptors consist of seven extracellular immunoglobulin-like domains, a transmembrane region, and an intracellular consensus tyrosine kinase domain interrupted by a kinase-insert domain. VEGFR-1 also exists as a soluble form (sVEGFR-1), resulting from alternative splicing, that lacks the transmembrane domain and cytoplasmic regions but retains the ability to bind its ligands. Additionally, neuropilin (NRP) coreceptors augment VEGF signaling in a ligand-specific, VEGFR-specific, and cell-type-dependent manner (Tjwa et al., 2003; Simons et al., 2016). Indeed, whereas all VEGF isoforms can bind VEGFR-1 and VEGFR2, only VEGF164, but not VEGF120, contains the domains that mediate binding to NRP coreceptors. Besides being known as a receptor for the semaphorin family involved in neuronal guidance, NRP1 also modulates the activation of VEGFR-2-mediated signal transduction. When coexpressed with VEGFR-2, NRP1 enhances the binding of VEGF164 to VEGFR-2 and increases VEGF164-mediated chemotaxis (Simons et al., 2016). Although VEGF has a higher affinity for VEGFR-1 than for VEGFR-2, the latter receptor is generally considered to primarily mediate endothelial cell mitogenesis and vascular permeability. In contrast, the role of VEGFR-1 is more complex and context dependent. Indeed, VEGFR-1 promotes the secretion of proteases and growth factors by endothelial cells and the migration of monocytes, whereas sVEGFR-1 negatively regulates VEGFR-2 signaling via VEGF sequestration (Shibuya, 2006). Activation of VEGFR-2 signaling in endothelial cells results in sprouting angiogenesis. During this process, a few endothelial cells with high VEGFR-2 signaling become invading tip cells that lead angiogenic sprouts toward the proangiogenic signal and thereby induce migration and vessel branching. Molecularly, VEGF induces the expression of delta-like ligand 4 (DLL-4) in tip cells. DLL-4 binds to its receptors, Notch 1 and Notch 4, on adjacent stalk endothelial cells to downregulate VEGFR-2 expression in these cells, thus functioning as a dampening mechanism that prevents excess angiogenesis and promotes the orderly development of new vessels. In a final step, proliferating stalk cells eventually form a lumen and thus establish a perfused new vessel, which is stabilized by the recruitment of perivascular cells and ECM deposition. These quiescent endothelial cells then depend on (autocrine) VEGF signaling for survival (Potente et al., 2011; Blanco and Gerhardt, 2013).

Taken together, extensive research has led to the discovery of a plethora of angiogenesis-stimulating growth factors produced by bone cells, of which VEGF is the most important driver of blood vessel growth.

Vascular endothelial growth factor and endochondral ossification

In general, the process of vascular invasion of cartilage and its conversion into bone is a coordinated interaction between several cell types. The best-characterized stage is the formation of the POC, where in response to the proangiogenic factor VEGF, activated endothelial cells in the perichondrium invade and migrate into the cartilage matrix, likely by local protease production (Shibuya, 2006). At the same moment, most of the terminally differentiated hypertrophic chondrocytes will undergo apoptosis. The growing blood vessels are accompanied by osteoclasts and chondroclasts, cells that are well equipped to resorb the cartilaginous matrix. Together with the invading vessels, Osx-positive osteoprogenitors migrate alongside and deposit a typical bone matrix on the remaining cartilage matrix that serves as scaffold (Maes et al., 2010b) (Fig. 46.2A).

The skeletal vasculature appears to be formed predominantly by angiogenesis (i.e., the formation of new blood vessels from preexisting ones) (Stegen and Carmeliet, 2018). The process of sprouting angiogenesis is likely active at the formation of the POC (Langen et al., 2017). However, a rather bone-specific angiogenic mechanism regulates vascular growth at the chondro−osseous junction. Here, no real tip cells are detected, although endothelial cells form filopodia. Vessel growth is rather characterized by bud-shaped protrusions developing from the distal arches that later form anastomoses between each other (Ramasamy et al., 2016). Little is known, however, about the type of angiogenesis during SOC formation, although recent evidence indicates that VEGF-expressing periarticular mesenchymal progenitors migrate ahead of endothelial cells and thereby promote vasculogenesis of the SOC (Tong et al., 2019).

The main angiogenic factor at these different stages of cartilage-to-bone transition is VEGF, as evidenced by different transgenic mouse models. Moreover, the different VEGF isoforms contribute in specific ways to each stage. The general concept is that local concentrations of VEGF are critical to attract and guide endothelial cells, and that a well-balanced combination of diffusible and matrix-binding VEGF isoforms results in a VEGF gradient that controls guided angiogenesis. Because VEGF164 combines both properties, mice that express only VEGF164 display normal bone development with appropriate conversion of cartilage into bone at the three different sites (Maes et al., 2004). On the other hand, mice that selectively express VEGF120 or VEGF188 show delayed vascular invasion at two of the three sites of endochondral ossification (Maes et al. 2002, 2004).

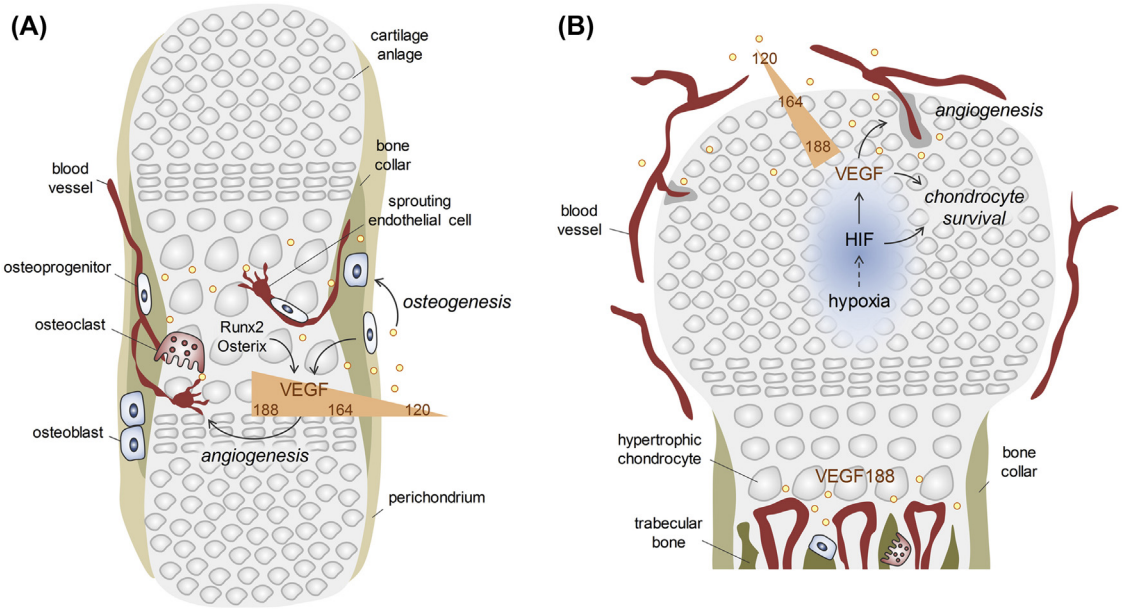

FIGURE 46.2 Angiogenic-osteogenic coupling during bone development. (A) After formation and growth of the cartilage anlage, perichondrial osteochondroprogenitors and hypertrophic chondrocytes start to secrete VEGF in a process mainly regulated by the transcription factors Runx2 and Osterix. An appropriate combination of three VEGF isoforms (VEGF120, VEGF164 and VEGF188) induces blood vessel invasion from the perichondrium, which is directed towards the cartilage template. This angiogenic response is accompanied by osteoclastic cartilage resorption and osteoprogenitors that move into the nascent primary ossification center. (B) During longitudinal bone growth, hypertrophic chondrocytes at the chondro-osseous interface secrete VEGF to attract the metaphyseal H-type blood vessels by a bone-specific angiogenic mechanism. Matrix-binding VEGF isoforms are needed to correctly orient blood vessel growth. In the avascular epiphyseal growth plate, the centrally localized chondrocytes become hypoxic, resulting in HIF stabilization and chondrocytic VEGF expression. The VEGF120 and VEGF164 isoforms are critical to diffuse to the outer layers of the epiphysis to stimulate ingrowth of the surrounding epiphyseal vessels. HIF is also essential for chondrocyte survival, possibly by mediating a metabolic switch.

First, the formation of the POC is delayed when only VEGF120 or VEGF188 is expressed (Maes et al. 2002, 2004), characterized by slower blood vessel invasion of the cartilage template and its removal by osteoclasts, similar to the phenotype observed in mice with deletion of *Vegf* in collagen type II (COL2)-expressing cells (Haigh et al., 2000; Zelzer et al., 2001). Together, these findings suggest that the diffusible VEGF120 isoform is required to attract blood vessels present in the perichondrium, whereas the matrix-binding VEGF188 likely provides directional cues upon the resorption of the cartilage matrix. A balanced secretion of all VEGF isoforms by hypertrophic chondrocytes in the center of the cartilage anlage is thus required for an adequate angiogenic response and timely formation of the POC (Fig. 46.2A).

Second, matrix-binding VEGF isoforms are required for the cartilage-to-bone conversion at the metaphyseal region. Here, VEGF is mainly secreted by the hypertrophic chondrocytes. Mice that only express the VEGF120 isoform display a decreased number of blood vessels near the growth plate, and these vessels are disorganized, lacking a longitudinal orientation (Maes et al., 2002). Consequently, the conversion of cartilage into bone is impaired, evidenced by lower trabecular bone mass together with an enlarged hypertrophic zone of the growth plate. When only VEGF164 or VEGF188 is present, the cartilage-to-bone transition in the metaphysis is normal, showing that matrix-binding VEGF isoforms need to be present to achieve normal endochondral ossification. Likely, these matrix-bound VEGF isoforms are released from the cartilage matrix by invading osteoclasts and orient the blood vessels longitudinally between the cartilage remnants. Indeed, mice with inactivation of matrix metalloproteinase 9 show decreased metaphyseal vascularization, and this phenotype was largely rescued by treating the mice with VEGF (Vu et al., 1998; Ortega et al., 2010). A comparable phenotype, showing an enlarged zone of hypertrophic chondrocytes in the growth plate, is also observed in mice in which VEGF action is inhibited by injection of a sFlt-1 chimeric protein (Gerber et al., 1999) or in mice with deletion of a single *Vegf* allele in COL2-expressing cells (Haigh et al., 2000).

The third site of angiogenesis coupled to cartilage-to-bone transition is the formation of the SOC at the ends of the long bones. When the epiphyseal growth plate enlarges during bone growth, the chondrocytes in the center of the avascular growth plate become hypoxic because they depend on the vascular network overlying the epiphysis for their oxygen and nutrient supply. Activation of the hypoxia signaling pathway (see below) stimulates VEGF expression to induce vascular

invasion (Pugh and Ratcliffe, 2003). This angiogenic response is certainly important, as VEGF deletion in chondrocytes results in cell death of the centrally localized chondrocytes (Zelzer et al., 2004). However, VEGF expression in the epiphyseal growth plate is not sufficient to prevent centrally localized chondrocytes from becoming hypoxic (Maes et al., 2012a) (see below). In addition, when only VEGF188 is produced, the number of chondrocytes in the center of the growth plate that become hypoxic is increased, resulting in enhanced cell death, and consequently reduced longitudinal bone growth (Maes et al., 2004). No changes in epiphyseal vascularization are observed when only VEGF120 or VEGF164 is expressed. These data indicate that diffusible VEGF isoforms need to be present for timely formation of the SOC. Likely, only diffusible VEGF molecules can reach the outer layers of the epiphysis to instruct endothelial cells to proliferate and invade the avascular epiphyseal growth plate.

A special type of cartilage is Meckel's cartilage in the mandible, where the chondrocytes derive from cranial neural crest cells (NCCs). These NCCs are an important source of VEGF during jaw morphogenesis. Deletion of *Vegf* from WNT1-positive NCCs results in reduced jaw vascularization (Wiszniak et al., 2015). Likely, the attracted blood vessels secrete factors that stimulate chondrocyte proliferation and thereby the extension of the mandible.

Taken together, not only appropriate VEGF levels but also the correct combination of VEGF isoforms is essential to allow timely and normal endochondral ossification at each of the three stages.

Vascular endothelial growth factor during intramembranous bone formation

In addition to their involvement in endochondral bone formation, blood vessels are also implicated during intramembranous ossification and are likely regulated through similar mechanisms (Percival and Richtsmeier, 2013). Intramembranous ossification is important for craniofacial development, where NCCs differentiate to osteoblasts, and for cortical bone formation, where osteoprogenitors in the perichondrium/periosteum directly differentiate into osteoblasts.

During craniofacial development, VEGF is expressed by NCCs. Mice with conditional deletion of *Vegf* in WNT1-positive NCCs show craniofacial defects including cleft palate, unfused cranial sutures, and shorter jaws (Hill et al., 2015). This bone phenotype results from reduced vascularization and decreased BMP2 expression, which is required for normal ossification. Mice expressing only VEGF120 show similar calvarial and mandibular malformations (Stalmans et al., 2003). Furthermore, inactivation of *Vegf* in Osx-positive osteoprogenitors of the cranial bones reduces the ossification of calvarial and mandibular bones (Duan et al., 2016). However, this effect was not due to changes in vascularization but likely to decreased BMP-mediated proliferation of cells in the jaw mesenchyme.

With respect to cortical bone formation of the long bones, mice with deletion of *Vegf* in Osx-positive osteolineage cells show decreased numbers of blood vessels in the perichondrium and impaired differentiation of osteogenic precursors into osteoblasts at these sites (Duan et al., 2015). Mechanistically, VEGF derived from perichondrial osteolineage cells controls osteoblast differentiation in a VEGFR2-dependent manner, likely involving Indian hedgehog, β-catenin, and Notch2-mediated pathways.

Taken together, adequate VEGF expression is required for the development of the craniofacial bones and the cortical part of the long bones by angiogenic and non-endothelial-specific effects.

Nonendothelial effects of vascular endothelial growth factor

Although the principal function of VEGF is to induce new blood vessel formation, its actions are not exclusive to endothelial cells and may influence skeletal cell behavior directly. Indeed, chondrocytes, skeletal progenitor cells, osteoblasts, and osteoclasts all express VEGF receptors. In vitro data show that these cell types respond to VEGF by enhanced recruitment, differentiation, activity, and/or survival, although not all findings are yet confirmed by observations in vivo (Dai and Rabie, 2007). Moreover, although VEGF primarily functions in a paracrine manner, it also controls the survival of HSCs and endothelial cells via autocrine or intracrine mechanisms (Gerber et al., 2002; Lee et al., 2007; Liu et al., 2012). Analogously, young mice with conditional deletion of *Vegfr1* or *Vegfr2* in osteoblastic cells show decreased bone mass (Liu et al., 2012), and their bone marrow contains reduced numbers of osteoprogenitors. Mechanistically, VEGF stimulates the formation of osteoblasts and suppresses adipogenesis through intracrine signaling in osteoprogenitors (Liu et al., 2012). These findings suggest that both VEGFR1 and VEGFR2 are positive regulators of skeletal development, and that VEGF regulates lineage specification of osteoprogenitors via intracrine mechanisms.

Although VEGF is a critical determinant of bone development, its expression levels need to be tightly controlled. Indeed, overexpression of VEGF in osteochondroprogenitors resulted in increased bone mass with abnormal vascularization and signs of myelofibrosis in the bone marrow (Maes et al., 2010a). Mechanistically, VEGF induces stabilization of β-catenin in endothelial and osteogenic cells by binding to VEGFR2.

Finally, VEGF can contribute to osteoclast formation. The differentiation and activation of osteoclasts are predominantly regulated by RANK ligand and macrophage colony-stimulating factor (M-CSF). However, VEGF can substitute for M-CSF to promote osteoclast differentiation and bone resorption (Niida et al., 1999).

Vascular endothelial growth factor homologues

PlGF is a homologue of VEGF and specifically binds to VEGR1. Deletion of *Plgf* does not affect angiogenesis during development, but in vivo observations indicate that PlGF becomes important during pathological processes. PlGF may then induce inflammation and angiogenesis and synergize with VEGF (Carmeliet et al., 2001; Luttun et al., 2002). Related to bone biology, mice with *Plgf* inactivation show normal bone development and homeostasis, but healing of a semistabilized fracture is impaired (Maes et al., 2006). PlGF regulates several phases during fracture repair, as PLGF (1) initiates the inflammatory and angiogenic response shortly after bone trauma, (2) stimulates the proliferation of osteolineage cells in the periosteum, (3) decreases the differentiation of periosteal cells into chondrocytes, and (4) promotes the conversion of cartilage callus into bone callus, likely by attracting osteoclasts.

VEGF-C is the major lymphangiogenic factor interacting with VEGFR2 and VEGFR3. Lymphatic vessels are present in most soft tissues but not in bone. However, inducible expression of VEGF-C in Osx-positive osteogenic cells induces the formation of lymphatic vessels in cortical bone, trabecular bone, and the bone marrow cavity. This increase in lymphatic vessels stimulates the formation of osteoclasts, resulting in increased cortical porosity, and mimics the bone pathology observed in patients with Gorham–Stout disease (Hominick et al., 2018).

Regulation of vascular endothelial growth factor expression by oxygen levels

Physiological VEGF levels in the bone are tightly regulated, since overactivation of osteoblastic VEGF signaling results in excessively ossified bones with bone marrow fibrosis, abnormal blood vessel morphology, and extramedullary hematopoiesis (Maes et al., 2010a). The precise mechanisms of the regulation of skeletal VEGF expression are not yet completely understood and may vary depending on the developmental state and specific cell type. Yet some regulators have been proposed, predominantly in vitro, including osteogenic transcription factors (Runx2, Osx), hormones (parathyroid hormone, 1,25-dihydroxyvitamin D_3), and growth factors (BMPs, FGFs, TGF-β) (Dai and Rabie, 2007; Zelzer et al., 2001; Tang et al., 2012) (Fig. 46.1A).

However, one of the most prominent regulatory factors of VEGF expression in skeletal tissues is the hypoxia-inducible transcription factor (HIF) (Pugh and Ratcliffe, 2003) (Fig. 46.1A). This family of transcription factors enables cells to survive and function in low-oxygen (i.e., hypoxic) conditions, among others, by stimulating angiogenesis to correct oxygen supply. HIF-1, HIF-2, and HIF-3 are heterodimeric proteins consisting of an oxygen-sensitive HIF-α subunit and a constitutively expressed HIF-β subunit (Ke and Costa, 2006; Weidemann and Johnson, 2008; Aragones et al., 2009). In well-oxygenated tissues, the half-life of HIF-α is less than 5 min, and this rapid turnover is facilitated by HIF prolyl hydroxylase (PHD)-mediated hydroxylation of specific proline residues within a central oxygen-dependent degradation domain. Hydroxylation prompts polyubiquitination of HIF-α and is essential for interaction with the von Hippel–Lindau tumor-suppressor protein (pVHL), which is the recognition component of an E3 ubiquitin ligase complex that will target HIF-α for proteolytic degradation (Ke and Costa, 2006; Weidemann and Johnson, 2008; Aragones et al., 2009). When physiological or pathological hypoxia occurs, as caused by absence, destruction, or malfunctioning of blood vessels, PHDs become inactive, resulting in reduced hydroxylation and thus stabilization of HIF-α. When stable, HIF-α translocates to the nucleus, dimerizes with HIF-β, and after recruitment of transcriptional coactivators such as Cbp/p300, binds to hypoxia response elements (HREs) of HIF-responsive genes (Ke and Costa, 2006; Weidemann and Johnson, 2008). Hypoxic induction of VEGF expression is regulated by active HIF signaling at multiple levels. First, *VEGF* transcription is directly controlled by binding of HIF heterodimers to an HRE located at base pairs −947 to −939 relative to the transcription start site (Forsythe et al., 1996). Second, the biological activity of secreted VEGF is further determined by hypoxia/HIF-induced expression of the Flt-1 receptor and posttranslational regulation of the Flk-1 receptor (Gerber et al., 1997; Waltenberger et al., 1996), possibly in an attempt to avoid uncontrolled vascular sprouting.

In recent years, several studies have linked HIF signaling and angiogenesis to skeletal cell function during bone development, homeostasis, and pathology (Maes et al., 2012b). During endochondral ossification, HIF-1α is necessary for the survival and function of epiphyseal growth plate chondrocytes (Schipani et al., 2001; Maes et al., 2012a) (Fig. 46.2B). Indeed, the centrally localized chondrocytes become hypoxic when the avascular growth plate expands, and deletion of HIF-1α in these cells results in massive apoptosis of the hypoxic chondrocytes (Schipani et al., 2001). Restoring VEGF expression in these HIF-1α-null chondrocytes diminishes, but does not prevent, chondrocyte cell death,

indicating that cell-intrinsic mechanisms, like metabolic adaptations, contribute to an appropriate hypoxic response (Maes et al., 2012a).

In addition to its prosurvival role in chondrocytes, activation of HIF signaling in bone-forming osteoblasts has been implicated in the stimulation of angiogenesis and the coupling of osteogenic and angiogenic processes. Conditional deletion of *Hif1α* in osteoprogenitors or mature osteoblasts decreases bone volume and blood vessel number, the latter being caused by downregulation of local VEGF production (Wang et al., 2007; Shomento et al., 2010; Rankin et al., 2012). Conversely, genetic ablation of *pVhl* or *Phd* isoforms stabilizes endogenous HIF, resulting in a high bone mass phenotype (Wang et al., 2007; Rankin et al., 2012; Stegen et al. 2016, 2018; Rauner et al., 2016). Although changes in vascular density have been proposed as the key mechanism for HIF-mediated effects on cartilage and bone, recent evidence indicates that HIF also controls skeletal cell function in an angiogenesis-independent manner. Indeed, HIF-induced cell-intrinsic adaptations in metabolism are likely necessary to support the bone anabolic response and maintain cell survival (Regan et al., 2014; Maes et al., 2012a; Stegen et al., 2016), whereas increased osteoprotegerin expression and enhanced WNT signaling affect bone turnover (Wu et al., 2015; Stegen et al., 2018). Recently, the role of HIF signaling specifically in skeletal blood vessels was investigated, adding another layer of complexity to the regulation of angiogenic−osteogenic coupling. H-type vessels express high HIF-1α levels, and consequently, postnatal inactivation of *Hif1α* in endothelial cells severely reduces metaphyseal and endosteal type H endothelium without affecting L-type vessels. This vascular defect is associated with a reduced number of perivascular Runx2 and Osx-positive osteoprogenitors. Conversely, activation of HIF signaling in bone endothelium through pVHL deletion results in the opposite phenotype, with increased osteoprogenitor numbers, bone formation, and consequently a higher trabecular bone volume (Kusumbe et al., 2014). The precise mechanisms that mediate this angiogenic−osteogenic coupling are not fully understood, but VEGF may be a coupling factor. Together, HIF signaling influences skeletal cell function during bone development and homeostasis at least in part through VEGF signaling and the resulting changes in vascularization.

Therapeutic potential of vascular endothelial growth factor for bone repair

VEGF is thus a critical factor that links angiogenesis and skeletal cell function during bone development and homeostasis. This interplay also exists in the context of bone repair, which critically depends on optimal proangiogenic signaling to induce sufficient and timely blood vessel ingrowth (Stegen et al., 2015).

As one of the few tissues in the human body, bone has the remarkable ability to heal without the formation of scar tissue. When bone fractures, disruption of the local vascular system results in blood clotting and hematoma formation (Gerstenfeld et al., 2003). The hematoma holds strong proangiogenic potential, likely caused by the high concentrations of angiogenic growth factors, and is thus indispensable for proper bone healing (Street et al., 2000). Indeed, removal of the hematoma attenuates fracture repair, whereas its transplantation stimulates new bone formation (Street et al., 2000). Although several proangiogenic growth factors are involved in the bone repair cascade, VEGF is the most extensively studied. VEGF levels are strongly increased locally in the early fracture hematoma, but also systemically in injured patients (Street et al., 2000; Beamer et al., 2010). The reestablishment of a vascular network is crucial to the success of the repair process, as blocking VEGF activity using VEGF antagonists or soluble VEGFR results in an impaired vascular response and consequently compromised bone healing (Street et al., 2002). On the other hand, administration of recombinant VEGF accelerates blood vessel ingrowth and bone formation in preclinical models of endochondral and intramembranous bone repair (Street et al., 2002). Since VEGF expression within the fracture callus is spatially and temporally tightly controlled, changes in the local microenvironment are likely to be involved in the regulation of the proangiogenic response. Indeed, as a consequence of the vascular damage, the fracture site becomes hypoxic, and to withstand hypoxia-induced apoptosis, cells activate a survival mechanism controlled by HIF (Maes et al., 2012b). Activation of HIF signaling by cells within the fracture callus is critical for adequate bone healing, since genetic inactivation of HIF-1α in mature osteoblasts impairs blood vessel ingrowth at the fracture site and consequently bone healing, whereas HIF-1α overexpression improves angiogenesis and bone repair (Wan et al., 2008; Shen et al., 2009). Whether other cell types of the fracture callus, including chondrocytes, also activate a vascular response via HIFs, or whether HIF signaling controls other angiogenesis-independent steps during bone healing, however, remains unknown.

The stimulatory effects of VEGF on angiogenesis and osteogenesis have prompted the exploration of these growth factors as therapeutic agents for bone repair. Administration of recombinant VEGF, alone or in combination with osteogenic growth factors, induces vascularization of the bone defect and in turn accelerates fracture healing in several preclinical models (Stegen et al., 2015). However, translation into the clinic is still limited, as administration of recombinant VEGF may have some limitations due to protein instability in vivo and undesirable side effects as mentioned earlier. Moreover, uncontrolled VEGF diffusion to surrounding tissues may increase the risk of developing adverse vascular

effects including malignancy. Current strategies are therefore focused on more localized, controlled release of these growth factors. Another approach to avoid the potential side effects of VEGF administration is to stimulate angiogenesis in a more physiological way. Activation of HIF signaling induces vascular ingrowth and accelerates bone repair, but therapeutic targeting of the HIF transcription factors is challenging (Stiers et al., 2016). PHD oxygen sensors, which act upstream of HIFs, are therefore increasingly being considered as druggable targets. Indeed, several studies in preclinical animal models have shown that blocking PHD activity improves bone repair, which is at least in part mediated by a VEGF-dependent increase in vascularization (Stegen et al., 2015; Stiers et al., 2016).

Thus, although stimulation of VEGF-dependent angiogenesis is an appealing strategy to enhance fracture repair, future studies are required to accelerate the development of novel therapies for patients with impaired bone healing.

Chapter outline

Transforming growth factor-βs as the molecular sensor in the extracellular matrix

Transforming growth factor (TGF)-β proteins belong to the TGF-β superfamily, which consists of TGF-β1−3, activins/inhibins/Müllerian-inhibiting substances, bone morphogenetic proteins (BMPs), nodal, growth/differentiation factors (GDFs), and the distantly related glial cell line–derived neurotrophic factors family (Chang et al., 2002; Javelaud and Mauviel, 2004; Kingsley, 1994). TGF-β1−3 are present only in mammals. They are pleiotropic; regulate cell proliferation, migration, and differentiation during embryonic development; and play an essential role in maintaining tissue homeostasis in adults. In mammals, distinct genes encode TGF-β 1-3 isoforms that are expressed in unique, occasionally overlapping patterns and can perform a variety of distinct functions in vivo (Letterio and Roberts, 1996; Proetzel et al., 1995; Sanford et al., 1997). Initially cloned from human term placenta mRNA, TGF-β1 is the most abundant and ubiquitously expressed isoform (Derynck et al., 1985). TGF-β1 has been identified in cartilage as well as endochondral and intramembranous bone

and skin during mouse development, thereby indicating its involvement in the development of these tissues/organs (Dickinson et al., 1990). TGF-β2, also known as glioblastoma-derived T cell suppressor factor, was first discovered in human glioblastoma cells. During embryonic development, TGF-β2 is expressed by neurons and astroglial cells (Flanders et al., 1991), while pathologically it is also involved in tumorigenesis by enhancing cell proliferation and reducing host immune surveillance against tumor development (de Martin et al., 1987). TGF-β3 was first identified from the cDNA library of a human rhabdomyosarcoma cell line. It plays an essential role in the development of the palate and lungs, mainly through the regulation of epithelial−mesenchymal interactions during embryonic, fetal, and neonatal development (Kaartinen et al., 1995; Proetzel et al., 1995). TGF-β3 is also possibly involved in the wound healing process, orchestrating an orderly migration of dermal and epidermal cells in injured skin (Bandyopadhyay et al., 2006b).

Unlike most growth factors, which are ready to function upon secretion, TGF-β is unique in that it is secreted as part of a latent complex stored in the extracellular matrix (ECM). Thereby, the magnitude and duration of TGF-β signaling is carefully controlled at multiple levels, including the synthesis and activation of latent TGF-β isoforms, receptor activation and stability, and the activation and stability of intracellular Smad molecules and other downstream signaling molecules. Plenty of molecules have been identified as "TGF-β activators" whose mutation will lead to aberrant activation of TGF-β and ultimately pathological phenotypes. Although distal effects from circulating factors have been reported, TGF-β-mediated effects are usually restricted at the sites where the active ligand is released. Therefore, the temporal and spatial activation of this growth factor is critical for its context-dependent physiological effects in vivo. Considering the close relationship of TGF-β and ECM homeostasis, increasing evidence has indicated that TGF-β complex is more like a molecular sensor that responds instantly to ECM perturbations through the release of an active ligand that exerts physiological effects at a cellular level, thus ensuring normal tissue homeostasis (Annes et al., 2003).

Latent transforming growth factor-βs in the extracellular matrix

TGF-β family members are typically secreted and deposited in ECM such as bone matrix in their latent form, and their biological effects can only be delivered upon ligand activation. TGF-βs contain a characteristic cysteine knot formed from multiple intrachain disulfide bonds (Chang et al., 2002; Javelaud and Mauviel, 2004; Kingsley, 1994). The precursor of TGF-β1 peptide contains 390 amino acid (aa), including a signal peptide and a TGF-β1 proprotein. This proprotein (361 aa) is processed intracellularly by a furin-like convertase to generate an N-terminal latency-associated peptide (LAP, 249 aa) and a C-terminal mature TGF-β1 (Clark and Coker, 1998; Derynck et al., 1986; Dubois et al., 1995; Kondaiah et al., 1988; Manning et al., 1995; Qian et al., 1990). Both LAP and mature TGF-β1 form homodimers via disulfide bonds. After secretion, the LAP and TGF-β1 homodimers are further noncovalently associated as the small latent TGF-β1 complex (SLC). LAP-growth factor association is both necessary and sufficient to confer latency of TGF-β1-3, BMP-10, and GDF-8/myostatin. However, for BMPs 4, 5, and 7, although LAP and the mature growth factor are also noncovalently associated, the complex is still active (Sengle et al., 2011).

In most cases, LAP of the SLC is further covalently associated with a latent TGF-β binding protein (LTBP) in the ECM, thus creating the large latent complex (LLC) that functions as an ECM reservoir of TGF-β. The LAP−LTBP association mainly functions to anchor the complex to ECM components such as fibrillin (Annes et al., 2003). LTBP is also involved in the proper folding and secretion of the SLC (Brunner et al., 1989; Gray and Mason, 1990; Mangasser-Stephan and Gressner, 1999; Mittl et al., 1996; Oklu and Hesketh, 2000; Saharinen et al., 1996). To date, four LTBPs (LTBP1−4) have been identified, among which LTBPs 1, 3, 4 are able to bind the SLC of all TGF-β isoforms (Koli et al., 2001). Therefore, although TGF-βs are abundant in the ECM (Bismar et al., 1999; Roberts et al., 1983; Seyedin et al., 1985), they are secreted and deposited in the latent form and not able to induce downstream signaling to elicit biological effects (Pedrozo et al., 1999; Pfeilschifter et al., 1990).

Activation of transforming growth factor-βs

Although TGF-β ligands and receptors are ubiquitous in many types of cells, their biological effects are usually restricted at sites where the ligand is activated. Storage of inactive TGF-β in the matrix enables temporal and spatial regulation of TGF-β activation during tissue homeostasis. Precise activation of latent TGF-β is a prerequisite for it to function in the right locations within a specific time frame. In general, the activation of TGF-β requires the release of the LLC from the ECM and further proteolysis/deformation of LAP to release active TGF-β (Jenkins, 2008). TGF-β1 can be activated by plasmin, matrix metalloproteinases (MMPs), thrombospondin-1 (TSP-1), lower pH, and reactive oxygen species (ROS) (Annes et al., 2003). More importantly, TGF-β can also be activated by specific integrins that bind the Arg−Gly−Asp (RGD) sequence of LAPs. The integrin−RGD association results in a contractile force-dependent conformational change

of the latent complex, which releases TGF-β in its active form (Munger et al., 1999; Shi et al., 2011). In addition, a plethora of soluble extracellular agonists and antagonists coexist at the site where active TGF-β is released and further complicate the temporal and spatial access of ligands to receptors (Derynck and Miyazono, 2008).

Proteolytic activation

Many proteases including plasmin and matrix metalloproteinases (e.g., MMP-2 and MMP-9) have been identified in vitro as TGF-β activators (Sato and Rifkin, 1989; Yu and Stamenkovic, 2000). Plasmin and MMP-2/9 are the primary enzymes involved in ECM degradation (Werb, 1997). Proteases can cleave the covalent bond between LAP and TGF-β peptide in the proLLC, thereby rendering the LLC activation competent. Proteases can also target the protease-sensitive hinge region of LTBP to liberate the LLC, which can then be further processed for activation (Taipale et al., 1994). Proteases may directly cleave LAP to release TGF-β in its active form (Lyons et al., 1988). The aforementioned enzymatic activation couples matrix turnover with the generation of active TGF-β to maintain matrix homeostasis (Ignotz and Massague, 1986; Verrecchia et al., 2001). More notably, plasminogen-null animals fail to replicate the pathology of TGF-β1-null animals, and the multisystem pathology of plasminogen-null animals can be alleviated by removal of fibrinogen (Bugge et al., 1996). These observations suggest that plasmin is not solely responsible for the majority of the activation of TGF-β1 in vivo.

Activation by thrombospondin-1

TSP-1 is a complex multifunctional glycoprotein that mediates cell-to-cell and cell-to-matrix interactions during multiple cellular events in a temporally regulated manner (Agah et al., 2002; DiPietro et al., 1996; Murphy-Ullrich and Mosher, 1985; Raugi et al., 1987; Reed et al., 1993). TSP-1 plays an important role in the wound healing process, regulating hemostasis, cell adhesion/migration/proliferation, ECM remodeling, and growth factor (e.g., TGF-β) activation (Adams and Lawler, 2004). In addition to tissue repair, TSP-1 is involved in tissue fibrosis, possibly by activating TGF-β. Either the blockage of TSP-1 activity or deletion of TSP-1 expression can attenuate pathological tissue fibrogenesis (Daniel et al., 2007; Hugo, 2003; Poczatek et al., 2000).

The primary role of TSP-1 in modulating TGF-β activation is observed during injury, under stress, or in other pathologies involved with ECM perturbations. This phenomenon further supports the concept that the latent TGF-β complex embedded in the ECM functions as a sensor to environmental stimuli. TSP-1 will mobilize the necessary molecular machineries to release TGF-β in its active form to meet the needs of tissue repair/remodeling, whereas an excessive response to ECM perturbation may superactivate TGF-β and exacerbate adversary effects such as fibrogenesis. Mechanistically, TSP-1 activates TGF-β by binding to specific sequences of the latent complex and inducing a conformational change to release active TGF-β (Murphy-Ullrich and Poczatek, 2000; Schultz-Cherry and Murphy-Ullrich, 1993). In the latent TGF-β complex, the RKPK sequence in the receptor-binding region of mature TGF-β binds to the LSKL sequence at the amino terminus of LAP, thus enabling ligand latency (Shi et al., 2011; Walton et al., 2010; Young and Murphy-Ullrich, 2004). TSP-1 activates TGF-β through the specific association of its type 1 repeats (TSRs) with LAP and the mature ligand. When the tryptophan-rich motifs present in each of the three TSRs of TSP-1 bind to the VLAL sequence in both LAP and the mature TGF-β ligand, it deforms the LAP—TGF-β complex by "inserting" a TSP-1 molecule. Additionally, the KRFK sequence in the second TSR of TSP-1 can competitively bind to the LSKL sequence in the LAP and present to the receptor the mature TGF-β domain (Sweetwyne and Murphy-Ullrich, 2012). In vivo evidence for the role of TSP-1 in TGF-β activation is shown by the fact that both TSP-1- and TGF-β1-null animals developed strikingly similar pathologies in multiple organs, particularly in the lungs and pancreas. During the perinatal period, administration of the KRFK peptide partially resolved the abnormal TSP-1 depletion phenotypes, specifically airway epithelial hyperplasia and pancreatic islet hyperplasia/acinar hypoplasia. In addition, wild-type mice treated with the LSKL blocking peptide in the perinatal period showed features similar to those of the TSP-1 knockout phenotype in both the airways and pancreas (Crawford et al., 1998). Double knockout of β6 integrin and TSP-1 led to a phenotype different from either single knockout, characterized by cardiac degeneration, severe inflammation, and epithelial hyperplasia, which suggests a potential synergy between β6 integrin and TSP-1 in regulating latent TGF-β activation (Ludlow et al., 2005).

TSP-1-mediated TGF-β activation is observed in multiorgan fibrosis. Moreover, the expression of TSP-1 is induced by factors such as ROS, high glucose, and angiotensin II that are closely associated with systemic diseases that have fibrotic end-organ involvement (Wang et al. 2002, 2004; Yevdokimova et al., 2001; Zhou et al., 2006). Studies using TSP-1 antagonist peptides and diabetic TSP-1 knockout mice have demonstrated that TSP-1 is a major factor inducing fibrotic end-organ complications in diabetes (Belmadani et al., 2007; Daniel et al., 2007; Lu et al., 2011). Treatment of diabetic mice with intraperitoneal injections of LSKL improved left ventricular function and reduced Smad phosphorylation

and cardiac fibrosis (Belmadani et al., 2007). Similarly, treatment with LSKL suppressed urinary TGF-β activity and improved markers of tubulointerstitial injury and podocyte function in diabetic mice (Lu et al., 2011). Moreover, TSP-1 can activate alveolar macrophage-dependent TGF-β in bleomycin-induced pulmonary fibrosis animal models, and either CD36 antagonist peptides or TSP-1 can reduce TGF-β activity and ameliorate pulmonary fibrosis (Chen et al., 2009; Yehualaeshet et al., 2000).

TSP-1-mediated TGF-β activation is also involved in the dermal wound healing process. The phenotype of excisional wound healing in the TSP-1-null mouse is consistent with a decrease in local TGF-β activation (Agah et al., 2002), a delay in macrophage recruitment and capillary angiogenesis, and a persistence of inflammation, granulation tissue, and neovascularization (Nor et al., 2005). The TSP-1-null wound phenotype can be largely rescued by topical treatment with the KRFK-activating peptide (Nor et al., 2005). KRFK treatment increased the TGF-β levels in these wounds, and its effects were blocked by a pan-specific anti-TGF-β antibody. These data suggest that TSP-1 is essential for the local activation of TGF-β during injury and may affect the wound healing process. In addition, subcutaneous implantation of TSP-1-soaked sponges increased the levels of active TGF-β and induced fibroblast migration (Sakai et al., 2003). Overexpression of TSP-1 in scleroderma and keloids induces increased TGF-β activity (Chen et al., 2011; Chipev et al., 2000; Mimura et al., 2005). All these data validate the involvement of TSP-1-induced TGF-β activation in dermal wound healing and sclerosis. However, how to modulate TSP-1 activity to avoid either defective or excessive wound repair processes in vivo remains to be determined.

Activation by integrins

Integrins are dimeric cell surface receptors composed of α and β subunits (van der Flier and Sonnenberg, 2001). They recently have been shown to play a central role in TGF-β activation (Nishimura, 2009). Current data show that at least two mechanisms are involved in the activation of latent TGF-β by integrins (Fig. 47.1). The first proposed mechanism is MMP-dependent. Specifically, integrins are suggested to spatially arrange MMPs, latent TGF-β, and the TGF-β receptor in close proximity, which promotes further activation of latent TGF-β by proteolytic cleavage. The second mechanism is proteolytic action-independent but more closely associated with cell traction forces directly transmitted to the LLC via integrin binding. The cellular contractile force can lead to conformational change of the latent complex, thus liberating TGF-β in its active form and/or presenting it to its receptor. It should be noted that both mechanisms are not mutually exclusive, and it is conceivable that cells can use either or both mechanisms at the same time depending on the specific organs or conditions (Wipff and Hinz, 2008).

$\alpha_v\beta_6$ was the first integrin identified as a TGF-β activator (Munger et al., 1999). The mechanism of activation depends on a direct interaction between $\alpha_v\beta_6$ and the RGD amino acid sequence of the prodomains (LAPs). The prodomains of TGF-β1 and TGF-β3 contain an RGD motif recognized by α_v integrins. Mice with the integrin-binding RGD motif mutation show similar phenotypes to TGF-β1-null mice, such as multiorgan inflammation and defects in vasculogenesis, confirming the essential role of integrins in TGF-β activation (Yang et al., 2007).

$\alpha_v\beta_6$ is normally expressed in epithelial cells at low levels (Breuss et al., 1993). Inflammation or injury can increase the expression of αvβ6 (Breuss et al., 1995; Miller et al., 2001). Therefore, upregulation of αvβ6 and subsequent TGF-β activation in epithelial cells are believed to be a cellular response to suppress perturbations such as inflammation. Consistent with the ability of β_6 integrin to activate latent TGF-β and the profibrotic effects of TGF-β (Border and Ruoslahti, 1992), in the mouse model of pulmonary fibrosis induced by bleomycin, wild-type mice develop pulmonary inflammation with subsequent fibrosis, while integrin $\beta_6^{-/-}$ mice show a minor fibrotic response in response to bleomycin (Munger et al., 1999). Moreover, TGF-β-targeted genes in the lungs of integrin $\beta6^{-/-}$mice are not significantly induced by bleomycin compared with wild-type mice. These data indicate that the inflammatory stimulus upregulates the expression of αvβ6 and consequently induces excessive activation of TGF-β that results in fibrosis. Since TGF-β dramatically upregulates expression of αvβ6 by primary airway epithelial cells in vitro (Wang et al., 1996), it is likely that bleomycin triggers a feed-forward mechanism for coordinately upregulating integrin expression and TGF-β generation. We suggest that fibrosis is the result of a failure to interrupt this feed-forward loop that is perpetuated by persistent ECM perturbation after injury or inflammation.

Accumulating evidence has suggested the important role of force-resistant ECM in contractile-force-dependent TGF-β activation. Activation by $\alpha_v\beta_6$ integrin requires LTBP-mediated incorporation of TGF-β into the ECM and the association of the β6 cytoplasmic domain with the actin cytoskeleton (Annes et al., 2004; Munger et al., 1999; Yoshinaga et al., 2008). Furthermore, contractile force is necessary for TGF-β activation by myofibroblasts (Wipff and Hinz, 2008). Thus, tensile force exerted by integrins across the LTBP—prodomain—TGF-β complex is necessary to change the conformation of the prodomain and free active TGF-β for receptor binding (Annes et al., 2004; Wipff and Hinz, 2008). A recent study by

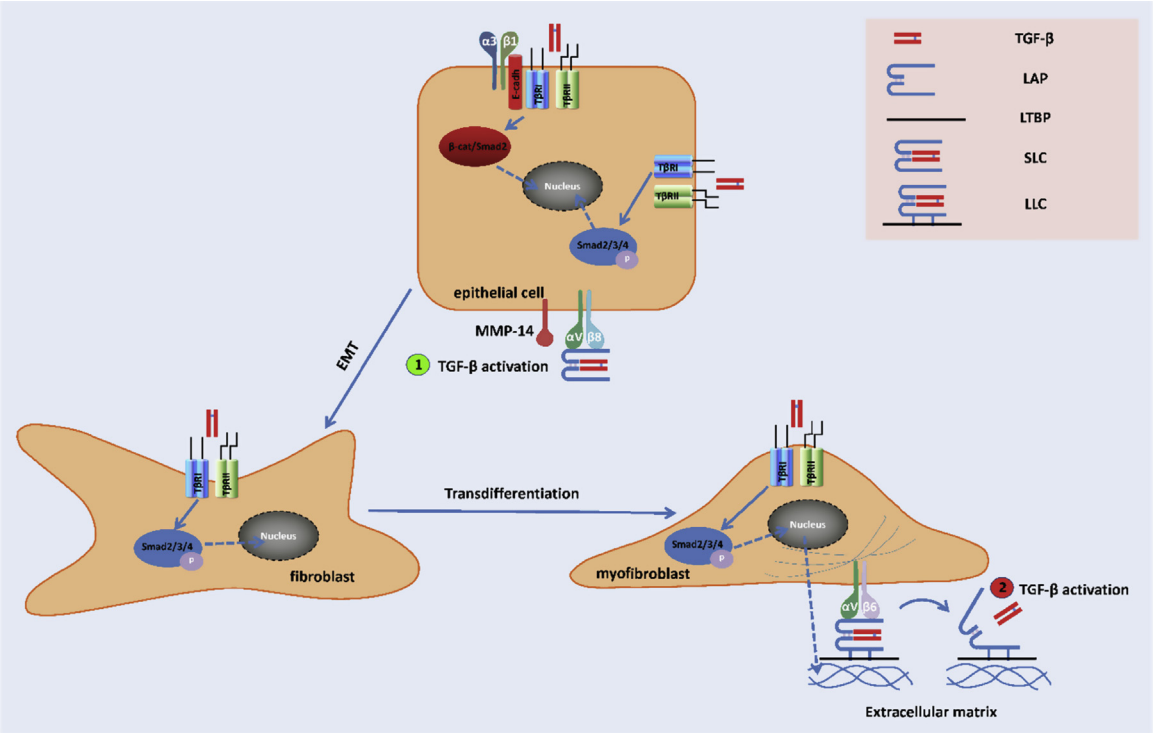

FIGURE 47.1 A model of integrin-mediated TGF-β activation during tissue/organ fibrosis. Epithelial cells activate TGF-β by enriching the latent complex through αvβ8-RGD association and recruiting membrane-bound matrix metalloproteinases (e.g., MMP-14) in proximity for further proteolytic cleavage ①. Active TGF-β can act on resident fibroblasts, inducing its transdifferentiation into myofibroblasts, which are the major contributor to excessive ECM (e.g., collagen) deposition and fibrosis. The myofibroblasts can further activate TGF-β in a contractile force-dependent manner through the αvβ6-RGD association ②. The active TGF-β can in turn act on epithelial cells, fibroblasts and myofibroblasts in a paracrine/autocrine manner, and thus form a feed-forward loop for a sustained TGF-β activation and fibrogenesis. Of note, sustained activation of TGF-β can also induce the epithelial–mesenchymal transition (EMT) of epithelial cells with the assistance of integrin α3β1, which forms a complex with TGF-β type I and II receptors (TβRI/II) and E-cadherin, facilitating β-catenin/Smad2 complex formation and nuclear translocation. LAP: latency-associated peptide; LTBP: latent TGF-β binding protein; SLC: small latent complex; LLC: large latent complex. *Figure is reused with authors' permission Xu, X, Zheng, L, Yuan, Q, Zhen, G, Crane, JL, Zhou, X, Cao, X. Transforming growth factor-β in stem cells and tissue homeostasis. Bone Res. 2018, 6, 2.*

Shi et al. has solved the structure of latent TGF-β and provided mechanistic insights into latency and force-dependent activation by integrins. By using multi- and single-wavelength anomalous diffraction, they found that the two prodomains (LAPs) form a ringlike structure with arms forming a "straitjacket" that fastens each TGF-β monomer. The RGD motifs of LAPs locate to each shoulder, binding to the α_v integrins. Upon applied tensile force, TGF-β1 is freed by the opening of the straitjacket and subsequently released from the prodomain and activated for receptor binding (Shi et al., 2011). At least four conditions need to be fulfilled to enable the cell traction-dependent integrin-mediated TGF-β1 activation: (1) the presence of the actin cytoskeleton to generate force and/or to provide mechanical resistance, (2) specific integrins that transmit this force on the LLC, (3) incorporation of latent TGF-β1 into the ECM as LLC, and (4) a second anchor point—i.e., an ECM that mechanically resists the cellular traction forces exerted on the LLC. Therefore, the activation of latent TGF-β1 is confined to cells expressing the appropriate integrin in a specific physiological/pathological context. Similar to contractile force-directed activation, a recent study from Coller's group revealed that intravascular shear force was also able to activate latent TGF-β1 released from platelets (Ahamed et al., 2008). Since TGF-β1 released from platelets during trauma or surgery might also contribute to the transient increase in plasma levels of plasminogen activator inhibitor-1 by activating endothelial cells (Aoki et al., 2001; Christ et al., 2005; Gando, 2001; Kluft et al., 1985; Pretorius et al., 2007; Rahr et al., 1995; Seeber et al., 1992), shear force–induced TGF-β1 activation likely coordinates the process of platelet activation to arrest hemorrhage and transient inhibition of fibrinolysis to allow an unopposed deposition of fibrin at the early stage of hemostasis. The shear force–activation model makes TGF-β1 a potential shear sensor as well as an effector. Hence, TGF-β1 may contribute to the vascular remodeling that occurs in response to changes in shear forces and maintain intravascular arterial shear within a limited range (Malek et al., 1999).

In addition to force-directed activation, integrins can also activate latent TGF-β1 with the assistance of protease. $\alpha_v\beta_8$ is believed to be able to recruit membrane-bound MT1-MMP to the latent complex. This close proximity promotes activation

of latent TGF-β1 by further proteolytic cleavage (Mu et al., 2002). Similarly, integrin $\alpha_v\beta_3$ has been proposed to act as a docking point for MMP-9 in metastatic breast cancer cells (Rolli et al., 2003) and for MMP-2 in melanoma cells (Brooks et al., 1996). Additionally, integrins can cluster with TGF-β-RII, thereby improving its availability to locally activate TGF-β1. Direct interaction with TGF-β-RII has been demonstrated for $\alpha_v\beta_3$ integrin upon stimulation with active TGF-β1 using a bioluminescence resonance energy transfer approach (Scaffidi et al., 2004) and immunoprecipitation. Interestingly, a similar interaction between different classes of latent TGF-β activator has also previously been suggested (Yehualaeshet et al., 1999)—the cell surface–associated proteins (CD36 and TSP-1) concentrate latent TGF-β on the membrane where it is subsequently activated by plasmin. This cell surface–enrichment theory might also explain why mice with null mutations in the genes encoding known protease activators thus far do not demonstrate any phenotype consistent with TGF-β deficiency. It is conceivable that protease activity is intricately modulated by its activators and inhibitors in vivo as well as the surface concentration of proteases, and a proper spatial arrangement of latent TGF-β1, proteases, and TGF-β receptor is a prerequisite for in vivo activation of TGF-β1 through proteolytic pathways.

The two sets of activation mechanisms by integrins may help explain some "contradictory" data about integrin-mediated TGF-β activation in different tissues/organs or disease models. The involvement of β integrins in the activation of TGF-β is equivocal, mainly because the deletion of β integrins usually presents contradictory phenotypes in different disease models. Deletion of β6 integrin has been reported to protect mice from bile duct ligation-induced hepatic fibrosis (Wang et al., 2007), while global deletion of β3, β5, or β6 integrins or the conditional deletion of β8 integrins in hepatic stellate cells cannot protect mice from carbon tetrachloride–induced hepatic fibrosis (Henderson et al., 2013). Because TGF-β activation in a bile duct ligation model is more likely to be contractile force-dependent, β6 anchorage to cytoskeleton is likely essential to ligand activation in the disease model, thereby conveying that β6 deletion is protective. Conversely, in carbon tetrachloride-induced hepatic fibrosis, excessive proteases are released due to extensive cytotoxic damage. In this case, integrin-mediated surface enrichment of proteases may be the major contributor to TGF-β activation, and hence single deletion of β subunits is not sufficient to disrupt superactivation of TGF-β. A similar theory can also explain the observation that integrin $\beta6^{-/-}$ mice have only minor lung fibrosis in response to bleomycin induction (105). Because the lungs are a highly contractile organ and its compliance is closely associated with the force-directed activation of TGF-β, β6 deletion directly disrupts intracellular anchorage and thus may significantly retard the activation of TGF-β and lung fibrosis.

Activation by osteoclasts

Latent TGF-β present in conditioned medium can be activated by mild acid treatment (pH = 4.5) (Lyons et al., 1988), which probably denatures LAP and thus dissociates TGF-β. In vivo, osteoclasts generate a similar pH during bone resorption when an integrin-dependent sealing zone is generated between the bone and the cell (Teitelbaum, 2000). Since the bone matrix deposited by osteoblasts contains abundant TGF-β in its latent form (approximately 200 μg/kg) (Hering et al., 2001; Seyedin et al., 1985), the acidic environment created by osteoclasts offers an ideal condition for TGF-β activation (Oreffo et al., 1989; Oursler, 1994). Bone-conditioned medium harvested from bone cultures during bone resorption usually contains an increased level of active TGF-β, and the isolated osteoclasts are able to activate bone-latent TGF-β in vitro (Pfeilschifter and Mundy, 1987; Tang et al., 2009). All this evidence indicates that latent TGF-β from surrounding bone tissue or stored in bone matrix becomes activated and released at this site during the bone resorption process. Alternatively, osteoclasts may activate latent TGF-β by secretion of proteases in the absence of a low-pH environment. Protease action at a pH higher than the optimum for lysosomal enzyme activity may sufficiently retard enzyme activity to prevent degradation of TGF-β. It is therefore possible that osteoclast-mediated activation of latent TGF-β occurs outside the low-pH resorption lacuna, resulting in the presence of active TGF-β within the immediate environment of the bone resorption site (Oursler, 1994). Since active TGF-β released during osteoclastic bone resorption is able to induce migration of osteogenic bone marrow mesenchymal stem cells (MSCs) to the bone resorption sites (Tang et al., 2009), osteoclast-mediated activation of TGF-β may represent one of the mechanisms that couples bone resorption to new bone formation. Indeed, our recent study has shown that osteoclast-mediated release of active TGF-β1 is essential for the recruitment of MSCs to the bone resorption site during the PTH-induced bone remodeling process. By inhibiting osteoclast bone resorption with alendronate, osteoblast recruitment is uncoupled from PTH-induced bone resorption (Wu et al., 2010).

Activation by reactive oxygen species

Another potential mechanism for in vivo activation of TGF-β involves ROS (Barcellos-Hoff et al., 1994; Barcellos-Hoff and Dix, 1996). Barcellos-Hoff and her coworkers have shown that ionizing radiation increases the level of active TGF-β in exposed tissues, and that a ROS-generating metal ion-catalyzed ascorbate system is also able to activate recombinant

latent TGF-β in vitro (Barcellos-Hoff et al., 1994; Barcellos-Hoff and Dix, 1996). ROS can stimulate the expression and secretion of TGF-β in a positive feedback loop in many types of cells, including hepatic stellate cells and hepatocytes (Boudreau et al., 2009; Proell et al., 2007). In addition, low-level photodynamic therapy (10 J/cm^2), which releases free radicals by light activation, has been shown to increase active TGF-β when applied to cultured smooth muscle cells (Statius van Eps and LaMuraglia, 1997). It is currently believed that site-specific oxidation of LAP elicits a conformational change in the latent complex releasing free active TGF-β (Barcellos-Hoff et al., 1994). ROS may also indirectly activate TGF-β through MMP activation (Wang et al., 2005). The activation of TGF-β in response to oxidative stress may reflect a need for the human body to produce TGF-β to maintain tissue homeostasis after perturbation such as inflammation. Indeed, the LAP/TGF-β1 complex has been proposed to function as an oxidative stress sensor (Jobling et al., 2006).

Transforming growth factor-β signaling

Active TGF-β ligands signal by binding and bringing together two transmembrane serine-threonine kinases, known as receptor types I and II (Derynck, 1994). In vertebrates, seven type I receptors, known as activin receptor-like kinases (ALKs) 1−7, and five type II receptors have been identified so far (Schmierer and Hill, 2007). TGF-β superfamily ligands bind to and signal through specific type I and type II receptor complexes. Accessory receptors, including the type III receptor TGF-βR III (also known as betaglycan), and endoglin, have also been identified (Chai et al., 2003; de Caestecker, 2004; Derynck and Feng, 1997; Javelaud and Mauviel, 2004; ten Dijke et al., 1996). Nevertheless, neither betaglycan nor endoglin is directly involved in intracellular TGF-β signaling due to the deficiency of a kinase domain. Instead, they affect the access of the TGF-β ligand to its receptors and consequently modulate intracellular signaling (Esparza-Lopez et al., 2001; Lopez-Casillas et al., 1993). Betaglycan binds all three isoforms of TGF-β, with a particularly higher affinity for TGF-β2. However, endoglin binds TGF-β1 and TGF-β3 with identical affinity, and it has weak affinity for TGF-β2 (Cheifetz et al., 1992; Yamashita et al., 1994).

Canonical signaling pathways (smad-mediated signaling)

In most contexts, active TGF-β signals through a canonical (Smad-mediated) pathway. Upon ligand activation, a type II receptor phosphorylates its type I receptor partner, which then transmits the signal by phosphorylation of intracellular downstream substrates—i.e., Smads. Eight Smads (Smad1 to Smad8) have been identified in vertebrates (Massague et al., 2005). They have conserved Mad homology 1 (MH1) and 2 (MH2) domains connected by a linker region. The N-terminal MH1 domain has a β-hairpin loop that can bind to DNA, and the C-terminal MH2 domain mediates interaction with other molecules (e.g., receptors and other Smad isoforms) (Moustakas and Heldin, 2009). The linker region is subject to posttranslational modifications that affect the interactions and stability of Smad molecules. Upon ligand stimulation and subsequent activation by type II receptors, type I receptors transmit intracellular signaling through phosphorylation of downstream effector Smads (Derynck and Zhang, 2003; Feng and Derynck, 2005; Massague et al., 2005). Specifically, Smad1/5/8 are activated by BMP receptors, whereas Smad2/3 are activated by TGF-β/activin/nodal receptors. These receptor-activated Smads (R-Smads) form heterotrimers with a common Smad (Smad4) shared by the TGF-β/activin/nodal and BMP signaling pathways, and translocate into the nucleus. The R-Smads, except Smad2, which has two extra sequences inserted in the MH1 domain perturbing its DNA binding affinity, can bind to preferred DNA sequences. The DNA sequence specificities of R-Smads add further diversity to the transcriptional responses of TGF-β signaling. Complexes of phosphorylated Smad2/3 and Smad4 bind to AGAC or its complement GTCT, known as a Smad-binding element (Dennler et al., 1998; Zawel et al., 1998). However, Smad4-pSmad1/5/8 complexes preferentially bind to GGCGCC or GGAGCC, known as the BMP-response element (BRE) (Katagiri et al., 2002; Korchynskyi and ten Dijke, 2002; Morikawa et al., 2011). Although most TGF-β signaling pathways go through phosphorylated R-Smads, not all transcriptional responses have Smad4 involvement. For example, in cultured epidermal keratinocytes, IκB kinase of the classical nuclear factor κB pathway recruits pSmad2/3 to a specific promoter region that drives cell differentiation (Descargues et al., 2008). R-Smads can regulate miRNA processing in a Smad4-independent and RNA-sequence-specific manner by associating with the p68/Drosha/DGCR8 miRNA processing complex (Davis et al. 2008, 2010).

Since TGF-β superfamily signaling requires the interaction of type I and type II receptors, the interplay between the canonical BMP and canonical TGF-β/activin signaling pathways has been noted (Hinck, 2012). The type 1 BMP receptors (ALK2/3/6) + BMPR2 specifically transduce BMP signals; the type 1 activin receptors (ALK4/7) specifically transduce signals from activin/activin-like ligands. In contrast, the type 2 receptors ACVR2A/B are shared between the BMP and activin pathways and elicit activation of Smad1/5/8 or Smad2/3 in response to BMP or activin-like ligands, respectively. TGF-β ligands elicit activation of Smad2/3 but do not share any receptors with BMPs or activin/activin-like ligands.

In addition, TGF-βs and BMPs bind and assemble their receptors in a distinct manner. TGF-β binds TβR-II first and then cross-links to TβR-I. This pattern was also adopted by activin (Attisano et al., 1996), suggesting that TGF-βs/activins assemble their receptors in an ordered manner (Massague, 1998). Conversely, BMPs and GDFs exhibit a much more heterogeneous pattern of cross-linking, with some binding to their receptors in a stepwise manner, while others exhibit weak affinity to a single receptor and instead cross-link to TβR-I and TβR-II simultaneously (Koenig et al., 1994; Liu et al., 1995; Nishitoh et al., 1996; Nohno et al., 1995; Penton et al., 1994; Yamashita et al., 1995). These findings indicate that TGF-β superfamily members might differ in how they bind and assemble their receptors into signaling complexes.

Notably, although TGF-β does not share or compete for receptors with BMPs, both strongly induce phosphorylation of Smad1/5/8 in many different cell types, including fibroblasts, endothelial cells, epithelial cells, and epithelium-derived cancer cells (Bharathy et al., 2008; Daly et al., 2008; Goumans et al., 2002; Liu et al., 2009; Wrighton et al., 2009b). Despite this common phosphorylation event, TGF-β cannot induce BMP-like transcriptional responses. Grönroos et al. found that although TGF-β is able to stimulate the phosphorylation of Smad1/5/8 in parallel with the classical induction of Smad2/3 phosphorylation, pSmad1/5 and pSmad3 can form complexes readily binding to BMP-responsive elements and mediate TGF-β-induced transcriptional repression on BMP responses (Gronroos et al., 2012). Therefore, Smad3 plays an important role in restricting TGF-β signaling to canonical transcriptional output and effectively prevents TGF-β from eliciting BMP-like "off-target" responses.

The DNA binding affinity of Smad complexes is not strong. Hence, they need to interact and cooperate with other DNA sequence-specific transcription factors to target specific downstream genes (Massague and Wotton, 2000). The requirement of DNA-binding cofactors either activates or represses transcription results in a context-dependent and cell type-specific response (Massague et al., 2005; Wrana and Attisano, 2000). The forkhead-box family member FoxH1 (previously known as Fast1) was the first identified transcription factor that facilitates Smad-mediated transcription. The Foxh1—Smad2/3—Smad4 complex binds to a composite site known as the "activin response element" on target differentiation genes in embryonic cells (Silvestri et al., 2008). Accredited to the advancement from ChIP-seq, various families of DNA-binding transcription factors that interact with Smads have been identified. These transcription factors cooperate with Smad complexes, targeting a specific subset of TGF-β-responsive genes for coordinated regulation of cellular activities (Massague and Gomis, 2006). Among the many factors utilizing Smad complexes as transcriptional cofactors, FOXH1 (Labbe et al., 1998), EOMES (Teo et al., 2011), OCT4 (Mullen et al., 2011), and NANOG (Suzuki et al., 2006; Vallier et al., 2009) are particularly involved in stem cells, while MYOD1 and PU.1 are more relevant to muscle cells and pro-B cells, respectively. These findings support the notion that the availability of cell type-specific cofactors determines the cellular response to TGF-β signaling by providing context and directing the transcriptional activity of Smad proteins. Smad-mediated assembly of basal transcription machinery is also dependent on chromatin conformation, and thus Smads interact with and recruit various chromatin-modifying enzymes to DNA (Ross and Hill, 2008; van Grunsven et al., 2005). Smad2/3 can interact with the histone acetyltransferases CBP/p300 and recruit basal transcription machinery, thus initiating transcription from the associated promoter (Feng et al., 1998; Janknecht et al., 1998). Alternatively, depending on the context, the Smad complex can recruit histone deacetylases (HDAC1/3/4/5/6) to remove acetyl residues on histone tails, and it thus condenses chromatin and represses transcription (Beyer et al., 2013).

In the unstimulated state, Smad proteins interact with components of the Ran GTPase export/import system (Watanabe et al., 2000) and the nuclear pore complex (Xu et al., 2002), resulting in the formation of a highly dynamic equilibrium in which unphosphorylated Smad proteins constantly shuttle between the nucleus and the cytoplasm (Hill, 2009). Upon phosphorylation of R-Smads and the formation of the heteromeric complex with co-Smad in the cytoplasm, the increased import rate and decreased export rate of the trimer lead to its accumulation in the nucleus. This increased nuclear retention is mediated by transcriptional cofactors such as TAZ and YAP, which are the downstream effectors of the Hippo pathway. This cross talk links the TGF-β and Hippo pathways and the sensing of cell density and cell polarity (Varelas et al. 2008, 2010). Protein phosphatases (e.g., PPMA1 or SCPs) can dephosphorylate R-Smads, leading to the disruption of the trimer and eventually turning off Smad signaling (Lin et al., 2006; Wrighton et al., 2009a).

Surface receptors are regulated by endocytosis and degraded by SMURF2 and other HECT E3 ligases (Di Guglielmo et al., 2003). Inhibitory Smads (I-Smads) such as Smad6 and Smad7 are transcriptional targets of TGF-β superfamily signaling and bind to activated receptors competing with R-Smad binding and recruiting the SMURF ubiquitin ligases, thus establishing a classical negative feedback loop (Hayashi et al., 1997; Nakao et al., 1997). Activated R-Smad proteins could also be degraded via the proteasome by ubiquitination through HECT E3 ligases such as SMURF1,2, NEDD4L, and WWP2 (Gao et al., 2009; Soond and Chantry, 2011; Zhu et al., 1999). R-Smad proteins contain multiple PY motifs in the linker region (Gao et al., 2009). The serine/threonine and proline residues of these PY motifs can be phosphorylated by ERK, GSK3 (Fuentealba et al., 2007), and CDKs 8 and 9 (Alarcon et al., 2009), thereby interacting with the WW domains

of HECT E3. R-Smads are subsequently degraded by the proteasome, and transcriptional activity is terminated. This provides a platform in which the duration of TGF-β family signaling integrates with other pathways such as insulin-like growth factor (IGF), fibroblast growth factor (FGF), and WNT.

TGF-β signaling can also be fine-tuned by association with other factors. Our recent study has shown that parathyroid hormone (PTH), which regulates calcium homeostasis and bone metabolism by binding to and activating a G-protein-coupled receptor, can induce the recruitment and colocalization of TβRII with β-arrestin, an adaptor protein involved in PTH receptor endocytosis, thus mediating the internalization of TβRII−PTH type 1 receptor (PTH1R) as a complex in osteoblasts (Qiu et al., 2010). The interaction of PTH and TGF-β signaling at the membrane receptor level may have significant physiological importance in maintaining tissue homeostasis, especially in coupling bone resorption to bone formation. We have demonstrated that the anabolic action of PTH on bone is dependent on active TGF-β1 released by PTH-mediated osteoclastic bone resorption (Wu et al., 2010). However, overproduction of active TGF-β ligand in the local microenvironment may blunt the migration of MSCs to the bone resorption sites for coupled bone formation (Tang et al., 2009). Through the endocytosis of the TβRII−PTH1R complex, PTH provides surveillance of the overactivation of TGF-β signaling so as to ensure proper MSC migration mediated by the local gradient of TGF-β.

Smad-independent signaling pathways

The Smad-independent signaling pathways of TGF-β are generally considered important effector pathways for tyrosine kinase receptors (Derynck and Zhang, 2003; Moustakas and Heldin, 2005; Zhang, 2009). TGF-β activates these non-Smad pathways through interactions of signaling mediators with type I/II receptors, either directly or through adaptor proteins. The Smad-mediated downstream gene expression may also activate non-Smad pathways. TGF-β can directly activate the Ras−Raf−MEK−ERK/MAPK pathway through the interaction of ShcA and the TGF-β receptor complex. In response to TGF-β, TGF-β type I receptor mediates tyrosine phosphorylation of ShcA, which then recruits Grb2 and Sos to form a complex, initiating Ras activation and consequently the ERK/MAPK signaling cascade (Lee et al., 2007). TGF-β can also activate TAK1 through TRAF6, a ubiquitin ligase that interacts with the TGF-β receptor complex, leading to induction of p38 and JNK MAPK signaling (Sorrentino et al., 2008; Yamashita et al., 2008). TGF-β also modulates the activities of the small GTPase proteins Rho, Rac, and Cdc42, which regulate cytoskeletal organization and gene expression (Bhowmick et al., 2001; Edlund et al., 2002; Ozdamar et al., 2005); however, the exact mechanism still remains to be explored. TGF-β-activated RhoA can activate its downstream targets ROCK and LIM kinase (Vardouli et al., 2005). TGF-β activates Akt through PI3K (Bakin et al., 2000; Shin et al., 2001) and consequently initiates signaling pathways—e.g., through mTOR—that play roles in cell survival, growth, migration, and invasion (Lamouille et al., 2012; Lamouille and Derynck, 2007). The roles of TGF-β-induced Smad-independent signaling in stem cells are still unclear and remain to be elucidated.

TGF-β can also cross talk with several other signaling pathways at the level of ligands, receptors, agonists, and antagonists, and thus elicits a context-dependent biological effect to meet specific needs during development or tissue repair (Ikushima and Miyazono, 2012).

Wnt is implicated in the stimulation of cell proliferation during embryonal development and tumorigenesis. Key molecules in the Wnt signaling pathway are the transcription factors β-catenin, T cell factor, and lymphoid enhancer factor (LEF). Smads form complexes with both LEF1 (Vincent et al., 2009) and β-catenin (Kim et al., 2009; Zhou et al., 2012) that enhance the induction of epithelial−mesenchymal transition (EMT). In addition, Smad7 forms a complex with β-catenin that is important for TGF-β-induced apoptosis (Edlund et al., 2005). Cross talk between the TGF-β superfamily and Wnt signaling pathways plays an essential role in dictating stem cell homeostasis in concert with combinatorial activities of other signaling pathways. A typical example of how cross talk between nodal/activin/Smad2/3, ERK/MAPK, and Wnt/GSK3β/β-catenin pathways affects the balance of self-renewal and the differentiation status of ESCs has recently been described by Singh et al. (Singh et al., 2012). Specifically, activation of PI3K/Akt signaling establishes conditions where activin A/Smad2/3 performs a pro-self-renewal function by activating target genes, such as Nanog. In the absence of PI3K signaling, Wnt effectors are activated by ERK targeting GSK3β and function in conjunction with Smad2/3 to promote differentiation. This signaling paradigm with convergence on Smad2/3 is believed to have far-reaching implications for cell fate decisions during early embryonic development.

PTH regulates calcium homeostasis and bone metabolism by binding to and activating a G-protein-coupled receptor. TβRII forms a complex with and phosphorylates the PTH receptor that modulates the internalization of the receptor complex. Specifically, PTH induces the recruitment of TβRII as an endocytic activator that phosphorylates the cytoplasmic domain of PTH1R and facilitates PTH-induced endocytosis of the PTH1R−TβRII complex and consequently results in downregulation of TGF-β signaling (Qiu et al., 2010).

The Notch pathway specifies cell fate determination during development. TGF-β induces several Notch receptor ligands including Jagged1 (Niimi et al., 2007; Zavadil et al., 2004), and Notch signaling induces TGF-β (Aoyagi-Ikeda et al., 2011). The cooperation between TGF-β and Notch signaling enhances EMT. However, there are reports that in certain cell types (e.g., esophageal epithelial cells), Notch signaling counteracts EMT by the induction of miR200 that targets ZEB and TGF-β (Ohashi et al., 2011).

The Hippo pathway senses cell density and controls cell growth via the transcriptional regulators TAZ and YAP. TAZ/YAP binds Smad complexes and sequesters them in the cytoplasm in high-density cell cultures, thereby attenuating TGF-β signaling (Varelas et al., 2008). Moreover, the Crumbs polarity complex interacts with TAZ/YAP and promotes their phosphorylation and cytoplasmic retention; disruption of the Crumbs complex enhances TGF-β signaling and promotes EMT (Varelas et al., 2010).

Transforming growth factor-β signaling and cell reprogramming

Adult somatic cells can be forced to reprogram into induced pluripotent stem cells (iPSCs) by ectopically expressing certain transcription factors. The classical iPSC techniques were pioneered by forced expression of the four "Yamanaka factors" *Oct4*, *Sox2*, *Klf4,* and *c-Myc* in mouse embryonic fibroblasts and thus reset the differentiation clock of these cells back to the pluripotent state equivalent to a blastocyst (Takahashi and Yamanaka, 2006). Many other reprogramming techniques and conditions were developed afterward, mainly aimed at decreasing the risk of genomic insertions of exogenous reprogramming factors or to increase the efficiency of the reprogramming process. Because the four "Yamanaka" factors orchestrate to inhibit the TGF-β signaling pathway that induces EMT through Snails, factors that antagonize TGF-β signaling are believed to enhance reprogramming. Indeed, small molecules that can selectively inhibit TGF-β type I receptor kinases enhance iPSC induction and can replace the requirement of Sox2 for iPSC induction. Inhibition of TGF-β signaling in partially reprogrammed iPSCs even induces Nanog expression and ultimately promotes full reprogramming (Ichida et al., 2009; Lin et al., 2009; Maherali and Hochedlinger, 2009). Like small molecules, Smad7, one of the I-Smad proteins, can also replace *Sox2* to enhance the reprogramming process (Li et al., 2010). Conversely, either treating reprogramming iPSCs with TGF-β or introducing an activated TGF-β type I receptor decreases reprogramming efficiency (Li et al., 2011; Maherali and Hochedlinger, 2009). Furthermore, miRNA expression that inhibits TGF-β signaling and EMT enhances iPSC reprogramming (Li et al., 2011; Miyoshi et al., 2011; Subramanyam et al., 2011). Therefore, TGF-β signaling suppresses somatic cell reprogramming, possibly by induction of EMT, although it is important for ESC self-renewal. Conversely, BMP signaling can induce the mesenchymal−epithelial transition (MET) process, a reversal process to EMT, and thus counteracts TGF-β stimulation in some contexts and promotes reprogramming into iPSCs (Li et al., 2010; Samavarchi-Tehrani et al., 2010).

Transforming growth factor-β signaling in mesenchymal stem cells

The differentiation potential of MSCs depends on the niche where they locate. The proliferation of human MSCs can be stimulated by Wnt or TGF-β signaling (Baksh et al., 2007; Boland et al., 2004; Jian et al., 2006). TGF-β1 induces Smad3-dependent nuclear accumulation of β-catenin, thereby stimulating MSC proliferation. On the other hand, BMP2 antagonizes Wnt3a signaling and inhibits the proliferation of MSCs through interaction of Smad1/5 with Dishevelled-1(Liu et al., 2006). In addition to proliferation, TGF-β signaling directs the differentiation fate of MSCs (Roelen and Dijke, 2003). BMPs can induce differentiation of MSCs into chondroblasts or osteoblasts in vitro. TGF-β and activin also promote chondroblast differentiation at early stages, whereas TGF-β inhibits osteoblast maturation at late stages in differentiation (Roelen and Dijke, 2003). Hence, inhibition of TGF-β/activin signaling strongly enhances osteoblast maturation (Maeda et al., 2004). These inhibitory effects of TGF-β/activin signaling on MSC differentiation are possibly mediated by the induction of expression of inhibitory Smads, such as Smad6, that in turn repress BMP signaling (Lin et al., 2003). In addition, BMP7 has been shown to induce the generation of brown fat from MSCs in the absence of the normally required hormonal induction (Tseng et al., 2008). TGF-β is also involved in cardiomyocyte lineage differentiation of MSCs. In human MSCs, TGF-β treatment induces the expression of cardiomyocyte markers including α-smooth muscle actin, myocardin, and calponin 1 along with the Notch ligand, Jagged 1. Increased expression of these genes is Smad3- and Rho kinase-dependent. Prevention of Jagged 1 expression blocks the expression of cardiomyocyte genes, suggesting that Jagged 1 plays an important role in the TGF-β-induced expression of cardiomyocyte marker genes (Kurpinski et al., 2010). These studies implicate that the microenvironment is critical for the induction of MSC differentiation into different lineages. Considering the complexity of the bone marrow niche and the involvement of multiple cell-secreted or bone-matrix-derived factors in the determination of cell fate, it is more likely that TGF-β functions as a pleiotropic growth

factor that reactivates quiescent stem cells into transient amplification in response to environmental cues (e.g., ECM perturbation). In the meantime, TGF-β acts as a promigratory factor recruiting MSCs to the sites where the cell fate is ultimately determined, in consultation with other niche-specific factors, to meet the tissue need.

Normal adult bone undergoes continual remodeling by precisely coordinating the activities of osteoblasts and osteoclasts. Osteoblasts derived from bone marrow MSCs deposit calcified bone matrix, while osteoclasts, which are multinucleated cells derived from macrophages/monocytes in the hematopoietic stem cell (HSC) lineage, resorb bone (Bianco et al., 2013; Zaidi, 2007). Factors released from bone matrix during osteoclastic bone resorption orchestrate the migration of MSCs to the resorptive surfaces of the bone. Particularly, osteoclastic bone resorption releases and activates TGF-β1 previously stored in the bone matrix, which recruits bone MSCs to active bone remodeling sites through the canonical pSmad2/3 signaling pathway. TGF-β recruits MSCs in a gradient-dependent manner—i.e., osteoclastic bone resorption induces the activation of TGF-β1, which diffuses from the bone resorption site and acts as a chemoattractant for bone marrow stromal cells (BMSCs). Osteoblastic progenitors sense the TGF-β1 gradient and subsequently migrate to the bone resorption site, where they are induced to differentiate into osteoblasts in response to other environmental factors such as bone matrix-derived IGF 1 (IGF-1) (Xian et al., 2012). Interestingly, either overactivation or inhibition of TGF-β signaling that distorts the local TGF-β gradient may impede the migration of MSCs to the normal bone remodeling surfaces. With this hypothesis, we have delineated the pathogenesis of Camurati−Engelmann disease (CED), in which mutations in LAP cause conformational dissociation (Janssens et al., 2005), resulting in increased release of activated TGF-β1 and distortion of resorption-induced TGF-β1 gradients. Due to inadequate recruitment of BMSCs to sites of resorption, poor-quality bone is formed with unfilled resorbed areas and haphazard sclerotic areas (Tang et al., 2009). This theory has also been expanded to explain the pathogenesis of osteoarthritis (OA), in which enhanced osteoclastic bone resorption caused by joint instability results in the release of excessive TGF-β1. The pathologically high level of TGF-β1 ligand in the tibial subchondral bone distorts the physiological TGF-β1 gradients, leading to osteoblastic progenitor aggregation in the bone marrow with compromised bone formation capability ("osteoid islet"). Aberrant bone formation in the subchondral bone in turn causes uneven distribution of stress on the articular cartilage, and in a feed-forward manner leads to cartilage degeneration (Zhen et al., 2013). In addition, we have demonstrated in vivo that the anabolic action of PTH on bone is dependent on the active TGF-β1 released during osteoclastic bone resorption. By inhibition of osteoclastic bone resorption with alendronate, the depleted active TGF-β1 released from bone matrix is insufficient to recruit MSCs to the proper resorptive sites, thus impairing the anabolic action of PTH on bone (Wu et al., 2010).

Active TGF-β also controls the mobilization and recruitment of MSCs to participate in tissue repair. A recent study of ours has shown that TGF-βs were activated in the vascular matrix in both rat and mouse models of mechanical injury of arteries. The active TGF-β released from injured vessels induced the migration of MSCs and the cascade expression of monocyte chemotactic protein-1 (MCP-1), which amplified the signal for migration. Specifically, sustained activation of TGF-β was observed in peripheral blood, and $Sca1^{+}CD29^{+}CD11b^{-}CD45^{-}$ MSCs, of which 91% were also $nestin^{+}$, were mobilized to peripheral blood and migrated to the remodeling arteries. The MSCs were noted to differentiate into endothelial cells for reendothelialization and myofibroblastic cells to form thick neointima. Intravenous injection of recombinant active TGF-β1 in uninjured mice was also sufficient to rapidly mobilize MSCs into circulation. Blockade of TGF-β signaling with TGF-β type I receptor kinase inhibitor significantly attenuated the mobilization and recruitment of MSCs to the injured arteries (Wan et al., 2012). These findings strongly indicate that TGF-β is an injury-activated messenger essential for the mobilization and recruitment of MSCs to participate in tissue repair/remodeling.

Consistently, our study on the pathogenesis of asthma demonstrates the involvement of TGF-β1 in MSC migration. By using a cockroach allergen-induced asthma mouse model, we found increased MSCs, TGF-β1 activation, and downstream signaling in the lungs of CRE (cockroach extract)-treated mice. Further, in vitro transwell assay confirmed that TGF-β1 released from allergen-activated epithelium functions as the primary chemoattractant that induces MSC migration. Consistently, by either intravenous injection of GFP^{+} MSCs (sorted from the bone marrow of Nestin-GFP mice) to CRE-treated mice, or directly immunizing Nestin-GFP mice with CRE, we observed significantly increased accumulation of GFP^{+} MSCs in asthma airways. Importantly, the airway accumulation of MSCs was significantly attenuated by systemic administration of a TGF-β1 neutralization antibody. Taken together, we believe that TGF-β1 is a primary promigratory factor released into the circulation from the injured vessels of the CRE-challenged lung tissue. It mediates the mobilization of MSCs to the circulation and further recruits these cells to the perturbed airways in asthma, likely to participate in tissue repair (Gao et al., 2014).

Interestingly, one study from Mao's group has also demonstrated the cell-homing capacity of TGF-β3 in the functional regeneration of the articular surface of the rabbit synovial joint (Lee et al., 2010). By replacing the excised proximal humeral condyles of skeletally mature rabbits with cell-free bioscaffolds spatially infused with TGF-β3-adsorbed hydrogel, weight-bearing and locomotion of the rabbits were resumed 3−4 weeks after surgery. Histological and mechanical analysis

of the joint revealed that the TGF-β3-infused bioscaffolds had recruited more cells than did spontaneous cell migration without TGF-β3. As a result, TGF-β3-infused bioscaffolds were fully covered with avascular hyaline cartilage and integrated with regenerated subchondral bone that had well-defined blood vessels 4 months after surgery. On the contrary, TGF-β3-free bioscaffolds had only scattered cartilage formation with compromised compressive and shear properties. It should be noted the that the lineage of the recruited endogenous cells was not delineated. However, this study further underscores the importance of TGF-β-mediated cell homing in tissue regeneration.

In addition to the mobilization and recruitment of MSCs to meet tissue needs, TGF-β mediates the homing of bone marrow-derived human MSCs to glioma stem cells (GSCs) (Shinojima et al., 2013). By using glioma models, Shinojima et al. found that TGF-β attracts BM-hMSCs via TGF-β receptors (TGFβRs). Intravascularly administered BM-hMSCs home to GSC-xenografts that express TGF-β. BM-hMSCs carrying the oncolytic adenovirus Delta-24-RGD prolonged the survival of TGF-β-secreting GSC xenografts, and this effect was abrogated by the inhibition of TGFβR on BM-hMSCs. These data show that the TGF-β/TGFβR axis can mediate the tropism of BM-hMSCs for GSCs, and TGF-β may serve as a predictor for patients in whom BM-hMSC delivery could be effective (Shinojima et al., 2013).

Transforming growth factor-β signaling and bone remodeling

The musculoskeletal system is dynamic in that it undergoes continual adaptations during vertebrate life to attain and preserve skeletal size, shape, and microstructure as well as regulate mineral homeostasis. In addition, its matrix is a major reservoir of growth factors whose bioavailability and temporal and spatial activation modulate the balance between normal physiology and pathology of tissue/organs involved. Skeletal homeostasis is maintained by intricate regulation of the bone remodeling process. A typical bone remodeling cycle consists of three distinct phases: (1) initiation phase, during which osteoclasts are formed and resorb damaged bone; (2) reversal phase, the transition of osteoclast to osteoblast activity; and (3) formation phase, when osteoblasts rebuild an equivalent amount of bone to that resorbed (Crane and Cao, 2014). Termination of osteoclast bone resorption and recruitment/differentiation of MSCs are generally recognized as essential steps in the reversal phase.

Transforming growth factor-β as the coupler of bone resorption and formation

Osteoblasts are derived from bone marrow MSCs (Bianco et al., 2013). Ex vivo mouse MSCs can be identified based on the absence of hematopoietic and endothelial markers and the presence of PDGFRa (Morikawa et al., 2009; Omatsu et al., 2010; Park et al., 2012). PDGFRa^{+} Sca-1^{-}CD45^{-}Ter119^{-} cells also express high levels of HSC niche factors *Cxcl12* and Stem cell factor (*Scf*) (Morikawa et al., 2009; Omatsu et al., 2010); hence they not only contribute to osteoblast and adipocyte lineage (Omatsu et al., 2010) but also constitute the cellular component of the HSC niche. Cells that express the Nestin-GFP transgene (Nes-GFP) contain all of the mesenchymal progenitor activity (fibroblastic colony-forming units; CFU-Fs) in mouse bone marrow (Kunisaki et al., 2013; Mendez-Ferrer et al., 2010). These Nes-GFP^{+} cells segregate with distinct vessels in vivo. The Nes-GFP bright cells, which exclusively locate along arterioles, are much rarer than the reticular Nes-GFP dim cells largely associated with sinusoids. Nes-GFP bright cells are quiescent, contain the most CFU-Fs, and closely associate with HSC quiescence and maintenance in bone marrow (Kunisaki et al., 2013). Notably, a recent study reported that the number of both Nes-GFP bright and Nes-GFP dim cells significantly decreased in adult endochondral bone, and only a small number of Nes-GFP dim cells were detectable in adult bone marrow (Ono et al., 2014). These data indicate that Nestin^{+} MSCs may be more relevant to endochondral ossification during development than the skeletal remodeling process in adulthood, or the expression of Nestin is transient in MSCs. The Morrison group has demonstrated that leptin receptor (LepR) is a marker that highly enriches bone marrow MSCs, accounting for 94% of adult bone marrow CFU-Fs (Zheng and Geiger, 2014). LepR^{+} cells are Scf-GFP^{+}, Cxcl12^{-}DsRed^{high}, and Nes-GFP dim. They emerge postnatally and give rise to most bone and adipocytes formed in adult bone marrow. LepR^{+} cells are normally quiescent, but they transiently proliferate to participate in bone regeneration after irradiation or fracture (Zheng and Geiger, 2014). Therefore, LepR^{+} cells may represent the major cellular source of bone and adipocytes in adult bone marrow and possibly account for the largest proportion of MSCs that participate in the bone remodeling process and maintain HSCs in adult bone marrow (Ding et al., 2012).

To overcome the challenge during evolution of vertebrate animals transitioning from ocean to land, cytokines and growth factors were likely selected to deposit in the bone matrix during bone formation. A large reservoir of factors in the bone matrix becomes available during osteoclastic bone resorption to induce recruitment and differentiation of MSCs and limit further osteoclastic resorption, thereby coupling bone resorption and formation. A critical step of coupled bone remodeling is to recruit MSCs to bone resorption sites. Vertebrate TGF-βs 1-3, which appear to have no counterparts in

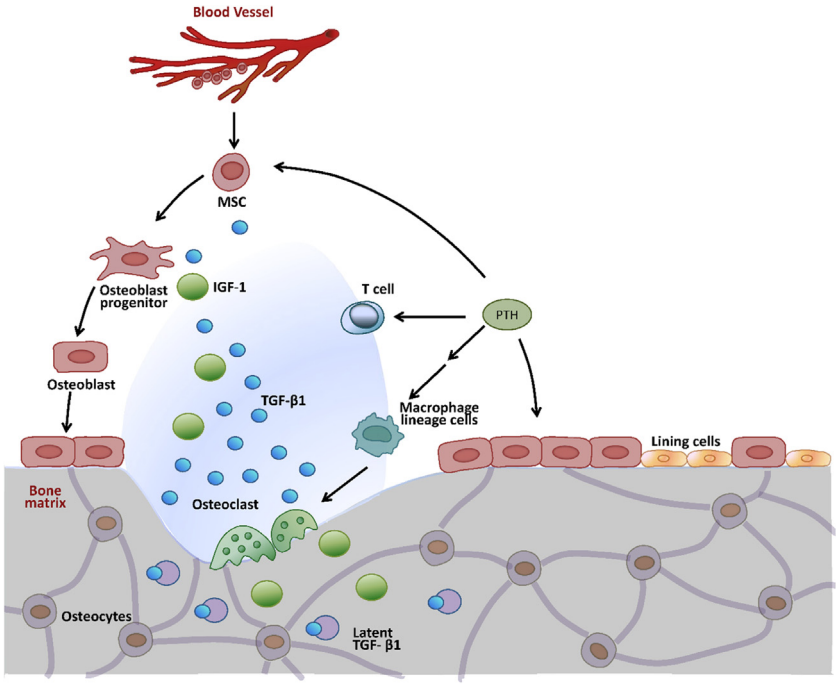

FIGURE 47.2 Activation of TGF-β recruits mesenchymal stem cells (MSCs) during bone remodeling. TGF-β1 is released from the bone matrix and activated during osteoclast-mediated bone resorption, creating a gradient. TGF-β1 induces migration of MSCs to the bone remodeling sites to couple bone resorption and formation. The bone-resorptive microenvironment also provides signals (e.g., IGF-1) that direct the lineage-specific differentiation of MSCs. In addition, PTH orchestrates signaling of local factors and thus regulates cellular activities, including those of MSCs, T cells, and other PTH-responsive cells in the bone marrow to coordinate bone remodeling. *Figure is reused with authors' permission Xu, X, Zheng, L, Yuan, Q, Zhen, G, Crane, JL, Zhou, X, Cao, X. Transforming growth factor-β in stem cells and tissue homeostasis. Bone Res. 2018, 6, 2.*

nematodes (*Caenorhabditis elegans*) or insects (*Drosophila*) (Lapraz et al., 2006), may have evolved to serve as the major coupling factor that coordinates the dynamic bone remodeling process of vertebrate mammals after they transitioned from ocean to land (Fig. 47.2). A more complex mechanical loading to terrestrial vertebrates may promote the release of active TGF-β from the bone matrix (Neidlinger-Wilke et al., 1995) for a coupled bone remodeling. In addition, osteoclastic bone resorption evolved by terrestrial vertebrates plays an essential role in activating TGF-β during bone remodeling. Osteoclasts can form an integrin-dependent sealing zone between bone and cell (Teitelbaum, 2000), generating an acidic environment ideal for the activation of latent TGF-β richly deposited in the bone matrix (Hering et al., 2001; Oreffo et al., 1989; Oursler, 1994; Seyedin et al., 1985). Osteoclasts can also activate latent TGF-β by secretion of proteases in the absence of a low-pH environment (Oursler, 1994), leading to proteolytic cleavage of LTBP1 (Dallas et al., 2002) and enrichment of active TGF-β within the immediate environment of the bone resorption site. More importantly, our recent work has clearly demonstrated that TGF-β1, as one of the most abundant bone matrix cytokines (Engler et al., 2006), is activated during osteoclastic bone resorption and induces the migration of MSCs to bone remodeling sites via Smad-dependent signaling (Tang et al., 2009). TGF-β can also promote the migration of MSCs via the JNK pathway and induced expression of MCP-1, although these findings have only been reported in an artery injury model (Wan et al., 2012). In parallel, other growth factors released from bone matrix during resorption, such as IGF-1, promote osteoblast differentiation of MSCs (Xian et al., 2012). Studies of the effects of TGF-β1 on osteoclast activity show that high concentrations and prolonged exposure to active TGF-β1 inhibit migration of osteoclast precursors (macrophages/monocytes) (Kim et al., 2006). Hence, the gradient of TGF-β1 generated at the resorptive site inhibits further recruitment of osteoclast precursors and avoids excessive bone resorption. This is particularly important for coupled bone remodeling since continuously elevated osteoclastic activity reduces the quality of bone and results in pathologic conditions.

Interestingly, osteoblast bone formation still exists in vertebrates that have defective osteoclast function to release sufficient bone matrix-derived growth factors, indicating that osteoclasts per se may also be able to produce coupling factor(s) (Martin and Sims, 2005). These potential coupling factors released by osteoclast include Sphingosine 1-phosphate, platelet-derived growth factor-bb (PDGF-bb), and the EphB4.ephrin-B2 bidirectional signaling complex. Sphingosine 1-phosphate is secreted by osteoclasts and functions to recruit osteoblasts and promote the survival of mature osteoblasts (Pederson et al., 2008). Osteoclasts can also secrete PDGF-bb, which not only induces the migration and

osteogenic differentiation of MSCs (Kreja et al., 2010) but also controls osteoblast chemotaxis via PDGF-bb/PDGFR-beta signaling (Sanchez-Fernandez et al., 2008). More importantly, our recent findings have shown that PDGF-bb secreted by preosteoclasts is able to induce the formation of CD31(hi)Emcn(hi) vessel, a specific vessel subtype that functions to couple angiogenesis and osteogenesis during bone modeling and remodeling (Xie et al., 2014). EphB4 receptors are expressed on osteoblasts, whereas the ligand ephrin-B2 is expressed by osteoclasts. Signaling through EphB4 receptors induces osteoblastic differentiation, whereas signaling through ephrin-B2 inhibits osteoclastogenesis (Zhao et al., 2006). The bidirectional signaling complex of EphB4−ephrin-B2 functions to activate osteoblastic bone formation and inhibit osteoclastic bone resorption simultaneously, and this is particularly critical at the transition point of bone remodeling. Notably, direct cell contact between osteoblasts and osteoclasts within the BMU is not always possible, and osteoblastic bone formation could sustain long after osteoclasts vacate the resorption site. This fact suggests that both contact-dependent and contact-independent signals are involved in a coupled bone remodeling process.

In addition, elasticity of the bone matrix plays an important role, with a stiffer matrix directing differentiation of MSCs into osteoblasts (Engler et al., 2006). At fresh bone resorption sites, the bone mineral matrix without lining cells is exposed, providing a stiff elastic microenvironment in favor of osteoblastic differentiation. Blood vessels are in close proximity to bone remodeling, and a complex interrelationship between angiogenesis and osteogenesis has been reported (Chim et al., 2013). Basic fibroblast growth factor (FGF2) is a potent mitogenic factor that can promote angiogenesis by inducing endothelial cell proliferation, migration, and the expression of necessary angiogenic factors including proteases, growth factors, and integrins (Beck and D'Amore, 1997; Klein et al., 1996; Klein et al., 1993; Seghezzi et al., 1998). TGF-β has been shown to enhance FGF2 production in osteoblasts (Sabbieti et al. 1999, 2005; Sobue et al., 2002). In aortic endothelial cells, TGF-β stimulation of an ALK5/TβRII-Smad2 complex enhances expression of vascular endothelial growth factor (VEGF) (Shao et al., 2009), which is a strong proangiogenic factor. Whether a similar mechanism of action exists in cells in the bone remodeling site remains to be investigated. HSCs are present in the same niche as MSCs (Morrison and Scadden, 2014). While MSCs and osteoblast precursors can influence the fate of HSCs by producing several key maintenance factors including CXC chemokine ligand 12, angiopoietin 1, KIT ligand, and vascular cell adhesion molecule 1 (Calvi et al., 2003; Hsu and Fuchs, 2012; Mendez-Ferrer et al., 2010; Morrison and Scadden, 2014), the opposite remains unknown.

Parathyroid hormone as an endocrine regulator of skeletal transforming growth factor-β signaling

The parathyroid gland evolved in amphibians (Okabe and Graham, 2004) and represents the transition of aquatic to terrestrial life. PTH is the major endocrine hormone produced by the parathyroid gland, which regulates calcium homeostasis. Interestingly, permanent emergence of osteoclasts and bone resorption is also observed as vertebrates transitioned to land (Glowacki et al., 1986; Moss, 1965; Weiss and Watabe, 1979; Witten and Huysseune, 2009) and favors survival by a lightening of skeletal weight and a ready source of calcium. In addition to the critical role of PTH mobilizing calcium in times of need, it has also been shown to orchestrate the signaling of local bone factors including TGF-β, Wnts, BMP, and IGF-1, integrating systemic control of bone remodeling (Bikle et al., 2002; Canalis et al., 1989; Lombardi et al., 2010; Miyakoshi et al., 2001; Pfeilschifter et al., 1995; Qiu et al., 2010; Wan et al., 2008; Watson et al., 1995; Yu et al., 2012) (Fig. 47.2).

PTH orchestrates the signaling of many local factors that determine the fate of MSCs. Endocytosis of growth factors and G-protein-coupled receptors is known to integrate different signaling pathways (Polo and Di Fiore, 2006). PTH can induce the recruitment of TβRII as an endocytic activator (Qiu et al., 2010). TβRII directly phosphorylates the cytoplasmic domain of PTH1R and facilitates PTH-induced endocytosis of a PTH1R−TβRII complex, resulting in downregulation of TGF-β effects, likely limiting further MSC recruitment. Concomitantly, PTH stimulates the commitment of MSCs to the osteoblast lineage by enhancing BMP and Wnt signaling. Low-density lipoprotein-related protein 6 (LRP6) serves as a coreceptor in the canonical Wnt pathway (He et al., 2004) and interacts with BMP signaling (Itasaki and Hoppler, 2010). PTH has been shown to recruit LRP6 as a coreceptor, which recruits axin from the cytoplasm to stabilize β-catenin (Wan et al., 2008). PTH binding to PTH1R can also induce endocytosis of a PTH1R/LRP6 complex, resulting in enhanced BMP-pSmad1 downstream signaling, and ultimately promotes osteoblastic differentiation of MSCs (Yu et al., 2012). Deleting LRP6 in mature osteoblasts in mice results in a loss of anabolic response to PTH (Li et al., 2013). PTH can expand Nestin-positive MSC populations (Calvi et al., 2003; Jiang et al., 2002; Mendez-Ferrer et al., 2010), although the precise mechanism of action remains unclear. PTH enhancement of MSC transient amplification, differentiation, and function is a part of the integration of the signaling networks of local factors for the spatial-temporal regulation of bone remodeling.

PTH can modify other cells in the bone marrow microenvironment. Intermittent PTH treatment increases the number of osteoblasts by converting lining cells to active osteoblasts (Kim et al., 2012). PTH stimulates bone marrow $CD8^+$ T cells to produce large amounts of Wnt10b, which activates Wnt signaling in MSCs and osteoblast precursors, thus increasing osteoblast proliferation and differentiation (Terauchi et al., 2009). PTH has also been shown to improve the bone marrow microenvironment by spatially relocating small blood vessels in proximity to sites of new bone formation, possibly via upregulation of VEGF-A and neuropilins 1 and 2 (Prisby et al., 2011). The consequent proximity of blood vessels allows more efficient delivery of nutrients to support new bone formation.

Taken together, TGF-β is a critical factor in the temporal and spatial coupling of bone remodeling. PTH, the hormone with evolutionary significance, may act as the major endocrine regulator of bone remodeling by orchestrating the signaling of many pathways and directing the fate of MSC.

Musculoskeletal pathologies associated with aberrant transforming growth factor-β signaling

Temporal and spatial regulation of TGF-β activation is essential for maintenance of musculoskeletal tissue homeostasis and regeneration of damaged tissue by recruiting stem/progenitor cells to the right place at the right time, whereas sustained abnormal activation of TGF-β may lead to pathological conditions due to excessive recruitment of stem/progenitor cells and their subsequent differentiation.

Osteoarthritis associated with aberrant activation of transforming growth factor-β signaling in the subchondral bone

OA is a degenerative joint disease characterized by progressive articular cartilage degradation, subchondral bone sclerosis, reduced mobility, and debilitating joint pain. Although it is still under debate whether OA starts in cartilage or bone (Goldring and Goldring, 2010), subchondral bone sclerosis has now been recognized as a major contributor to cartilage degeneration by generating unevenly distributed stress on the articular cartilage, leading to its gradual deterioration (Newberry et al., 1997; Radin and Rose, 1986). Recent evidence has demonstrated that the onset of OA is associated with increased bone remodeling in the early stage (Intema et al., 2010; Sniekers et al., 2008), subsequent slow turnover/densification of the subchondral plate, and complete loss of cartilage (Burr and Gallant, 2012; Grynpas et al., 1991; Karsdal et al., 2008). Notably, subchondral sclerosis without a precedent stage of increased bone remodeling does not lead to progressive OA in experimental models (Burr and Gallant, 2012; Huebner et al., 2002). Therefore, both early-stage increased bone loss and late-stage subchondral densification are important for the pathogenesis of cartilage degeneration in OA. Importantly, our recent findings have shown that this spatial and temporal separation of subchondral bone phenotype is likely initiated by the abnormal activation of TGF-β (Zhen et al., 2013).

Bone is constantly remodeled or modeled in response to changes in mechanical loading, particularly when joint stability is decreased such as occurs during aging or with ligament injury or obesity. As osteocytes are the principal mechanosensors, aberrant mechanical loading may result in alterations in the release of signaling molecules such as OPG, RANKL, and sclerostin to increase osteoclast activity and turnover rate in OA subchondral bone. In the postsurgery of anterior cruciate ligament transection (ACLT) OA mice, osteoclastic bone resorption in the subchondral bone was significantly increased as early as 7 days. The excessive release of active TGF-β1 to the bone marrow caused by osteoclastic bone resorption recruits $nestin^+$ MSCs to form marrow osteoid islets. Notably, osteoclastic bone resorption was temporally and spatially separated from TGF-β1-induced recruitment of MSCs in the marrow, resulting in aberrant bone formation. The uncoupled bone remodeling process in subchondral bone alters its microarchitecture and eventually compromises the functional integrity of the "subchondral bone-articular cartilage complex" (Burr and Radin, 2003). This notion was further supported by the development of OA-like changes in the CED mouse model with aberrant activation of TGF-β1 (Zhen et al., 2013).

Biomechanical factors play an essential role in the degenerative process of articular cartilage, which is maintained in a mechanically active environment. Subchondral bone volume and subchondral bone plate (SBP) thickness fluctuate substantially in ACLT rodent models. In human OA joints, SBP is markedly thicker relative to those of healthy subjects (Burr and Gallant, 2012). Computerized stimulation models of human knee OA suggest that expansion of 1%−2% subchondral bone significantly changes the distribution of articular cartilage stress. In addition, the formation of osteoid islets and aberrant bone formation induced by TGF-β1 changes the microarchitecture of subchondral bone (Zhen et al., 2013). Although intermittent articular loading seems necessary for normal cartilage metabolism, abnormal loading patterns

mediated by TGF-β1 may irregularly induce progressive cartilage degeneration (Ni et al., 2011). Cell death, water content, and fibronectin content in cartilage explants were increased in a load-duration and magnitude-dependent manner (Farquhar et al., 1996). Chondrocytes in the superficial zone are more vulnerable to repetitive mechanical loading than those in the deeper layer of articular cartilage (Chen et al., 2003; Clements et al., 2001). Vigorous cyclic loading also leads to cartilage matrix damage such as breakage of collagen fiber and proteoglycan depletion, possibly due to increased MMP-3 (Lin et al., 2004). Therefore, fluctuation of the mechanical property of subchondral bone inevitably affects its capacity to dissipate mechanical stimuli from the joint surface and consequently leads to cartilage degeneration in OA. The loss of cartilage integrity will in turn increase the overload of the joint, leading to subchondral bone sclerosis as the joint attempts to adapt to the increased loads. Ultimately, this positive feedback loop causes progressive deterioration of articular cartilage in clinically evident OA (Burr and Gallant, 2012).

In addition to induction of aberrant bone formation in the subchondral bone of OA, excessive activation of TGF-β can affect multiple joint tissues. TGF-β signaling is crucial in normal cartilage development and the maintenance of articular chondrocyte homeostasis in synovial joints (Serra et al., 1997; Yang et al., 2001). However, recent findings by van der Kraan et al. have shown that the aging process may switch TGF-β signaling in chondrocytes from the canonical anabolic ALK5-Smad2/3 pathway to the catabolic ALK1-Smad1/5/8 pathway (van der Kraan et al., 2012), suggesting that excessive activation of TGF-β in aged individuals might actually exacerbate cartilage deterioration. Excessive TGF-β also induces synovial fibrosis and osteophyte formation (Scharstuhl et al., 2003; van Beuningen et al., 1994), which are common features of OA and also closely associated with its progression.

Intriguingly, our recent study on rheumatoid arthritis (RA) also showed an aberrant activation of TGF-β in the subchondral bone marrow of RA-afflicted knee joints. Either systemic or local blockade of TGF-β activity in the subchondral bone attenuated articular cartilage degeneration in RA. Moreover, conditional deletion of TGF-β receptor II (Tgfbr2) in nestin^{+} cells effectively halted progression of RA joint destruction (Xu et al., 2015). Our data indicate that the pathogenesis of cartilage degeneration in RA and OA may converge on the aberrant activation of TGF-β in the subchondral bone, although they are recognized as two different arthritic diseases with distinct etiologies and clinical manifestations. Inhibition of TGF-β activity in the subchondral bone could help quell cartilage degeneration and joint damage and offers an additional therapeutic drug target to improve outcomes in both OA and RA.

Musculoskeletal disorders associated with genetic mutations in transforming growth factor-β signaling components

TGF-β and its family members are multifunctional growth factors that play critical roles in the development and maintenance of the skeleton. Various pathological skeletal phenotypes are consequent to mutations in genes encoding ligands, receptors, and signaling molecules of the TGF-β family. TGF-β-related diseases form an important subgroup of skeletal dysplasia (Warman et al., 2011), which covers both monogenic and polygenic diseases involving the skeletal system. Monogenic skeletal disease is caused by a single gene mutation and belongs to relatively simple and traceable Mendelian disease. In contrast, polygenic skeletal disease is multifactorial (e.g., osteoporosis). Its phenotype is determined by combined and concerted effects of a group of genes (susceptibility genes) and the environment. Hence, its inheritance is complex and less predictable. These diseases give us clues to delineate the roles of TGF-β in the skeleton in vivo as well as the physiological mechanisms controlling the skeletal system. Here we discuss representative monogenic and polygenic bone disorders associated with TGF-β mutations with a focus on their significance for understanding mechanisms regulating the skeletal system.

In general, most if not all monogenic TGF-β-related skeletal disorders share a common pathogenesis. A specific gene mutation leads to excessive and sustained production or activation of TGF-β ligand (Fig. 47.3) that distorts the normal bone remodeling process. The temporally and spatially regulated physiological TGF-β gradient may be disrupted and lead to excessive recruitment of MSCs or altered downstream targeted effects. Skeletal phenotypes with uncoupled bone remodeling appearing as sclerosis result in addition to other specific end-organ effects.

CED is characterized by a fusiform thickening of the diaphysis of the long bones and skull. CED is caused by mutations in the TGF-β1 gene, resulting in premature activation of TGF-β1 (Janssens et al. 2000, 2003; Kinoshita et al., 2000; Saito et al., 2001). Approximately 11 different TGF-β1 mutations have been identified from CED-afflicted families (Janssens et al., 2006; Whyte et al., 2011). All mutations are in the region encoding LAP and either destabilize the disulfide bridging of LAP or affect secretion of the protein, leading to enhanced TGF-β1 signaling. Patients with CED show a typical uncoupled bone remodeling phenotype characterized by decreased trabecular connectivity despite normal osteoblast and osteoclast numbers (Bondestam et al., 2007; Whyte et al., 2011). The conditioned medium collected from cells expressing CED mutant TGF-β1 shows a significantly increased ratio of active/total TGF-β1, and it hyperactively induces the

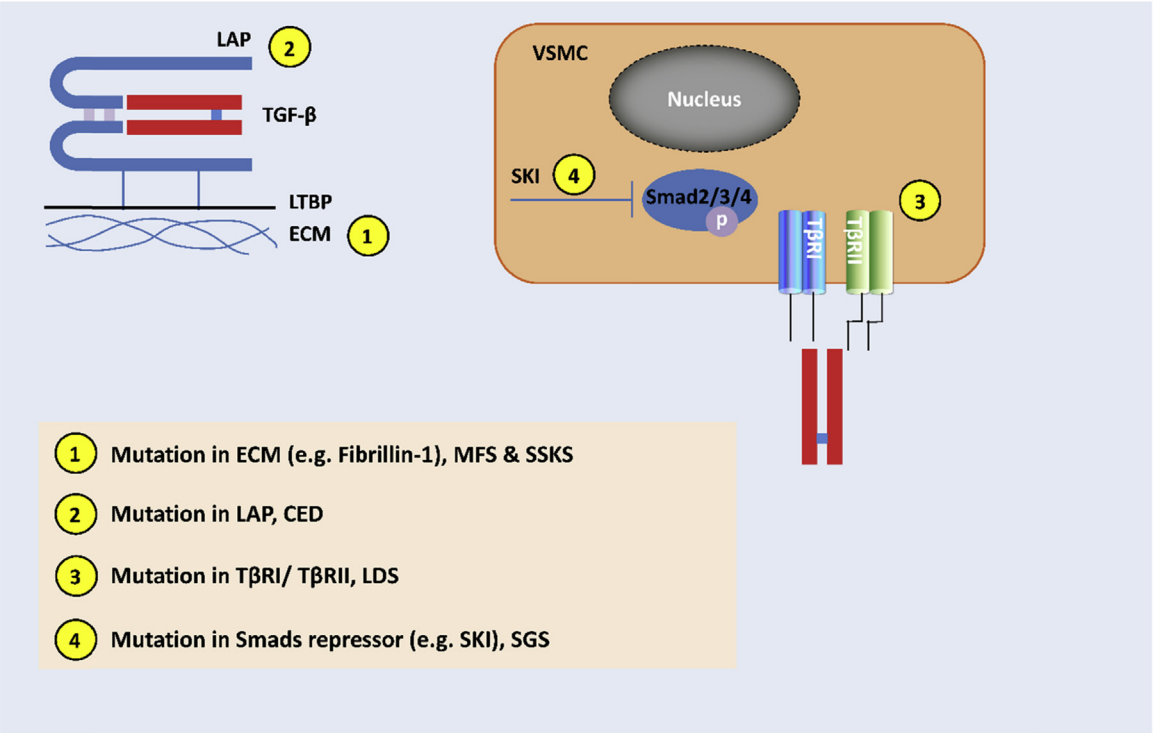

FIGURE 47.3 Common genetic disorders with aberrant TGF-β activity. ① Mutations in genes involved in the synthesis/assembly of extracellular matrix (ECM), e.g., Fibrillin-1, cause compromised matrix sequestration of the large latent complex of TGF-β and excessive TGF signaling, ultimately resulting in genetic disorders such as Marfan syndrome (MFS) and stiff skin syndrome (SSKS). ②Mutations in the region encoding latency-associated peptide (LAP) increase the release of active TGF-β, and cause Camurati−Engelmann disease (CED). ③ Mutations in genes encoding TGF-β type I and II receptors (TβRI/II) lead to compensatory synthesis of TGF-β ligand, and cause Loeys−Dietz syndrome (LDS). ④ Mutations in Smad repressors, such as SKI, superactivate TGF-β signaling and cause Shprintzen−Goldberg syndrome (SGS) phenotypes. VSMC: vascular smooth muscle cell. *Figure is reused with authors' permission Xu, X, Zheng, L, Yuan, Q, Zhen, G, Crane, JL, Zhou, X, Cao, X. Transforming growth factor-β in stem cells and tissue homeostasis. Bone Res. 2018, 6, 2.*

migration of MSCs (Tang et al., 2009). However, targeted recruitment of MSCs to the bone remodeling site is likely disrupted due to loss of the TGF-β gradient.

In addition to CED, several other genetic disorders with skeletal manifestations including Marfan syndrome (MFS), Loeys−Dietz syndrome (LDS), Shprintzen−Goldberg syndrome (SGS), and neurofibromatosis type 1 (NF1) also involve aberrant TGF-β signaling. MFS is caused by mutations in the fibrillin-1 encoding gene and often results in aortic dilatation, myopia, bone overgrowth, and joint laxity (Dietz et al. 1991a, 1991b, 2005; Kainulainen et al., 1994). Fibrillin-1 is deposited in the ECM and interacts directly with latent TGF-β-binding proteins (LTBPs), keeping TGF-β sequestered and unable to exert its biological activity. In MFS, secondary to mutated structural fibrillin-1, excessive activation of TGF-β in the lungs, heart valves, and aorta causes pathological features (Dietz et al., 2005; Neptune et al., 2003). LDS is caused by inactivating mutations in genes encoding TβRI and TβRII (Loeys et al., 2005). Physical manifestations of LDS include arterial aneurysms, hypertelorism, bifid uvula/cleft palate, and bone overgrowth resulting in arachnodactyly, joint laxity, and scoliosis. Although the exact mechanism is still unclear, TGF-β signaling is elevated in the affected tissues of LDS despite the inactivating mutation (Loeys et al., 2005). A recent study by Dietz et al. suggests that vascular smooth muscle cells (VSMCs) that carry the LDS mutation may compensate for their signaling deficiency by upregulating the expression of TGF-β ligands (Gallo et al., 2014). Indeed, tissue from LDS patients and mice shows increased expression of TGF-β1 regardless of etiology (Lindsay et al., 2012; van de Laar et al., 2011). Upregulated TGF-β1 production by specific cell types (e.g., VSMCs) could lead to paracrine overdrive of TGF-β signaling in neighboring cells despite the presence of mutant receptors. Infiltrating $CD45^{+}$ cells in the aortic root adventitia as the disease progresses might also contribute to excessive TGF-β1 production (Gallo et al., 2014). SGS is caused by mutations in the Sloan-Kettering Institute proto-oncoprotein (SKI) (Carmignac et al., 2012; Doyle et al., 2012) and results in physical features similar to those of MFS plus craniosynostosis. SKI negatively regulates Smad-dependent TGF-β signaling by impeding Smad2 and Smad3 activation, preventing nuclear translocation of the SMAD4 complex, and inhibiting TGF-β target gene output by

competing with p300/CBP for SMAD binding and recruiting transcriptional repressor proteins, such as mSin3A and HDACs (Nomura et al., 1999; Prunier et al., 2003; Reed et al., 2001). The neurocutaneous syndrome NF1 has skeletal features including kyphoscoliosis, osteoporosis, and tibial pseudoarthrosis. The $Nf1^{flox/};Col2.3^{Cre+}$ mouse model that closely recapitulates the skeletal abnormalities found in human NF1 disease has hyperactive TGF-β1 signaling (Rhodes et al., 2013). The exact mechanisms underlying mutant neurofibromin-associated hyperactivation of TGF-β signaling remain unknown, particularly in relation to osseous defects.

Osteoporosis is the pathological decrease of bone tissue leading to an increased risk of fracture, mainly in the spine (vertebral body), distal radius, and femoral neck. It has been estimated that osteoporosis results in more than 1.3 million osteoporotic fractures per year in the US, and more than 40% of postmenopausal women are reported to have sustained a fracture (Cummings et al., 1985; Ray et al., 1997). Osteoporosis is classified as primary and secondary osteoporosis based on its etiology. Primary osteoporosis consists of postmenopausal and senile osteoporosis. Postmenopausal osteoporosis is the most common bone and joint disease in women after menopause. Secondary osteoporosis results from various diseases relating to bone metabolism or prolonged use of medications such as glucocorticoids. The underlying mechanism in all cases of osteoporosis is an imbalance between bone resorption and bone formation. Three main mechanisms interplay and underlie the development of bone fragility, including inadequate peak bone mass, excessive bone resorption, and inadequate bone formation during remodeling (Raisz, 2005). Polymorphisms in several genes associated with bone mass or osteoporotic fracture have been identified by population-based and case-controlled studies. Candidate genes include TGF-β, vitamin D receptor, estrogen receptor, and type I collagen (Xu et al., 2010). Specific TGF-β gene polymorphisms associated with BMD and/or osteoporotic fractures have been identified (Langdahl et al., 1997; Yamada et al., 2001). A C/T polymorphism that causes a proline−leucine substitution at amino acid 10 in the TGF-β1 encoding region has been identified. The C allele is associated with increased BMD and reduced osteoporotic fracture risk in postmenopausal Japanese women. In addition, the C allele is associated with circulating levels of TGF-β1, suggesting that the C allele may influence protein secretion or stability (Yamada et al., 1998). However, the underlying molecular mechanisms are still unclear. Of note, subsequent large-scale association studies in Japanese (Kou et al., 2011) and other ethnic populations (Hubacek et al., 2006; Tural et al., 2013) have not been able to replicate the association.

Skeletal metastases of cancer associated with bone matrix−derived transforming growth factor-β

Cancer diagnosed at an early stage can usually be effectively treated with some combination of surgery, radiation, hormonal therapy, and chemotherapy. However, treatment options for metastatic or recurrent cancer with acceptable outcomes are still limited. Bones are a common place for metastasis. Skeletal metastasis of cancer is a complex process, including cancer cells escaping the primary site, circulating to distant sites, evading the host immune response, and proliferating into the metastatic site (Gupta and Massague, 2006). Tumor cells could generate adhesive molecules that mediate binding to BMSCs and bone matrix. The interactions between tumor cells and bone promote the production of angiogenic and bone-resorbing factors by tumor and further enhance tumor growth in bone (van der Pluijm et al., 2001). Of note, the bone microenvironment houses abundant growth factors including TGF-β, IGF1/2, FGFs, PDGFs, and BMPs (Mohan and Baylink, 1991). During tumor-induced osteoclastic bone resorption, these factors are released and enriched in the bone microenvironment. These bone matrix-derived factors, particularly TGF-β, can act back upon the tumor to facilitate further tumor expansion and enhance cytokine production and upon osteoblasts to suppress bone formation, further promoting tumor growth and metastasis in bone (Juarez and Guise, 2011).

In cancer, TGF-β can be either a tumor suppressor or a tumor promoter depending on the temporal stage of the disease (Siegel and Massague, 2003). In the early stage of tumor initiation, TGF-β limits the growth of tumor cells through its antiproliferative and proapoptotic actions (Derynck et al., 2001). Conversely, during tumor progression, TGF-β acts as a tumor promoter by inducing proliferation, angiogenesis, and immunosuppression, and thus promotes the invasion and metastasis of cancer (Massague, 2008). The loss of function of TGF-β signaling also contributes to certain tumor types. Mutations in TβRII are frequently detected in colon cancer, gastric tumors, and gliomas. These mutations may result in DNA repair defects and cancer predisposition, likely due to cellular escape from TGF-β-mediated growth surveillance (Izumoto et al., 1997; Markowitz and Roberts, 1996; Ohue et al., 1996; Park et al., 1994). Loss-of-function mutations in TβRI have been observed in ovarian cancers, metastatic breast cancers, pancreatic carcinomas, and T cell lymphomas (Chen et al. 1998, 2001; Goggins et al., 1998; Schiemann et al., 1999). In addition, mutations in the TGF-β signaling components, such as Smad protein mutations, have been detected in several carcinomas. Smad2 mutations have been identified in human colorectal cancer and lung cancers (Eppert et al., 1996; Takagi et al., 1998). Smad4 mutations have been detected in pancreatic carcinomas and familial juvenile polyposis (Howe et al., 1998; Schutte et al., 1996), and Smad2

and Smad4 double mutations have been detected in hepatocellular carcinoma (Yakicier et al., 1999). Moreover, Smad3 is frequently downregulated in cancer, and inactivating mutations have also been reported (Daly et al., 2010; Jones et al., 2008; Leary et al., 2008). TGF-β can antagonize BMP-like responses by the formation of a pSmad1/5-pSmad3 complex specifically binding to BRE and suppressing the transcription of downstream genes (Gronroos et al., 2012). Inactivation of Smad3 in cancer alleviates the antagonism of TGF-β on BMP responses and enables TGF-β to induce BRE downstream ID genes (Gronroos et al., 2012) that are potent tumor promoters normally suppressed by canonical TGF-β signaling (Massague, 2008). The induction of ID genes thus deregulates tumor cell proliferation and confers invasiveness, angiogenesis, and metastasis (Iavarone and Lasorella, 2006).

In advanced cancer, cells lose TGF-β suppressive effects, resulting in compensatory overproduction of TGF-β. Elevated levels of TGF-β in serum are often observed in the later stages of cancer and are associated with increased invasiveness and a poor clinical outcome of cancer (Gold, 1999). TGF-β signaling can act on multiple cells in the local microenvironment of bone and consequently enhance tumor growth and invasiveness (Padua and Massague, 2009; Siegel and Massague, 2003). Specifically, TGF-β could induce the expression, secretion, and activation of MMPs that mediate the migration of endothelial cells, thus promoting tumor angiogenesis (Hagedorn et al., 2001; Padua and Massague, 2009). TGF-β could also indirectly induce the expression of proangiogenic factors such as VEGF and connective tissue growth factor (CTGF) in fibroblastic and epithelial cells (Kang et al., 2003; Pertovaara et al., 1994) and thus further contribute to the angiogenesis and invasiveness of tumor (de Jong et al., 1998; Hasegawa et al., 2001). Inhibition of TGF-β signaling with TGF-β-neutralizing antibodies can suppress angiogenesis in human breast and prostate cancers (Tuxhorn et al., 2002), further validating the critical role of TGF-β as a proangiogenic factor during tumor. Furthermore, excessive production of tumor-derived TGF-β could suppress T lymphocytes and natural killer cells, leading to cellular escape of cancer cells from cytotoxic T lymphocyte clearance (Thomas and Massague, 2005). Target blockade of TGF-β signaling in T cells results in eradication of tumors in mice challenged with live tumor cells (Gorelik and Flavell, 2001), indicating the suppressive action of TGF-β signaling on T cell−mediated antitumor immunity.

TGF-β is also involved in the EMT of cancer (Lopez-Novoa and Nieto, 2009; Xu et al., 2009), which is essential for increasing tumor cell mobility and invasiveness closely related to metastasis. TGF-β interacts with other oncogenic pathways to maintain the mesenchymal phenotype of tumor cells by downregulating E-cadherin and upregulating mesenchymal genes (Zavadil and Bottinger, 2005). Smads, Ras, Rho, ERK MAPK, p38 MAPK, and Wnt signaling pathways have been implicated in TGF-β-induced EMT (Xu et al., 2009). TGF-β activates transcriptional factors such as Snail and Slug to regulate EMT (Batlle et al., 2000; Cano et al., 2000). Particularly, Snail could repress E-cadherin and activate the transcription of mesenchymal genes, such as vimentin and αSMA. In addition, Snail could promote collagen I synthesis/deposition and upregulate proinflammatory interleukins (ILs) such as IL-1, IL-6, and IL-8 (Boutet et al., 2006; Lyons et al., 2008), thus enhancing the invasiveness of tumor.

Based on the aforementioned oncogenic activity of TGF-β, a feed-forward loop has been proposed to describe skeletal metastasis. Tumor cells in bone secrete osteolytic factors, such as PTHrP and IL-11, leading to osteolytic bone resorption. Active TGF-β is released from bone matrix by osteoclastic resorption and further induces tumor production of osteolytic and prometastatic factors including PTHrP and IL-11. Of note, PTHrP is a central mediator of TGF-β-induced osteolytic metastases. Increased expression of PTHrP has been observed in human breast cancer with bone metastases, compared with that of primary breast cancers (Henderson et al., 2006). PTHrP can stimulate RANKL and inhibit OPG expression in osteoblasts to favor osteoclastogenesis (Thomas et al., 1999). TGF-β induces PTHrP secretion from MDA-MB-231 cells via Smad and p38 MAP kinase pathways (Kakonen et al., 2002). Stable inactivation of TβRII in the breast cancer cell line MDA-MB-231 inhibited TGF-β-induced PTHrP secretion and suppressed bone metastases in a mouse model (Yin et al., 1999). Direct neutralization of PTHrP with PTHrP-neutralizing antibodies inhibits the development and progression of breast cancer bone metastases in mouse models (Guise et al., 1996). TGF-β released during bone resorption can also directly act on bone cells. Within a given range of concentrations, TGF-β stimulates osteoclastic bone resorption while inhibiting osteoblastic differentiation. Transcriptional profiling of human breast cancer cells with an aggressive bone metastatic phenotype has identified the upregulation of several genes, such as IL-11, CTGF, CXCR4, and MMP1, associated with bone metastases. These genes act cooperatively to cause skeletal metastasis by promoting homing to bone, angiogenesis, and invasion of tumor. Notably, these genes are all regulated by TGF-β via the canonical TGF-β/Smad pathway in metastatic cells (Dunn et al., 2009; Kang and Massague, 2004; Kang et al., 2003). Inhibition of either TGF-β signaling with small-molecule inhibitors or bone resorption with bisphosphonate is effective in decreasing TGF-β signaling activity in bone metastases (Korpal et al., 2009). This indicates that TGF-β released by osteoclastic bone resorption is the major source of TGF-β acting on tumor cells in bone. Inhibition of either the TGF-β pathway or osteoclastic bone resorption may represent a novel therapeutic for the treatment of skeletal metastasis.

Several preclinical studies have shown that the TGF-β signaling pathway is a potential target for the inhibition of bone metastases. Knockdown of Smad4 expression in breast cancer cells reduces growth of bone metastases (Deckers et al., 2006; Kang et al., 2005), while overexpression of Smad7 reduces bone metastases of melanoma (Javelaud et al., 2007). Small-molecule inhibitors of the TβRI kinase have been used to reduce bone metastasis through blockage of TGF-β signaling. Systemic administration of small molecule [3-(pyridine-2yl)-4-(4-quinonyl)]-1H pyrazole], which is able to inhibit TβRI kinase activity, has been shown to effectively reduce the number and size of lung metastases and the incidence of skeletal metastases in an experimental mice model of bone and lung metastasis (Bandyopadhyay et al., 2006a). Systemic administration of Ki26894 (a TβRI kinase inhibitor) decreased skeletal metastasis and prolonged survival of a nude mouse model with bone metastasis (Ehata et al., 2007). Consistently, preventive treatment with TβRI the kinase inhibitor LY2109761 led to a reduction in the number of bone lesions and skeletal tumor burden in a bone metastatic mice model. Although LY2109761 was less effective in the treatment of established bone metastases (Korpal et al., 2009), SD-208, a more potent TβRI kinase inhibitor, was effective in the treatment of mice with established bone metastases (Dunn et al., 2009). The use of TGF-β-neutralizing antibodies is another possible modality for the treatment of bone metastases (Biswas et al., 2007). Treatment with a neutralizing pan-TGF-β antibody (1D11, Genzyme) has been shown to decrease metastases to the lungs in a transplantable 4T1 mice model of metastatic breast cancer (Nam et al., 2008) and reduce skeletal tumor burden in mice while also increasing bone volume (Biswas et al., 2011).

The combination of anti-TGF-β therapies with other therapeutics is promising for the treatment of patients with bone metastases. Bone is a hypoxic microenvironment, and hypoxia-inducible factor 1α (HIF-1α) has been implicated in enhancing tumor growth and metastasis (Dunn et al., 2009; Hiraga et al., 2007). Hypoxia also stimulates the expression of CXCR4 and DUSP1 (Lu et al., 2010), whose upregulation is associated with bone metastatic (Kang et al., 2003). TGF-β stabilizes HIF-1α by inhibiting its degradation (McMahon et al., 2006). TGF-β and hypoxia signaling pathways in breast cancer cells are additive to induce VEGF and CXCR4 (Dunn et al., 2009; McMahon et al., 2006). Inhibition of both TGF-β and hypoxia signaling pathways decreased bone metastases more than inhibition of either alone, resulting in enhanced osteoblastic activity and suppressed osteoclastic bone resorption as well as reduced tumor growth (Dunn et al., 2009). Other possible therapies include halofuginone, a natural product derivative that inhibits TGF-β signaling possibly via induction of Smad7. Halofuginone treatment can significantly suppress osteolysis and skeletal tumor burden in mice with established bone metastases (Juarez et al., 2012).

In conclusion, bone is the most common site of cancer metastases. Active TGF-β released from bone matrix is the major component of the bone microenvironment, functioning to drive a feed-forward cycle of tumor growth and osteolysis in bone. Modulation of TGF-β signaling in cancer cells has been proven effective in decreasing bone metastases in in vitro and animal models. Development of anti-TGF-β therapies, administered alone or supplementing other therapies, for bone metastasis of cancer is promising. Since TGF-β can be either tumor-suppressive or prometastatic, a long-term global blockade of this signaling pathway may result in off-target effects. Hence, delicate modulation of TGF-β signaling during tumor onset and progression is necessary for the development of the most effective antineoplastic therapy with minimal toxicity but potent efficacy.

Transforming growth factor-β modulation as a promising approach to the management of osteoarthritis

Excessive activation of TGF-β in subchondral bone has been reported at the onset of OA in animal models (Zhen et al., 2013). Active TGF-β1 concentrations are also high in the subchondral bone of people affected by OA. All these data suggest that modulation of TGF-β signaling may provide a promising disease-modifying approach for OA. In ACLT rodent models, systemic inhibition of TGF-β signaling with intraperitoneal administration of TβRI inhibitor or specific blockade of active TGF-β ligand in the tibial subchondral bone with TGF-β-neutralizing antibody at the time of injury was sufficient to attenuate the degeneration of articular cartilage (Zhen et al., 2013). Furthermore, TGF-β signaling activated in the subchondral bone through osteoclast bone resorption in these animal OA models suggests that inhibition of osteoclast bone resorption may also delay the progression of OA. Several clinical trials and preclinical studies support this hypothesis. In addition to many animal studies that reveal the positive effect of bisphosphonates for delaying OA progression (Hayami et al., 2004; Panahifar et al., 2012; Shirai et al., 2011; Zhang et al., 2011; Zhu et al., 2013), in the most recent prospective 2-year trial, alendronate treatment successfully improved the Western Ontario and McMaster Universities Osteoarthritis (WOMAC) pain scores and decreased biochemical markers in hip OA patients (Nishii et al., 2013). In a cross-sectional study, elderly women who were being treated with alendronate were found to have significantly decreased the prevalence of knee OA as assessed by WOMAC pain scales, and subchondral bone lesions by MR imaging, compared

with elderly women not taking alendronate (Carbone et al., 2004). Randomized controlled trials are needed to assess the efficacy of bisphosphonates as a potential OA treatment. The detailed mechanisms also still need to be further elucidated, anticipating that at least part of the effect is through the inhibition of osteoclast activity and subsequent reduction in TGF-β levels. As many musculoskeletal disorders also involve excessive TGF-β signaling, attenuating the TGF-β signaling pathway could also benefit the management of these diseases.

High levels of active TGF-β also alter the microenvironment of subchondral bone, leading to aggregation of osteoprogenitors and increased angiogenesis in bone marrow. PTH is FDA-approved as an anabolic therapy for osteoporosis. Daily injection of PTH increases bone formation with normal microarchitecture (Bikle et al., 2002; Canalis et al., 1989; Lombardi et al., 2010; Miyakoshi et al., 2001; Pfeilschifter et al., 1995; Qiu et al., 2010; Wan et al., 2008; Watson et al., 1995; Yu et al., 2012). PTH can improve the bone marrow microenvironment by orchestrating the signaling of local factors for bone remodeling, reducing ROS, and stimulating Wnt signaling in bone of senescent mice (Bikle et al., 2002; Canalis et al., 1989; Jilka et al., 2010; Khosla et al., 2008; Lombardi et al., 2010; Miyakoshi et al., 2001; Pfeilschifter et al., 1995; Qiu et al., 2010; Raggatt and Partridge, 2010; Wan et al., 2008; Watson et al., 1995; Yu et al., 2012). In addition, PTH has demonstrated potent chondroprotective and chondroregenerative effects by inducing cartilage matrix synthesis and suppressing chondrocyte hypertrophy and matrix metalloproteinase 13 expression in different OA animal models (Orth et al., 2013; Sampson et al., 2011). The dual beneficiary effects of PTH on both cartilage and subchondral bone make PTH another promising candidate for the treatment of OA. A recent study using a rabbit model of OA preceded by osteoporosis has demonstrated that PTH treatment in the early stage of OA is able to improve the microstructure and quality of subchondral bone and thus attenuate subsequent cartilage damage (Bellido et al., 2011). This data supports the relevance of the role of subchondral bone osteopenia in the pathogenesis of OA and indicates the potential application of anabolic agents (such as PTH) to treatment in the early stages of OA associated with osteoporosis. The osteogenic microenvironment created by PTH has also been shown to expand HSPC niches (Calvi et al., 2003; Mendez-Ferrer et al., 2010) and could also potentially be translated into therapies for hematologic diseases such as cytopenias, myelodysplastic syndromes, and myeloproliferative disorders (Smith and Calvi, 2013).

Articular cartilage and subchondral bone constantly interact as a functional unit. TGF-β plays a critical role in maintaining bone and articular cartilage homeostasis. Joint instability causes increased subchondral bone remodeling, which releases excessive active TGF-β1 through osteoclastic bone resorption. The pathologically high level of TGF-β1 in subchondral bone leads to aberrant bone remodeling and the formation of marrow osteoid islets. The abnormal subchondral bone microstructure in turn likely alters the stress distribution on the articular cartilage, eventually resulting in cartilage degeneration. The concept of holism is essential for exploring therapeutic strategies for OA. Improving the mechanical properties of subchondral bone and its physiological function are at least equally important as directly targeting articular cartilage. Therapies that can normalize TGF-β signaling, either directly by neutralizing TGF-β overactivation or indirectly by PTH-mediated modulation of the bone marrow microenvironment, may serve as a potential approach to the management of joint disorders.

Summary

TGF-β, as a dual functional growth factor, has been attracting major research efforts ever since its discovery. Unlike most growth factors that are ready to function upon secretion, TGF-β is unique because it is secreted as part of a latent complex stored in the ECM for activation and action at a later time point. Precise temporal and spatial activation of TGF-β signaling is necessary to counter tissue perturbations, either by suppressing excessive adversary cellular responses such as inflammation or by recruiting adult stem cells to participate in the tissue repair/remodeling process. The bone remodeling process clearly underscores the importance of proper activation of TGF-β in the maintenance of tissue homeostasis. The physiological gradient of active TGF-β formed by normal bone remodeling functions as a coupling factor that directs MSCs/osteoprogenitors to bone-resorbing sites for coupled bone formation, whereas sustained activation of TGF-β by either genetic mutations or pathologically elevated osteoclastic activity recruits excessive MSCs/osteoprogenitors for aberrant bone remodeling. The same theory can be applied to other pathologies with TGF-β involvement, where the normal functions of this growth factor are switched to an off-target activity that disrupts tissue homeostasis. Therefore, a comprehensive understanding of the mechanisms that underlie the physiological and pathological effects of TGF-β, and full interpretation of how cells integrate these signals into coherent responses in a context-dependent way, can lead to promising therapeutics for TGF-β-involved pathologies. Novel strategies that intricately tune TGF-β signaling to properly respond to specific contexts are being developed with anticipated clinical implications.

Chapter outline

Introduction

Bone morphogenetic proteins (BMPs) regulate endochondral ossification and postnatal skeletal growth, bone homeostasis, and fracture repair. Without BMP signaling, limb skeletogenesis cannot occur—ablation of BMP signaling by deletion of type I BMP receptors or *Smad4* results in failure of mesenchyme condensation prior endochondral ossification (Lim et al., 2015), while conditional deletion of *Smad4* in chondrocytes or osteoblasts is sufficient to cause severe skeletal growth retardation or decreased bone mass in mice (Zhang et al., 2005; Tan et al., 2007). Clinical studies have demonstrated that exogenously supplied BMPs are safe and efficient bone-inducing agents for use in specific orthopedic and dental surgery procedures. Yet comparatively little is known about the roles of endogenous BMPs in skeletal tissue throughout development, adulthood, and aging, which is information required to expand their therapeutic utility. Over the last decade, research has begun to shed light on the complexity of BMP signaling mechanisms. With more evidence for the fine-tuning of BMPs and BMP signaling in spatial and temporal contexts, we have come closer to appreciating the importance of their intricate biology. This chapter aims to review our current understanding of BMP signaling and its importance during skeletal development and maintenance.

Canonical bone morphogenetic protein signaling

The intracellular signaling pathway triggered by BMP involves a cascade of phosphorylation. Upon binding a BMP ligand, a Type II and a Type I receptor form an active complex. The Type II receptor kinase phosphorylates the Type I receptor, which in turn activates a subset of intracellular mediators, SMAD1/5/8. Activated SMAD1/5/8 recruits SMAD4 to form complexes (Salazar et al., 2016). SMAD1/5/8 proteins are the direct mediators of BMP signaling and have distinct roles during endochondral ossification. SMADs 1 and 5 are required for limb formation, whereas SMAD8 is not essential for skeletal development, as evidenced by SMAD8 knockout mice, which are viable and do not exhibit any skeletal phenotype (Retting et al., 2009). When activated, SMAD complexes translocate to the nucleus to regulate gene expression (Fig. 48.1). Osteo-associated genes specifically induced by BMP signaling include *Runx2*, Distal-Less Homeobox 5 (*Dlx5*), and Osterix (*Sp7*).

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00048-8

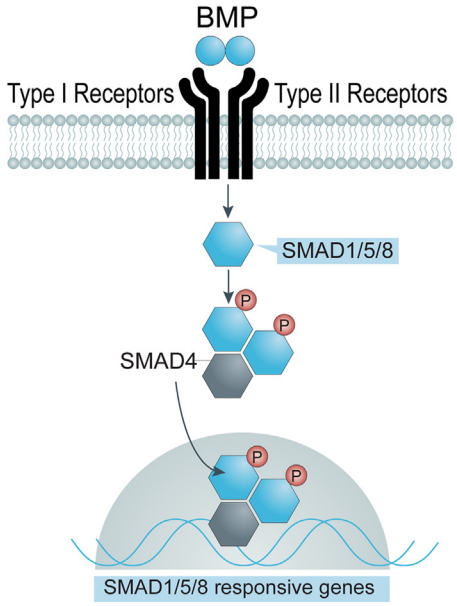

FIGURE 48.1 Canonical BMP signaling. Binding of BMP to its receptor results in the phosphorylation of SMAD1/5/8, which then recruits SMAD4 to form a complex capable of translocating to the nucleus to activate or inhibit the transcription of specific genes.

In addition to canonical BMP signaling, some studies suggest that other BMP pathways (noncanonical) play a role in bone formation. One such noncanonical BMP pathway is initiated by TGF-β activated kinase 1 (TAK1). The deletion of TAK1 results in fusion of joints, highlighting an important regulatory role in bone development (Greenblatt et al., 2010; Gunnell et al., 2010). While the canonical pathway remains the cornerstone of BMP signaling in the skeleton, the discovery of a myriad of ligands and multiple receptors suggested that this seemingly simple BMP signaling mechanism is actually much more complex than originally appreciated.

Diversity of the ligand and receptor environment

BMP signaling is mediated by the binding of ligand dimers to heteromeric receptor complexes. This simple system in theory is made complex by the diversity of BMP ligands and receptor components. To date, over 15 BMPs have been identified in humans and rodents. In the skeleton, multiple BMP ligands are synthesized and secreted by osteoblasts, chondrocytes, and their progenitors. Invading macrophages and vascular endothelial cells are also known to secrete BMPs during fracture repair (Rosen V and J.M. Wozney, 2002; Sipe et al., 2004; Csiszar et al., 2005). Not only is the ligand environment heterogeneous, its diversity is regulated and modified throughout life. For example, while BMPs 2, 4, and 7, as well as GDF5, are all expressed in early stages of skeletogenesis, embryonic deletions of each result in early diverse skeletal phenotypes. Deletion of *Bmp4* within the limb bud mesenchyme with *Prx1-Cre* causes a delayed formation of the apical ectodermal ridge and polydactyly affecting hind limbs more severely than forelimbs (Selever et al., 2004). Mice lacking GDF5 have defects in early mesenchymal condensation required for chondrogenesis, which leads to shorter limbs, with distal elements more affected than proximal elements, and missing or altered joints at some sites within appendages (Mikic, 2004). BMPs 6 and 7, and GDF6, are present in later stages of skeletal development. Global deletion of the *Bmp6* gene results in a mild skeletal phenotype with delayed ossification of the sternum (Solloway et al., 1998), while *Gdf6*-null mice show fusion between some bones in the wrists and ankles and variable alterations of cartilage and ligaments (Settle et al., 2003). No skeletal phenotypes were reported in mice with deletions of *Bmp8* or *Bmp10* (Zhao et al., 1998; Chen et al., 2004). Taken together, these findings suggest that specific BMPs need to be present during specific times, at a specific place, in order for bone formation to occur normally.

With the availability of floxed alleles, studies using CRE drivers have shed light on the complexity of BMP activity in the skeleton. For instance, deletion of *Bmp2* with *Prx1-Cre* results in mice with limbs that appear indistinguishable from wild-type littermates at birth, but who then suffer from multiple spontaneous fractures that do not heal, a phenotype thought to be caused by a failure of mesenchymal stem cells to undergo the chondrogenesis necessary for bone

repair (Tsuji et al., 2006). Furthermore, when *Bmp2* was removed specifically in early osteoblasts using the *3.6Col1a1-Cre* driver, mice also had increased bone fragility and decreased osteoblast function with altered vasculature of the long bones (Yang et al., 2013). However, experiments using *Osx-Cre* revealed that only the bones were altered by deletion of *Bmp2* in osteoblasts without affecting the vasculature (McBride et al., 2014). This demonstrates that BMP2 needs to be expressed at specific times and stages in osteogenic lineage cells in order to orchestrate bone development, homeostasis, and repair.

The importance of the spatiotemporal regulation of BMP ligands may be in part due to the ability of these signaling molecules to act in both an autocrine and a paracrine manner. When BMPs are secreted from cells, they may either act locally via BMP receptors on the surface of target cells or interact with extracellular matrix proteins that anchor BMPs to the matrix. Matrix interactions can then either augment or sequester BMP activity by modulating BMP availability for target cell interactions (Arteaga-Solis et al., 2001; Ohkawara et al., 2002; Larrain et al., 2001). Storage within the bone matrix allows BMPs to participate in osteoblast- and osteoclast-directed bone modeling and remodeling. Thus, the availability of BMP to bind its receptor is governed by its expression, cellular localization, and storage in extracellular matrix for later use.

Multiple receptors on bone cells

The BMP receptor environment on skeletal cells is also diverse. There are three Type I receptors (ACVR1, BMPR1A, and BMPR1B) and three Type II receptors (BMPR2, ACVR2A, and ACVR2B) expressed by bone cells. Each has specific and often overlapping patterns of expression in the skeleton. Additionally, while Type 1 BMP receptors only bind BMP ligands, ACVR2A and ACVR2B are multifunctional and capable of binding BMPs and related BMP family members including activin, Gdf8, and Gdf11. Hence, the loss of any individual receptor in mice causes unpredictable phenotypes. For example, removing *Bmpr2* in *Prx1*$^{+}$ cells results in high bone mass due to increased osteoblastic activity, which is thought to be due to altered competition between ligands for the remaining type II receptors (Lowery et al., 2015). Deletion of *Bmpr1a* in *Prx1*$^{+}$ progenitors results in shorter limbs and the loss of autopod skeletal elements, while deletions of the same receptor in osteoblasts and osteocytes result in high bone mass in both instances (Ovchinnikov et al., 2006; Kamiya et al, 2008b, 2016). Thus, the presence of multiple receptors in bone allows for binding by multiple BMPs, which creates a complex environment of competition and collaboration between BMPs to direct specific outcomes for the skeleton (Fig. 48.2).

Combinatorial signals

At the molecular level, the distinct receptor affinities and activities of individual BMPs create a system by which skeletal target cells respond to the distribution of available ligands in their environment. For example, a BMP ligand with higher affinity and weaker activity could antagonize a higher activity but weaker affinity BMP ligand by competing for shared receptors, resulting in functional antagonism via weak agonism. Recently, this mechanism was demonstrated using a cell-based reporter system, which established that cells perceive combinations of BMP ligands. Investigators demonstrated that BMP signaling by 15 different ligands was attenuated by increasing concentrations of either BMP3 or GDF5, whereas BMP signaling was increased universally by the addition of BMP2 to the ligand environment. Most interestingly, it was found that some BMPs, for example BMPs 7 and 4, exhibited a mixture of antagonistic and synergistic interactions with

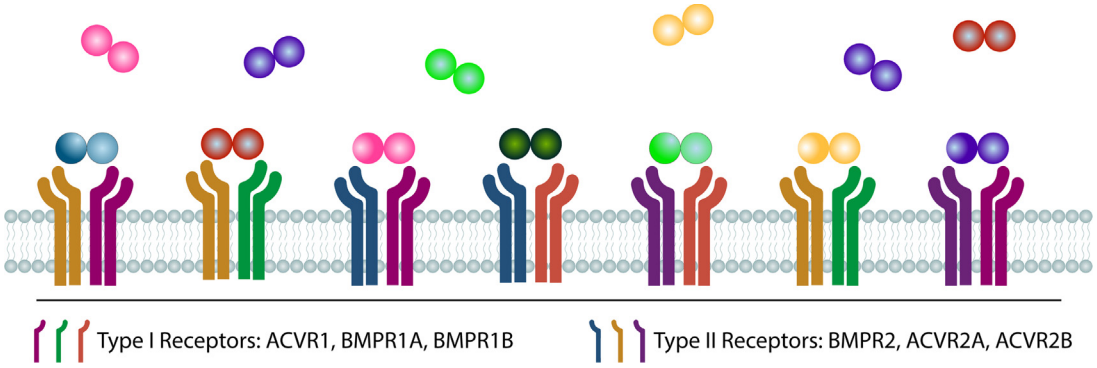

FIGURE 48.2 Multiple BMPs and receptors expressed in bone. In the bone microenvironment, BMPs are present as dimers forming a multitude of possible complexes. These complexes then interact with several type I and type II receptors.

other ligands (Antebi et al., 2017). This concept of combinatorial signals helps to explain the phenotypes observed in mice carrying multiple BMP deletions such as mice lacking both *Bmp5* and *Bmp7*, which die after embryonic day 10, with more severe phenotypes than seen in either *Bmp5* and *Bmp7* single-knockout mutants (Solloway and Robertson, 1999). Similarly, mice carrying both *Gdf5* and *Gdf6* deletions manifest an accentuated phenotype as compared with the single knockout with many reduced or absent bones. Double-mutant mice also have vertebral defects not seen in *Gdf5* and *Gdf6* single knockouts (Settle et al., 2003). Thus, mixtures of BMP dimers in the ligand environment are capable of altering signaling output in a nonlinear fashion, with the cell perceiving more than simple antagonism or agonism.

Antagonizing bone morphogenetic protein signaling

Another layer of regulation of BMP signaling in the skeleton is orchestrated by the presence of endogenous BMP antagonists including gremlin and noggin. Noggin and gremlin bind to distinct subsets of BMPs, GDFs, and/or activins to titrate active ligands out of the extracellular environment (Balemans and Van Hul, 2002). Gremlin is expressed in the posterior limb bud mesenchyme and is required for normal skeletal development. Mice lacking *Grem1* have abnormal forelimbs and hind limbs, with fewer digits (Khokha et al., 2003; Canalis et al., 2012). Noggin is expressed early in the notochord and dorsal neural tube and is required for chondrocyte condensation and joint formation but not for early limb patterning. Noggin-deficient mice lack joints and manifest fused digits and bones (Brunet et al., 1998). In addition, conditional deletion of noggin in osteoblasts results in decreased bone mass in adult mice (Canalis et al., 2012). In both gremlin and noggin deficiency, the skeletal phenotype results from unabated BMP signaling, demonstrating the importance of precise titration of the BMP pathway in skeletal development and homeostasis.

Activins display another mechanism of antagonizing BMP signaling in the skeleton. Activins inhibit BMP signaling by binding to ACVR2A and ACVR2B, receptors that are also utilized on skeletal cells by BMPs. By binding to ACVR2A or ACVR2B, activins prevent BMPs from activating SMAD1/5/8. Furthermore, they activate SMAD2/3, which serves to dampen endogenous BMP signaling (Olsen et al., 2015). Another form of BMP signaling antagonism occurs when BMP3 is present in the skeletal environment. While noggin and gremlin associate with BMPs to prevent BMP binding to receptors, BMP3 directly binds ACVR2B, inhibiting the interaction of this receptor with other BMPs. Mice overexpressing *Bmp3* under the *Col1* promoter have normal skeletal patterning but develop multiple spontaneous rib fractures around E17 due to defects in chondrogenesis that occur when BMP signaling is suppressed (Gamer et al., 2009). Whether direct or indirect, multiple types of BMP antagonism allow skeletal target cells to precisely balance the amount of BMP available to activate signaling, such that neither too much nor too little BMP signaling occurs (Fig. 48.3).

Pathway cross talk in bone

BMP signaling can regulate the expression of proteins involved in other signaling pathways important in skeletal homeostasis, creating a complex mechanism of cross talk (Fig. 48.4). For example, BMP signaling can induce expression

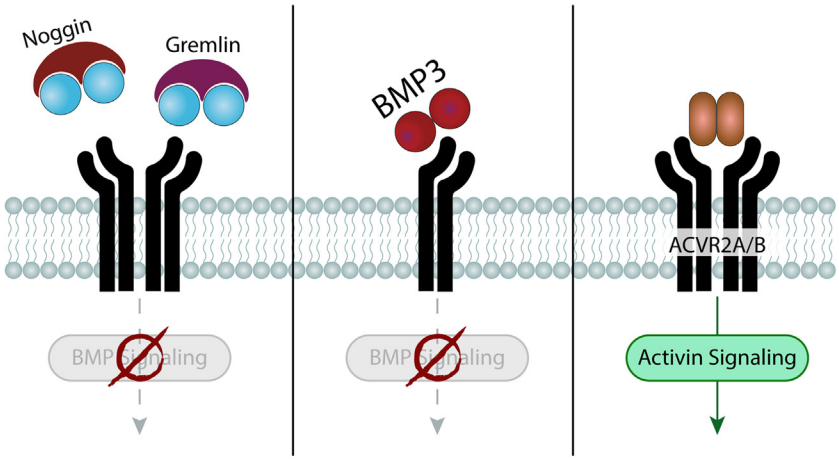

FIGURE 48.3 Antagonism of BMP signaling by endogenous factors. BMPs can be sequestered by noggin and gremlin and no longer capable of binding to their receptors. BMP3 is a particular BMP that binds to the ACVR2B receptor but does not recruit a type I receptor and therefore does not produce a signal acting as an inhibitor by competition. Activins compete with BMPs for their shared receptors ACVR2A and ACVR2B.

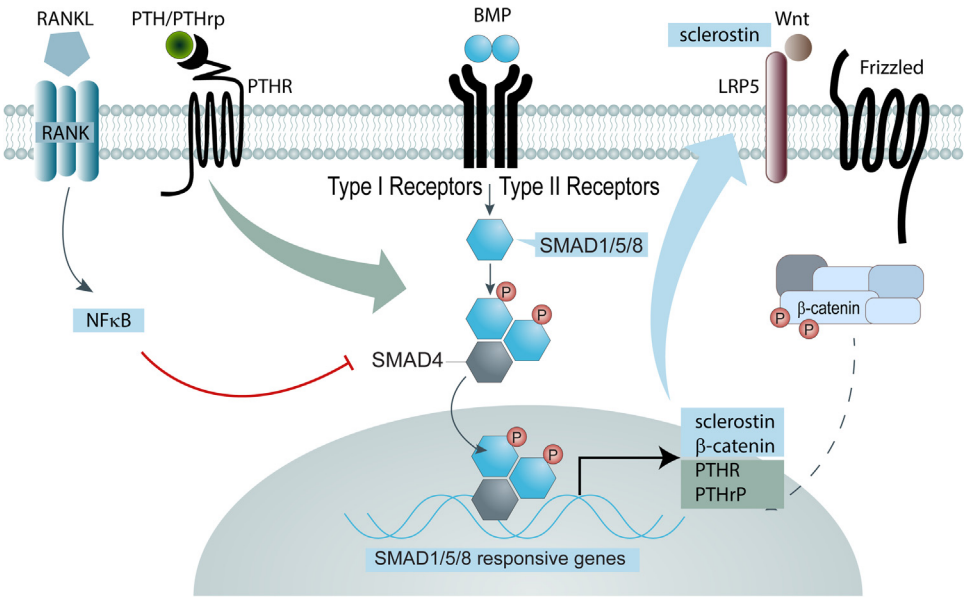

FIGURE 48.4 Intersection with other pathways in bone. BMP signaling can regulate the expression of factors involved in other pathways important in bone such as Wnt, PTH/PTHrp, and NFkB. Reciprocally, those other pathways can also modulate the downstream targets of canonical BMP signaling.

of sclerostin through BMPR1A activation (Kamiya et al, 2008a). Sclerostin acts as an inhibitor of Wnt activity to prevent bone formation by osteoblasts, thus establishing a regulatory intersection between BMP and Wnt signaling pathways. In addition, in vitro experiments have revealed that SMAD4 can regulate β-catenin expression, and in turn β-catenin can directly interact with SMAD4 (Freeman et al., 2012; Salazar et al., 2013), therefore forming a link between BMP signaling and the downstream target of Wnt signaling. Interestingly, Wnt and BMP signaling can be synergistic or antagonistic depending on the genes targeted (Itasaki and Hoppler, 2010), as it has been reported that BMP2 could synergize with Wnt in multipotent murine cell lines containing a constitutively active β-catenin signal (Mbalaviele et al., 2005).

Parathyroid hormone (PTH) and PTHrp analogs are also crucial regulators of bone homeostasis, and the PTH signaling pathway appears to intersect with BMP signaling. PTH is capable of inducing SMAD1/5/8 phosphorylation and activating the BMP signaling pathway in periosteal cells to induce osteoblast differentiation (Ogita et al., 2008). One in vitro model using C2C12 cells showed that BMP2 could decrease the expression of *Pthrp* while increasing the expression of its receptor (Susperregui et al., 2008). However, another study indicates that BMP signaling does not regulate *Pthrp* directly, but rather acts indirectly through IHH to orchestrate chondrogenesis (Susperregui et al., 2008). These data suggest intersections between BMP and PTH/PTHrp signaling pathways that are crucial for both chondrocyte and osteoblast differentiation. However, more research is required to clarify the times and places in which PTH and BMP cross talk occurs.

There is also evidence that BMP and NFκB signaling intersect. In MC3T3 cells, which are an osteoblast precursor cell line derived from mouse calvaria, NFκB activation by TNFα diminishes the binding of Runx2 on the *Bglap* promoter induced by BMP2 (Tarapore et al., 2016). An earlier article suggested that NFκB is able to bind directly or indirectly to SMAD1 and SMAD4 and interfere with their subsequent binding to DNA targets (Yamazaki et al., 2009). Since NFκB is known to induce osteoclastogenesis (Boyce et al., 2015), this could be a biological mechanism by which NFκB can reduce osteoblastic function while inducing osteoclastogenesis.

Much remains to be uncovered regarding the intersection of BMP and other signaling pathways, and this lack of knowledge has reduced our ability to use BMPs as therapeutics since one must consider the ligand/receptor environment, the target cell, the timing, and the integration with other signaling pathways in order to engineer a precise and efficient drug.

Therapeutics and bone diseases

Therapeutic applications for BMPs are wide-ranging, from bone grafting in orthopedic and dental applications to the enhancement of fracture healing. Recombinant human BMPs (rhBMPs) were first approved by the US Food and Drug Administration for clinical use in 2002. Today, two BMPs are available in clinical care: rhBMP2 and rhBMP7.

Officially, BMP2 is approved in adult patients for anterior lumbar interbody fusion, for augmentation of tibial fracture repair, and to aid in bone regeneration in the oral cavity. BMP7 received a humanitarian use device approval in 2003 for treatment of recalcitrant tibial nonunions. In these clinical settings, BMPs are typically applied with a matrix that serves as a carrier for the recombinant protein and also aids in defining the shape and volume of the new bone produced. Improvements in BMP delivery are an area of active investigation, with novel developments including BMP sequestering extracellular matrix mimetic hydrogels (Yan et al., 2018) and immune-modulated gelatin microspheres for spatiotemporal control of BMP release (Annamalai et al., 2018). More recently, genetically modified BMPs have been synthesized with properties that enhance their binding to their carrier matrix. Specifically, modified BMP2 has been generated that contains a collagen-binding domain, allowing for more efficient binding to a collagen carrier matrix and thus enhanced biological performance (Chen et al, 2007a,b; Zhao et al., 2009). Studies in animal models suggest that collagen-based BMP2 targeting improved bone formation when compared with unmodified recombinant BMP2; however, genetically modified BMPs have not yet undergone clinical trials in humans.

Fracture repair and periosteum

Studies examining the expression pattern of BMP ligands, receptors, and antagonists demonstrate that BMP signaling is an essential component of the fracture repair process. Mice lacking *Bmp2* are unable to initiate fracture healing, but this deficit can be rescued by the addition of exogenous BMPs (Tsuji et al., 2006; Meyer et al., 2004). The BMP antagonists BMP3 and noggin exhibit enhanced expression in the inflammatory stage of the fracture repair process as well as in the soft-callus stage. Their expression is reduced at the hard callus stage of repair consistent with the idea that BMP signaling is required for initiation of fracture healing but then needs to be tightly regulated (Morgan et al., 2016; Ehnert et al., 2016). Interestingly, BMP signaling is barely detectable in the process of intramembranous fracture repair (Yu et al, 2010b).

Periosteal cells have a crucial role during fracture repair, as the periosteum contains skeletal progenitors that participate in the healing response. Recent studies have demonstrated that BMP2 is produced by periosteal skeletal progenitors at the site of the fracture and promotes callus formation to stimulate fracture healing (Yu et al, 2010a). This effect starts at the early stages of repair during inflammation and continues to the last stage of remodeling (Yu et al, 2010a). In addition, mice lacking *Bmp2* cannot support bone graft healing despite having periosteal progenitors, indicating that *Bmp2* is required for skeletal progenitor cell activation to initiate repair but not for maintenance of the skeletal progenitor cell niche within the periosteum (Chappuis et al., 2012), consistent with the ability of BMP2 to induce endochondral ossification of the periosteum in a model of middle phalanx regeneration (Dawson et al., 2017). With regard to human periosteal progenitors, a combination of BMP2 and BMP6 was shown to promote chondrogenesis and matrix deposition that was sustained for 4 weeks after human cells underwent implantation in mice (Mendes et al., 2016).

Osteoporosis

BMP expression levels are decreased in aged bone in parallel with declining anabolic function of skeletal progenitors (Bessho and Iizuka, 1993; Fleet et al., 1996). In addition, in mouse models of bone loss, decreased expression of BMP family members has been associated with the development of osteoporosis. *Bmp2* expression is decreased in both steroid-induced osteopenic mice and ovariectomized mice (Lee et al., 2015). In vitro studies revealed that osteoprogenitors from older mice exhibit reduced differentiation potential when stimulated with rhBMP2 (Tang et al., 2008; Pountos et al., 2010). Local administration of rhBMP7 improves bone microarchitecture and strength in an osteoporotic sheep model (Phillips et al., 2006). Moreover, ovariectomized rats were shown to have accelerated fracture repair upon systemic administration of BMP7 (Mathavan et al., 2017; Blokhuis et al., 2012). These data suggest that BMP signaling is fundamental to bone homeostasis throughout life.

Osteoarthritis and articular cartilage maintenance

BMP signaling is also important for maintaining healthy articular cartilage. BMP2 and BMP6 are highly expressed in the superficial zone, while the BMP antagonists, gremlin and noggin, are highly expressed in the middle and deeper zones consistent with reduced levels of pSMAD1/5/8 in these zones of articular cartilage (Garrison et al., 2017). This BMP signaling gradient may maintain the function of normal articular cartilage (Garrison et al., 2017; Lui et al., 2015) and may be disrupted upon development of osteoarthritis (OA). Data in support of this hypothesis come from the observation that loss of BMP signaling results in degeneration of articular cartilage and early onset of OA in mice (Tsuji et al., 2006; Rountree et al., 2004). However, the roles of individual BMPs in joint homeostasis, independent of joint formation, remain

largely unexplored. BMP7 appears to be of particular importance for the maintenance of articular cartilage (Abula et al., 2015; Hurtig et al., 2009; Sekiya et al., 2009), but further studies are needed to separate out developmental effects from those specific to adult articular cartilage maintenance. GDF5 appears to have a fundamental role in determining joint shape, which has an important role in the development of OA (Pregizer et al., 2018; Baker-LePain & Lane, 2010). Concordantly, single-nucleotide polymorphisms (SNPs) in GDF5 have been associated with development of OA; some variants are associated with increased susceptibility, while others are associated with a lower risk of developing OA (Yin and Wang, 2017). These discrepancies highlight the complicated role that GDF5 plays in synovial joints. Since the regulation of *Gdf5* expression is complex (Chen et al., 2016; Capellini et al., 2017), it is possible that SNPs in different regions of *Gdf5* have unique effects on gene expression. A clear consensus is also lacking for the true role of BMP signaling in OA—evidence consistent with a deleterious effect is counterbalanced by data suggesting a positive therapeutic role. The ability to specifically activate or extinguish BMP signaling in adult joint tissues should begin to resolve this dilemma (Tardif et al., 2009; Leijten et al., 2013; Yu et al., 2017).

Conclusions

BMPs are involved in almost every aspect of skeletal biology. BMPs exert their effects on skeletal cells through signaling cascades that are increasingly appreciated to be tightly regulated and highly dependent on cell-type, timing, and the receptor-ligand environment. Several important questions about the role of BMP signaling in the skeleton remain to be addressed, including the ways in which BMP signaling is integrated with other signals to maintain skeletal homeostasis, and the composition of BMP ligand and receptor partners in osteoprogenitors and differentiated bone cells. With a more comprehensive understanding of BMP biology in bone, the potential for BMPs as therapeutics could be greatly maximized.

Chapter outline

The role of RANKL in mammary gland development and tumorigenesis

RANKL in the lactating mammary gland

One of the first studies to demonstrate the potential extraskeletal effects of receptor activator of nuclear factor-κB ligand (RANKL) was on its expression in several murine tissues, such as the brain, heart, kidney, muscle, skin, and spleen (Kartsogiannis et al., 1999). Studies using RANKL-deficient mice were key to establishing its role in bone, but importantly also pointed to a role in mammary gland physiology (Fig. 49.1).

The development of a lactating mammary gland during pregnancy is essential for the nutrition, passive immunity, and survival of the newborn. The mammary ductal and alveolar epithelium undergoes expansion and proliferation to increase ductal side branching and to form lobuloalveolar structures. This process of cellular development arrests in pregnant *RANKL*$^{-/-}$ mice before the final differentiation of lobuloalveolar mammary structures (Fata et al., 2000). In line with this finding, mouse mammary glands overexpressing RANK display increased proliferation and decreased apoptosis (Gonzalez-Suarez et al., 2007). In addition, newborn *RANKL*$^{-/-}$ pups die due to an incomplete composition of milk lacking milk proteins such as β-casein. These detrimental effects can be rescued by administration of recombinant RANKL. Mechanistically, progesterone, prolactin, and parathyroid hormone−related peptide, which are upregulated during pregnancy and important for lactation, induce RANKL expression in mammary epithelial cells (Fata et al., 2000). The induction of proliferation by progesterone is mediated both directly in progesterone receptor−positive epithelial cells and indirectly by a paracrine mechanism involving RANKL in those cells that lack this receptor (Beleut et al., 2010). Progesterone also mediates the expansion of mammary stem cells during the reproductive cycle, at least partially by RANKL serving as a paracrine effector (Joshi et al., 2010). The concerted regulation of the RANKL/progesterone axis on mammary tissue architecture has been confirmed for human breast using an ex vivo system with mammoplasty specimens (Tanos et al., 2013).

RANKL in breast cancer development and metastasis

Mammary gland epithelium is the predominant site for the development of breast cancer (Hinck and Näthke, 2014). As RANKL supports mammary gland differentiation during pregnancy and is controlled by sex hormones, subsequent studies focused on hormone-driven mammary tumor models. The RANKL receptor, RANK, was found to be expressed on

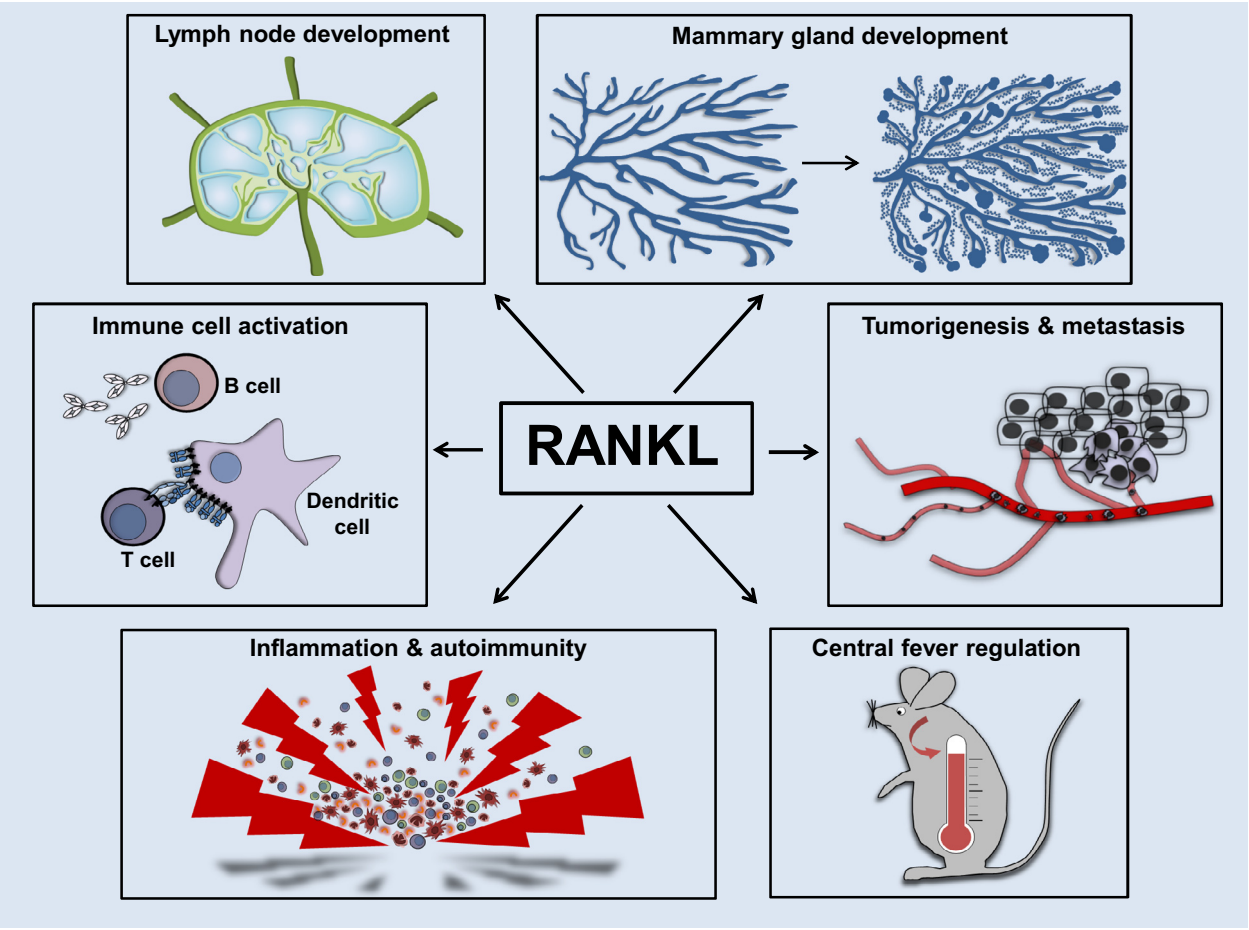

FIGURE 49.1 Nonskeletal effects of receptor activator of nuclear factor-κB ligand (*RANKL*). Despite its central role in bone physiology, RANKL has pleiotropic nonskeletal effects in mammary gland and lymph node development, tumorigenesis and metastasis, and central fever regulation as well as in inflammation and autoimmunity.

primary breast cancer cells, and treatment with recombinant RANKL enhanced migration of both normal and malignant mammary epithelial cells (Jones et al., 2006). The synthetic progesterone medroxyprogesterone acetate was shown to massively induce RANKL expression in mammary epithelial cells and to trigger carcinogenesis when combined with tumorigenic agents, such as the DNA-damaging agent 7,12-dimethylbenz[*a*]anthracene. The development of tumors was significantly suppressed in mice in which RANK was genetically inactivated in mammary epithelial cells (Schramek et al., 2010). The contribution of RANKL to mammary tumorigenesis was conclusively established by similar work in which RANKL signaling was inhibited by the pharmacological inhibitor RANK-Fc. These studies highlighted RANKL's role in promoting initial steps in breast cancer development (Gonzalez-Suarez et al., 2010) and led to further studies in humans.

In line with the findings of Schramek et al. and Gonzalez-Suarez et al., postmenopausal women with high serum progesterone and RANKL are at increased risk of developing breast cancer (Kiechl et al., 2017). Remarkably, RANK expression in primary human breast cancer is associated with an increased sensitivity to chemotherapy, but RANK is also a predictor of relapse and poor survival (Pfitzner et al., 2014). In addition, RANK expression in primary human breast tumors is a predictive marker for the occurrence of bone metastases and skeletal disease-free survival (Santini et al., 2011). Data indicate that the contribution of RANKL signaling to mammary tumorigenesis is not limited to hormone-dependent cancer cells. Triple-negative breast cancers (TNBCs) have a high propensity to relapse, to metastasize, and to resist multimodal therapies. The dual expression of RANK and RANKL in these patients has been shown to be associated with a poorer recurrence-free and overall survival compared with patients with RANK-positive RANKL-negative TNBCs (Reyes et al., 2017).

Further investigations were conducted in hereditary forms of breast cancer: women carrying *BRCA1/2* mutations have an increased risk of developing breast cancer (Robson and Offit, 2007). Mechanistic studies have shown that the progesterone receptor in mammary epithelial cells that lack a functional BRCA1 is stabilized, and progesterone serves as a

mitogen in these cells (Poole et al., 2006). The dysregulation of osteoprotegerin (OPG), the natural decoy receptor of RANKL, might mediate the relationship between progesterone and the breast cancer risk in *BRCA1* mutation carriers. Here, the presence of progesterone was associated with low serum OPG levels, which in turn showed an inverse correlation with breast cancer risk. Reduced OPG was hypothesized to increase the net RANKL signaling in the mammary tissue (Widschwendter et al., 2015; Rachner and Rauner, 2015).

The contribution of RANKL to mammary tumorigenesis appears to be even more complex, as tumor-infiltrating regulatory T cells (Tregs) support pulmonary metastasis by producing RANKL in mammary carcinoma cells overexpressing the protooncogene *Erbb2* (Tan et al., 2011). In addition, novel RANK isoforms have been identified through alternative splicing, one of which was shown to impair cell survival and migration of invasive breast cancer cells (Papanastasiou et al., 2012).

In summary, these results confirm a role for the RANKL system in breast cancer (Fig. 49.1) and make it a chemotherapeutic target (Infante et al., 2019).

The role of RANKL in other malignancies

The central function of RANKL in bone homeostasis and bone-metastatic malignancies (summarized in Chapter 73) has led to investigations using other osteotropic cancer models. RANKL supports the migration of clear cell renal cell carcinomas, and elevated RANKL serum levels are an independent predictor for recurrence and poor prognosis (Mikami et al., 2009). In prostate cancer, RANKL is associated with enhanced epithelial−mesenchymal transition (EMT), a process that favors the migratory and metastatic potential of tumor cells, thereby potentially serving as a link between primary tumor and the formation of bone metastases (Odero-Marah et al., 2008). A supportive role of RANKL has also been confirmed for hepatocellular carcinoma. Here, RANKL is increased in patient-derived tumor specimens and favors EMT, migration, and invasion involving an NF-κB-dependent mechanism (Song et al., 2014).

The RANKL/RANK system has been studied in other human cancer subtypes, including bladder, colon, and cervical cancer; lymphoma; myeloma; and thyroid cancer. These studies revealed a wide distribution of either RANK or RANKL, or both, within tumor tissue and confirmed the principle of RANKL-induced cancer cell migration (reviewed in Renema et al., 2016). In addition to migration, RANKL promotes angiogenesis in cooperation with vascular endothelial growth factor, which increases RANK in endothelial cells. RANKL enhances their survival and the production of inflammatory cell adhesion molecules as well as in vitro and in vivo angiogenesis (Min et al., 2007).

Functions of RANKL in immune and thermal regulation

A number of studies in the last 10 years have contributed to an enhanced understanding of the functions of RANKL beyond its key role in bone homeostasis. The identification of cross talk between bone and other organ systems led to the emergence of new concepts and research fields such as osteoimmunology and osteohematology in which the RANKL/RANK/OPG system links bone with the immune system and hematopoiesis (Takayanagi, 2007; Bulycheva et al., 2015).

Immune system development and thermoregulation

RANKL-deficient mice lack lymph nodes and have an impaired early differentiation of B and T lymphocytes (Fig. 49.1) (Kong et al., 1999). These mice also show a marked decrease of microfold cells (M cells) and cryptopatches. M cells are specialized epithelial cells situated over Peyer patches, which are important for the sampling of potential antigens (e.g., bacteria) from the intestinal lumen (Knoop et al., 2009). Cryptopatches are an organized lymphoid system in the intestine, which contains RANKL-expressing stromal cells. RANKL-deficient mice show no B cell development in these cryptopatches of the small intestine (Knoop et al., 2011). In addition, RANKL is implicated in the development of medullary thymic epithelial cells, which are important for central tolerance and protecting the body from self-reactive T cells. Consequently, central tolerance limits the generation of tumor-specific T cells. The blockade of RANKL was able to rescue melanoma-specific T cells from thymic selection and to enhance antitumor immunity (Khan et al., 2014). Furthermore, RANKL supports the survival of dendritic cells, their interaction with T cells (Wong et al., 1997), and their potential to stimulate T cell proliferation (Anderson et al., 1997).

In humans, mutations of the RANK gene *TNFRSF11A* lead to an impairment of immunoglobulin production by B cells (Guerrini et al., 2008). However, in patients exposed to RANKL-blocking antibodies, no specific immune disturbances have been described, including no effects on normal B-cell physiology (Nagy and Penninger, 2015), lack of opportunistic infections (Watts et al., 2017), and normal response to influenza infection (Miller et al., 2007).

Apart from the immune system, RANKL and RANK are both expressed in the brain (Kartsogiannis et al., 1999), where they play an essential role in the regulation of central fever. Intracerebroventricular injections of RANKL induce a strong fever response in mice and rats (Fig. 49.1), which is reversible by OPG. RANKL specifically stimulates thermoregulatory brain regions and induces fever by activation of prostaglandins. By contrast, intraperitoneal injections of RANKL have no impact on body temperature. Hence, the fever response requires only central RANKL/RANK signaling. In line with this, patients suffering from a severe form of autosomal-recessive osteopetrosis due to RANK mutations fail to develop fever during pneumonia (Hanada et al., 2009). Hence, the RANKL/RANK axis is an important thermoregulatory system. Apart from this very rare disease, it is important to note that RANKL blockade has not been linked to altered thermoregulation in humans.

Inflammation, autoimmunity, and antitumor effects

A disturbance of the RANKL/RANK/OPG system is a common characteristic of inflammatory diseases. Inflammation is a tightly controlled defense strategy to protect the host from pathogens. The failure to resolve this inflammatory process leads to a chronic setting associated with tissue damage and an increased risk of developing secondary complications (Schett and Neurath, 2018). RANKL exerts pleiotropic effects in normal and pathological inflammatory conditions. In inflammatory bowel disease, such as Crohn's disease and ulcerative colitis, the RANKL/OPG system is activated and seems to contribute to bone loss in affected patients (Moschen et al., 2005). Furthermore, patients suffering from systemic lupus erythematosus (SLE) display an increased ratio of soluble RANKL/OPG levels, which may contribute to the lower bone mineral density in these patients. SLE is a complex disease, characterized by systemic chronic inflammation and multiple tissue damage (Carmona-Fernandes et al., 2011). In chronic obstructive pulmonary disease (COPD), osteoporosis is a common co-morbidity. In COPD patients with lower bone mineral density, RANKL and RANKL/OPG ratios are increased, a potential link between inflammation and bone loss. During intestinal inflammation, mediated by autoreactive T cells, dendritic cell survival is enhanced by RANKL, and its neutralization by recombinant OPG decreases inflammation and associated bone abnormalities (Ashcroft et al., 2003). In addition, in rheumatoid arthritis, T cells in arthritic joints express RANKL and promote RANKL production in osteoblasts by the release of inflammatory cytokines as a self-amplifying effect, thereby promoting bone destruction (Holstead Jones et al., 2002).

Whereas the former studies present disease-promoting effects of RANKL, other investigations report that RANKL protects from autoimmunity and excessive inflammation. Using a cytotoxic T cell−mediated model of type 1 diabetes, RANKL signaling has been demonstrated to be essential for the generation and activation of Tregs, which prevent β-cell destruction in Langerhans islets (Green et al., 2002). During skin inflammation, RANKL is expressed in keratinocytes and alters the function of epidermal dendritic cells as well as increasing Tregs, thereby mediating immunosuppression and reduction of contact hypersensitivity responses (Loser et al., 2006). The same group demonstrated that RANK/RANKL signaling in the skin is involved in inducing and sustaining a cytotoxic T cell−mediated immune response against herpes simplex virus by supporting antigen transport to lymph nodes, improving dendritic cell function and preventing their apoptosis (Klenner et al., 2015). Furthermore, RANKL signaling supports the function of Tregs in limiting the excess of mucosal inflammation during colitis (Totsuka et al., 2009). Whether an increased incidence of skin eczema and cellulitis after treatment with RANKL antibodies in humans (Cummings et al., 2009) is linked to these mechanisms is unclear. Of note, the induction of Tregs is considered a limiting factor in the effectiveness of antitumor therapies, as they are used by tumors as an immune escape mechanism. Data demonstrated that the combination of immunotherapy (e.g., checkpoint inhibitors such as anti-CTLA-4) can be potentiated by the blockade of RANKL (van Dam et al., 2019). In a clinical case of metastatic melanoma, the concomitant administration of denosumab and the anti-CTLA-4 antibody ipilimumab led to a dramatic partial response including pain resolution (Smyth et al., 2016).

These results emphasize a regulatory role of the RANKL/RANK system in human immunity (Fig. 49.1) and should pave the way to clinical studies investigating the potential of its therapeutic modification in inflammatory and autoimmune diseases as well as a strategy to improve the immunotherapy of a variety of disorders.

Chapter 50

Local regulators of bone

Interleukin-1, tumor necrosis factor, interferons, the IL-6 family, and additional cytokines

Natalie A. Sims[1] **and Joseph A. Lorenzo**[2]

Chapter outline

Introduction

Bone development, bone growth, and the bone remodeling cycle are regulated by a variety of factors (e.g., hormones, cytokines, growth factors, and physical force). These are produced both locally and systemically and act in concert to direct local rates of bone resorption and formation. Many studies of the mechanisms regulating bone resorption and formation have concentrated on the role of cytokines because these factors appear to have crucial roles in both normal and pathological bone cell function. A variety of cytokines originally identified by their ability to regulate immune and hematopoietic cells are produced in the bone microenvironment either spontaneously or in response to specific stimuli. It has become apparent that during both health and disease, the production of cytokines by cells in the bone microenvironment and the responses of bone cells to these cytokines are regulated in a highly ordered manner. It is

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00050-6

hypothesized that the spectrum of cytokines that are produced in bone defines the responses of bone cells to a particular state and predicts the subsequent development of normal and pathological bone. Diseases of bone where cytokines are believed to play an important role include osteoporosis, Paget's disease, periodontal disease, inflammatory arthritis, and the effects of malignancy on bone. Studies of the production of cytokines in bone and the responses of bone cells to these cytokines provide insights into not only normal physiological mechanisms, but also mechanisms that regulate the development of these diseases and could lead to new therapies for these conditions. The following is a broad overview of the actions of a number of cytokines on bone and the mechanisms by which bone cells respond to these cytokines.

Interleukin-1

Interleukin-1 (IL-1) is a cytokine with a wide variety of activities. It comprises two gene products, IL-1α and IL-1β, with identical activities (Dinarello, 1991). IL-1 is a potent stimulator of in vitro bone resorption (Lorenzo et al., 1987) and has powerful in vivo actions (Sabatini et al., 1988). Its effects on resorption appear to be both direct on osteoclasts (Jimi et al., 1999) and indirect through its ability to stimulate RANKL production (Hofbauer et al., 1999). In addition, both RANKL- and 1,25-dihydroxyvitamin D_3-stimulated osteoclast formation in vitro were found to be mediated in part by IL-1 production (Lee et al., 2002a, 2005a; Nakamura and Jimi, 2006). IL-1 also increases prostaglandin synthesis in bone (Lorenzo et al., 1987; Sato et al., 1986), which may enhance its resorptive activity because prostaglandins are potent resorption stimuli (Klein and Raisz, 1970). Importantly, the rate at which IL-1 enhances RANKL-induced osteoclastogenesis is partially dependent on the type of osteoclast precursor examined (Cao et al., 2016).

In mouse models, IL-1 appears to be involved in normal growth plate development (Simsa-Maziel et al., 2013) and bone remodeling (Lee et al., 2010). It also may be essential for the systemic bone loss seen in some inflammatory conditions due to high tumor necrosis factor (TNF) production (Polzer et al., 2010). In addition, it mediates some effects of estrogen withdrawal on bone loss in mice (Lorenzo et al., 1998) and humans (Charatcharoenwitthaya et al., 2007), potentially through effects on p38α MAPK (Thouverey and Caverzasio, 2015). In humans, serum IL-1 levels have been linked to measurements of bone mass (Ivanova et al., 2012; Zupan et al., 2012) and bone turnover (Al-Daghri et al., 2017).

IL-1 is produced in bone (Lorenzo et al., 1990), and its activity is present in bone marrow serum (Kawaguchi et al., 1995; Miyaura et al., 1995). One source of bone cell-derived IL-1 is osteoclast precursor cells, which produce IL-1 when they interact with bone matrix (Yao et al., 2008). A natural inhibitor of IL-1, IL-1 receptor antagonist, is an analogue of IL-1 that binds but does not activate the biologically important type I IL-1 receptors (Arend et al., 1990; Eisenberg et al., 1990; Hannum et al., 1990).

There are two receptors for IL-1, type I and type II (Dinarello, 1993). All known biologic responses to IL-1 are mediated exclusively through the type I receptor (Sims et al., 1993). IL-1 receptor type I requires interaction with a second protein, IL-1 receptor accessory protein, to generate postreceptor signals (Huang et al., 1997; Korherr et al., 1997; Wesche et al., 1997). Signaling through type I receptors involves activation of specific TRAFs and NF-κB (Eder, 1997; Martin and Falk, 1997). IL-1 receptor type II is a decoy receptor that prevents activation of type I receptors (Colotta et al., 1993). One report found a decrease in the bone mass of mice deficient in the bioactive type I IL-1 receptor (Bajayo et al., 2005). However, this has not been our experience (Vargas et al., 1996).

Expression of myeloid differentiation factor 88 (MyD88), but not Toll/IL-1 receptor domain-containing adaptor inducing interferon-beta, was necessary for IL-1 to stimulate RANKL production in osteoblasts and prolong the survival of osteoclasts (Sato et al., 2004). Survival of osteoclasts by treatment with IL-1 appears to require PI3-kinase/AKT and ERK (Lee et al., 2002c).

The effects of IL-1 on bone in inflammatory states, such as rheumatoid arthritis, are multiple and mediated by both direct and indirect mechanisms. IL-1 stimulates bone resorption and inhibits bone formation through, respectively, its effects on osteoclasts and osteoblasts (Boyce et al., 1989; Canalis, 1986; Tsuboi et al., 1999). In addition, it stimulates the production of a variety of secondary factors in the bone microenvironment including prostaglandins and GM-CSF, which have complex effects of their own on bone cells (Niki et al., 2007). IL-1 has been reported both to inhibit and stimulate production of osteoprotegerin (OPG) in various osteoblastic cell models in vitro (Tanabe et al., 2005; Lambert et al., 2007). Its stimulatory effect was dependent on p38 and ERK MAP kinases (Lambert et al., 2007). The ability of IL-1 to enhance osteoclastogenesis is in contrast to the inhibitory effects of toll-like receptors (TLRs). Why these responses differ is a matter of some investigation because both signaling pathways overlap through MyD88 adaptor protein. One possible reason is their divergent effects on B lymphocyte—induced maturation protein-1 (Blimp1), a transcriptional repressor of antiosteoclastogenic genes—IL-1 enhances RANKL-induced Blimp1 gene expression while TLR inhibits Blimp1 (Chen et al., 2015).

IL-1 induces the differentiation of mesenchymal stem cells toward osteoblasts via the noncanonical Wnt-5a/Ror2 pathway (Sonomoto et al., 2012) and inhibits osteoblast migration (Hengartner et al., 2013). Osteocytes regulate osteoclastogenesis by producing a variety of factors including RANKL (Nakashima et al., 2011; Xiong et al., 2011). Treatment of the MLO-Y4 osteocyte-like cell line with IL-1 enhanced RANKL and decreased OPG production, which was reversed by mechanically loading the cells (Kulkarni et al., 2012).

Tumor necrosis factor

Like IL-1, TNF represents a family of two related polypeptides (α and β) that are the products of separate genes (Beutler and Cerami, 1986, 1987; Old, 1985; Oliff, 1988; Paul and Ruddle, 1988). TNFα and TNFβ have similar biologic activities and are both potent stimulators of bone resorption (Bertolini et al., 1986; Lorenzo et al., 1987; Tashjian et al., 1987).

In vivo administration of TNFα to mice was shown to increase their serum calcium (Tashjian et al., 1987) and stimulate new osteoclast formation and bone resorption (Stashenko et al., 1987b). Like IL-1, TNF also enhances the formation of osteoclast-like cells in bone marrow culture (Tashjian et al., 1987) through its ability to increase RANKL production and the RANKL/OPG ratio (Hofbauer et al., 1999). In mixed cultures of osteoblast and osteoclast precursors, TNF was most effective at stimulating osteoclastogenesis when osteoblasts were derived from calvaria rather than long bones (Wan et al., 2016). It also has direct effects on RANKL-induced osteoclastogenesis that vary depending on the type of osteoclast precursor examined and timing of TNF exposure relative to RANKL (Cao et al., 2017; Zhao et al., 2015) and can be dependent on the degradation of TRAF3 (Yao et al., 2009, 2017).

In addition to RANKL, TNF stimulates a variety of additional cytokines in the bone microenvironment, and many of these enhance the response to RANKL (Boyce et al., 2005). For example, TNF stimulates osteoclast formation in mixed stromal cell/osteoclast precursor cell cultures by a mechanism that was partially dependent on the production of IL-1 (Wei et al., 2005; Zwerina et al., 2007; Polzer et al., 2009). In addition, TNF-induced osteolysis was found to be dependent on CSF-1 production (Kitaura et al., 2005).

TNF can also directly stimulate osteoclast formation in vitro, independent of RANK, because it occurred in cells from RANK-deficient mice (Azuma et al., 2000; Kim et al., 2005; Kobayashi et al., 2000). However, the significance of this in vitro finding is questionable because in vivo administration of TNF to RANK-deficient mice caused only an occasional osteoclast to form (Li et al., 2000). In addition, RANK-deficient mice that overexpressed TNF had severe osteopetrosis and no osteoclasts (Li et al., 2004a). It was also demonstrated that TNF can stimulate osteoclastogenesis in the absence of RANKL in mice that are deficient in the p100 precursor protein of NF-κB, which is a critical signaling molecule in RANKL-mediated stimulation of osteoclastogenesis and bone resorption (Yao et al., 2009). TNF also stimulated production of Blimp1, an inhibitor of multiple antiosteoclastogenic genes (Wu et al., 2017). These results demonstrate that although both TNF and RANKL are members of the same cytokine superfamily and share multiple overlapping signaling pathways, there are crucial differences between RANKL- and TNF-induced signaling pathways in osteoclast precursor cells.

As with IL-1, TNF binds to two cell surface receptors, TNF receptor 1, or p55, and TNF receptor 2, or p75 (Fiers and Sim, 1993). In contrast to IL-1, both receptors transmit biologic responses. However, the principal effects on bone cells appear to be mediated through TNF receptor 1 (Zhang et al., 2001; Abbas et al., 2003). Mice deficient in both TNF receptor 1 and TNF receptor 2 appear healthy and are not reported to have an abnormal bone phenotype (Erickson et al., 1994; Pfeffer et al., 1993; Rothe et al., 1993).

TNF can stimulate expression of colony-stimulating factor 1 receptor in osteoclast precursor cells (Yao et al., 2006a), and through this mechanism increase the abundance of these cells (Yao et al., 2006b). It also enhances RANK signaling, which activates osteoclasts and their precursor cells (Lam et al., 2000), and increases the expression of the costimulatory molecule, paired Ig-like receptor A, which augments NFATc1 activation (Ochi et al., 2007). Mice that overexpress TNF have an increased number of $CD11b^{high}$ osteoclast precursor cells in their spleen and blood (Li et al., 2004b).

TNF has biphasic effects on bone formation and osteoblast function, which may be dose- and time-dependent (Osta et al., 2014; Daniele et al., 2017). At lower doses, it is stimulatory for the differentiation of mesenchymal precursor cells into osteoblasts (Osta et al., 2014; Daniele et al., 2017), while at higher concentrations it inhibits osteoblast function and bone formation (Bertolini et al., 1986; Canalis, 1987; Stashenko et al., 1987a; Nanes et al., 1989). It was reported to promote fracture repair by enhancing the recruitment of precursor cells to the osteoblastic lineage (Glass et al., 2011). The inhibitory effects of TNF on osteoblasts appear to be direct and mediated by downregulation of the critical transcription factors RUNX2 and osterix (Gilbert et al., 2002, 2004) as well as type 1 collagen (Mori et al., 1996) and osteocalcin (Gowen et al., 1988; Nanes et al., 1991), which are essential for differentiated osteoblast function. It also stimulates

osteoblast apoptosis (Kitajima et al., 1996; Hock et al., 2001) and suppresses production of insulin-like growth factor-1 in osteoblasts (Scharla et al., 1994).

TNF mediates many effects of inflammatory arthritis on periarticular bone, and some of these responses may be selectively mediated by its interactions with TNFR1 (Espirito Santo et al., 2015). Most recently, patients with inflammatory diseases who were treated with anti-TNF therapy were found to have increased bone mineral density (Nigil Haroon et al., 2014; Durnez et al., 2013). These results suggest that circulating TNF, which is produced by localized inflammatory pathology, has systemic effects on bone mass. TNF may also be involved in the development of osteoporosis because mice in which the activity of this cytokine was blocked or are deficient in TNF fail to lose bone after ovariectomy (Kimble et al., 1997; Roggia et al., 2001). In addition, men with relatively high serum TNF levels have an increased risk of hip and vertebral fractures (Cauley et al., 2016).

Additional tumor necrosis factor superfamily members

Fas-ligand

Fas-ligand (FasL) binds its receptor, Fas, on responsive cells, and regulates apoptosis and other cellular processes in multiple cell types (Wesche et al., 2005). In osteoblasts, FasL inhibits differentiation through a caspase 8-mediated mechanism (Kovacic et al., 2007). Osteoclast precursors and mature osteoclasts express Fas and FasL (Park et al., 2005), and this pathway has been shown to mediate apoptosis in mature osteoclasts (Wang et al., 2015) and in osteoclast precursor cells (Liu et al., 2015). However, at high concentrations RANKL inhibited the ability of FasL to induce apoptosis in osteoclasts (Wu et al., 2005). The effect that FasL deficiency has on bone mass is controversial. One group has found bone mass to be decreased in FasL-deficient mice (Wu et al., 2003) while another found it to be increased (Katavic et al., 2003). However, the significance of studying bone mass in Fas- or FasL-deficient mice is difficult to interpret because these models have a generalized lymphoproliferative disorder that activates a wide variety of immune responses that can affect bone.

It appears the Fas signaling is involved in the effects of estrogen on bone, although there is controversy about its role. One group found that stimulation of estrogen receptor α in osteoclasts in mice enhanced FasL production, which in turn reduced rates of bone loss by increasing osteoclast apoptosis (Nakamura et al., 2007). In contrast, a second group failed to detect expression of FasL in osteoclasts (Krum et al., 2008). Rather, they found that estrogen enhanced FasL production in osteoblasts. They speculated that the estrogen-induced increase in FasL production by osteoblasts regulates osteoclast apoptosis through a paracrine mechanism (Krum et al., 2008). More recently, Fas receptor was shown to be required for estrogen deficiency-induced bone loss (Kovacic et al., 2010) and that estrogens interacting through ERα regulate metalloproteinase 3 expression on osteoblasts, which in turn induces FasL cleavage from osteoblasts and osteoclast apoptosis (Garcia et al., 2012). Fas/FasL interactions may also mediate some effects of interferon γ on bone (Kohara et al., 2011). Production of receptor-interacting protein 140 by a Fas/FasL pathway has been implicated in the effects of estrogen on bone (Piao et al., 2017).

Tumor necrosis factor–related apoptosis-inducing ligand

TNF-related apoptosis-inducing ligand (TRAIL) is another TNF-superfamily member that has a wide variety of activities. Its effects on osteoclast function and bone are also controversial. Some groups have found that treatment of osteoclasts with TRAIL induced apoptosis (Roux et al., 2005) through effects that were mediated by the receptor TRAIL-R2, also known as "death receptor 5" (DR5) (Zauli et al., 2010; Colucci et al., 2007). Others have found that TRAIL stimulated osteoclast differentiation through a TRAF-6-dependent mechanism (Yen et al., 2012). In vivo, injection of TRAIL for 8 days into 4-week-old mice induced an increase in bone mass. In vitro, this effect was associated with an increase in the cyclin-dependent kinase inhibitor $p27^{Kip1}$ through effects of TRAIL on the ubiquitin–proteasome pathway (Zauli et al., 2008). TRAIL may also be a factor in the effects of myeloma on osteoblasts (Tinhofer et al., 2006), the effects of microgravity on bone (Sambandam et al., 2016), and the bone disease associated with chronic obstructive pulmonary disease (Kochetkova et al., 2016). Significantly, one group failed to find either in vitro or in vivo effects of recombinant TRAIL on osteoclasts or in vivo effects on bone mass (Labrinidis et al., 2008).

In cultured human osteoblasts, the ability of TRAIL to induce apoptosis was dependent on their differentiation state, with early cells being more responsive than more mature cells (Brunetti et al., 2013). This effect was regulated by differential expression of the active DR5 and decoy DcR2 TRAIL receptors during osteoblast differentiation.

Cluster of differentiation 40 ligand

Cluster of differentiation 40 ligand (CD40L) is involved in the differentiation of naïve T lymphocytes into T_H1 effector cells (Loskog and Totterman, 2007). In humans, deficiency of CD40L causes X-linked hyper IgM (XHIM) syndrome. Bones of XHIM patients develop spontaneous fractures and are osteopenic (Lopez-Granados et al., 2007). Activated T lymphocytes from XHIM patients have normal amounts of RANKL but deficient INFγ production, which may contribute to the decreased bone mass in these individuals (Lopez-Granados et al., 2007). In addition, expression of CD40L in rheumatoid arthritis synovial cells induced RANKL expression in these cells and enhanced their ability to stimulate osteoclastogenesis. This suggests that this mechanism is involved in the destructive effects of rheumatoid arthritis on bone (Lee et al., 2006a). CD40L was also found to accelerate the osteoclastogenesis induced by RANKL and lipopolysaccharide (LPS) (Yokoyama et al., 2011). The ability of parathyroid hormone (PTH) to stimulate osteoclastogenesis involves induction of CD40L on T lymphocytes and the subsequent induction of responses in stromal cells expressing the CD40 receptor (Gao et al., 2008). T cell CD40L also potentiates the bone anabolic activity of intermittent PTH treatment (Robinson et al., 2015). CD40L has been implicated in the bone loss that occurs after ovariectomy in mice (Li et al., 2011), and T lymphocyte−derived CD40L mediates the ability of osteoclasts to suppress T lymphocyte activation (Li et al., 2014). A polymorphism in CD40 has also been correlated with bone mass (Panach et al., 2016).

Interferons

Type I interferons (IFNα and IFNβ) are typically produced in response to invading pathogens (Takayanagi, 2005). Mice deficient in IFNα/β have reduced trabecular bone mass and an increased number of osteoclasts (Takayanagi et al., 2002). RANKL induces IFNβ in osteoclasts, and IFNβ in turn inhibits RANKL-mediated osteoclastogenesis by decreasing c-fos expression (Takayanagi et al., 2002) and inducing the production of micro-RNA 155 (Zhang et al., 2012). Osteocytes are also a source of IFNβ (Hayashida et al., 2014). IFNα has also been shown to inhibit bone resorption although its mechanism of action is not as well studied as that of IFNγ and β (Jilka and Hamilton, 1984). In vivo, IFNα had no effect on bone turnover (Goodman et al., 1999). The ability of titanium wear debris to induce osteoclastogenesis and aseptic artificial joint loosening may be mediated by downregulation of IFNβ production (Wang et al., 2017).

Interferon γ (IFNγ) is a type II interferon with a wide variety of biologic activities. In vitro, IFNγ has generally been found to have inhibitory actions on bone resorption (Gowen and Mundy, 1986; Peterlik et al., 1985). These appear to be direct and are mediated by its effects on osteoclast progenitor cells. IFNγ inhibits the ability of 1,25-dihydroxyvitamin D_3, PTH, and IL-1 to stimulate the formation of osteoclast-like cells in cultures of human bone marrow (Takahashi et al., 1986). IFNγ also inhibits RANK signaling by accelerating the degradation of TRAF6 through activation of the ubiquitin/proteasome system (Takayanagi et al., 2000), by inhibiting NFATc1 expression, and by activating the NF-κB and JNK pathways (Cheng et al., 2012). Curiously, it is reported to not inhibit resorption in mature osteoclasts (Hattersley et al., 1988). IFNγ is also reported to have stimulatory effects on resorption through its ability to increase RANKL and TNFα production in T lymphocytes (Gao et al., 2007) and through its ability to enhance the fusion of preosteoclasts (Kim et al., 2012). It appears to mediate the ability of γδ T lymphocytes, CD8 regulatory T lymphocytes, IL-27, and M1 macrophages to inhibit osteoclastogenesis and resorptive activity (Pappalardo and Thompson, 2013; Park et al., 2012; Shashkova et al., 2016; Yamaguchi et al., 2016). T cell−derived IFNγ has been shown to induce osteoclasts to secrete factors that feed back to T cells to limit their proliferation (Li et al., 2014).

In osteoblasts, IFNγ is an inhibitor of proliferation (Cornish et al., 2003; Gowen et al., 1988; Nanes et al., 1989) and has variable effects on differentiation (Gowen et al., 1988; Shen et al., 1988; Smith et al., 1987).

The effects of IFNγ on bone in vivo are also variable, as both inhibitory and stimulatory effects have been reported. In mice with collagen-induced arthritis, loss of the IFNγ receptor (IFNγR) leads to increased bone destruction (Manoury-Schwartz et al., 1997; Vermeire et al., 1997). Similarly, in mice that are injected over their calvaria with bacterial endotoxin, which activates TLRs, loss of IFNγR resulted in an enhanced resorptive response (Takayanagi et al., 2000). This result is consistent with findings demonstrating that the inhibitory effects of IFNγ on osteoclastogenesis are enhanced by activation of TLRs (Ji et al., 2009). Finally, in mice that underwent ovariectomy to induce estrogen withdrawal, administration of IFNγ prevented the development of the bone loss otherwise seen in this condition (Duque et al., 2011).

In contrast, intraperitoneal injection of IFNγ for 8 days in rats induced osteopenia (Mann et al., 1994). In patients who have osteopetrosis, because they produce defective osteoclasts, administration of IFNγ stimulated bone resorption and appeared to partially reverse the disease. The latter effects are possibly due to the ability of IFNγ to stimulate osteoclast superoxide synthesis (Key et al., 1992, 1995), osteoclast formation in vivo (Vignery et al., 1990), or a generalized immune response (Schoenborn and Wilson, 2007).

Interleukin-7

Interleukin-7 (IL-7) is a cytokine that has diverse effects on the hematopoietic and immunologic systems (Namen et al., 1988). It is best known for its nonredundant role in supporting B- and T lymphopoiesis. Studies have demonstrated that IL-7 also plays an important role in the regulation of bone homeostasis (Miyaura et al., 1997; Weitzmann et al., 2002). However, the precise nature of how IL-7 affects osteoclasts and osteoblasts is controversial because it has a variety of actions in different target cells. Systemic administration of IL-7 upregulated osteoclast formation in human peripheral blood cells by increasing osteoclastogenic cytokine production in T lymphocytes (Weitzmann et al., 2000). Furthermore, mice with global overexpression of IL-7 had a phenotype of decreased bone mass with increased osteoclasts and no change in osteoblasts (Salopek et al., 2008). Significantly, IL-7 did not induce bone resorption and bone loss in T cell−deficient nude mice (Toraldo et al., 2003). In addition, treatment of mice with a neutralizing anti-IL-7 antibody inhibited ovariectomy-induced proliferation of early T cell precursors in the thymus, demonstrating that ovariectomy upregulates T-cell development through IL-7. This latter effect may be a mechanism by which IL-7 regulates ovariectomy-induced bone loss (Ryan et al., 2005). However, the interpretation of results from in vivo IL-7 treatment studies is complicated by secondary effects of IL-7, which result from the production of bone-resorbing cytokines by T cells in response to activation by this cytokine (Toraldo et al., 2003; Weitzmann et al., 2000; Gendron et al., 2008).

In contrast with previously reported studies (Miyaura et al., 1997; Toraldo et al., 2003; Weitzmann et al., 2000), we found differential effects of IL-7 on osteoclastogenesis (Lee et al., 2003). IL-7 inhibited osteoclast formation in murine bone marrow cells cultured for 5 days with CSF-1 and RANKL (Lee et al., 2003). Furthermore, IL-7-deficient mice had markedly increased osteoclast number and decreased trabecular bone mass compared with wild-type controls (Lee et al., 2006b). In addition, we found that trabecular bone loss after ovariectomy was similar in wild-type and IL-7-deficient mice (Lee et al., 2006b). Curiously, IL-7 mRNA levels in bone increase with ovariectomy, and this effect may be linked to alterations in osteoblast function with estrogen withdrawal (Sato et al., 2007; Weitzmann et al., 2002). Treatment of newborn murine calvaria organ cultures with IL-7 inhibited bone formation, as did injection of IL-7 above the calvaria of mice in vivo (Weitzmann et al., 2002). When IL-7 was overexpressed locally by osteoblasts, trabecular bone mass was increased compared with wild-type mice (Lee et al., 2004). Furthermore, targeted overexpression of IL-7 rescued the osteoporotic bone phenotype of IL-7-deficient mice (Lee et al., 2005b). These studies indicated that the actions of IL-7 on bone cells are dependent on whether IL-7 is delivered systemically or locally. Production of IL-7 by osteoblasts appears critical for normal B lymphopoiesis (Wu et al., 2008). This effect may be mediated by the response of osteoblasts to PTH (Panaroni et al., 2015) because induction of this cytokine in osteoblasts is mediated by $G_s\alpha$-dependent signaling. Osteoclast-mediated bone resorption can also influence B lymphopoiesis through effects on local IL-7 production in the bone marrow (Mansour et al., 2011).

Interleukin-10

Interleukin-10 (IL-10), the product of activated T and B lymphocytes (Moore et al., 2001), is a direct inhibitor of osteoclastogenesis (Owens et al., 1996; Xu et al., 1995) and osteoblastogenesis (Van Vlasselaer et al., 1993). These effects are associated with increased tyrosine phosphorylation of multiple proteins in osteoclast precursor cells (Hong et al., 2000). The direct effects of IL-10 on RANKL-stimulated osteoclastogenesis include decreases in NFATc1 expression, its reduced translocation into the nucleus (Evans and Fox, 2007), and suppressed c-Fos and c-Jun expression (Mohamed et al., 2007). Administration of IL-10 may have utility as a mechanism to control wear-induced osteolysis (Carmody et al., 2002) and the alveolar bone loss of periodontal disease (Zhang et al., 2014). In dental follicle cells, which function to regulate tooth eruption, in vitro treatment with IL-10 inhibited RANKL production and enhanced OPG (Liu et al., 2006). Hence, there also appears to be an indirect effect of IL-10 on osteoclastogenesis that is mediated by its ability to regulate RANKL and OPG production.

Treatment of bone marrow cell cultures with IL-10 suppressed the production of osteoblastic proteins and prevented the onset of mineralization (Van Vlasselaer et al., 1993). IL-10 also inhibited osteoclast formation in bone marrow cultures without affecting macrophage formation or the resorptive activity of mature osteoclasts (Owens and Chambers, 1995). This effect appears to involve the production of novel phosphotyrosine proteins in osteoclast precursor cells (Hong et al., 2000). IL-10 also stimulates a novel inducible nitric oxide synthase (Sunyer et al., 1996), and it regulates macrophage-mediated clearance of apoptotic cells (efferocytosis) (Michalski et al., 2016). IL-10-deficient mice have decreased alveolar bone and indices of osteoblast differentiation (Claudino et al., 2010). Most recently, polymorphisms of the IL-10 gene in humans have been associated with an increased risk of osteoporosis (Kotrych et al., 2016; Tural et al., 2013).

The inducible T cell costimulatory molecule 4-1BB interacts with the 4-1BB ligand. In vitro treatment of RANKL-stimulated osteoclast precursor cells with 4-1BB ligand enhanced IL-10 production. In addition, expression of IL-10 was greater in RANKL-stimulated wild-type osteoclast precursor cell cultures than in cultured cells from 4-1BB-deficient mice (Shin et al., 2006). These results imply that some effects of IL-10 on osteoclasts are mediated through interactions of 4-1BB and 4-1BB ligand.

Interleukin-12

Interleukin-12 (IL-12) is a cytokine produced by myeloid and other cell types. It induces T_H1 differentiation in T lymphocytes and the subsequent expression of IFNγ (Hsieh et al., 1993). IL-12 has an inhibitory effect on osteoclastogenesis (Horwood et al., 2001). However, the mechanisms by which this effect occurs in vitro are controversial. Some authors have demonstrated direct inhibitory effects of IL-12 on RANKL-stimulated osteoclastogenesis in purified primary osteoclast precursors and RAW 264.7 cells (Amcheslavsky and Bar-Shavit, 2006), which was associated with the inhibition of NFATc1 expression in the osteoclast precursor cells. Interestingly, the inhibitory effects of IL-12 on osteoclastogenesis were absent in cells pretreated with RANKL (Amcheslavsky and Bar-Shavit, 2006). In contrast, others have found that the inhibitory effects of IL-12 on osteoclastogenesis are indirect. One group demonstrated that the inhibitory effects of IL-12 are mediated by T lymphocytes and do not involve production of IFNγ (Horwood et al., 2001). A second group disputes this result and found inhibition of osteoclastogenesis by IL-12 in cells from T lymphocyte−depleted cultures and cells from T lymphocyte−deficient nude mice (Nagata et al., 2003). The latter authors also demonstrated that antibody neutralization of IFNγ blocked some of the inhibitory effect of IL-12 on RANKL-stimulated osteoclast formation. Production of IL-12 by M1 inflammatory macrophages was shown to be a mechanism by which these cells downregulated RANKL-induced osteoclastogenesis (Yamaguchi et al., 2016). Unexpectedly, one group found that IL-12 enhanced RANKL production in human periodontal ligament cells (Issaranggun Na Ayuthaya et al., 2017).

The effects of IL-12 on TNFα- and LPS-induced osteoclastogenesis have been examined in vivo (Yoshimatsu et al., 2009, 2015). It was found that osteoclastogenesis stimulated by the injection of TNFα or LPS over the calvariae of mice decreased when the mice were also treated with IL-12. In addition, the Fas/FasL system seems to be involved in these responses (Kitaura et al., 2002; Yoshimatsu et al., 2015).

Interleukin-15

Interleukin-15 (IL-15), like IL-7, is a member of the interleukin-2 (IL-2) superfamily and shares many activities with IL-2 including the ability to stimulate lymphocytes. It has been shown to enhance osteoclast progenitor cell number in culture (Ogata et al., 1999). Production of IL-15 by T lymphocytes has been linked to the increased osteoclastogenesis and bone destruction seen in the bone lesions of rheumatoid arthritis (Miranda-Carus et al., 2006). In animal models of inflammatory bowel disease and *Staphylococcus aureus* sepsis, lack of IL-15 or treatment with an IL-15 inhibitor reduced the severity of the disease and bone loss (Brounais-Le Royer et al., 2013; Henningsson et al., 2012). Mice with deficient IL-15 receptor α were found to have a low rate of bone formation (Loro et al., 2017). In vitro, IL-15 treatment of mixed murine bone marrow and osteoblast cocultures demonstrated a role of natural killer (NK) cells in the ability of IL-15 to induce apoptosis in osteoblasts (Takeda et al., 2014; Feng et al., 2015). IL-15 was also shown to enhance RANKL-mediated stimulation of osteoclastogenesis in vitro through an ERK-mediated mechanism (Okabe et al., 2017). Polymorphisms of the IL-15 gene have also been linked to variations in bone mineral density in women (Koh et al., 2009). In rheumatoid arthritis, IL-15 is reported to promote osteoclastogenesis via a pathway dependent on phospholipase D1 (Park et al., 2011).

Interleukin-17

Interleukin-17 (IL-17) is a family of related cytokines that are unique and contain at least six members (A−F) (Weaver et al., 2007). IL-17E is also called interleukin-25 (Fort et al., 2001). These cytokines are central for the development of the adaptive immune response and the products of a subset of CD4 T lymphocytes with a unique cytokine expression profile, termed T_H17. This is in contrast to the more traditional T lymphocyte cytokine-expressing subsets T_H1 and T_H2.

IL-17A was initially shown to be a stimulator of osteoclastogenesis in mixed cultures of mouse hematopoietic cells and osteoblasts (Kotake et al., 1999). This enhanced resorptive activity was mediated through increased production of prostaglandin and RANKL. The direct effects of IL-17A on the differentiation of osteoclast precursor cells is controversial, with some investigators finding stimulatory (Yago et al., 2009) and others finding inhibitory effects (Kitami et al., 2010).

These conflicting results may be due to variations in the response to IL-17A of different osteoclast precursor subtypes (Sprangers et al., 2016). In another report, IL-17 stimulated rheumatoid synoviocytes (Zhao et al., 2016) to produce RANKL only with 1,25 dihydroxy-vitamin D_3 and PGE_2 (Ota et al., 2015). Production of IL-17A in rheumatoid arthritis appears to be involved in the production of activated osteoclasts and bone destruction in involved joints (Kotake et al., 1999; Lubberts et al., 2000, 2003). Effects of IL-17 on osteoclastogenesis and bone resorption are enhanced by TNFα, which is also produced in the inflamed joints of patients with rheumatoid arthritis (Van Bezooijen et al., 1999) and inhibited by shear stress (Liao et al., 2017). Inhibition of IL-17A in an antigen-induced arthritis model reduced the joint and bone destruction typically seen and decreased the production of RANKL, IL-1β, and TNFα in the involved lesions (Koenders et al., 2005). Multiple reports have now implicated IL-17 as a critical mediator of the bone loss that occurs in animal models after estrogen withdrawal (Tyagi et al., 2012, 2014; DeSelm et al., 2012). In addition, patients with osteoporosis have higher serum levels of IL-17A than osteopenic and normal subjects (Zhang et al., 2015; Zhao et al., 2016). This effect may be related to estrogen levels, as postmenopausal women have higher serum IL-17 levels than premenopausal women (Molnar et al., 2014). In addition, a polymorphism of the IL-17 gene was associated with decreased bone mineral density in humans (Boron et al., 2014).

The effects of IL-17 on bone formation are complex. It stimulates mesenchymal cell proliferation (Huang et al., 2009). However, it inhibits mature osteoblast differentiation in vitro and the reparative response to a calvaria critical size defect in vivo (Kim et al., 2014). In an inflammatory arthritis model and a skin inflammation model, deletion or inhibition of IL-17A enhanced bone formation through a mechanism dependent on Wnt signaling (Shaw et al., 2016; Uluckan et al., 2016). In contrast, it was found that IL-17A-producing γδ and T_H17 T cells can enhance bone formation (Ono et al., 2016; Croes et al., 2016).

Interleukin-23

Interleukin-23 (IL-23) is an IL-12-related cytokine composed of one subunit of p40, which it shares with IL-12, and one subunit of p19, which is unique (Kastelein et al., 2007). It is critical for the differentiation of the T_H17 subset of T lymphocytes along with TGFβ and IL-6 (Bettelli et al., 2006). IL-23 appears most important for expanding the population of T_H17 T lymphocytes. This subset of T lymphocytes, which produces RANKL, has a high osteoclastogenic potential that is mediated by their production of IL-17 (Sato et al., 2006). In an LPS-induced model of inflammatory bone destruction, it was found that there was markedly less bone loss in mice deficient in either IL-17 or IL-23 (Sato et al., 2006). Hence, production of both is involved in the bone loss in this model. IL-23 induces RANKL expression in CD4 T lymphocytes (Ju et al., 2008) and RANK expression in osteoclast precursor cells (Chen et al., 2008). However, the actions of IL-23 on bone in vivo are controversial. IL-23-deficient mice have decreased bone mass in one report (Quinn et al., 2008) but increased bone mass in another (Adamopoulos et al., 2011). In some studies, IL-23 inhibited osteoclastogenesis through actions mediated by CD4 T lymphocytes (Quinn et al., 2008; Kamiya et al., 2007). In contrast, in another study it stimulated osteoclastogenesis in mixed osteoblast-osteoclast precursor cultures (Kang and Zhang, 2014). Shin et al. reported that IL-23 promoted osteoclastogenesis through a DNAX-activating protein of 12 kDa-dependent pathways (DAP12)−mediated mechanism (Shin et al., 2015).

Interleukin-18 and interleukin-33

Interleukin-18 (IL-18) is similar to IL-1 in its structure and a member of the IL-1 superfamily (Orozco et al., 2007). IL-18 synergizes with IL-12 to induce INFγ production (Okamura et al., 1995), and its levels are increased at sites of inflammation in rheumatoid arthritis (Yamamura et al., 2001). Osteoblastic cells express IL-18, and its production is induced by treatment with endothelin-1 (Zhong et al., 2014). IL-18 inhibits osteoclast formation through a variety of mechanisms. These include its ability to stimulate GM-CSF (100), which is produced by T cells in response to IL-18 treatment (Horwood et al., 1998b). It also stimulates INFγ production in vivo in bone (Kawase et al., 2003), and its inhibitory effects on osteoclastogenesis and bone resorption are enhanced by cotreatment with IL-12 (Yamada et al., 2002). IL-18 has been shown to indirectly stimulate osteoclastogenesis through its effects on T lymphocytes (Dai et al., 2004). Finally, IL-18 is reported to increase the production of OPG (Makiishi-Shimobayashi et al., 2001). In IL-18-overexpressing transgenic mice, osteoclasts were decreased, although curiously, so was bone mass. These results indicate that IL-18 may also have effects on bone formation (Kawase et al., 2003). In confirmation of this hypothesis, it was demonstrated that PTH treatment of osteoblasts stimulated IL-18 production. In addition, the anabolic effects of intermittent PTH treatment on trabecular bone mass in IL-18-deficient mice were reduced (Raggatt et al., 2008). IL-18 is also a mitogen for osteoblastic cells in vitro (Cornish et al., 2003).

An antagonist of IL-18, named IL-18 binding protein (IL-18BP), was shown to prevent some bone loss associated with ovariectomy in mice, and it was found that osteoporotic postmenopausal women had lower levels of IL-18BP compared to controls (Mansoori Sci Rep, 2016).

Interleukin-33 (IL-33) is another member of the IL-1 family that has primarily been studied for its effects on T lymphocytes (Villarreal and Weiner, 2014). Its specific receptor is the orphan IL-1 receptor ST2 (also called IL-1R-like-1) (Villarreal and Weiner, 2014). IL-33 is expressed by osteoblasts (Schulze et al., 2011; Saleh et al., 2011), and production in these cells is stimulated by PTH and oncostatin M (Saleh et al., 2011). Its effects on bone cells are varied. One report found it to stimulate osteoclastogenesis (Mun et al., 2010), while multiple others have found it to be inhibitory (Zaiss et al., 2011; Schulze et al., 2011; Saleh et al., 2011; Kang et al., 2017). In addition, there is a report that it had no effect on bone remodeling (Saidi et al., 2011), although these same authors suggested that it may be involved in the development of osteonecrosis of the femoral head (Saidi and Magne, 2011). These conflicting results may reflect differences in the response to IL-33 by different types of osteoclast progenitors (Eeles et al., 2015). IL-33-deficient mice had a higher bone mass phenotype only in the lumber vertebrae and distal femur of female mice with no change in cortical bone parameters through 8 months of age (Okragly et al., 2016). ST2-deficient mice demonstrated increased bone resorption with mechanical loading compared with controls (Lima et al., 2015). In transgenic mice that overexpress IL-33 in osteoblasts, osteoclastogenesis was decreased (Keller et al., 2012). In osteoblasts, hypoxia-inducible factor-1α activation facilitates IL-33 expression (Kang et al., 2017).

Interleukin-4, interleukin-13, and interleukin-32

IL-4 and IL-13 are members of a group of locally acting factors that have been termed "inhibitory cytokines." The effects of IL-4 and IL-13 seem related and appear to affect both osteoblasts and osteoclasts. Transgenic mice that overexpress IL-4 had an osteoporotic phenotype (Lewis et al., 1993). This effect may result from an inhibition of both osteoclast formation and activity (Nakano et al., 1994; Shioi et al., 1991) and an inhibition of bone formation (Okada et al., 1998). IL-13 and IL-4 inhibited IL-1-stimulated bone resorption by decreasing the production of prostaglandins and the activity of cyclooxygenase-2 (Onoe et al., 1996). The direct inhibitory effects of IL-4 on osteoclast precursor cell maturation are more potent than that of IL-13 and involve effects on signal transducer and activator of transcription (STAT) 6 (or STAT6), NF-κB, peroxisome proliferator-activated receptor γ1, mitogen-activated protein kinase signaling, Ca^{++} signaling, NFATc1, c-Fos, and enhanced apoptosis (Bendixen et al., 2001; Kamel Mohamed et al., 2005; Mangashetti et al., 2005; Moreno et al., 2003; Wei et al., 2001; Yamada et al., 2007; Wu et al., 2016). IL-4 induces myeloid cell differentiation toward the dendritic cell lineage and M2 macrophage activation away from the osteoclast lineage (Hiasa et al., 2009; Freire et al., 2016).

IL-13 and IL-4 induce cell migration (chemotaxis) in osteoblastic cells, and they regulate the ability of osteoblasts and vascular endothelial cells to control OPG and RANKL production (Palmqvist et al., 2006; Yamada et al., 2007; Stein et al., 2008; Fujii et al., 2012). IL-13 also inhibits Cyp27b1 in human CD14-expressing myeloid cells (Ding et al., 2017). This is the enzyme that hydroxylates 25 OH vitamin D at the 1-α position to activate it.

IL-32 is a cytokine involved in innate and adoptive immunity. It is produced by T lymphocytes, NK cells, and epithelial cells (Felaco et al., 2009). IL-32 stimulates the formation of multinuclear cells that were TRAP- and vitronectin receptor-positive but did not resorb. In addition, it inhibited resorption that was stimulated by RANKL (Mabilleau and Sabokbar, 2009). IL-32γ was also shown to enhance osteoblast differentiation (Lee et al., 2015), and mice that overexpress IL-32γ were found to have increasing bone mass with age and increased bone formation (Lee et al., 2017).

Macrophage migration inhibitory factor
