Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication of Fourth Edition to Lawrence G. Raisz

By the end of the 1970s, when the bone research community felt that it was ready for its own scientific society, Larry Raisz was one of the leaders of the group that founded the American Society for Bone and Mineral Research (ASBMR). The ASBMR had its first annual conference in 1979, with Larry serving as its second president. As the first editor of the *Journal of Bone and Mineral Research*, for a decade, Larry set the highest scientific standards for quality and integrity. That standard remains untarnished today.

Larry's knowledge of the facts in our field was prodigious. His expertise and experience in basic elements of bone biology were exceptional. He had great understanding and wisdom in interpretation of the clinical implications of basic bone biology. But he always wanted to know more. At ASBMR and other annual meetings, it was always Larry who rose to the microphone after a presentation to ask, not only the first question, but typically the best one! Remarkably, Larry could translate basic bone biology to the clinical arena. Few in our field then or now could so smoothly integrate clinical aspects of metabolic bone diseases with the burgeoning knowledge of underlying pathophysiological mechanisms. Adding to these talents was a collegiality and an exuberant enthusiasm that pervaded all venues of Larry Raisz's world. As osteoporosis became more widely recognized to be a medical scourge, then and now, Larry quickly grasped the need to speak about the burden of the disease and contributed to the international dialogue, raising awareness among us all. This awareness was a major factor in the recognition among countries that we are dealing with a disease that needs greater understanding at all levels. And, indeed, at all levels, Larry contributed so much.

These qualities made Larry Raisz a wonderfully effective coeditor of the first three editions of *Principles of Bone Biology*. Much more than that, though, he was a pleasure to work with as a colleague and friend, exceptionally efficient and with unfailing humor and optimism when faced with any adversity. Larry would share the highs and lows with you, but the lows were rare and short lived.

We remember him constantly and dedicate to Lawrence G. Raisz, MD, this fourth edition of what he called "Big Gray."

Preface to the Fourth Edition

The first edition of *Principles of Bone Biology* was published about 24 years ago, in 1996. Our field was ready then for a compendium of the latest concepts in bone biology. Now, several decades and two editions later, we are pleased to welcome you to the fourth edition of "Big Gray." Since the third edition was published in 2008, our field has continued to undergo sea changes of knowledge and insights. As a result of these advances since then, all chapters have undergone major revisions. In addition, areas not previously covered in depth are featured, such as vascular and nerve interactions with bone, interorgan communicants of bone, hematopoietic−bone cell interactions, nonskeletal aspects of vitamin D and RANK ligand, newly recognized signaling molecules and systems, and advances in methodological aspects of skeletal research. Illustrative of the vibrancy of our field, over 50% of the authors in this edition are new to it. Our returning and new authors are the very best.

We remember Larry Raisz. He, along with Gideon Rodan, constituted the triumvirate of coeditors for the first and second editions. We dedicated the third edition to the memory of Gideon. We dedicate *Principles of Bone Biology*, fourth edition, to the memory of Larry. In these front pages, we reprint our dedication to Gideon and remember Larry with a separate dedication for this edition. We miss them both very much.

We want to acknowledge Jasna Markovac, who has served as our liaison to our authors and our publisher. Given the nature of the times, this book would not have been completed without her dedication, perseverance, and single-minded purpose not to let anything disrupt our publishing goals. She accomplished this feat with an even handedness and a professionalism that was remarkable and remarkably effective. We are grateful to you, Jasna.

Finally, we are grateful to our authors, who have made this book what it is, namely a repository of knowledge and concepts in bone biology and a resource for us all in the years to come.

Chapter 1

Molecular and cellular regulation of intramembranous and endochondral bone formation during embryogenesis

Christine Hartmann[1] and Yingzi Yang[2]

Chapter outline

Introduction

The skeletal system performs vital functions: support, movement, protection, blood cell production, calcium storage, and endocrine regulation. Skeletal formation is also a hallmark that distinguishes vertebrate animals from invertebrates. In higher vertebrates (i.e., birds and mammals), the skeletal system contains mainly bones and cartilage, as well as a network of tendons and ligaments that connects them. During embryonic development, bones and cartilage are formed by osteoblasts and chondrocytes, respectively, both of which are derived from common mesenchymal progenitor cells called osteochondral progenitors. Skeletal development starts from mesenchymal condensation, during which mesenchymal progenitor cells aggregate at future skeletal locations. As mesenchymal cells in different parts of the embryo are derived from different cell lineages, the locations of initial skeletal formation determine which of the three mesenchymal cell lineages contribute to the future skeleton. Neural crest cells from the branchial arches contribute to the craniofacial bone, the sclerotome compartment of the somites gives rise to most of the axial skeleton, and lateral plate mesoderm forms the limb mesenchyme, from which limb skeletons are derived.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00001-4

How osteoblast cells are induced during bone development is a central question for understanding the organizational principles underpinning a functional skeletal system. Abnormal osteoblast differentiation leads to a broad range of devastating skeletal diseases. Therefore, it is imperative to understand the cellular and molecular mechanisms underlying temporal and spatial controls of bone formation. Bone formation occurs by two essential processes: intramembranous ossification and endochondral ossification during embryonic development. Osteochondral progenitors differentiate into osteoblasts directly to form the membranous bone during intramembranous ossification, whereas during endochondral ossification, they differentiate into chondrocytes instead to form a cartilage template of the future bone. Both ossification processes are essential during the natural healing of bone fractures. In this chapter, we focus on current understanding of the molecular regulation of endochondral and intramembranous bone formation and its implication in diseases.

Intramembranous ossification

Intramembranous ossification mainly occurs during formation of the flat bones of the skull, mandible, maxilla, and clavicles. The mammalian cranium, or neurocranium, is the upper and back part of the skull. It protects the brain and supports the sensory organs, such as the ear, and the viscerocranium, which supports the face. The neurocranium can be divided into calvarium and chondrocranium, which grow to be the cranial vault that surrounds the brain and the skull base, respectively. The calvarium is composed of flat bones: frontal bones, parietal bones, the interparietal part of the occipital bone, and the squamous parts of the temporal bone (Jin et al., 2016). In mice, the calvarium consists of frontal bones, parietal bones, interparietal bone, and squamous parts of the temporal bone, all going through intramembranous ossification (Ishii et al., 2015). By lineage analysis in mouse models, frontal bones show a major contribution from neural crest and a small contribution from head mesoderm, while parietal bones entirely originate from head mesoderm (Jiang et al., 2002; Yoshida et al., 2008; Deckelbaum et al., 2012). Neural crest–derived and head mesoderm–derived cells coalesce to form calvarial bone primordia (Jiang et al., 2002; Yoshida et al., 2008). The mandible and maxilla are derived from the neural crest cells originating in the mid- and hindbrain regions of the neural folds that migrate ventrally, while the clavicles are formed from mesoderm.

The process starts from mesenchymal condensation and progresses through formation of the ossification center, ossification expansion, trabecula formation, and compact bone formation and the development of the periosteum (Fig. 1.1).

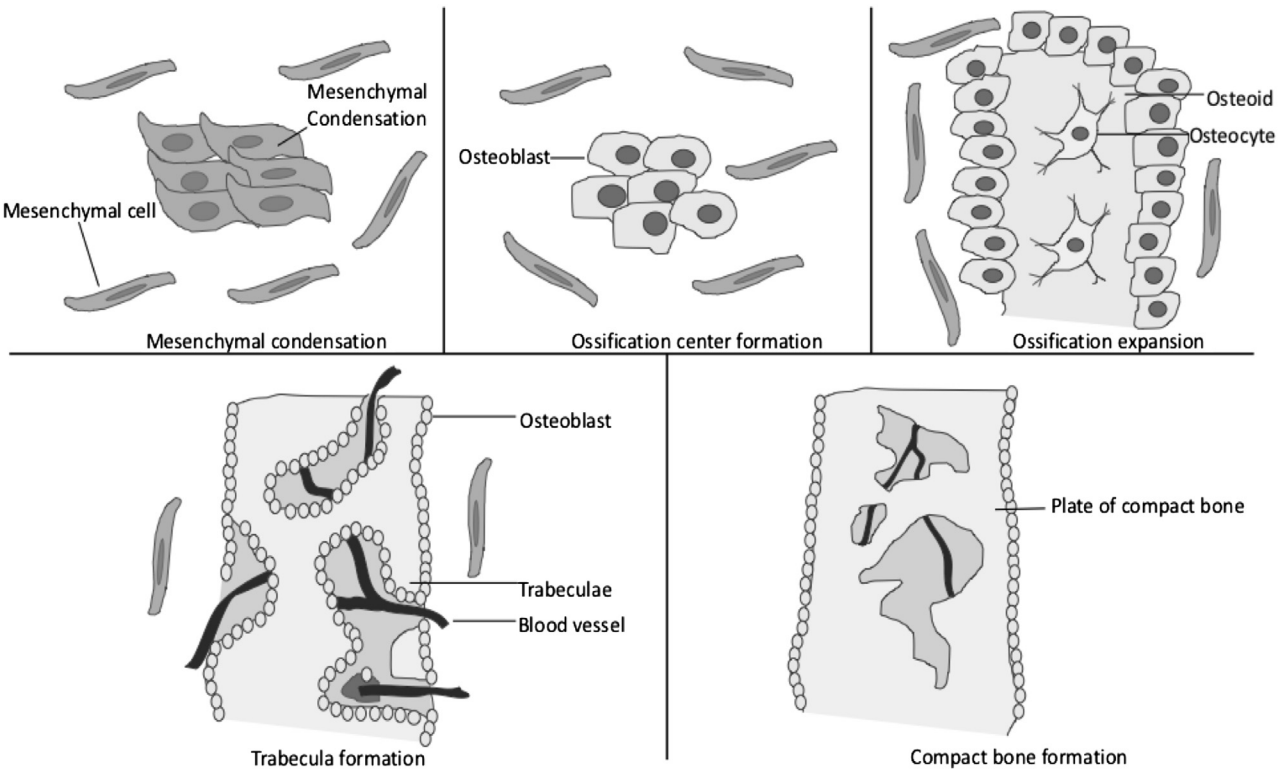

FIGURE 1.1 Schematics of intramembranous cranial bone formation. See text for details.

Condensation of mesenchymal progenitor cells is the first step for both intramembranous and endochondral ossification. During intramembranous ossification, mesenchymal progenitor cells differentiate into osteoblasts instead of chondrocytes as occurs during endochondral ossification. The osteoblasts that appear first in the condensation secrete bone matrix and form the ossification center. The early osteoblasts secrete osteoid, uncalcified matrix, which calcifies soon after, while the osteoblasts mature and terminally differentiate into osteocytes that are entrapped in the osteoid. As osteoblasts differentiate into osteocytes, more mesenchymal progenitors surrounding the osteoid differentiate into new osteoblast cells at the osteoid surface to expand the calcification center. Osteoid expansion around the capillaries results in a trabecular matrix of the spongy bone, while osteoblasts on the superficial layer become the periosteum. The periosteum is a layer that also contains mesenchymal progenitor cells, osteoblast differentiation of which contributes to the formation of a protective layer of compact bone. The blood vessels along with other cells between the trabecular bone eventually form the red marrow. Intramembranous ossification begins in utero during fetal development and continues on into adolescence. At birth, the skull and clavicles are not fully ossified. Sutures and fontanelles are unossified cranial regions that allow the skull to deform during passage through the birth canal. Sutures are joints between craniofacial bones, which are composed of two osteogenic fronts with suture mesenchyme between them (Fig. 1.2). Fontanelles are the space between the skull bones where the sutures intersect and are covered by tough membranes that protect the underlying soft tissues and brain. In humans, cranial sutures normally fuse between 20 and 30 years of age and facial sutures fuse after 50 years of age (Badve et al., 2013; Senarath-Yapa et al., 2012). Most sutures in mice remain patent throughout the animal's lifetime. Sutures and fontanelles allow the craniofacial bones to expand evenly as the brain grows, resulting in a symmetrically shaped head. However, if any of the sutures close too early (fuse prematurely), in the condition called craniosynostosis, there may be no growth in that area. This may force growth to occur in another area or direction, resulting in an abnormal head shape.

Apart from craniofacial bone development, intramembranous ossification also controls bone formation in the perichondral and periosteal regions of the long bone, where osteoblasts directly differentiate from mesenchymal progenitor cells. Yet, this requires a signal from the cartilaginous element. Furthermore, intramembranous ossification is an essential mechanism underlying bone repair and regeneration in the following processes: fracture healing with rigid fixation; distraction osteogenesis, a bone-regenerative process in which osteotomy followed by gradual distraction yields two vascularized bone surfaces from which new bone is formed (Ai-Aql et al., 2008); and blastemic bone creation, which occurs in children with amputations (Fernando et al., 2011).

Intramembranous ossification is tightly regulated at both molecular and cellular levels. Cranial malformations are often progressive and irreversible, and some of them need aggressive surgical management to prevent or mitigate severe impairment such as misshapen head or abnormal brain growth (Bronfin, 2001). For instance, craniosynostosis is a common congenital disorder that affects 1 in 2500 live births. It is characterized by premature cranial suture fusion, which may result in severe conditions such as increased intracranial pressure, craniofacial dysmorphism, disrupted brain development, and mental retardation. Craniosynostosis is generally considered a developmental disorder resulting from a disrupted balance of cellular proliferation, differentiation, and apoptosis within the suture (Senarath-Yapa et al., 2012; Levi et al., 2012; Slater et al., 2008; Lattanzi et al., 2012; Ciurea and Toader, 2009). Surgical correction followed by reshaping of the calvarial bones remains the only treatment available for craniosynostosis patients (Martou and Antonyshyn, 2011; Posnick et al., 2010; Hankinson et al., 2010). In contrast to craniosynostosis, cleidocranial dysplasia (CCD) is caused by reduced intramembranous bone formation, underdeveloped or absent clavicles (collarbones) as well as delayed maturation of the skull, manifested by delayed suture closure and larger than normal fontanelles that are noticeable as "soft spots" on the heads of infants (Farrow et al., 2018). Severe cases of CCD require surgical intervention. Identifying molecular pathways that control intramembranous ossification is critically important in the mechanistic understanding of craniofacial bone diseases and their targeted therapeutic development.

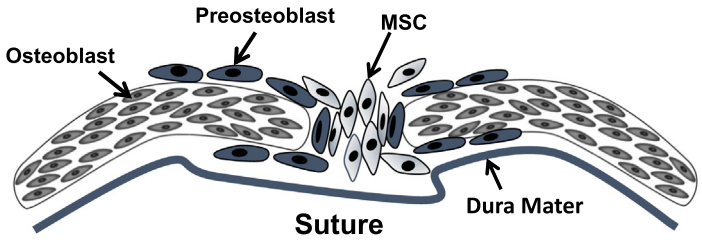

FIGURE 1.2 Schematics of cellular composition of the suture. In the suture, mesenchymal stem cells (MSCs) are located in the middle. They may first become committed preosteoblasts and then finally mature osteoblasts.

Studies of both developmental biology and rare genetic diseases have led to the identification of critical regulators of intramembranous ossification. Transcriptional regulation of the osteoblast lineage is considered in detail in Chapter 7. The runt-related transcription factor 2, RUNX2 (also known as CBFA1), and a zinc finger transcription factor, Osterix (OSX), are osteoblast lineage−determining factors required for both intramembranous and endochondral ossifications. *Runx2* is expressed in osteogenic progenitor cells and required for osteoblast cell fate determination by driving osteoblast-specific gene expression (Ducy et al., 1997; Otto et al., 1997). *Runx2* loss-of-function mutations are found in both mice and humans and cause CCD (Otto et al., 1997; Mundlos et al., 1997; Lee et al., 1997). RUNX2 induces the expression of *Osx*, which is required for osteoblast cell fate commitment, as loss of *Osx* leads to conversion from osteoblasts to chondrocytes (Nakashima et al., 2002). Under the control of RUNX2 and OSX, osteoblast cells produce osteoblast-specific collagen I together with a variety of noncollagenous, extracellular matrix (ECM) proteins that are deposited along with an inorganic mineral phase. The mineral is in the form of hydroxyapatite, a crystalline lattice composed primarily of calcium and phosphate ions.

Cell−cell communication that coordinates cell proliferation and differentiation also plays a critical role in intramembranous ossification. The WNT and Hedgehog (HH) signaling activities are required for cell fate determination of osteoblasts by controlling the expression of *Runx2*. Active WNT/β-catenin signaling is detected in the developing calvarium and perichondrium, where osteoblasts differentiate through intramembranous ossification. Indeed, enhanced WNT/β-catenin signaling enhances bone formation and *Runx2* expression, but inhibits chondrocyte differentiation and *Sox9* expression (Hartmann and Tabin, 2000; Guo et al., 2004; Day et al., 2005). *Sox9* is a master transcription factor that determines chondrocyte cell fate (Bi et al., 1999; Akiyama et al., 2002). Conversely, removal of *β-catenin* in osteochondral progenitor cells resulted in ectopic chondrocyte differentiation at the expense of osteoblasts during both intramembranous and endochondral ossification (Hill et al., 2005; Hu et al., 2005; Day et al., 2005). Therefore, during intramembranous ossification, WNT/β-catenin signaling levels in the mesenchymal condensation are higher, which promotes osteoblast differentiation while inhibiting chondrocyte differentiation. In addition, upregulated WNT/β-catenin signaling in the perichondrium also promoted osteoblast differentiation. In contrast to the WNT/β-catenin signaling, Indian hedgehog (IHH) signaling is not required for osteoblast differentiation of intramembranous bones in the skull (St-Jacques et al., 1999). It is still not clear what controls *Ihh*-independent *Runx2* expression during intramembranous ossification and it is important to understand further the differential regulation of intramembranous versus endochondral ossification by cell signaling. As removing Smoothened, which mediates all HH ligand-dependent signaling, does not abolish intramembranous ossification either (Jeong et al., 2004), HH signaling is likely to be activated in a ligand-independent manner in the developing calvarium. Indeed, it has been found that in the rare human genetic disease progressive osseous heteroplasia, which is caused by null mutations in *Gnas*, which encodes $G\alpha_s$, HH signaling is upregulated. Such activation of HH signaling is independent of HH ligands and is both necessary and sufficient to induce ectopic osteoblast cell differentiation in soft tissues (Regard et al., 2013). Importantly, *Gnas* gain-of-function mutations upregulate WNT/β-catenin signaling in osteoblast progenitor cells, resulting in their defective differentiation and in fibrous dysplasia that also affects intramembranous ossification (Regard et al., 2011). Therefore, $G\alpha_s$ is a key regulator of proper osteoblast differentiation through its maintenance of a balance between the WNT/β-catenin and the HH pathways. The critical role of WNT and HH signaling in intramembranous ossification is also shown in the suture. Mesenchymal stem cells that give rise to the cranial bone and regulate cranial bone repair in adult mice have been identified in the suture. These cells are either $GLI1^+$ or $AXIN2^+$ (Zhao et al., 2015; Maruyama et al., 2016), which marks cells that receive HH or WNT signaling, respectively (Bai et al., 2002; Leung et al., 2002; Jho et al., 2002).

Other signaling pathways, including those mediated by transforming growth factor (TGF) superfamily members, Notch, and fibroblast growth factors (FGFs), are also important in intramembranous ossification. Mutations in the FGF receptors FGFR1, FGFR2, and FGFR3 cause craniosynostosis. The craniosynostosis syndromes involving FGFR1, FGFR2, and FGFR3 mutations include Apert syndrome (OMIM 101200), Beare−Stevenson cutis gyrata (OMIM 123790), Crouzon syndrome (OMIM 123500), Pfeiffer syndrome (OMIM 101600), Jackson−Weiss syndrome (OMIM 123150), Muenke syndrome (OMIM 602849), crouzonodermoskeletal syndrome (OMIM 134934), and osteoglophonic dysplasia (OMIM 166250), a disease characterized by craniosynostosis, prominent supraorbital ridge, and depressed nasal bridge, as well as rhizomelic dwarfism and nonossifying bone lesions. All these mutations are autosomal dominant and many of them are activating mutations of FGF receptors. FGF signaling can promote or inhibit osteoblast proliferation and differentiation depending on the cell context. It does so either directly or through interactions with the WNT and bone morphogenetic protein (BMP) signaling pathways.

Apart from RUNX2 and OSX, other transcription factors are also important, as mutations in them cause human diseases with defects in intramembranous ossification. Mutations in the human *TWIST1* gene cause Saethre−Chotzen syndrome (OMIM 101400), one of the most commonly inherited craniosynostosis conditions. In addition, mutations in the homeobox

genes *MSX1*, *MSX2*, and *DLX* are also associated with human craniofacial disorders (Cohen, 2000; Kraus and Lufkin, 2006). *MSX2* haploinsufficiency decreases proliferation and accelerates the differentiation of calvarial preosteoblasts, resulting in delayed suture closure, whereas its "overexpression" results in enhanced proliferation, favoring early suture closure (Dodig and Raos, 1999). It is likely that *MSX2* normally prevents differentiation and stimulates proliferation of preosteoblastic cells at the osteogenic fronts of the calvariae, facilitating expansion of the skull and closure of the suture. It would be critical to understand further how these transcription factors interact with one another and the signaling pathways to regulate intramembranous bone formation, maintenance, and repair.

The axial skeleton

The axial skeleton consists of the occipital skull bones, the elements of the vertebral column, and the rib cage (ribs and sternum). With the exception of the sternum, the axial skeleton is derived from the paraxial mesoderm, which is segmented into somites during early embryonic development. The occipital skull bones are generated from the fused sclerotomes of the cranial-most 4.5 somites (Goodrich, 1930). The bilateral anlagen of the sternum originate from the lateral plate mesoderm and fuse at the ventral midline in the course of the formation of the rib cage (Chen, 1952).

Somitogenesis

The basic body plan of vertebrates is defined by the metameric segmentation of the musculoskeletal and neuromuscular systems, which originates during embryogenesis from the segmentation of the paraxial mesoderm (for reviews see Winslow et al., 2007; Pourquie, 2000). The paraxial mesoderm is laid down during gastrulation, appearing as bilateral strips of unsegmented tissue (referred to as segmental plate in the avian embryo and presomitic mesoderm in the mouse). It flanks the centrally located neural tube and notochord and gives rise to the axial skeleton (head and trunk skeleton) and all trunk and limb skeletal muscles, as well as the dermis, connective tissue, and vasculature of the trunk. During development, the paraxial mesoderm is segmented through a series of molecular and cellular events in an anterior to posterior (craniocaudal) sequence along the body axis, the anterior-most somites being the more mature ones. The posterior, unsegmented part of the paraxial mesoderm is also referred to as the presomitic mesoderm (PSM), and the sequentially arising, paired tissue blocks are called somites. The PSM is a loose mesenchymal tissue. The cells reaching the anterior border of the PSM progressively undergo a mesenchymal-to-epithelial transition (Christ et al., 2007). Newly formed somites are epithelial balls with a mesenchymal core. As the somites mature, accompanied by the commitment of the cells to the different lineages, this organization changes. In response to signals from the notochord and the ventral floor plate of the neural tube (Sonic Hedgehog [SHH] and the BMP antagonist Noggin), cells on the ventral margin undergo an epithelial−mesenchymal transition, scatter, and move toward the notochord (Christ et al., 2004; Cairns et al., 2008; Yusuf and Brand-Saberi, 2006). These cells will express the transcription factors PAX1, NKX3.1, and NKX3.2 and form the sclerotome, giving rise to the vertebrae and ribs. The dermomyotome is specified by WNT ligands secreted from the dorsal neural tube and the ectoderm covering the dorsal somite. Low levels of SHH signaling are, in combination with WNT signaling, required to maintain the expression of dermomyotomal and myotomal markers (Cairns et al., 2008). The dermomyotome remains epithelial and eventually gives rise to the epaxial muscles of the back and vertebrae, the hypaxial muscles of the body wall and limb, the dermis underneath the skin of the trunk, and the brown adipose tissue (Scaal and Christ, 2004; Atit et al., 2006). Tendons and ligaments of the trunk arise from the fourth somitic compartment, the syndetome, which is induced by the newly formed sclerotome and dermomyotome (Brent et al., 2003; Dubrulle and Pourquie, 2003).

The molecular mechanism driving somitogenesis at the anterior end of the PSM is intrinsic to the PSM, while new cells are continuously added to the PSM from a posteriorly located progenitor pool (Martin, 2016). The so-called segmentation clock, a molecular oscillator coordinating the rhythmic activation of several signaling pathways and the oscillatory expression of a subset of genes in the PSM, is thought to be at the molecular heart of somite formation (Hubaud and Pourquie, 2014). One of the main signaling pathways with oscillatory gene expression is the Notch/Delta/DELTA pathway. This pathway also synchronizes the oscillations between the individual cells (Hubaud and Pourquie, 2014). Also, members of the WNT/β-catenin and the FGF signaling pathway display cyclic gene expression (Aulehla and Pourquie, 2008). The oscillatory expression of these genes appears to go like a wave from the caudal end, sweeping anteriorly through the PSM (Fig. 1.3A). Another molecular system involved in somite formation is the wave front, which is defined by opposing signaling gradients in the PSM (Fig. 1.3B). Here, a posterior−anterior gradient of FGF8 and nuclear β-catenin is opposed by an anterior−posterior gradient of retinoic acid (RA) activity (Mallo, 2016). Despite the fact that the existence of an RA gradient is debated, there is clear genetic evidence that a gradient of WNT signaling activity interacts with the

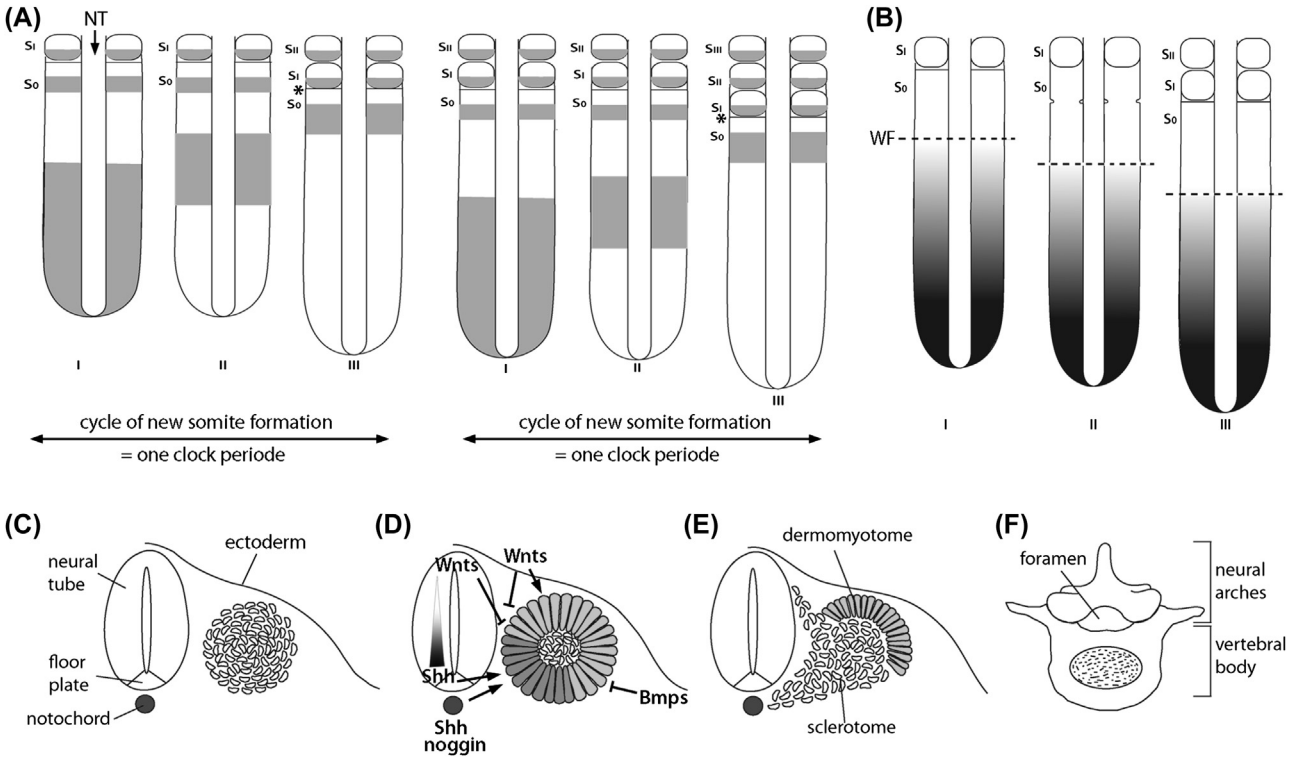

FIGURE 1.3 Somite formation and differentiation. (A) Cyclic gene expression during somite formation. segmentation clock to determine the posterior border of a newly forming somite (Mallo, 2016). The morphological changes that eventually lead to the formation of a new somite at the anterior end of the PSM are triggered by Notch activity in combination with the T-box transcription factor, TBX6, and start with the expression of the basic helix–loop–helix transcription factor mesoderm posterior 2 (MESP2) (Saga, 2007; Sasaki et al., 2011). In cells posterior to the determination front, *Mesp2* is repressed by FGF signaling (Sasaki et al., 2011). In addition, *Mesp2* expression becomes restricted to the anterior half of the newly formed somite, as TBX6-mediated transcription of *Mesp2* is suppressed by the RIPPLY1/2 proteins expressed in the posterior part of the somite (Morimoto et al., 2007; Takahashi et al., 2007). MESP2 activity is essential for establishing somite polarity, which is in turn vital for the later formation of the vertebral bodies from the caudal/posterior part of one somite and the rostral/anterior part of the neighboring somite (Christ et al., 2007).

The positional identity of a somite defines the type of vertebral element (occipital, cervical, thoracic, lumbar, or sacral) it will eventually contribute to, and this is controlled, in part, by the regional code of *Hox* genes along the rostral–caudal body axis (for review see Wellik, 2007). Humans and all other bilateral animals have multiple *Hox* genes, encoding transcription factors with a homeobox DNA-binding domain, which are clustered together (Krumlauf, 1992). Through duplication events, the ancestral cluster of originally eight *Hox* genes has been multiplied to four gene clusters (*HoxA*, *HoxB*, *HoxC*, and *HoxD*) of 13 paralogous *Hox* genes in vertebrates. A particular feature of *Hox* gene expression from one cluster is that they are expressed in a temporal and spatial order that reflects their order on the chromosome, with the most 3′ *Hox* gene being expressed first and in the most anterior region. It is thought that the *Hox* genes provide a sort of positional code through their overlapping expression domains, which are characterized by a relatively sharp anterior border. For example, the expression of the *Hox5* paralogs (*HoxA5*, *HoxB5*, and *HoxC5*) correlates in different species such as mouse and chicken, always with the position of the last cervical vertebra, while the anterior domains of the *Hox6* paralogs lie close to the boundary between cervical and thoracic vertebrae (Burke et al., 1995; Burke, 2000). Yet, this correlation is not maintained at the levels of the somites, as mouse and chicken differ in their numbers of cervical elements. Changes in the HOX code can lead to homeotic transformation, which reflects a shift in the regional borders and axial identities.

Members of the polycomb family (*Bmi* and *Eed*) and the TALE class of homeodomain transcription factors are involved in further refining the positional identity provided by the *Hox* code. BMI and EED are transcriptional repressors limiting the rostral (anterior) transcription boundary of individual *Hox* genes (Kim et al., 2006). The TALE proteins, encoded by the *Pbx* and *Meis* genes, further modify the transcriptional activity of the Hox proteins through heterodimerization (Moens and Selleri, 2006).

Sclerotome differentiation

The earliest sclerotomal markers are the transcription factors *Pax1*, *Nkx3.1*, and *Nkx3.2/Bapx1*, which become expressed under the influence of SHH and Noggin signaling in the ventral somite region (Kos et al., 1998; Ebensperger et al., 1995; Murtaugh et al., 2001). *Pax9* expression appears slightly later in the sclerotome and overlaps in part with *Pax1* (Muller et al., 1996). Both genes act redundantly in the ventromedial region of the sclerotome, as in the *Pax1/Pax9* double-mutant mice the development of the ventral vertebra is strongly affected (Peters et al., 1999). NKX3.2 appears to act downstream of *Pax1/Pax9* and can be ectopically induced by PAX1 (Tribioli and Lufkin, 1999; Rodrigo et al., 2003). Although the initial *Pax1* expression is not affected by the loss of *Nkx3.2*, the vertebral differentiation also depends on the function of NKX3.2 (Tribioli and Lufkin, 1999). *Nkx3.1* mutant mice, on the other hand, do not display any skeletal defects (Schneider et al., 2000). As PAX1 is able to activate the expression of early chondroblast markers in vitro, it has been suggested that the activation of PAX1 is the key event that triggers sclerotome formation (Monsoro-Burq, 2005).

After their induction, the sclerotomal cells undergo epithelial−mesenchymal transition and migrate toward the notochord, around the neural tube, and in the thoracic segments also laterally, and then condense to form the vertebral bodies and the intervertebral discs, neural arches, and proximal part of the ribs, respectively (Fig. 1.3C−F). Some notochordal cells surrounded by sclerotomal cells die, while others become part of the intervertebral disc and form the nucleus pulposus (McCann and Seguin, 2016). The neural arches and spinous processes are derived from the mediolateral regions of the sclerotomes and from sclerotomal cells that migrated dorsally. The activity of PAX1/PAX9 is not required for these two compartments (Peters et al., 1999). The dorsally migrating sclerotomal cells contributing to the dorsal part of the neural arches and spinous processes do not express *Pax1* but another set of transcription factors, *Msx1* and Msx2 (reviewed in Monsoro-Burq, 2005; Rawls and Fischer, 2010). Other transcription factors, such as the winged-helix factor, MFH1 (FOXC2), are possibly required for the clonal expansion of cells taking place within the individual sclerotome-derived populations, as they migrate ventrally, laterally, and medially and then condense (Winnier et al., 1997). In addition, the homeodomain transcription factors *Meox1* and *Meox2* have been implicated in vertebral development and may even act upstream of PAX1/PAX9 (Mankoo et al., 2003; Skuntz et al., 2009). Within the individual sclerotomal condensations the chondrogenic and osteogenic programs are then initiated to eventually form the vertebral elements.

The limb skeleton

Overview of limb development

The mesenchymal cells contributing to the skeleton of the appendages (limbs) originate from the bilaterally located lateral plate mesoderm. The lateral plate mesoderm is separated from the somitic mesoderm by the intermediate mesoderm, which gives rise to the kidney and genital ducts. Our knowledge about limb development during embryogenesis is primarily based on two experimental model systems, chick and mouse. In all tetrapods, forelimb development precedes hindlimb development. The axial position of the prospective limb field is in register with the expression of a specific set of *Hox* genes within the somites (Burke et al., 1995). The limb fields are demarcated by the expression of two T-box transcription factors, *Tbx5* in the forelimb and *Tbx4* in the hindlimb field (Petit et al., 2017; Duboc and Logan, 2011). Yet, the identity of the limb is conveyed by the activity of another transcription factor, PITX1, which is expressed specifically in the hindlimb region and specifies hindlimb identity (Logan and Tabin, 1999; Minguillon et al., 2005). In mouse, the forelimb bud starts to develop around embryonic day (E) 9 and the hindlimb around E10. In chick, forelimb development starts on day 2½ (Hamburger Hamilton stage 16) with a thickened bulge (Hamburger and Hamilton, 1992). In humans, the forelimb is visible at day 24 of gestation. Experimental evidence from the chick suggests that WNT signaling induces FGF10 expression and the FGF-dependent initiation of the limb outgrowth (Kawakami et al., 2001). For continuous limb outgrowth the expression of *Fgfs* in the mesenchyme and in an epithelial ridge called the apical ectodermal ridge (AER) is essential (Benazet and Zeller, 2009; Martin, 2001) (Fig. 1.4A). Patterning of the outgrowing limb occurs along all three axes, the proximal−distal, the anterior−posterior, and the dorsal−ventral (Niswander, 2003). For example, in the human arm, the proximal−distal axis runs from the shoulder to the fingertips and can be subdivided into the stylopod (humerus),

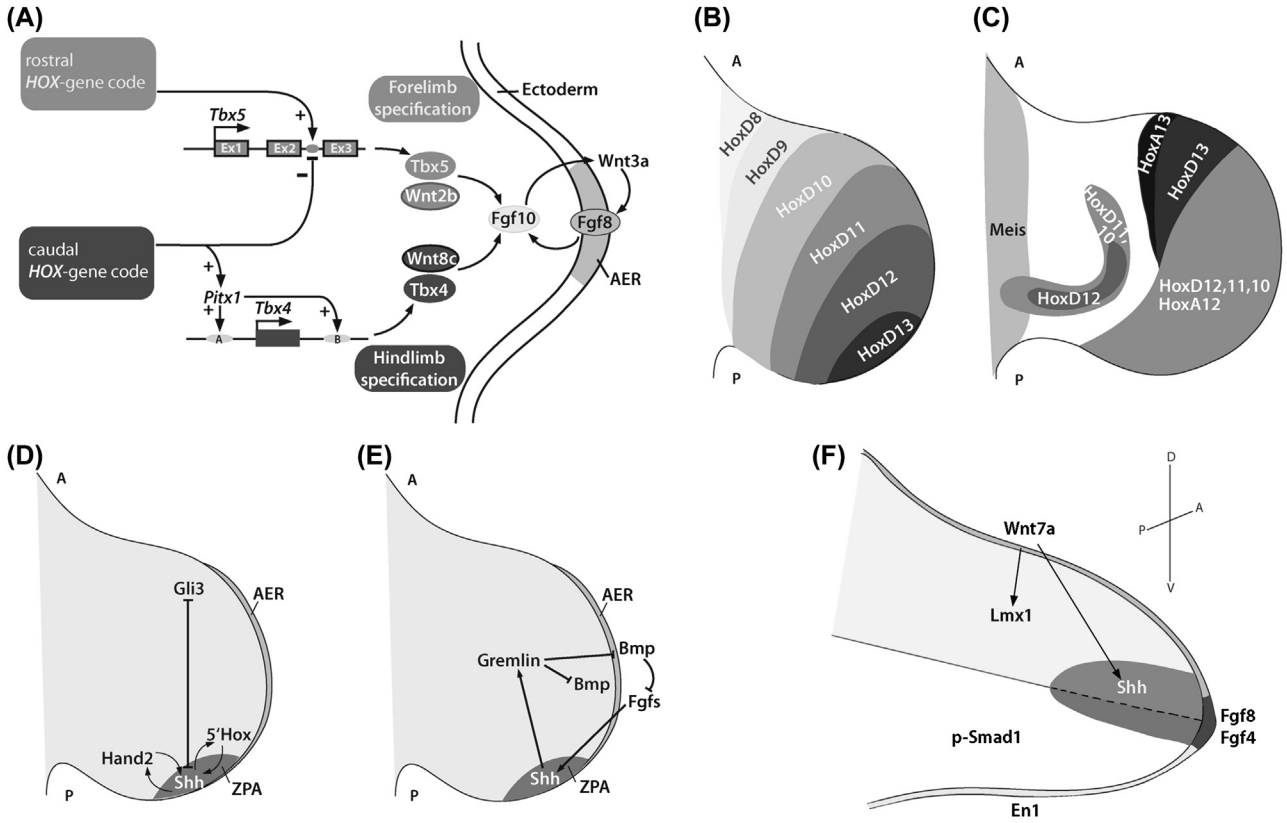

FIGURE 1.4 Limb development overview. (A) Early events in limb bud development: factors involved in the establishment of the limb identity and signals required for the initiation of limb outgrowth. *Hox* genes in the lateral plate mesoderm define the positions where the limbs will develop and activate or repress via specific enhancers the expression of *Pitx1* and the *Tbx4/5* genes. Together with the activity of limb field−specific WNTs an FGF10/WNT3a/FGF8 loop is established, which drives proximal−distal limb outgrowth. *AER*, apical ectodermal ridge. (B) Early nested expression of the HOXD cluster in the limb. *A*, anterior; *P*, posterior. (C) Late expression of the *HoxA* and *HoxD* genes in the autopod stage and expression of the proximal determinant *Meis1*. (D) Factors involved in anterior−posterior patterning of the limb, with *Shh* expressed in the zone of polarizing activity (*ZPA*) under the positive control of the transcription factors HAND2 and the 5′HOX proteins, while its activity in the anterior is opposed by the repressor GLI3. (E) Molecules involved in the interregulation of the anterior−posterior and proximal−distal axes. (F). Molecules involved in the specification of the dorsal−ventral axis: *Wnt7a* expressed in the dorsal ectoderm activates *Lmx1* expression in the dorsal mesenchyme specifying dorsal fate, while EN1 in the ventral ectoderm and phospho-SMAD1 in the ventral mesenchyme specify ventral fate. WNT7a also positively enforces the expression of *Shh*. *(A) Adapted from Fig. 1.2, Petit, F., Sears, K.E., Ahituv, N., 2017. Limb development: a paradigm of gene regulation. Nat. Rev. Genet. 18, 245−258.*

zeugopod (radius and ulna), and autopod regions (wrist and digits of the hand) (Fig. 1.5A). The anterior−posterior axis runs from the thumb to the little finger and the dorsal−ventral axis extends from the back of the arm/hand to the underside of the arm/palm. These three axes are established very early in development, and specific signaling centers, which will be briefly discussed in the following, coordinate the outgrowth and patterning of the limb.

Proximal−distal axis

As already mentioned, during the initiation stage, a positive FGF feedback loop is established between the *Fgfs* expressed in the mesenchyme (*Fgf10*) and the *Fgfs* in the AER (*Fgf8, Fgf4, Fgf9, Fgf17*). Mesenchymal FGF10 activity is essential for the formation of the AER (Sekine et al., 1999). In the positive feedback loop, FGF10 induces *Fgf8* expression in the AER, which is probably mediated by a *Wnt* gene's expression (*Wnt3a* in chick and *Wnt3* in mouse) (Kawakami et al., 2001; Kengaku et al., 1998; Barrow et al., 2003). The AER plays a critical role in the limb outgrowth. Removal of the AER at different time points of development leads to successive truncation of the limb (Saunders, 1948; Summerbell, 1974; Rowe and Fallon, 1982). The *Fgf* genes expressed in the AER confer proliferative and antiapoptotic activity on the distal mesenchyme and maintain the cells in an undifferentiated state (Niswander et al., 1994; Niswander et al., 1993; Fallon et al., 1994; Ten Berge et al., 2008). This is further supported by genetic studies showing that FGF4 and FGF8 are both required for the maintenance of the AER (Boulet et al., 2004; Sun et al., 2002). The most proximal part

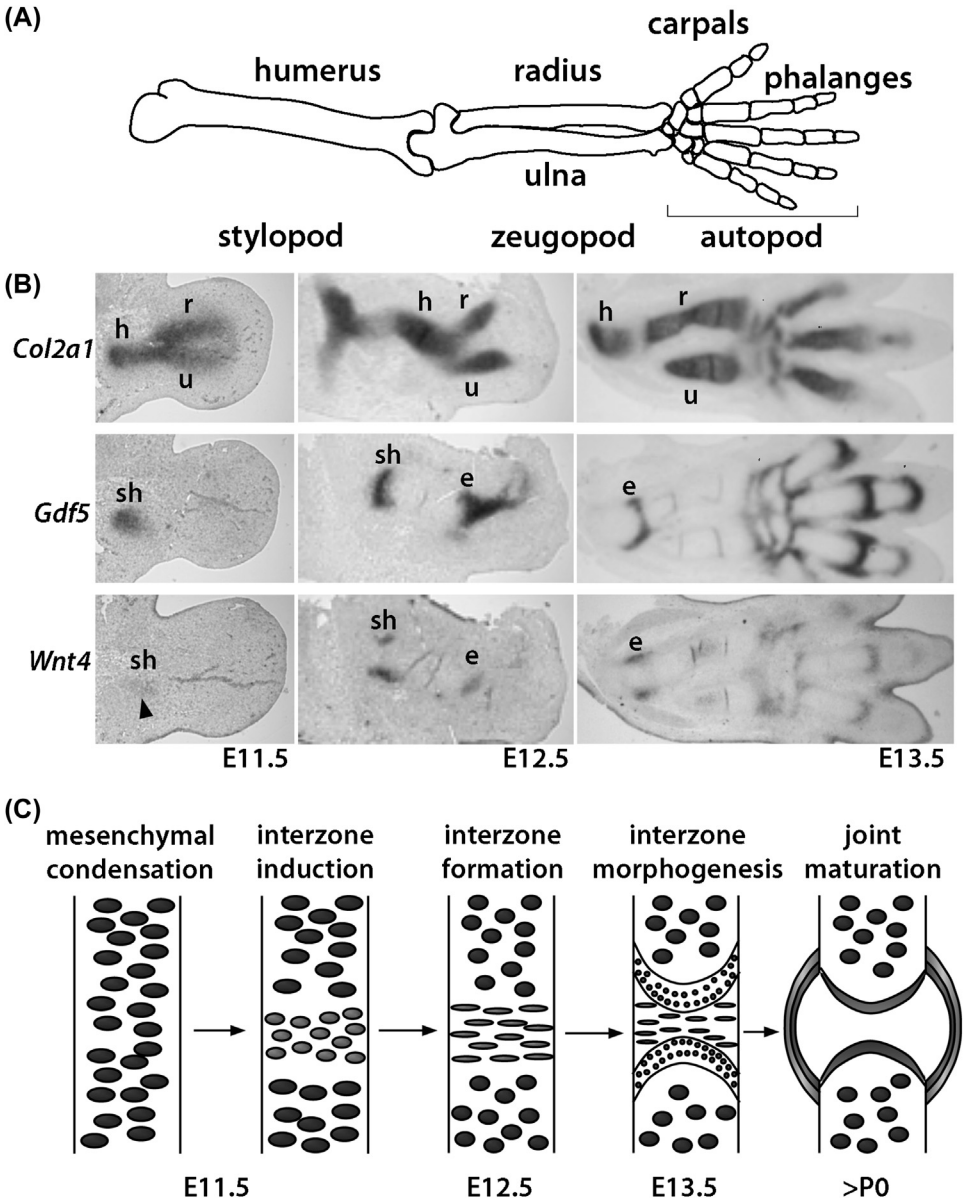

FIGURE 1.5 Patterning of the appendicular skeleton. (A) Schematic overview of the skeletal elements in a human arm. (B) In situ hybridizations on adjacent sections of a mouse forelimb (embryonic stages E11.5, E12.5, and E13.5), showing the branched structure of an early cartilaginous template (*Col2a1* expressing) consisting of the humerus (*h*), radius (*r*), and ulna (*u*). Note that at E11.5 markers of the joint interzone (*Gdf5* and *Wnt4*) are expressed in cells that also express the chondrogenic marker *Col2a1*. At E12.5, during interzone formation, *Col2a1* becomes downregulated in the shoulder (*sh*) and elbow (*e*) region, while the expression patterns of *Gdf5* and *Wnt4* undergo refinement. At E13.5, *Col2a1* is no longer expressed in the joint areas and the expression domains of *Gdf5* and *Wnt4* become distinct. (C) Schematic representation of the major steps during synovial joint formation.

of the limb expresses the TALE homeobox transcription factor MEIS1 under the control of opposing RA and FGF signaling (Mercader et al., 2000). MEIS1 alone is sufficient to proximalize the limb in the chick and mouse systems (Mercader et al., 1999, 2009). Along the proximal–distal axis, the 5′*Hox* genes, which are expressed early in a nested pattern (see Fig. 1.4B), are thought to provide positional cues for growth. As such, members of the group 11 paralogs (HOXA11 and D11 in the forelimb and HOXA11, C11, and D11 in the hindlimb) are required for the growth of the zeugopod, while the autopod establishment depends on the function of group 13 paralogs (Zakany and Duboule, 2007). *Hox* genes are also involved in connective tissue patterning in the limb (Pineault and Wellik, 2014). In addition to their role with regard to the proximal–distal axis, *Hox* genes also play an important role in establishing the signaling center within the limb bud regulating the anterior–posterior axis.

Anterior–posterior axis

Classical embryologic transplantation experiments uncovered the existence of a region present in the posterior limb bud conveying patterning information along the anterior–posterior axis (Saunder and Gasseling, 1968). Transplantation studies also revealed that this region, which was referred to as the zone of polarizing activity (ZPA), must contain some kind of positional information in the form of a secreted morphogen that specifies digit identity along the anterior–posterior axis (Tickle, 1981; Tickle et al., 1975; Wolpert, 1969). The molecular identity of this morphogen was uncovered only in 1993 with the cloning of a vertebrate homolog of the *Drosophila hh* gene, called *Shh*. *Shh* expression overlaps with the ZPA, and Shh-producing cells transplanted into the anterior mesoderm of the limb bud could reproduce mirror-image duplications of ZPA grafts (Riddle et al., 1993). Genetic experiments confirmed that *Shh* is required to establish posterior structures of the limb (Chiang et al., 1996). The *Shh* expression domain is established by the activity of positive and negative regulators. The transcription factor HAND2 (dHAND) is expressed in a posterior domain preceding and encompassing the *Shh* domain and acts as a positive regulator of SHH, which feeds back positively on the expression of HAND2 (Charite et al., 2000; Fernandez-Teran et al., 2000). Early in limb development, *Hand2* is expressed complementary to the transcription factor *Gli3* and GLI3 represses *Hand2* in the anterior (Wang et al., 2000). HAND2, on the other hand, represses *Gli3* in the posterior (Te Welscher et al., 2002). SHH signaling in the posterior prevents the cleavage of the full-length activator GLI3 into the GLI3 repressor (GLI3R) form. Hence, the GLI3R form is restricted to the anterior of the limb bud. The *5′Hox* genes and SHH signaling are also connected by a positive feed-forward regulatory loop (Tarchini et al., 2006; Ros et al., 2003), which may also involve FGF signaling (Rodrigues et al., 2017) (Fig. 1.4D). There is also an interconnection between the anterior–posterior and the proximal–distal axis: SHH signaling upregulates the BMP antagonist Gremlin in the posterior half of the limb. Gremlin antagonism of BMP signaling is required to maintain the expression of *Fgf4*, *Fgf9*, and *Fgf17* in the AER, and FGF signaling feeds positively onto *Shh* (Khokha et al., 2003; Laufer et al., 1994) (Fig. 1.4E).

Dorsal–ventral axis

The third axis that needs to be established is the dorsal–ventral axis. Here, the WNT ligand WNT7a is expressed in the dorsal ectoderm and regulates the expression of the LIM homeobox transcription factor LMX1 (LMX1B in the mouse) in the dorsal mesenchyme (Riddle et al., 1995; Vogel et al., 1995). LMX1B is required to maintain the dorsal identity of structures such as tendons and muscles in the limb (Chen et al., 1998). The ventral counterplayer is the transcription factor Engrailed 1 (EN1), which is expressed in the ventral ectoderm and the ventral half of the AER, and is essential for the formation of ventral structures (Davis et al., 1991; Gardner and Barald, 1992; Cygan et al., 1997; Loomis et al., 1996). BMP signaling appears also to be required for establishment of the dorsal–ventral axis, as the activated downstream component, phospho-SMAD1, is detected throughout the ventral ectoderm and mesenchyme (Ahn et al., 2001) (Fig. 1.4F). Deletion of a BMP receptor gene, *Bmpr1a*, from the limb bud ectoderm results in an expansion of *Wnt7a* and *Lmx1b* into ventral territories, an almost complete loss of *En1*, and severe malformation of the limbs missing the ventral flexor tendons (Ahn et al., 2001).

Mesenchymal condensation and patterning of the skeleton

Patterning of the somitic tissue and the limbs along the different axes is a prerequisite for the mesenchymal condensations to take place. In the craniofacial skeleton, epithelial–mesenchymal interactions occur during the precondensation phase (Hall and Miyake, 1995). Mesenchymal condensations are pivotal for intramembranous and endochondral bone formation. They define the positions and the basic shapes of the future skeletal elements. They can be visualized in the sclerotome, developing skull, and limbs in vivo and in micromass cell cultures in vitro by the presence of cell surface molecules that bind peanut agglutinin (Stringa and Tuan, 1996; Milaire, 1991; Hall and Miyake, 1992). During the prechondrogenic and preosteogenic condensation phase ECM molecules, such as the glycoproteins Fibronectin, Versican, and Tenascin; cell–cell adhesion molecules, such as N-CAM and N-cadherin; the gap-junction molecule Connexin43 (CX43); and Syndecans (type I transmembrane heparan sulfate proteoglycan) become upregulated, but their expression often changes dynamically during the subsequent differentiation process (for review see Hall and Miyake, 2000; DeLise et al., 2000). Cell adhesion and ECM proteins promote the formation of the condensations by establishing cell–cell contacts and cell–matrix interactions. Yet, through genetic studies, their functional requirement for the condensation process has not been demonstrated so far. For the cell–matrix interactions, integrins also play an important role as they act as receptors for Fibronectin (α5β1; αVβ3), types II and VI collagen (α1β1, α2β1, α10β1), Laminin (α6β1), Tenascin (α9β1, αVβ3, α8β1, αVβ6), and Osteopontin (OPN) (αVβ1; αVβ3; αVβ5; α8ßβ1) (Loeser, 2000, 2002; Tucker and Chiquet-Ehrismann, 2015; Docheva et al., 2014).

Various growth factors, such as members of the TGFβ superfamily, regulate the condensation process (reviewed in Moses and Serra, 1996). This has also been elegantly demonstrated in vitro for a subclass of this superfamily of growth factors, the BMP family (Barna and Niswander, 2007). For the proximal elements (femur, tibia, and fibula) in the hindlimb, genetics revealed a dual requirement for the zinc finger transcription factors GLI3 and PLZF to establish the correct temporal and spatial distribution of chondrocyte progenitors (Barna et al., 2005).

Mesenchymal cells within the condensations can differentiate into either osteoblasts (intramembranous ossification) or chondrocytes (endochondral ossification). WNT/β-catenin signaling is essential for the differentiation of osteoblasts, as no osteoblasts develop in conditional mouse mutants in which the β-catenin-encoding gene *Ctnnb1* was deleted in mesenchymal precursor cells of the limb and/or skull (Hu et al., 2005; Hill et al., 2005; Day et al., 2005). Instead, the precursor cells differentiate into chondrocytes (Day et al., 2005; Hill et al., 2005). Hence, β-catenin activity is not essential for chondrogenesis. WNT/β-catenin signaling is most likely acting as a permissive pathway at this early step of differentiation, as too high levels of WNT/β-catenin signaling block osteoblast as well as chondrocyte differentiation (Hill et al., 2005). WNT/β-catenin signaling in perichondrial cells is amplified by SOXC protein family members to further secure the nonchondrogenic fate of these cells (Bhattaram et al., 2014). For osteoblast differentiation to occur, the transcription factor RUNX2 needs to be upregulated within the preosteogenic condensations, while the HMG-box transcription factor SOX9 is required for the further differentiation of cells within the condensations along the chondrocyte lineage and probably also for the condensation process itself (Bi et al., 1999; Akiyama et al., 2002; Karsenty, 2001; Lian and Stein, 2003). The latter aspect has been challenged by the results of in vitro experiments by Barna and Niswander (2007) showing that *Sox9*-deficient mesenchymal cells compact and initially form condensations, yet the cells within the condensations do not differentiate into chondroblasts (Barna and Niswander, 2007).

The skeletal elements in the limbs, which are formed by the process of endochondral ossification, develop in part as continuous, sometimes bifurcated (pre)chondrogenic structures, such as, e.g., the humerus branching into the radius and ulna in the forelimb (Fig. 1.5B), being subsequently segmented by the process of joint formation (Shubin and Alberch, 1986; Hinchliffe and Johnson, 1980; Oster et al., 1988). Furthermore, studies have shown that the cartilage morphogenesis of the developing long bones also occurs in a modular way, with two distinct pools of progenitor cells contributing to the primary structures and the bone eminences (Blitz et al., 2013; Sugimoto et al., 2013). Cells within the bifurcated, $SOX9^{+}$ primary structures express the gene *Col2a1*, characteristic of chondroblasts/chondrocytes. Although they appear during early limb development (E11.5) to be morphologically uninterrupted, the region where a joint (here the shoulder joint) will be formed can be visualized using molecular joint markers, such as *Gdf5* (growth differentiation factor 5) or *Wnt4* (see Fig. 1.5B). Interestingly, the cartilage matrix protein Matrilin-1 is never expressed in the interzone region, nor in the adjacent chondrogenic region, which possibly gives rise to the articular cartilage (Hyde et al., 2007). How the position of joint initiation within the limb is determined is not completely understood as of this writing. A limb molecular clock operating in the distal region may be involved in this process. It has been proposed that two oscillation cycles of the gene *Hairy 2* (*Hes2*) are required to make one skeletal element in the zeugopod and stylopod region of the limb (Sheeba et al., 2016). As the joints develop sequentially along the proximal−distal axis at a certain distance from each other, secreted factors produced by the joint itself may provide some kind of self-organizing mechanism (Hartmann and Tabin, 2001; Hiscock et al., 2017). WNT/β-catenin signaling is also required for joint formation (Hartmann and Tabin, 2001; Guo et al., 2004; Spater et al., 2006a, 2006b). Yet, again, it may act in this process also as a permissive pathway, repressing the chondrogenic potential of the joint interzone cells. However, as WNT/β-catenin signaling also induces the expression of *Gdf5*, it may also play an active role in joint induction by inducing cellular and molecular changes required for joint formation. The AP1-transcription factor family member c-JUN acts upstream of WNT signaling in joint development regulating the expression of *Wnt9a* and *Wnt16*, which are both expressed in the early joint interzone (Kan and Tabin, 2013). Numerous other genes, including *Noggin*, *Hif1α*, *Gdf5*, *Gdf6*, *Gli3*, *Ihh*, *PTH/PTHrPR1*, *Tgfβ*, *Mcp5*, and *Crux1*, have been implicated in a variety of cellular processes during joint formation based on genetic or misexpression experiments (Brunet et al., 1998; Amano et al., 2016; Spagnoli et al., 2007; Longobardi et al., 2012), for review see (Archer et al., 2003; Pacifici et al., 2006).

Endochondral bone formation

Overview

The axial and appendicular skeletal elements are formed by the process of endochondral bone formation starting with a cartilaginous template (Fig. 1.6A−E). This process starts with the condensation of mesenchymal cells at the site of the future skeleton. As mentioned already, this involves alterations in cell−cell adhesion properties and changes in the ECM

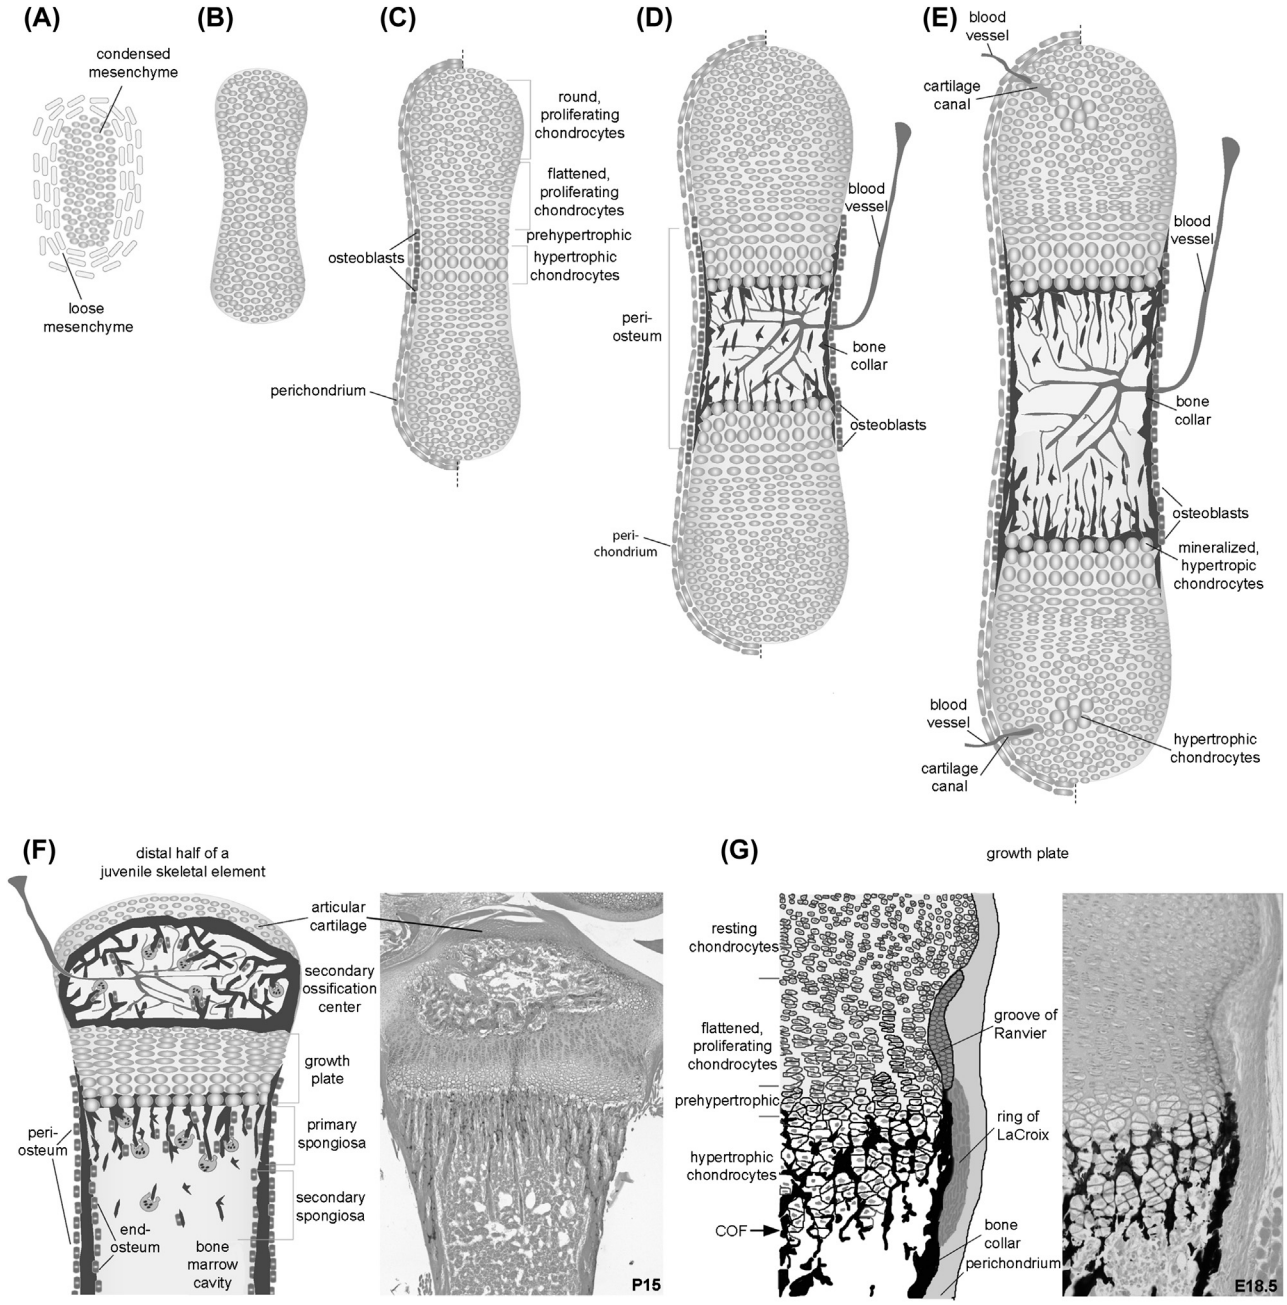

FIGURE 1.6 Schematic representation of the formation and growth of long bones by endochondral ossification. (A) Mesenchymal condensation with surrounding loose mesenchymal cells. (B) Cartilaginous template prefiguring the future skeletal element. (C) Chondrocyte differentiation within the cartilaginous template and differentiation of osteoblasts within a region of the perichondrium, which is then referred to as the periosteum. (D) Blood vessel invasion and onset of bone marrow cavity formation. (E) Onset of the formation of the secondary ossification center with differentiation of hypertrophic chondrocytes in the central region of the epiphysis and blood vessel invasion from the perichondrium through the cartilage canals. (F) Schematic representation on the left and corresponding Alcian blue/eosin−stained image of the proximal end of a postnatal day 15 (P15) mouse tibia on the right. (G) Schematic representation of the different features of a mouse growth plate based on the von Kossa/Alcian blue−stained proximal end of a mouse humerus at embryonic day 18.5 (E18.5). *COF*, chondro-osseous front.

(DeLise and Tuan, 2002a; Delise and Tuan, 2002b; Hall and Miyake, 1995; Bhat et al., 2011). Mesenchymal cells within the condensations start to express chondro-osteogenic markers, such as the transcription factors *Sox9* and *Runx2* (Hill et al., 2005; Akiyama et al., 2005; Wright et al., 1995). Next, the prechondrogenic precursor population of chondroblasts differentiates into chondrocytes, which produce an ECM rich in the proteoglycan aggrecan and fibrillar collagen of type II.

Cartilaginous template formation prefigures the future skeletal element and is surrounded by the so-called perichondrium, a layer of mesenchymal cells. As cartilage is avascular, limb vasculature regression needs to occur where cartilaginous structures form (Hallmann et al., 1987). Yet, interestingly, the chondrogenic condensation does express vascular endothelial growth factor (VEGF) (Eshkar-Oren et al., 2009). The outgrowth of vertebrate limbs occurs progressively along the proximal−distal axis (Newman et al., 2018; Zeller et al., 2009). Concomitantly, the skeletal elements develop in a proximodistal sequence, with the anlagen of the proximal elements (humerus in the forelimb and femur in the hindlimb) forming first, branching into more distal elements, and then being segmented into individual elements as the limb grows (Hinchliffe, 1994). The cartilaginous template increases in size by appositional and interstitial growth (Johnson, 1986). Interstitial growth by dividing chondrocytes allows the cartilage to grow rapidly along the longitudinal axis. The width of the cartilage element is controlled by appositional growth, whereby the perichondrium surrounding the cartilage template serves as the primary source of chondroblasts. Early on, all chondrocytes are still proliferating. As development progresses, the chondrocytes distant to the articulations in the central diaphysis will start to undergo a differentiation program. First, they flatten and rearrange into proliferative stacks of chondrocytes forming the zone of columnar proliferating chondrocytes. The elongation of these columns occurs internally through oriented cell division followed by intercalation movements of the daughters (Ahrens et al., 2009; Li and Dudley, 2009). A 2014 study showed that the daughter cells maintain intimate contact after cell division, preserving cadherin-mediated cell−cell interaction until the end of the rotational movement (Romereim et al., 2014). Interfering with cadherin-mediated cell−cell adhesion stalls the rotation process in vitro (Romereim et al., 2014). A similar rotation defect was observed in mice lacking integrin β1 (Aszodi et al., 2003). Chondrocytes at the lower end of the columns will then exit the cell cycle and become prehypertrophic; a stage that is not morphologically distinct but can be visualized using molecular markers such as the expression of the genes *Ihh* and parathyroid hormone/parathyroid hormone-like peptide receptor 1 (*Pthr1*). Next, the prehypertrophic chondrocytes increase dramatically in volume and become hypertrophic (Cooper et al., 2013; Hunziker et al., 1987). The almost 10-fold increase in volume occurs in parts by true cellular hypertrophy and swelling and significantly contributes to the longitudinal expansion of the skeletal elements as the cells are laterally restricted by matrix channels (Cooper et al., 2013). Hypertrophic chondrocytes (HCCs) are distinct in their ECM producing type X instead of type II collagen. Furthermore, they produce VEGF, which in this context attracts blood vessels to the diaphysis region (Gerber et al., 1999). The ECM of mature HCCs mineralizes and the cells produce matrix metalloproteinase 13 (MMP13) as well as OPN/SSP1. MMP13 (collagenase 3) breaks up the matrix of HCCs for the subsequent removal by osteoclasts (Inada et al., 2004; Stickens et al., 2004), while SSP1 has multiple functions; it regulates mineralization, serves as a chemoattractant for osteoclasts, and is functionally required for their activity (Franzen et al., 2008; Rittling et al., 1998; Boskey et al., 2002; Chellaiah et al., 2003). The final fate of HCCs has long been believed to be apoptotic cell death (Shapiro et al., 2005). Yet, ex vivo and in vitro experiments already hinted at an alternative fate, with HCCs transdifferentiating into osteoblasts (Shapiro et al., 2005). Lineage tracing experiments have confirmed this alternative fate, proposing a model of dual osteoblast origin (Zhou et al., 2014; Yang et al., 2014a, 2014b; Park et al., 2015). At least during embryonic development, about 20% of osteoblasts are chondrocyte derived and about 80% are derived from the perichondrium/periosteum. The latter population migrates into the bone marrow cavity along the invading blood vessels (Maes et al., 2010). This invasion originates from the periosteal collar, the area of the perichondrium in which osteoblasts differentiate and the bone collar is being formed (Colnot et al., 2004). In addition, monocytic osteoclast precursors as well as macrophages, both of which are of hematopoietic origin, enter the remodeling zone via the vascular system, which is attracted by VEGF (Henriksen et al., 2003; Engsig et al., 2000). Blood vessels have additional roles during trabecular bone formation in the primary spongiosa, which will be further discussed in the following. Endothelial cells, chondroclasts, and osteoclasts act together to erode the bone marrow cavity by removing HCC remnants. Interestingly, a bone marrow cavity can form in mouse mutants lacking osteoclasts or even macrophages and osteoclasts (Ortega et al., 2010). In these mutants, MMP9-positive cells are still present at the chondro-osseous junction and may be in part responsible for bone marrow cavity formation (Ortega et al., 2010). With the formation of the marrow cavity in the diaphysis, the two growth plates become separated from each other. The growth plates serve as a continual source of cartilage being converted into bone at the chondro-osseous front during the late stages of development and postnatally. In most species, a second ossification center appears during postnatal development within the epiphyseal cartilage. The onset differs between species for the individual bones and even within one bone for the two epiphyses (Adair and Scammin, 1921; Shapiro, 2001; Zoetis et al., 2003). Here, cartilage canals containing mesenchymal cells and blood vessels enter from the surrounding perichondrium, reaching eventually the hypertrophic center of the epiphysis (Blumer et al., 2008; Alvarez et al., 2005). After the formation of the secondary ossification center, the epiphyseal articular cartilage becomes distinct and the metaphyseal growth plate is sandwiched between the epiphyseal secondary ossification center and the primary ossification center in the diaphysis (Fig. 1.6F).

The growth plate

The cellular organization within the growth plate (schematically depicted in Fig. 1.6F) of a juvenile bone resembles the different zones in embryonic skeletal elements (Fig. 1.6G). There is a zone of small round chondrocytes, some of which are mitotically inert, that is often referred to as the resting zone. Stemlike or progenitor cells are thought to reside in this zone and require the activity of β-catenin for their maintenance (Candela et al., 2014). Concomitant with the growth plate closure that occurs in most vertebrates, with the exception of rodents, these progenitor cells eventually become senescent at the end of puberty and lose their proliferative potential, putting an end to long bone growth (Nilsson and Baron, 2004). The zone next to the resting zone contains flattened, stacked chondrocytes, which are mitotically active and form fairly regular columns. Eventually, the chondrocytes at the lower end of the zone will begin to enlarge, becoming first prehypertrophic and then HCCs (Ballock and O'Keefe, 2003). As already mentioned, some of the HCCs will undergo apoptosis (programmed cell death), while others survive and eventually differentiate into osteoblasts or other cells of the bone marrow cavity (Farnum and Wilsman, 1987; Shapiro et al., 2005; Tsang et al., 2015). The exact cellular and molecular mechanism of the transdifferentiation process of the surviving HCCs is not understood as of this writing. Earlier experiments suggested that this involves asymmetric cell division (Roach et al., 1995). According to the lineage tracing experiments, the transdifferentiating cells express at one point the gene *Col10a1*, encoding the α chain of type X collagen, but were they truly hypertrophic cells? If so, how was their cellular volume adjusted? Or alternatively, is there a pool of "stem cells" residing within the hypertrophic zone? So far, expression of stem cell markers has not been reported in HCCs of a normal growth plate. Yet, cells originating from the hypertrophic zone expressing the lineage tracer also express stem cell markers such as *Sca1* and *Sox2* in vitro (Park et al., 2015). Furthermore, a 2017 publication reported that during fracture healing HCCs express the stem cell markers *Sox2*, *Nanog*, and *Oct4* and that this is triggered by the invading vasculature (Hu et al., 2017). Other experiments such as one in rabbits, in which transdifferentiation was observed after physically preventing vascular invasion at the lower hypertrophic zone, suggest that the vasculature is not required for the transdifferentiation process to occur (Enishi et al., 2014). So far there are only a few molecules known to be required for the chondrocyte-derived differentiation of osteoblasts. One of them is β-catenin (Houben et al., 2016) and the other one SHP2, a protein tyrosine phosphatase (Wang et al., 2017). Mice lacking SHP2 activity in HCCs display a slight reduction in chondrocyte-to-osteoblast differentiation, and the mechanism behind this blockade is the persistence and/or upregulation of SOX9 protein in HCCs (Wang et al., 2017). Mice lacking β-catenin activity in HCCs display an even more severe reduction of chondrocytes differentiating into osteoblasts and its absence also affects in part the transdifferentiation of chondrocytes into other cell types (Houben et al., 2016). The mechanism by which β-catenin affects this transdifferentiation process is unknown as of this writing. Unlike what has been shown in perichondrial osteoblast precursors or in the case of SHP2, persistence of SOX9 protein was not observed (Houben et al., 2016). Furthermore, the loss of β-catenin activity in HCCs affects indirectly the differentiation of perichondrial-derived osteoblast precursors (Houben et al., 2016). HCCs also produce receptor activator of NF-κB ligand (RANKL) and its decoy receptor Osteoprotegerin, which positively and negatively, respectively, influence the differentiation of monocytes into osteoclasts at the chondro-osseous front (Usui et al., 2008; Silvestrini et al., 2005; Kishimoto et al., 2006). The expression of *Rankl* in HCCs is negatively controlled by β-catenin, leading to increased osteoclastogenesis and reduced trabecular bone formation in conditional *Ctnnb1* mice (Houben et al., 2016; Golovchenko et al., 2013; Wang et al., 2014a). As mentioned already, the matrix of the lower rows of HCCs mineralizes. HCCs utilize matrix vesicles to produce large amounts of microcrystalline, Ca^{2+}-deficient, acid-phosphate-rich apatite deposits in the collagen-rich matrix (Wuthier and Lipscomb, 2011). Matrix vesicle release occurs in a polarized fashion from the lateral edges of the growth plate HCCs, resulting in the mineralization of the longitudinal septae, while transverse septae remain unmineralized (Anderson et al., 2005a). The matrix vesicles then release the apatite crystals, which self-nucleate and grow to form spherical mineralized clusters in the calcified zone of the HCCs. Mitochondria may serve as storage containers for Ca^{2+}, with the mitochondria in HCCs reaching the highest Ca^{2+} concentrations and serving as the Ca^{2+} supply for matrix vesicles. The mitochondria loaded with Ca^{2+} can no longer produce sufficient amounts of ATP and the cells undergo a physiological energy crisis. As a consequence, the mitochondria produce increased amounts of reactive oxygen species (ROS) (Wuthier and Lipscomb, 2011). Increased ROS levels feed back on the chondrocytes, inducing them to hypertrophy (Morita et al., 2007).

Through knockout studies in mouse, numerous genes were identified that are involved in the regulation of the mineralization process, such as matrix Gla protein and tissue nonspecific alkaline phosphatase (encoded by the *Akp2* gene), ectonucleotide pyrophosphatase/phosphodiesterase type 1, progressive ankylosis gene, phosphoethanolamine/phosphocholine phosphatase, membrane-anchored metalloproteinase ADAM17, and, as already mentioned, OPN (Anderson et al., 2004, 2005b; Fedde et al., 1999; Hessle et al., 2002; Zaka and Williams, 2006; Harmey et al., 2004; Hall et al., 2013).

After the removal of HCCs, the mineralized longitudinal septae remain and are used by osteoblasts as a scaffold for the deposition of osteoid that calcifies into woven bone.

At the periphery, the growth plate is surrounded by a fibrous structure that consists of the wedge-shaped groove of Ranvier and the perichondrial ring of LaCroix (see Fig. 1.6G) (Brighton, 1978; Langenskiold, 1998). The groove of Ranvier serves as a reservoir for chondro-osteoprogenitor cells and fibroblasts, while the perichondrial ring of LaCroix may serve as a reservoir of precartilaginous cells (Fenichel et al., 2006; Shapiro et al., 1977). Interestingly, the two growth plates within a skeletal element have different activities leading to the differential growth of the distal and proximal parts (Pritchett, 1991, 1992; Farnum, 1994). Curiously, there seems to exist a temporal and local correlation between the appearance of the secondary ossification center and the activity of the nearby growth plate. For instance, in the humerus the secondary ossification center appears first in the proximal epiphysis and here, the proximal growth plate is more active than the distal one.

Mediators of skeleton formation

Accurate skeletogenesis, as well as postnatal growth and repair of the skeleton, depends on the precise orchestration of cellular processes such as coordinated proliferation and differentiation in time and space. Several signaling pathways impinge on the differentiation of the mesenchymal precursors as well as on the subsequent differentiation of chondrocytes and regulate the growth of the skeletal elements. Growth factor signaling is also partly controlled by the ECM and integrins (Munger and Sheppard, 2011; Ivaska and Heino, 2011). Cell-type-specific differentiation is under the control of distinct transcription factors with their activity being modulated by epigenetic factors and microRNAs. In addition to systemic and local factors, oxygen levels and metabolism also influence endochondral bone formation.

Systemic mediators

Longitudinal bone growth after birth is under the influence of various hormones, such as growth hormone (GH), insulin-like growth factors (IGFs), thyroid hormones, estrogen and androgens, glucocorticoids, vitamin D, and leptin. The importance of these hormones in skeletal growth has been demonstrated by genetic studies in animals and by "natural experiments" in humans (for reviews see Nilsson et al., 2005; Wit and Camacho-Hubner, 2011). Many of these systemic mediators interact with one another during linear growth of the juvenile skeleton and are differentially controlled by the nutritional status (Robson et al., 2002; Lui and Baron, 2011; Gat-Yablonski et al., 2008). Yet, only IGF signaling plays a role in endochondral ossification prior to birth.

Mice deficient for either *Igf1* or *Igf2* or the *Igf1r* gene display prenatal as well as postnatal growth defects, suggesting that IGFs act independent of GH on linear growth (Baker et al., 1993; Liu et al., 1993; Powell-Braxton et al., 1993). IGF1 was thought to affect chondrocyte proliferation, yet, a study on longitudinal bone growth in the *Igf1*-null mouse revealed no change in growth plate chondrocyte proliferation or cell numbers, despite the observed 35% reduction in the rate of long bone growth that was attributed to the 30% reduction in the linear dimension of HCCs (Wang et al., 1999). For more detailed information on the activities of GH and IGF signaling see reviews by Giustina et al. (2008), Kawai and Rosen (2012), Svensson et al. (2001), and Lindsey and Mohan (2016).

Local mediators

The various local mediators of endochondral and intramembranous ossification, which will be briefly discussed in the following, interact at multiple levels. Because of space constraints not all of these interactions can be mentioned.

Growth factor signaling pathways

Transforming growth factor β and bone morphogenetic proteins

The TGFβ superfamily is a large family of secreted polypeptides that can be divided into two subfamilies based on the utilization of the downstream signaling mediators, the regulatory SMADs (R-SMADs). The first one, encompassing TGFβ1−β3, activins, inhibins, nodal, and myostatin (GDF8), transduces the canonical signal through the R-SMADs 2 and 3. The second one consists of the BMPs 2 and 4−10 and most GDFs, transducing the canonical signal through R-SMADs 1, 5, and 8. The cofactor SMAD4 is utilized by both groups, forming a complex with the different activated R-SMADs. The receptor complexes are heterodimers consisting of serine/threonine kinase types I (ALKs 1−7) and II (TβRII, ActRII, ActRIIb, BMPRII, and MISRII) receptors. Ligand binding activates the type II receptor, leading to transphosphorylation

of the type I receptor. In addition to the SMAD-dependent canonical signaling, TGFβ/BMPs can signal through numerous SMAD-independent noncanonical signaling pathways (reviewed in Wang et al., 2014c; Wu et al., 2016).

Many of the TGFβ and BMP signaling molecules are involved in endochondral bone formation. In the mouse, all three *Tgfβ* isoforms are expressed in mesenchymal condensations, perichondrium/periosteum, and appendicular growth plates (Pelton et al., 1990, 1991; Schmid et al., 1991). Despite the numerous in vitro reports indicating a role for TGFβ molecules promoting mesenchymal condensation and the onset of chondrocyte differentiation, none of the individual *Tgfβ* knockouts supports such an early role in vivo. It has been proposed that transient activation of TGFβ and/or activin signaling primes mesenchymal cells to become chondroprogenitors (Karamboulas et al., 2010). Of the individual *Tgfβ* knockouts, only the $Tgf\beta2^{-/-}$ mutants displayed defects in intramembranous and endochondral bone formation (Sanford et al., 1997), some of which may be secondary due to defects in tendon formation (Pryce et al., 2009). The conditional ablation of the primary receptor for all three TGFβs and *Alk5*, in mesenchymal cells using the *Dermo1*-Cre line, resulted also in skeletal defects affecting intramembranous and endochondral bones (Matsunobu et al., 2009). The endochondral bone elements in the $Alk5^{-/-}$ animals were smaller and malformed, with ectopic cartilaginous protrusions present in the hindlimb. Conditional deletion of the *Tgfbr2* gene, encoding the TβRII receptor, in the limb mesenchyme with the *Prx1*-Cre line results in the absence of interphalangeal joints, probably due to a defect in downregulation of the chemokine MCP-5 in the joint interzone cells (Spagnoli et al., 2007; Longobardi et al., 2012). The appendicular skeletal elements of the *Tgfbr2*;*Prx1*-Cre embryos are also shorter, associated with altered chondrocyte proliferation and an enlarged HCC zone (Seo and Serra, 2007). This phenotype was also observed upon the expression of a dominant-negative form of the TβRII receptor or by expressing a dominant-negative TβRI (*Alk5*) construct in chondrocytes (Serra et al., 1997; Keller et al., 2011). Surprisingly, deletion of *Tgfbr2* in *Col2a1*-expressing cells resulted in defects only in the axial skeleton and not in the appendicular skeleton (Baffi et al., 2004). Nevertheless, the long bones of the *Tgfbr2;Col2a1*-Cre newborn mice were consistently shorter, but the difference was not significant. Sueyoshi and colleagues reported that deletion of *Tgfbr2* in HCCs results in a minor delay in chondrocyte differentiation around E14.5/15.5. Yet, at birth, no differences regarding the length of the long bones were observed, suggesting that this is a transient effect (Sueyoshi et al., 2012). Deletion of *Tgfbr2* in *Osx*-Cre-positive pre-HCCs and osteoblast precursors in the perichondrium led to postnatal alteration in the growth plate and affected osteoblastogenesis (Peters et al., 2017). This is probably associated with a loss of *TGFβ1* signaling (Tang et al., 2009). Nevertheless, inactivation of *Tgfbr2* may not be sufficient to eliminate all Tgfβ signaling, as TGFβ ligands were still capable of eliciting signals in the $Tgfbr2^{-/-}$ mice (Iwata et al., 2012). Furthermore, TGFβs can activate the canonical BMP/SMAD1/5/8 pathway through engagement of ALK1 (Goumans et al., 2002). TGFβ proproteins are sequestered by the ECM and can then be released and activated through, for instance, the activity of ECM degrading enzymes (Hildebrand et al., 1994; Pedrozo et al., 1998; Annes et al., 2003). For further information, in particular on the involvement of noncanonical TGFβ pathways in chondrogenesis and skeletogenesis and the implications of TGFβ signaling in osteoarthritis, see reviews by van der Kraan et al. (2009), Wang et al. (2014c), and Wu et al. (2016).

The cofactor SMAD4 is thought to mediate canonical signaling downstream of TGFβ and BMP signaling. Yet surprisingly, conditional mutants lacking *Smad4* in *Col2a1*-expressing cells are viable and display only mild phenotypic changes in the growth plate (Zhang et al., 2005; Whitaker et al., 2017). However, the prechondrogenic condensations do not form in mice lacking SMAD4 in the limb mesenchyme, supporting an essential role for TGFβ/BMP signaling in the early steps of chondrocyte differentiation, which appears to be independent of SOX9 (Lim et al., 2015; Benazet et al., 2012). Mice lacking either R-SMAD1/5 in *Col2a1*-expressing cells or all three R-SMADs (SMAD1, 5, and 8) acting downstream of BMP signaling are not viable and display a nearly identical severe chondrodysplasia phenotype (Retting et al., 2009). The axial skeleton is severely compromised, with vertebral bodies replaced by fibroblasts and loose mesenchymal tissue. This suggests that SMAD8 plays only a minor role in chondrogenesis. Furthermore, these results challenge the dogma that SMAD4 is required to mediate SMAD-dependent signaling downstream of BMPs and TGFβs.

Based on the analyses of gene knockout animals, the *Bmp/Gdf* family members *Bmp8*, *Bmp9/Gdf2*, *Bmp10*, and *Gdf10* appear to play no role in embryonic skeletogenesis (Zhao et al., 1996, 1999; Chen et al., 2004; Levet et al., 2013). The *short-ear* mouse is mutant for *Bmp5* and displays defects in skeletal morphogenesis and has weaker bones (Kingsley et al., 1992; Mikic et al., 1995). *Bmp6* mutants have sternal defects (Solloway et al., 1998). Mice mutant for *Bmp7* display skeletal patterning defects restricted to the rib cage, skull, and hindlimbs (Luo et al., 1995; Jena et al., 1997). In addition to *Bmp7*, *Bmp2* and *Bmp4* are expressed in the early limb bud. Conditional deletion of *Bmp2* and *Bmp4* in the limb mesenchyme results in an abnormal patterning of the appendicular skeleton with a loss of posterior elements in the zeugopod and autopod region probably due to a failure of chondrogenic differentiation of the mesenchymal cells caused by insufficient levels of BMP signaling (Bandyopadhyay et al., 2006). In addition, the skeletal elements that form are shorter and thinner. Chondrocyte differentiation within the skeletal elements is delayed but otherwise normal. Concomitantly, the endochondral ossification process is also delayed and bone formation is severely compromised in these

mice (Bandyopadhyay et al., 2006). Yet, of the two BMPs, BMP2 appears to be the crucial regulator of chondrocyte proliferation and maturation (Shu et al., 2011). GDF11/BMP11 is required for axial skeleton patterning and acts upstream of the *Hox* genes (McPherron et al., 1999; Oh et al., 2002). Postnatally, GDF11 acts on bone homeostasis by stimulating osteoclastogenesis and inhibiting osteoblast differentiation (Liu et al., 2016). Mutations in human *GDF5* (*BMP14, CDMP1*) or *BMPR1B* (*ALK6*) cause brachydactyly type C (OMIM 113100) and A2 (OMIM 112600), respectively (Lehmann et al., 2003; Polinkovsky et al., 1997). *Gdf5* and *Bmpr1b* mutant mice also display a brachydactyly phenotype (Storm et al., 1994; Baur et al., 2000; Yi et al., 2000). Closer examination of the *Gdf5* mutant brachypodism mouse revealed that the absence of the joint separating phalangeal elements 1 and 2 is due to the loss of the cartilaginous anlage and subsequent formation of the skeletal element by intramembranous instead of endochondral bone formation (Storm and Kingsley, 1999). The related family members *Gdf5*, *Gdf6*, and *Gdf7* are expressed in the interzone of different subsets of joints. *Gdf6* mutants display fusions of carpal and tarsal joints, and double mutants for *Gdf5/6* show additional skeletal defects (Settle et al., 2003). Interestingly, postnatally, GDF5 and GDF7 modulate the rate of endochondral tibial growth by altering the duration of the hypertrophic phase in the more active growth plate in opposite ways (Mikic et al., 2004, 2008). Bead-implant experiments in chicken and mouse embryos as well as various in vitro experiments revealed a prochondrogenic activity of BMP2, BMP4, or GDF5 protein, which can be antagonized by the secreted molecule Noggin (Zimmerman et al., 1996; Merino et al., 1999; Wijgerde et al., 2005). Consistent with this, Noggin-knockout mice display appendicular skeletal overgrowth and lack synovial joints (Brunet et al., 1998). Yet, surprisingly the caudal axial skeleton does not develop in the *Noggin* mutants. The vertebral phenotype can in part be reverted by the loss of one functional *Bmp4* allele, supporting the notion that too high levels of BMP4 signaling in the axial mesoderm may actually inhibit the differentiation of sclerotomal cells to chondrocytes. Instead, these cells take on a lateral mesodermal fate (Wijgerde et al., 2005; Murtaugh et al., 1999; Hirsinger et al., 1997). Double knockout of the BMP receptors *Bmpr1a* (*Alk3*) and *Bmpr1b* (*Alk6*) revealed a functional redundancy of these two receptors in endochondral ossification. Chondrocyte differentiation in the axial and appendicular skeleton is severely compromised in the mice lacking both receptors (Yoon et al., 2005). Conditional mutants for activin receptor type IA (*Alk2*) display only mild axial phenotypes. Double mutant analysis revealed a functional redundancy with *Bmpr1a* and *Bmpr1b* in endochondral skeletogenesis (Rigueur et al., 2015). Conditional postnatal deletion of *Bmpr1a* revealed a role for BMP signaling in the maintenance of the chondrogenic cell fate in the growth plate (Jing et al., 2013). Constitutively activating mutations in *ALK2* are found in patients with fibrodysplasia ossificans progressiva (OMIM 156400), a rare disorder in which the connective tissue progressively ossifies after traumatic injury (Shore et al., 2006). For further reading see reviews by Rosen (2006), Pogue and Lyons (2006), Wu et al. (2007, 2016), and Wang et al. (2014b).

Parathyroid hormone-related protein and Indian hedgehog

The paracrine hormone parathyroid hormone-related protein (PTHrP) and its receptor PTH1R are part of a crucial regulatory node, also referred to as the IHH/PTHrP feedback loop, coordinating chondrocyte proliferation with maturation in endochondral bone formation (Fig. 1.7). PTHrP is also required for normal intramembranous ossification (Suda et al., 2001). In the appendicular skeletal elements, PTHrP is expressed locally at high levels in the periarticular cells and at lower levels in the proliferating chondrocytes. Its receptor is expressed also at low levels in proliferating and at higher levels in pre-HCCs (Lee et al., 1996; Vortkamp et al., 1996; St-Jacques et al., 1999). *PTHrP* and *Pthr1* mutant mice display similar, but not identical phenotypes, with numerous skeletal abnormalities, including severely shortened long bones (Karaplis et al., 1994; Lanske et al., 1996). In both, the shortening of the long bones is associated with reduced chondrocyte proliferation and accelerated HCC maturation and bone formation (Amizuka et al., 1996; Lee et al., 1996; Lanske et al., 1998). Chimeric mice with $Pth1r^{-/-}$ clones in their growth plates revealed that the effects on chondrocyte maturation were direct but influenced by positional cues, as these clones expressed either *Ihh* or *Col10a1* ectopically dependent on their location within the proliferative zone (Chung et al., 1998). Concomitantly, mice overexpressing either PTHrP or a constitutively active form of PTH1R in chondrocytes show a delay in HCC maturation early and a prolonged persistence of HCCs associated with a delay in blood vessel invasion at later stages of development (Weir et al., 1996; Schipani et al., 1997b). PTH1R is a seven-transmembrane receptor coupled to heterotrimeric G proteins, consisting of α, β, and γ subunits. Its activation by PTHrP results in signaling via either the $G_s(\alpha)$/cAMP or the $G_q(\alpha)$/inositol-3-phosphate-dependent pathway. The two downstream pathways have opposing effects on chondrocyte hypertrophy with $G_q(\alpha)$/inositol-3-phosphate-dependent signaling cell-autonomously accelerating hypertrophic differentiation, while $G_s(\alpha)$/cAMP-signaling delays it (Guo et al., 2002; Bastepe et al., 2004). The intracellular mediator of the canonical WNT signaling pathway, β-catenin, interacts with the PTH1R and may modulate the switch from $G_s(\alpha)$ to the $G_q(\alpha)$ signaling (Yano et al., 2013; Yang and Wang, 2015). The $G_s(\alpha)$/cAMP signaling pathway is also involved in the maintenance of the pool of round proliferating

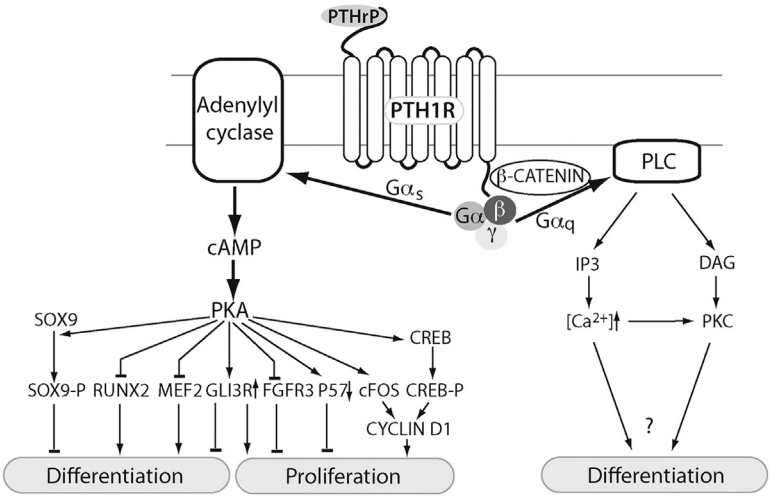

FIGURE 1.7 PTHrP/PTH1R signaling pathways and their functional consequences on chondrocyte differentiation and proliferation. The molecular mechanism underlying the differentiation-promoting effect of the PLC signaling branch is not yet understood. *PKA*, protein kinase A; *PLC*, phospholipase C; *PTHrP*, parathyroid hormone-related protein; *PTH1R*, PTHrP receptor.

chondrocytes (Chagin and Kronenberg, 2014). The inhibitory effect on chondrocyte hypertrophy is mediated through the activation of protein kinase A (PKA) downstream of $G_s(\alpha)$/cAMP signaling. This, in turn, promotes the following response: translocation of histone deacetylase 4 (HDAC4) into the nucleus where it binds to and inhibits the transcriptional activity of MEF2 transcription factors (Kozhemyakina et al., 2009). Furthermore, PTHrP signaling increases the expression of the transcription factor ZFP521, which negatively influences the transcriptional activity of RUNX2, again through recruitment of HDAC4 (Correa et al., 2010). In addition, PTHrP can decrease RUNX2 production and enhance its degradation specifically in chondrocytes (Guo et al., 2006; Zhang et al., 2009, 2010). MEF2 and RUNX2 are both positive regulators of chondrocyte hypertrophy (see later). PKA also phosphorylates SOX9, enhancing its DNA-binding activity, and stimulates GLI3 processing into its repressor fragment, thereby potentially interfering with chondrocyte maturation (Huang et al., 2000; Wang et al., 2000; Mau et al., 2007). PTH1R signal via PKA also inhibits the transcription of FGFR3 (McEwen et al., 1999). Furthermore, it leads to a downregulation of the cell-cycle-dependent inhibitor P57, a negative regulator of chondrocyte proliferation (Yan et al., 1997; MacLean et al., 2004). Last but not least, PTHrP signaling may stimulate proliferation through AP1/CREB dependent activation of cyclin D1 (Ionescu et al., 2001).

The findings in the different *Pthrp*/*Pth1r* mouse models can be correlated with activating mutations in the human PTH1R that lead to ligand-independent cAMP accumulation in patients with Jansen-type metaphyseal dysplasia (OMIM 156400) (Schipani et al., 1995, 1996, 1997a, 1999). On the other hand, the loss-of-function mutants correlate with the Blomstrand chondrodysplasia disorder (OMIM 215045) associated with the absence of a functional PTH1R (Karaplis et al., 1998; Zhang et al., 1998; Jobert et al., 1998). Interestingly, in the recessive Eiken skeletal dysplasia syndrome (OMIM 600002), a mutation leading to a C-terminal truncation of PTH1R has been identified that results in a phenotype opposite to that of Blomstrand chondrodysplasia and resembles a transgenic mouse model in which PTH1R signal transduction via the phospholipase C/inositol-3-phosphate-dependent pathway is compromised (Guo et al., 2002; Duchatelet et al., 2005).

Ihh, encoding a secreted molecule of the HH family, is expressed in pre-HCCs and has been shown to regulate the expression of *PTHrP* (Vortkamp et al., 1996; St-Jacques et al., 1999). This regulation is probably mediated by TGFβ2 signaling (Alvarez et al., 2002). *Ihh*-knockout mice display defects in endochondral and intramembranous bone formation (St-Jacques et al., 1999; Abzhanov et al., 2007; Lenton et al., 2011). In endochondral bone formation, IHH has multiple functions; it regulates proliferation and chondrocyte hypertrophy and is essential for osteoblastogenesis in the perichondrium. The last function of IHH apparently requires additional effectors other than RUNX2 (Tu et al., 2012). Conditional deletion of *Ihh* in *Col2a1*-CRE-expressing cells recapitulates the total knockout phenotype, including the multiple synostosis phenotype, a severe form of synchondrosis (Razzaque et al., 2005). In humans, *IHH* mutations are associated with brachydactyly type A1 (OMIM 112500), while copy number variations including the *IHH* locus are associated with syndactyly and craniosynostosis (Gao et al., 2009; Klopocki et al., 2011). The effects of *Ihh* on chondrocyte hypertrophy are PTHrP dependent as well as independent, while those on proliferation, osteoblastogenesis, and joint formation are PTHrP independent (Karp et al., 2000; Long et al., 2001, 2004; Kobayashi et al., 2005; Amano et al., 2016; Mak et al., 2008).

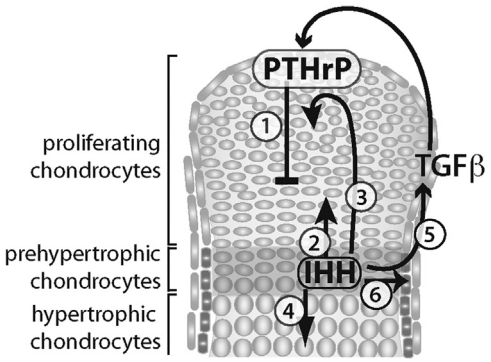

FIGURE 1.8 Parathyroid hormone-related protein (*PTHrP*) and Indian Hedgehog (*IHH*) interactions and functions in the growth plate. IHH and PTHrP participate in a negative feedback loop to regulate chondrocyte proliferation and differentiation. PTHrP is expressed from the perichondrial cells at the articular region and at low levels in round proliferative chondrocytes. It acts on proliferating chondrocytes, keeping them in a proliferative state and preventing their differentiation to prehypertrophic and hypertrophic chondrocytes (**1**). When the PTHrP concentration is sufficiently low enough, chondrocytes drop out of the cell cycle and differentiate into IHH-producing prehypertrophic chondrocytes. IHH, in turn, stimulates the proliferation of the adjacent flattened proliferating chondrocytes (**2**) and accelerates the progression of round to flattened proliferating chondrocytes (**3**) as well as the differentiation of prehypertrophic to hypertrophic chondrocytes (**4**). IHH also stimulates, probably mediated by transforming growth factor β (*TGFβ*) signaling, PTHrP production at the articular ends of the skeletal element (**5**) and acts on perichondrial cells, stimulating their differentiation into osteoblasts (**6**).

As mentioned earlier, the transcription factor GLI3 acts downstream of HH signaling, whereby HH signaling prevents the proteolytic conversion of GLI3 into the repressor form GLI3R. Mutations in *GLI3* are associated with Greig cephalopolysyndactyly (OMIM 175700) and Pallister−Hall syndrome (OMIM 146510) (Demurger et al., 2015). The mouse mutant extra-toes (Xt), a model for Greig cephalopolysyndactyly syndrome, has a deletion in the *Gli3* gene and displays numerous skeletal abnormalities, such as polydactyly, shortened long bones, split sternum, and craniofacial defects (Hui and Joyner, 1993; Vortkamp et al., 1992; Mo et al., 1997). Craniofacial abnormalities and shortened appendicular long bones are also reported in *Gli2* mutants (Mo et al., 1997). Interestingly, in double mutants for *Ihh* and *Gli3* the proliferation defect observed in the *Ihh* mutants is restored and the accelerated HCC differentiation, observed in $Ihh^{-/-}$ specimens, reverted (Hilton et al., 2005; Koziel et al., 2005). In contrast, the defects in osteoblastogenesis and cartilage vascularization are only partially rescued by the loss of *Gli3* (Hilton et al., 2005). Based on the observations in $Ihh^{-/-}$;$Gli3^{-/-}$ double mutants, Koziel and colleagues proposed a model whereby the IHH/GLI3 system regulates two distinct steps in chondrocyte differentiation: first, the transition from distal, round chondrocytes to the columnar chondrocytes, which appears to occur in a PTHrP-independent fashion, and second, the transition from proliferating to HCCs occurring in a PTHrP-dependent fashion (Koziel et al., 2005). Yet, Mak and colleagues proposed that Ihh also promotes chondrocyte hypertrophy in a PTHrP-independent way (Mak et al., 2008) (Fig. 1.8). In addition, Ihh activity is required for the maturation of the perichondrium and, in a cell-autonomous fashion, for the maintenance of endothelial cell fate (Colnot et al., 2005).

WNTs and β-catenin

As mentioned earlier β-catenin-mediated WNT signaling plays an important role as a permissive signal in the early steps of endochondral bone formation, enabling the differentiation of osteoblasts and cells contributing to the joint by repressing the chondrogenic potential within the respective precursor populations. The critical role of WNT/β-catenin signaling in osteoblastogenesis is first shown by the findings that human mutations in the WNT receptor LRP5 cause osteoporosis−pseudoglioma syndrome (OMIM 259770) (Gong et al., 2001; Lara-Castillo and Johnson, 2015). Mutations in the *WNT1* gene are causative for osteogenesis imperfecta, type XV, and an autosomal-dominant form of susceptibility to early onset of osteoporosis (OMIM 615220, 615221) (Keupp et al., 2013; Laine et al., 2013; Pyott et al., 2013). Numerous WNT-pathway molecules have been identified in genome-wide association studies related to skeletal phenotypes (Hsu and Kiel, 2012).

Stabilization of β-catenin in limb mesenchymal cells interferes with the initiation process of endochondral ossification (Hill et al., 2005). In contrast, expression of a constitutively active form of the downstream transcription factor LEF1 in *Col2a1*-expressing cells inhibits further maturation of chondrocytes and interferes with the formation of joints (Tamamura et al., 2005). Later during chondrocyte differentiation, WNT/β-catenin signaling regulates chondrocyte maturation in a positive manner (Hartmann and Tabin, 2001; Enomoto-Iwamoto et al., 2002; Akiyama et al., 2004; Day et al., 2005; Hill et al., 2005; Hu et al., 2005; Spater et al., 2006b; Joeng et al., 2011; Dao et al., 2012). This is mediated in multiple ways,

via direct regulation of *Ihh*, through interference with SOX9, and in a RUNX2-dependent fashion (Akiyama et al., 2004; Yano et al., 2005; Spater et al., 2006b; Dong et al., 2006; Dao et al., 2012; Mak et al., 2008). In HCCs, β-catenin signaling downregulates the expression of *Rankl*, thereby locally regulating the differentiation of osteoclasts at the chondro-osseous border (Golovchenko et al., 2013; Wang et al., 2014a; Houben et al., 2016). Based on overexpression of an intracellular inhibitor of β-catenin, ICAT, it has been proposed that β-catenin positively regulates VEGF and MMP13 (Chen et al., 2008). Yet, this has not been confirmed in conditional β-catenin mutants. Transient activation of β-catenin during early postnatal development leads to abnormal growth plate closure and promotes secondary ossification center formation (Yuasa et al., 2009; Dao et al., 2012). For further information see reviews by Baron and Kneissel (2013), Wang et al. (2014d), and Usami et al. (2016).

In addition to WNT/β-catenin-mediated signaling, a number of additional WNT signaling pathways are important within the growth plate. One that is highly relevant is the planar cell polarity pathway and its components, WNT5a and receptor tyrosine kinase orphan receptor (ROR2). Mutations in WNT5a and ROR2 are associated with Robinow syndrome (OMIM 268310; 164975) and brachydactyly type B1 (OMIM 113000) (Patton and Afzal, 2002; Person et al., 2010; Roifman et al., 2015). In mice, loss-of-function mutations in *Wnt5a*, *Ror2*, *Vangl2*, *Prickle1*, and *Ryk* result in skeletal dysplasias resembling those associated with Robinow syndrome (DeChiara et al., 2000; Takeuchi et al., 2000; Wang et al., 2011; Andre et al., 2012; Macheda et al., 2012; Gao et al., 2011; Yang et al., 2013b; Liu et al., 2014). In mice, *Wnt5a* and its related family member *Wnt5b* are both expressed in pre-HCCs (Yamaguchi et al., 1999; Yang et al., 2003; Witte et al., 2009). WNT5a promotes chondrocyte proliferation, as such mice lacking *Wnt5a* develop shorter skeletal elements due to a reduction in chondrocyte proliferation in zone II of the proliferating chondrocytes, encompassing the flattened proliferating chondrocytes (Yamaguchi et al., 1999; Yang et al., 2003). Furthermore, chondrocyte differentiation of HCCs is severely delayed in $Wnt5a^{-/-}$ mice as it is in *Ror2* mutants (DeChiara et al., 2000; Takeuchi et al., 2000; Oishi et al., 2003). Overexpression of either *Wnt5a* or *Wnt5b* primarily in chondrocytes also delays chondrocyte differentiation, yet, the two WNT ligands act on different chondrocyte subsets (Yang et al., 2003). The intracellular pathways underlying these effects are not known as of this writing. Compromised differentiation of HCCs may be associated with the capacity of WNT5a to induce the proteolytic cleavage of the transcription factor NKX3.2, which inhibits chondrocyte hypertrophy (Provot et al., 2006). In vitro, WNT5a and WNT5b can both activate calcium-dependent signaling leading to nuclear localization of nuclear factor of activated T cells (NFAT), as well as NF-κB signaling, and the kinase JNK (Oishi et al., 2003; Bradley and Drissi, 2010, 2011). The two pathways have differential effects on chondrogenesis (Bradley and Drissi, 2010). WNT5a signaling has also been shown to downregulate WNT/β-catenin signaling (Topol et al., 2003; Mikels and Nusse, 2006). However, experiments suggest that it can also enhance WNT/β-catenin signaling during osteoblastogenesis (Okamoto et al., 2014). Which pathway is preferentially activated may be decided at the level of the coreceptors (Grumolato et al., 2010).

Fibroblast growth factors and their receptors

FGF signaling also plays a critical role in the growth plate. Mutations in all three human *FGFRs* cause skeletal malformations, such as craniosynostosis syndromes (see also intramembranous ossification) and chondrodysplasia. Constitutively activating mutations in *FGFR3* are associated with hypochondrodysplasia (OMIM 146000), achondrodysplasia (OMIM 100800), and thanatophoric dysplasias type I (OMIM 187600) and type II (OMIM 187601). For reviews see Robin et al. (1993) and Ornitz and Marie (2015).

In the murine growth plate, *Fgfr2* is expressed at low levels in the round proliferating zone, also referred to as the resting zone. Proliferating and pre-HCCs express high levels of *Fgfr3*, and HCCs express high levels of *Fgfr1* (Ornitz and Marie, 2015). The growth retardation in conditionally deleted *Fgfr2* mice is attributed to alterations at the chondro-osseous junction (Yu et al., 2003). Yet, chondrocyte proliferation was unaffected in these mice. An increase in the zone of proliferating chondrocytes as well as HCCs was observed upon loss of *Fgfr3* (Colvin et al., 1996; Deng et al., 1996). In contrast, mice carrying an *Fgfr3* gene with human achondroplasia mutations display the opposite phenotype, a decrease in chondrocyte proliferation and a reduced zone of HCCs (Chen et al., 1999; Li et al., 1999). Of the different ligands, FGF9 and FGF18 have been identified based on their mutant phenotypes to be relevant in endochondral bone formation. Both are expressed in the perichondrium and periosteum. FGF9 and FGF18 are both required for chondrocyte maturation, as the onset of hypertrophy is delayed in $Fgf9^{-/-}$ and $Fgf18^{-/-}$ embryos (Hung et al., 2007; Liu et al., 2007). Yet, in the $Fgf9^{-/-}$ mutant only the stylopod elements are affected (Hung et al., 2007). Due to the delay in chondrocyte maturation vascular invasion is also delayed in both mutants. However, there is evidence that FGF18 may directly stimulate the expression of VEGF (Liu et al., 2007). In addition, FGF18 is required for chondrocyte proliferation. A 2016 allelic series study of *Fgf9*/*Fgf18* mutant embryos revealed unique and redundant roles of the two ligands in endochondral ossification (Hung et al., 2016).

C-type natriuretic peptide

In the growth plate, C-type natriuretic peptide (CNP) and its receptor GC-B are primarily expressed in proliferative and pre-HCCs (Chusho et al., 2001). In humans, homozygous loss-of-function mutations in the receptor cause acromesomelic dysplasia Maroteaux type (OMIM 602875), while heterozygous mutations are associated with short stature (Bartels et al., 2004; Olney et al., 2006; Vasques et al., 2013). Yet, the CNP/GC-B system is widely distributed in the body and as such, it was unclear whether it acts systemically or locally on endochondral ossification. Evidence for the latter is based on conditional knockouts of *Cnp* or *Gc-b* in *Col2a1*-Cre-expressing cells that recapitulate the dwarfism phenotypes of the respective full knockouts (Chusho et al., 2001; Tamura et al., 2004; Nakao et al., 2015). Dwarfism is associated with a decrease in the proliferative zone and in the number and size of HCCs. In contrast, loss of the clearance receptor NPR-C results in skeletal overgrowth similar to that in mice overexpressing the related molecule BNP (Suda et al., 1998; Jaubert et al., 1999). Skeletal growth can also be stimulated in a dose-dependent fashion by interfering with the clearance of CNP by overexpressing osteocrin, a natural NPR-C ligand (Kanai et al., 2017). In humans, overexpression of CNP is also associated with skeletal overgrowth (Bocciardi et al., 2007). Craniofacial studies in mice suggest that CNP/GC-B signaling primarily stimulates endochondral ossification (Nakao et al., 2013). Downstream signaling involves cyclic GMP-dependent kinase II but also interferes with the activation of the mitogen-activated protein kinase cascade downstream of FGF signaling (Miyazawa et al., 2002; Ozasa et al., 2005). For further reading see the review by Peake et al. (2014).

Notch signaling

Mutations in the Notch signaling components cause at least two human disorders with vertebral column defects, spondylocostal dysostosis (OMIM 277300, 608681, and 609813) and Alagille syndrome (OMIM 118450 and 610205) (Baldridge et al., 2010). Gain-of-function mutations in *NOTCH2* are found in Hajdu−Cheney syndrome, a rare skeletal disorder characterized by osteoporosis (OMIM 102500) (Majewski et al., 2011; Isidor et al., 2011). These diseases highlight, among others, the critical role of the segmentation clock in human axial skeletal development.

In chick and mouse, the Notch receptors 1−4 and the ligands, Delta1 and Jagged1/2, are expressed in a dynamic way within the developing limb skeleton, and inhibition of Notch signaling disrupts chondrocyte differentiation (Williams et al., 2009; Dong et al., 2010). Misexpression of the ligand Delta1 in chick inhibits the transition from pre-HCC to HCC (Crowe et al., 1999). A similar phenotype is observed upon conditional expression of the active Notch intracellular domain (NICD) in chondrocytes within the long bones, while a loss of skeletal elements due to impaired chondrogenesis is observed in the axial skeleton (Mead and Yutzey, 2009). The latter is associated with a downregulation of *Sox9* and, as shown in additional studies, with an enhanced proliferation of the mesenchymal progenitor cells, which is dependent on the activity of the transcriptional cofactor RBPjκ (recombination signal binding protein for immunoglobulin κ J region), which interacts with the NICD in the nucleus (Dong et al., 2010; Chen et al., 2013). Consistent with the osteoporosis phenotype in humans, the gain of Notch signaling in mice affects osteoblastogenesis of endochondral and membranous bones (Hilton et al., 2008; Mead and Yutzey, 2009; Dong et al., 2010). In contrast, interference with the Notch pathway by conditional deletion of *Presenilin 1/2*, encoding proteins required for the NICD release, or the *Notch1/2* receptors in the limb mesenchyme results initially in a delay of the onset of chondrocyte maturation and later in a delay of terminal differentiation leading to an elongated hypertrophic zone (Hilton et al., 2008). Conditional loss of the Notch effector RBPjκ results in a similar phenotype (Kohn et al., 2012). RBPjκ-independent Notch signaling, in contrast, affects the morphology of all growth plate chondrocytes and enhances osteoblast maturation (Kohn et al., 2012). In the articular chondrocytes, Notch signaling may be required for the maintenance of a chondroprogenitor population (Sassi et al., 2011).

Transcription factors

SOX9 and RUNX2 are master transcription factors that determine chondrocyte and osteoblast cell fates, respectively. It is not surprising that genetic defects in chondrocyte or osteoblast cell fate determination cause severe skeletal defects. Haploinsufficiency of SOX9 protein in humans causes campomelic dysplasia (OMIM 114290) with cartilage hypoplasia and a perinatal lethal osteochondrodysplasia (Meyer et al., 1997). Mutations in human *RUNX2* cause CCD (OMIM 119600), an autosomal-dominant condition characterized by hypoplasia/aplasia of clavicles, patent fontanelles, supernumerary teeth, short stature, and other changes in skeletal patterning and growth (Mundlos et al., 1997). The transcription factor OSX/SP7 acts downstream of RUNX2 within the osteoblast lineage (Nakashima et al., 2002; Nishio et al., 2006). Mutations in the human SP7 gene may be associated with osteogenesis imperfecta type XII (OMIM 613849) (Lapunzina et al., 2010).

Genetic studies in mice revealed that SOX9 plays numerous roles in skeletogenesis, from the initial differentiation of mesenchymal cells to chondrocytes to the maintenance of chondrogenic phenotype, survival, and the control of chondrocyte maturation (reviewed in Lefebvre and Dvir-Ginzberg, 2017). Its necessity for chondrocyte differentiation was first demonstrated by chimeric studies showing that *Sox9*-deficient cells are excluded from the cartilage (Bi et al., 1999). SOX9 activates the expression of two related family members, *Sox5* and *Sox6*, and cooperates with them, establishing and maintaining chondrocyte identity (Smits et al., 2001; Akiyama et al., 2002). SOX9 also interacts directly with and blocks the activity of the transcription factor RUNX2 at target promoters (Zhou et al., 2006). *Runx2* is expressed in pre-HCCs, HCCs, and osteoblast precursors and is important for HCC and osteoblast differentiation (Komori et al., 1997; Otto et al., 1997; Inada et al., 1999; Kim et al., 1999). Thus, this interaction maintains chondrocytes in a proliferative state and blocks their differentiation into HCCs and transdifferentiation into osteoblasts (Dy et al., 2012). RUNX2 acts partially redundantly with the related RUNX-family member RUNX3 on HCC maturation (Yoshida et al., 2004). *Mef2c* and *Mef2d*, members of the myocyte enhancer factor 2 family of transcription factors, are also expressed in pre-HCCs/HCCs. In contrast to *Mef2d*-knockout mice, which have no reported skeletal phenotype, *Mef2c*-deficient mice have shorter long bones associated with a delay in chondrocyte hypertrophy and downregulation of *Runx2* expression (Arnold et al., 2007; Kim et al., 2008). A constitutively active form of MEF2C upregulates *Runx2* and promotes chondrocyte hypertrophy, suggesting that MEF2C acts upstream of RUNX2 (Arnold et al., 2007). The activity of both transcription factors, MEF2C and RUNX2, is modulated by the histone deacetylase HDAC4 (see later). RUNX2 activity in HCCs is probably also modulated by interactions with other transcription factors such as *Dlx5/6*, which both physically interact with RUNX2 (Roca et al., 2005; Chin et al., 2007). Two members of the forkhead family of transcription factors, *Foxa2* and *Foxa3*, also play a role in HCCs. Both are expressed in HCCs and the loss of *Foxa2* results in decreased expression of hypertrophic markers, such as *Col10a1* and *Mmp13*, which is aggravated by the additional loss of *Foxa3* (Ionescu et al., 2012). The *SoxC* genes, *Sox4*, *Sox11*, and *Sox12*, are initially expressed in the mesenchymal progenitors of endochondral and intramembranous bone and become restricted to the perichondrium and joint as the chondrocytes differentiate (reviewed in Lefebvre and Bhattaram, 2016). In the progenitors, SOXC proteins are required for cell survival (Bhattaram et al., 2010). Later, during endochondral ossification, they are required for growth plate formation in part by promoting noncanonical WNT5a signaling (Kato et al., 2015). Other transcription factors, such as *Prrx1/Mhox* in combination with *Prrx2*, *Msx2*, and the *AP1* family member *Fra2*, also play roles in endochondral ossification (Martin et al., 1995; Lu et al., 1999; Karreth et al., 2004; Satokata et al., 2000). These can be acting locally restricted as is the case for *Prrx1/2* (Lu et al., 1999). For further information see reviews by Hartmann (2009), Karsenty (2008), and Nishimura et al. (2018).

The hypoxia-inducible transcription factor HIF consists of an α subunit that is regulated by oxygen and a β subunit that is constitutively expressed (Semenza, 2012; Ratcliffe, 2013). In growth plate chondrocytes, which are hypoxic, the subunit protein HIF-1α is stabilized and, on one hand, induces the expression of VEGF in HCCs and, on the other hand, regulates the oxygen consumption of chondrocytes through stimulation of anaerobic metabolism or glycolysis. Both downstream mechanisms are necessary for chondrocyte survival (Maes et al., 2012; Schipani et al., 2001, 2015; Cramer et al., 2004; Zelzer et al., 2004). The delayed differentiation observed in *Hif1a* mutants is probably a consequence of the initial delay in the initiation of chondrogenesis earlier in development (Provot et al., 2007; Amarilio et al., 2007). In contrast, mutation in the related α-subunit-encoding gene *Hif2a* results in only a transient and modest delay in endochondral ossification (Araldi et al., 2011). Yet, HIF2a appears to play a more prominent role postnatally in articular chondrocyte homeostasis (Pi et al., 2015; Yang et al., 2010).

Epigenetic factors and microRNAs

Since 2009, novel regulators of chondrogenesis and osteoblastogenesis have emerged, including epigenetic factors (reviewed in Furumatsu and Ozaki, 2010; Bradley et al., 2015). Among them is the histone deacetylase HDAC4, which plays a prominent role in HCC differentiation (Vega et al., 2004). HDAC4 binds to and inhibits the activity of two transcription factors that promote HCC differentiation, RUNX2 and MEF2C (Vega et al., 2004; Arnold et al., 2007). Histone-acetyl transferases such as P300 are important cofactors for BMP/SMAD1- and TGFβ/SMAD3-dependent signaling (Furumatsu et al., 2005; Pan et al., 2009; Sun et al., 2009). P300 also acts as a cofactor within the WNT/β-catenin pathway (Levy et al., 2004) and interacts with SOX9 (Furumatsu et al., 2005). SOX9 is also acetylated, which reduces its transcriptional activity, and this can be modulated by the NAD-dependent class III protein deacetylase Sirtuin (SIRT1) (Buhrmann et al., 2014; Bar Oz et al., 2016). SIRT1 and the histone methyltransferases SET7/SET9 also interact with P300 on the type II collagen promoter, promoting transcription (Oppenheimer et al., 2014). Conditional mouse mutants for the histone methyltransferase *Eset* have severely shortened limbs, a split sternum, and a widening of the sagittal suture of the skull (Yang et al., 2013a). The growth plates of *Eset* conditional knockout mice are disorganized, and HCC

differentiation appears to be accelerated. ESET interacts with HDAC4 to repress RUNX2 activity, thereby delaying hypertrophic differentiation (Yang et al., 2013a). Overall changes in the chromatin acetylation status in chondrocytes are induced through the interaction of the transcription factor TRPS1 with HDAC1 and HDAC4 (Wuelling et al., 2013).

Conditional deletion of *Dicer*, an enzyme that is required for the biogenesis of microRNAs, in chondrocytes revealed a functional role for microRNAs in chondrocyte proliferation and differentiation (Kobayashi et al., 2008). The latter is associated with a widened hypertrophic zone. Some of the specific microRNAs involved in these phenotypes are let-7 and miR-140 (Miyaki et al., 2010; Nakamura et al., 2011; Papaioannou et al., 2013). The noncoding RNA Dnm3os, a precursor for the microRNAs miR-199a, miR-199a*, and miR-214, is required for normal growth and skeletal development (Watanabe et al., 2008). In vitro, numerous microRNAs are differentially regulated during chondrogenesis and in osteoarthritis (Swingler et al., 2012; Crowe et al., 2016). For additional information on the role of microRNAs in skeletal development and homeostasis see Hong and Reddi (2012), Mirzamohammadi et al. (2014), and Fang et al. (2015).

Another class of RNA molecules with emerging functions in skeletal development are the long noncoding RNAs (lncRNAs). Mutations in the lncRNA *DA125942*, which interacts with PTHrP, result in brachydactyly type E (OMIM 613382) (Maass et al., 2012). The lncRNA *DANCR* promotes the chondrogenic differentiation of human synovial stem cell−like cells and is involved in osteoblastogenesis (reviewed in Huynh et al., 2017).

The functional roles of the vasculature in endochondral bone formation

Cartilage is an avascular and hypoxic tissue, yet, the ossification process and the remodeling of the cartilage template into cancellous bone require blood vessel invasion. Proliferating chondrocytes express numerous antiangiogenic factors, such as Chondromodulin I, Tenomodulin, Tissue-localized inhibitors of MMPs, and others (Maes, 2013). HCCs, in contrast, express VEGF, which is required to attract blood vessels to the perichondrium flanking the hypertrophic zone, as exemplified by mutant mice in which *Vegf* was deleted in cartilage or which lacked specifically the diffusible splice isoforms VEGF120 and VEGF164 (Zelzer et al., 2004; Maes et al., 2004, 2012). *Vegf* expression in HCCs is controlled by RUNX2 and, as mentioned earlier, by HIF1 (Zelzer et al., 2001). The invasion of blood vessels probably play an important role in the formation of the bone marrow cavity during endochondral ossification. Evidence for this is based on blocking VEGF signaling, which affects cartilage resorption, resulting in the elongation of the zone of HCCs (Gerber et al., 1999). Yet, as the monocytes, which are precursors for chondroclasts and osteoclasts, enter the bone marrow cavity via blood vessels, it is difficult to unambiguously distinguish between the functional requirements of the two components for the formation of the bone marrow cavity. Chondroclasts and osteoclasts produce matrix-degrading enzymes. Yet, the mineral dissolution function of osteoclasts is dispensable for the degradation of HCCs during long bone growth (Touaitahuata et al., 2014). Blood vessel endothelial cells also produce and secrete, among others, MMP9/Gelatinase B under proangiogenic conditions and may, therefore, be actively involved in the degradation of the cartilage matrix (Taraboletti et al., 2002). Blood vessels are, furthermore, important for trabecular bone formation during endochondral ossification. As mentioned previously, osteoblast precursors migrate into the forming bone marrow cavity along the blood vessels (Maes et al., 2010). In addition, it has been shown that the bone marrow cavity contains at least two types of blood vessels. In the embryo, an E and an L type can be distinguished, whereof the E type strongly supports osteoblast lineage cells (Langen et al., 2017). In the adult, the H-type vessels are the ones supporting osteoblast maturation (Kusumbe et al., 2014). Blood vessels also play a role as a structural component in trabecular bone formation. In addition to the mineralized cartilage matrix remnants, the vessels serve as structures for osteoid deposition (Ben Shoham et al., 2016).

Chapter 2

Skeletal stem cells: tissue-specific stem/progenitor cells of cartilage, bone, stroma, and marrow adipocytes

Pamela Gehron Robey[1] and Mara Riminucci[2]

[1]National Institute of Dental and Craniofacial Research, National Institutes of Health, Department of Health and Human Services, Bethesda, MD, United States; [2]Department of Molecular Medicine, Sapienza University of Rome, Rome, Italy

Chapter outline

Introduction

Stem cells are often thought of as a relatively new discovery, yet the existence of some sort of a stem/progenitor cell in bone from either the periosteum or the marrow was suggested as early as the 1860s in studies on bone regeneration by Ollier and Goujon (Goujon, 1869; Ollier, 1867). The concept of a stem cell was further crystalized in the late 1800s through the early 1900s by a group of astute biologists from diverse fields of interest (e.g., Boveri, Häcker, Regaud, Weidenreich, Dantschakoff, Maximow, and others, reviewed in Ramalho-Santos and Willenbring, 2007; Robey, 2000). They hypothesized that the ability of a tissue to maintain itself throughout the lifetime of an organism is based on the existence of a "stem" cell ("Stammzelle," a term first coined in German by Haeckel; Haeckel, 1868) that would remain primarily quiescent and undifferentiated, but also be able to regenerate the functional parenchyma of its tissue of origin following injury or the need for tissue rejuvenation (tissue turnover). Originally thought to exist only in tissues with high rates of turnover, such as blood, skin, and the gastrointestinal tract, evidence suggested that stem cells do exist in tissues with substantially lower rates of turnover, such as bone, with the ability to repair injury. Even tissues never thought to turn

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00002-6

over or repair, such as brain, do in fact contain stem cells (reviewed in Robey, 2000; see https://stemcells.nih.gov/info/basics/1.htm for more information). It was subsequently thought that virtually every tissue in the body contains some type of a stem/progenitor cell, although the existence of cardiomyocyte stem cells has been called into question (Kretzschmar et al., 2018). Nonetheless, the very notion of stem cells has had a major impact on both biological and medical sciences since the early 1990s, in terms of understanding the dynamics of tissue homeostasis in health and disease and the thought that they could be useful in tissue regeneration.

Following upon the early work of Ollier and Goujon, the hematologists Tavassoli and Crosby, aiming to better understand the support of hematopoiesis, took bone-free fragments of hematopoietic marrow and transplanted them under the kidney capsule. Remarkably, they found that marrow could be regenerated, but only after the formation of bone (Tavassoli and Crosby, 1968). It was Friedenstein et al., later in collaboration with Owen et al., who determined that the origin of bone in those marrow fragments was in fact a subpopulation of nonhematopoietic cells of the stroma upon which hematopoiesis occurs. When single-cell suspensions of bone marrow were plated into tissue culture plastic dishes at low density, a small proportion of single fibroblastic cells rapidly attached and began to proliferate to form a colony in a density-independent fashion. Friedenstein termed the initial adherent single cells as colony-forming units—fibroblasts (CFU-Fs), being cognizant of the fact that many cells could attach, but could not form a colony in a density-independent fashion. Subsequently, when the progeny of CFU-Fs (bone marrow stromal cells, BMSCs) were transplanted in vivo inside diffusion chambers that prevent vascularization (closed system), cartilage was formed in the relatively anaerobic interior of the chamber, and bone formed at the periphery, which was in close proximity to (but not in direct contact with) blood vessels. When single colonies were transplanted in conjunction with a collagen sponge under the kidney capsule with complete access to the vasculature (an open system), some colonies not only were able to form bone, stroma, and marrow adipocytes of donor origin, but also supported the formation of hematopoietic tissue of recipient origin (an ectopic bone/marrow organ) (Friedenstein et al., 1974). From this clonal analysis (and notice the emphasis on clones; i.e., the progeny of a single cell), Friedenstein and Owen proposed the existence of the first multipotent tissue-specific stem/progenitor cell from a solid connective tissue, which they termed a bone marrow stromal stem cell, able to differentiate into four different phenotypes: chondrogenic, osteoblastic, stromogenic, and adipogenic (Fig. 2.1) (Owen and Friedenstein, 1988). Later, the term "skeletal stem cell" (SSC) was adopted based on this ability to re-create all of the cells found in skeletal tissue proper (reviewed in Bianco and Robey, 2004, 2015; Owen and Friedenstein, 1988). Of note, this groundbreaking work clearly demonstrated that the stroma created by these stem/progenitor cells transfers the hematopoietic microenvironment (Friedenstein et al., 1974), contributing to the concept of a "niche" as later formulated by Schofield (1978).

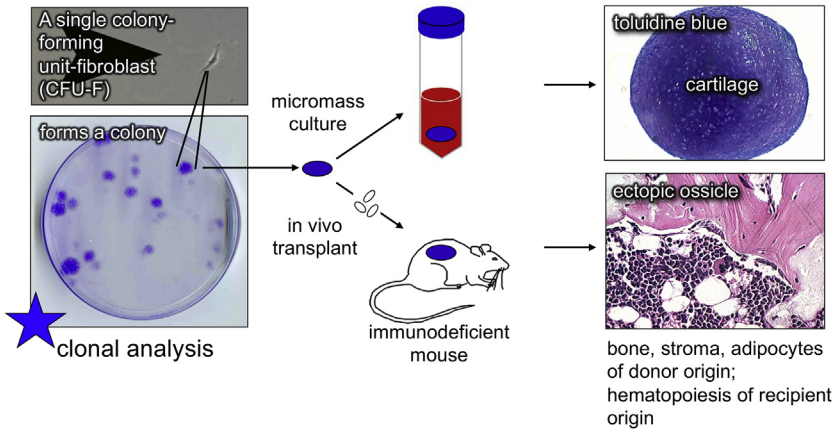

FIGURE 2.1 Proof of the existence of a postnatal multipotent skeletal stem cell. When single-cell suspensions of bone marrow are plated at low density, a single cell (colony-forming unit—fibroblast) rapidly attaches and proliferates to form a colony of bone marrow stromal cells. Clonal analysis is performed by placing clonally derived strains: (1) into micromass cultures (anaerobic) to observe the formation of cartilage or (2) onto appropriate scaffolds followed by subcutaneous transplantation into immunocompromised mice to observe the formation of a bone/marrow organ. This ectopic ossicle is composed of bone, hematopoiesis-supportive stroma, and marrow adipocytes of donor origin and hematopoiesis of recipient origin. *Modified from Bianco, P., Kuznetsov, S., Riminucci, M., Robey, P.G., 2006. Developmental origins of bone and skeletal stem cells

Germ-layer specifications

During embryonic development, the body pattern is first laid out by gastrulation of the inner cell mass of the blastocyst (the source of embryonic stem cells) to form germ layers for definitive endoderm, mesoderm, and ectoderm (which includes neural crest). Bone is formed by three different specifications of mesoderm and ectoderm (Olsen et al., 2000). Temporary embryonic cartilages in the cranium are formed from paraxial mesoderm by a process of cartilage regression followed by intramembranous bone formation (Holmbeck et al., 2003). Paraxial mesoderm also forms part of the dorsal cranial vault through primarily intramembranous bone formation, and the axial skeleton through primarily endochondral bone formation. Somatic lateral plate mesoderm forms the appendicular skeleton through intramembranous and endochondral bone formation, and last, neural crest forms the frontal cranium and facial bones through both intramembranous and endochondral pathways (Berendsen and Olsen, 2015; Olsen et al., 2000). It has also been suggested that the dorsal root of the aorta gives rise to skeletal cells through a process whereby specialized angioblasts (mesoangioblasts) bud cells into the extravascular space that go on to form connective tissues, including skeletal tissue (Bianco and Cossu, 1999), analogous to hemangioblasts budding cells into the vessel lumen to form definitive hematopoietic stem cells (HSCs) (Dzierzak and Medvinsky, 2008). Consequently, there are at least three (and possibly four) embryonic sources of skeletal tissue; that is, there is no single common skeletal stem/progenitor cell during embryonic development (Fig. 2.2A and B).

During development of the axial skeleton, the primitive streak (the precursor of mesoderm and endoderm) migrates caudally to form mesendoderm. Cephalic mesendoderm further specifies into paraxial and lateral plate mesoderm. Paraxial mesoderm segments into somites with definitive borders (Pourquie, 2001). Somitomeres with less definitive borders are formed in the head region (Bothe et al., 2011). Somites further differentiate into the dermatome that will form the dermis upon which ectoderm will form skin, the myotome that will form skeletal muscle, the syndetome that will form tendons and ligaments, and the most ventral part of the somite, the sclerotome, which will form the axial skeleton. Lateral plate mesoderm undergoes a splitting process to form the intraembryonic coelom (future peritoneum) and the splanchnic and somatic lateral plate mesoderm, the latter of which goes on to form the appendicular skeleton along with part of the body wall and dermis. Splanchnic mesoderm forms viscera, the heart, and associated blood vessels, including the dorsal root of the aorta (Onimaru et al., 2011). Last, following delamination from the border of the neural plate, neural crest cells migrate into the branchial arches and form cartilage and bone of the head, all epidermal pigment cells, and most of the peripheral nervous system in the trunk (Bronner, 2015) (Fig. 2.2A). It is generally thought that neural crest cells do not contribute to skeletal tissues below the neck; however, based on the expression of the neural crest marker, Wnt1, and expression of Nestin, this concept is currently being questioned (Danielian et al., 1998; Isern et al., 2014).

Patterns of bone formation and development of pericytes/skeletal stem cells

The different patterns of skeletal tissue formation differ from one another based on the involvement (or lack thereof) of cartilage (Fig. 2.2B). During intramembranous bone formation, there is no cartilage template. Embryonic mesenchymal condensations organize into two opposing layers of committed osteoprogenitors that begin to secrete and deposit bone matrix proteins into a sequestered area between the two layers of cells. Due to the activity of alkaline phosphatase on the surface of the committed osteogenic cells, pyrophosphate (a mineralization inhibitor) is cleaved to provide free phosphate for precipitation of a carbonate-rich apatite. In endochondral bone formation, embryonic mesenchyme condenses and differentiates into a cartilage template, the interior portion of which undergoes hypertrophy and calcification, while the outer surface (perichondrium) becomes committed to osteogenesis (periosteum). In this case, bone formation occurs in two ways: (1) between a fully committed osteogenic layer of cells and a layer of hypertrophic chondrocytes, in the bony collar, and (2) through cartilage hypertrophy and subsequent replacement by bone (Hall, 2015). In another pattern of skeletal tissue formation, best exemplified in the cranium, embryonic cartilage templates undergo regression rather than hypertrophy. These cartilages serve as a pathway to guide the formation of new bone by an intramembranous process, and ultimately disappear (Holmbeck et al., 2003) (Fig. 2.2B).

Irrespective of the pattern of formation, newly formed capillaries invade the developing bone, but lack pericytes, a cell type that has numerous cell processes that wrap around developing blood vessels to provide stability (Armulik et al., 2011). As the "naked" blood vessels begin to invade the newly formed woven bone and hypertrophic cartilage (in the case of endochondral bone formation), they form an association with committed osteoprogenitors (and possibly with hypertrophic chondrocytes) based on their expression of fibroblastic cell surface proteins. Because the osteogenic cells are no longer opposing a cell layer that is secreting bone matrix proteins, they undergo a shape change and downregulate expression of bone matrix proteins due to their association with endothelial cells, and become pericytes, cells that wrap around blood

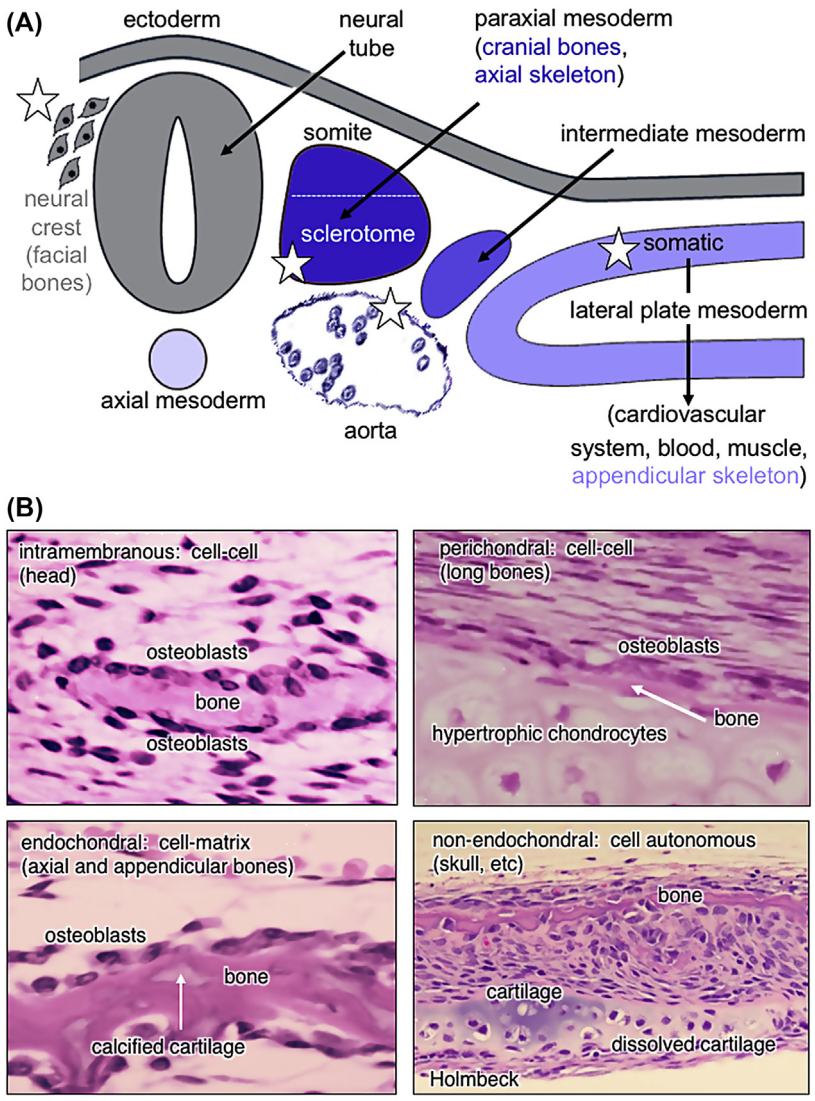

FIGURE 2.2 Development origins and patterns of bone formation. (A) During embryonic development, bone is formed by neural crest cells (ectoderm in origin) and two different specifications of mesoderm (paraxial mesoderm and somatic lateral plate mesoderm). It is also thought that mesangioblasts in the dorsal root of the developing embryo shed cells into the extravascular spaces to give rise to embryonic mesoderm. (B) Bone is formed through several different processes: (1) intramembranous (between two layers of osteoblastic cells), (2) perichondral (between a layer of osteoblastic and hypertrophic cells), (3) endochondral (calcified cartilage is replaced by woven bone), and (4) a nonendochondral replacement process (cartilage regresses, leading the way for intramembranous bone). *(A) Modified from Bianco, P., Robey, P.G., 2015. Skeletal stem cells. Development 142, 1023–1027.*

vessels to provide stability (Fig. 2.3). These pericytic cells proliferate along with the blood vessels into the interior of the bone, with osteoclasts leading the way to carve out the future marrow spaces. The pericytic cells proliferate further into the newly liberated space to form the prehematopoietic bone marrow stroma. Once sufficient bone has formed on the exterior of the rudiment to provide a protected environment, HSCs migrate through the circulation from the thymus, liver, and spleen to the bone, and escape from the circulation to establish definitive hematopoiesis in the bone marrow, the final home of the HSCs under normal conditions (Bianco et al., 1999, 2008b).

The skeletal lineage

As described earlier, embryonic skeletogenic mesenchyme, which contains the most primitive SSC, forms cartilage, bone, bone marrow stroma, and marrow adipocytes in a sequential fashion in time and space. Thus, during fetal development, chondrocytes, osteoblasts, SSCs/BMSCs, and marrow adipocytes can be seen as different stages of maturation rather than

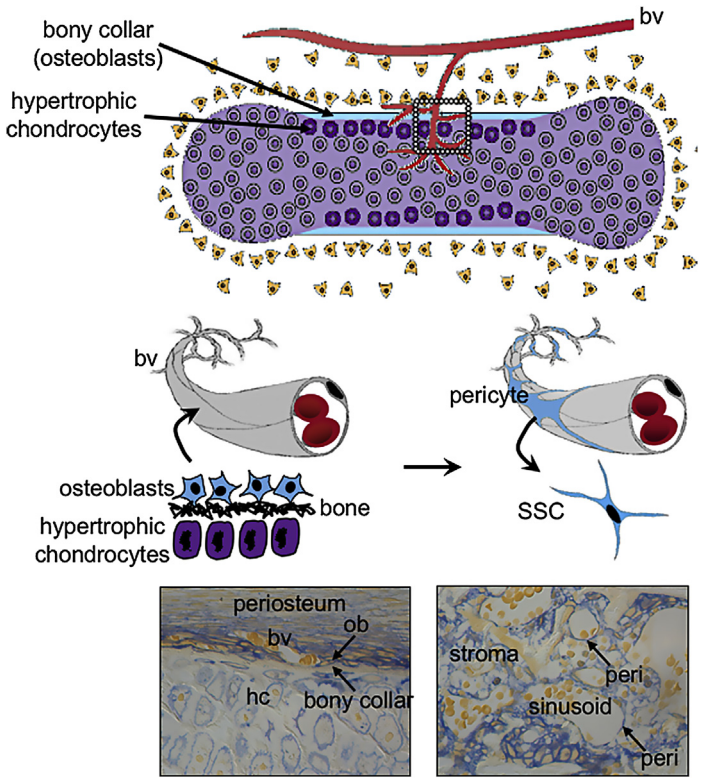

FIGURE 2.3 Development of pericytes/skeletal stem cells. As bone develops (in a long bone, as an example), blood vessels that are devoid of pericytes (cells surrounding blood vessels to give them stability) invade the developing rudiment, passing through the bony collar and hypertrophic cartilage. In doing so, ALP^{+} osteogenic cells (colored blue in the cartoons and photomicrographs) from the perichondrium are relocated into the forming marrow cavity and become primitive stromal cells that coat the forming sinusoids as pericytes, as can be seen in rodents at embryonic day 18. The pericytes (a subset of which are skeletal stem cells) remain quiescent on the blood vessel surfaces until released by injury or the need for bone turnover. *bv*, blood vessel; *hc*, hypertrophic cartilage; *ob*, osteoblast; *peri*, pericyte; *SSC*, skeletal stem cell. *Modified from Bianco, P., Robey, P.G., 2015. Skeletal stem cells. Development 142, 1023–1027.*

as separate lineages (Bianco and Robey, 2015) (Fig. 2.4A). Chondrogenesis, osteogenesis, and adipogenesis are controlled by three master transcription factors: Sox 9 (chondrogenic) (Bi et al., 1999), Runx2 (osteogenic and, to a lesser extent, chondrogenic) (Komori et al., 1997), and peroxisome proliferator-activated receptor γ2 (PPARγ2) (adipogenic) (reviewed in Muruganandan et al., 2009). In the case of cartilage, there are two potential fates: to undergo hypertrophy and be replaced by bone or to remain as hyaline cartilage on the articular surfaces of long bones in joints and in the ears and nose. The factors that maintain cartilage in a hyaline state are not well delineated as of this writing. Knowledge of this key point of regulation is of high interest based on the need to make new cartilage from an appropriate cell type that will not undergo hypertrophy, such as periosteal cells or SSCs/BMSCs.

In the context of embryonic development, a subset of committed osteogenic cells is recruited by blood vessels to form pericytes, which subsequently form stroma that supports hematopoiesis (Bianco et al., 1999, 2008b; Maes et al., 2010). As longitudinal bone growth slows and establishment of hematopoiesis is at a sufficient level to support the organism, stromal cells convert into marrow adipocytes to form yellow marrow, primarily in the distal regions of long bones. During postnatal growth (modeling), homeostasis, and aging (remodeling), cells in bone marrow stroma give rise to bone, hematopoiesis-supportive stroma, and marrow adipocytes (but rarely cartilage under normal conditions), and these tissues are thought to emanate from a single common primordial precursor, the SSC (Fig. 2.4B). Consequently, whether it be during embryonic development, postnatal growth, or adult homeostasis, there is a lineage that gives rise to skeletal tissues (chondrocytes, osteogenic cells, stroma, and marrow adipocytes), not multiple different precursor cells that give rise to different phenotypes. This has implications for the maintenance of skeletal tissues and their adaptations. Cells in the skeletal lineage are flexible; i.e., they can convert from one cell phenotype to another based on changes in the microenvironment. For example, it is well known that with aging, there is an increase in marrow adipocytes (yellow marrow) at the expense of osteogenic differentiation and support of hematopoiesis (red marrow) (Bianco and Riminucci, 1998).

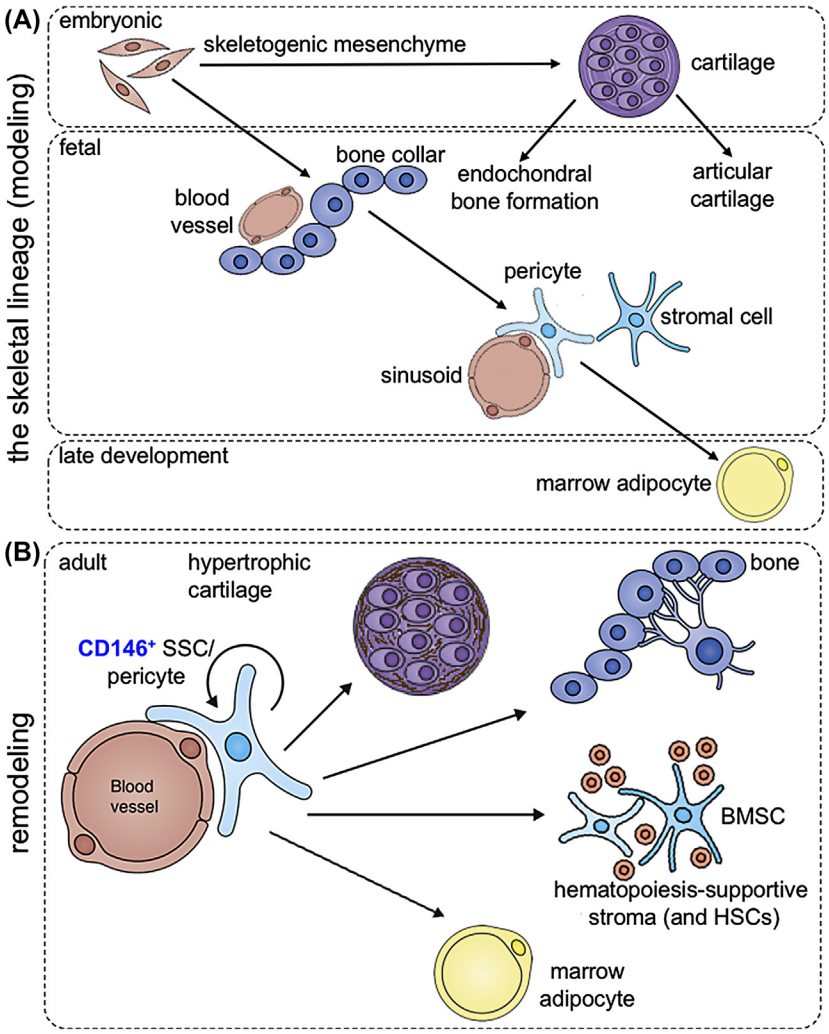

FIGURE 2.4 The skeletal lineage during embryonic development (modeling) and postnatal homeostasis (remodeling). (A) During embryonic development and postnatal maturation (modeling), cells emerging from skeletogenic mesenchyme sequentially form cartilage or bone. Cartilage either undergoes hypertrophy and is replaced by bone or remains as articular cartilage in joints. Osteogenic cells are recruited by blood vessels to form pericytes and stromal cells, which support hematopoiesis. At late stages of postnatal maturation, stromal cells accumulate fat and become marrow adipocytes. (B) In the mature postnatal organism, a subset of pericytes are skeletal stem cells that are capable of forming cartilage (rarely), bone, hematopoiesis-supportive stroma, or marrow adipocytes during skeletal remodeling. *BMSC*, bone marrow stromal cell; *HSC*, hematopoietic stem cell; *SSC*, skeletal stem cell. *Modified from Bianco, P., Robey, P.G., 2015. Skeletal stem cells. Development 142, 1023–1027.*

Cartilage is not normally seen in healthy bone marrow, and during fracture repair, the callus emanates from cells in the periosteum rather than from bone marrow stroma (O'Driscoll and Fitzsimmons, 2001). These periosteal cells are similar to, but not identical with, SSCs from bone marrow (Duchamp de Lageneste et al., 2018; Sacchetti et al., 2016). The role of marrow SSCs/BMSCs is probably to mediate remodeling of the bone in the fracture callus to restore the medullary cavity (reviewed in Einhorn and Gerstenfeld, 2015). This calls into question why SSCs/BMSCs would have the ability to make cartilage at all. The answer may be that during bone development, as blood vessels invade through the bony collar, they capture not only committed osteogenic cells, but hypertrophic chondrocytes as well, and orchestrate their conversion into pericytes. The association with endothelial cells may prevent their demise, but they may also retain a chondrogenic memory, to be recalled when released from the endothelial cell surface. Of note, it is most often reported that cartilage formed by SSCs/BMSCs undergoes hypertrophy and is converted into bone. This notion is supported by reports that not all hypertrophic chondrocytes die, and that some become osteogenic (Holmbeck et al., 2003; Muraglia et al., 2003; Roach et al., 1995; Scotti et al., 2013; Serafini et al., 2014), as has been rediscovered by Yang et al. (2014).

Regulation of SSC/BMSC fate

In postnatal life, SSCs are quiescent due to their association with blood vessels, until liberated by the need for bone turnover or injury. Upon liberation from blood vessel walls during bone turnover or following local injury, SSCs have the possibility of forming osteogenic cells, adipogenic cells, or more hematopoiesis-supportive stroma (Fig. 2.4B). The balance between osteogenic and adipogenic differentiation has received a large amount of attention due to its relevance to bone fragility and osteoporosis (Chen et al., 2016; Devlin and Rosen, 2015; James, 2013; Meyer et al., 2016; Teven et al., 2011). On the other hand, there is little information on how the SSC is directed into becoming a hematopoiesis-supporting stromal cell that is not a stem/progenitor cell. There are clear examples of the expansion of hematopoiesis, which relies on an increase in stroma, such as in hemolytic diseases where bone is lost to accommodate increased blood formation (Bianco and Riminucci, 1998). However, it has not been determined if the increase in hematopoiesis-supportive BMSCs is matched by an increase in SSCs. It has been shown that excess production of erythropoietin by platelet-derived growth factor subunit B-positive ($PDGFB^{+}$) cells (which include SSCs/BMSCs) causes expansion of red marrow (and thus, expansion of stroma) at the expense of bone and marrow adipocytes. However, the colony-forming-efficiency assay, the closest approximation of the number of SSCs available as of this writing, did not show a change in the number of colonies in these mice (Suresh et al., 2019). This suggests that expansion of the stromogenic pool does not necessarily equate with expansion of the SSC population.

Regulation of cell fate is complex, and is controlled by many factors, including hormones, cytokines, growth factors, and their downstream signaling pathways, all of which have an impact on the epigenetic pattern of the genome and subsequent transcriptional activity. Further control arises from posttranscriptional modifications (splice variants and isoforms), translational variation (small noncoding RNAs), and posttranslational modifications (reviewed in Chen et al., 2016). Mechanical forces and cell−matrix and cell−cell interactions are also influential. What follows is a very brief summary of regulatory factors influencing SSC/BMSC fate. However, it must be noted that there is some confusion in adipogenic fate choices based on the fact that it is considered by many that adipocytes from white or brown fat are equivalent to those in marrow, and they are not. Furthermore, in some cases, it is assumed that factors that induce osteogenic differentiation of SSCs/BMSCs will induce osteogenic differentiation of adipose-derived "mesenchymal stem cells" (and other nonskeletal "MSCs"). These nonskeletal "MSCs" are reported to become osteogenic based on an overreliance on artifactual in vitro assays after heavy treatment with chemical modifiers, and/or molecular engineering, but these nonskeletal "MSCs" are not inherently osteogenic.

Hormonal regulation

SSCs/BMSCs express receptors for many of the hormones that control skeletal growth and homeostasis, such as the parathyroid hormone (PTH) receptor, vitamin D receptor, glucocorticoid receptors, sex hormone receptors, thyroid hormone receptor, etc. If and how the corresponding ligands of these receptors control SSC/BMSC fate have not been closely examined in many cases. However, there are a few instances in which hormonal control or changes in their downstream signaling pathways (briefly described in the following) do have an impact on the fate of SSCs/BMSCs. For example, in hyperparathyroidism, it is thought that the ensuing endosteal fibrosis is due to the enhanced proliferation of stromal progenitor cells that accumulate and partially differentiate into osteoblastic cells (Bianco and Bonucci, 1991). Along this same line, excess PTH signaling due to a constitutively activating mutation in the PTH/PTH-related protein receptor (H223R, the causative mutation in Jansen's metaphyseal chondrodysplasia; Schipani et al., 1995), expressed specifically in mature osteoblasts in mice, led to the formation of excessive medullary bone due to the proliferation and maturation of SSCs/BMSCs, at the expense of marrow stromal cells and adipocytes (Kuznetsov et al., 2004). Interestingly, this phenotype resolved with age, with the subsequent removal of excess bone and establishment of a marrow cavity composed of stromal cells that were not multipotent SSCs based on in vivo transplantation assays. On the other side of the coin, it has long been known that estrogen deficiency leads to expansion of adipocytes at the expense of hematopoiesis-supportive stroma and bone, especially in females (e.g., Rosen and Bouxsein, 2006), which is thought to reflect a commitment of SSCs to adipogenesis at the expense of osteogenesis (e.g., Georgiou et al., 2012). However, it is also possible that direct conversion of stromal cells (rather than directing the fate of the SSC) into adipocytes contributes to this phenomenon. Likewise, glucocorticoid treatment in vivo leads to conversion of red marrow to yellow marrow, again thought to be due to a switch in fate of SSCs/BMSCs (e.g., Li et al., 2013). Paradoxically, a glucocorticoid, dexamethasone, is commonly used in medium used to osteogenically differentiate SSCs/BMSCs (Robey et al., 2014), implying that other factors are at play in vivo that drive glucocorticoid-mediated adipogenic differentiation of SSCs/BMSCs.

Signaling pathways and transcription factors

The levels of expression of Runx2, the master regulator of osteogenesis, and PPARγ, the master regulator of adipogenesis, are controlled by a number of signaling pathways activated by Wnts, members of the transforming growth factor β (TGFβ)/bone morphogenetic protein (BMP) superfamily, Notch, Hedgehogs, and fibroblast growth factors (FGFs) (and others), with extensive cross talk between these pathways (reviewed in Chen et al., 2012, 2016; Cook and Genever, 2013; Lin and Hankenson, 2011). Generally speaking, these pathways increase Runx2 expression with a concomitant decrease in PPARγ, or vice versa, during commitment and differentiation of SSCs. Runx2 is the first upregulated gene during osteogenic commitment and, in turn, upregulates Osterix, which along with Runx2 is essential for osteogenesis. Adipogenesis is initiated by upregulation of CCAAT/enhancer binding protein β (C/EBPβ) and C/EBPδ, which in turn induces PPARγ2. PPARγ2 upregulates C/EBPα, which maintains PPARγ2 expression via a positive feedback loop (reviewed in Cook and Genever, 2013).

Perhaps one of the most important signaling pathways that promotes osteogenesis of SSCs at the expense of adipogenesis is the Wnt/β-catenin pathway, which stimulates Runx2 expression and inhibits C/EBPα, thereby inhibiting adipogenesis (Monroe et al., 2012; Taipaleenmaki et al., 2011; reviewed in Cook and Genever, 2013). Members of the TGFβ superfamily also exert major influences mediated by pSmads 2/3, and have multiple effects on differentiation of SSCs/BMSCs. While TGFβs stimulate proliferation, they inhibit osteogenic differentiation (Alliston et al., 2001) and adipogenic differentiation (Kumar et al., 2012). In addition, BMPs play a major role in osteogenic commitment via pSmads 1/5/8 and Msx/Dlx homeoproteins to increase expression of Runx2 (reviewed in Cook and Genever, 2013). However, BMPs also appear to play a role in early adipogenic commitment, although the mechanisms are not clear. Adipogenic differentiation may be related to the type of BMP and its concentration and/or the type of receptors that are present on the cells at different stages of commitment (reviewed in Chen et al., 2012, 2016). It is generally reported that Notch signaling mediated by Delta/Jagged suppresses osteogenic differentiation (Zanotti and Canalis, 2016) and maintains SSCs in a primordial state (Hilton et al., 2008; Tu et al., 2012); however, positive effects on osteoblastogenesis have been reported (reviewed in Chen et al., 2012; Lin and Hankenson, 2011). Notch signaling also appears to have negative and positive effects during adipogenic commitment and differentiation (reviewed in Muruganandan et al., 2009). Indian hedgehog signaling, mediated by the Kinesin family protein Kif7, and the main intracellular Hedgehog pathway regulator, SUFU, is typically thought of in the context of growth plate dynamics, where it promotes osteogenic differentiation (Jemtland et al., 2003). However, in the context of the bone marrow microenvironment, Hedgehog signaling decreases with adipogenic differentiation of SSCs/BMSCs, suggesting that it is a negative regulator of adipogenesis (Fontaine et al., 2008). Hedgehogs may also interact with BMP signaling to promote osteogenic commitment (reviewed in Chen et al., 2016). FGFs can also be osteogenic (FGF2, FGF4, FGF3, FGF9, and FGF19) and adipogenic (FGF1, FGF2, and FGF10) and signal via a number of pathways that include extracellular signal-regulated kinase 1/2 (ERK1/2), p38 mitogen-activated protein kinase, Jun N-terminal kinase (JNK), protein kinase C, and phosphatidylinositol 3-kinase (PI3K) (Ling et al., 2006; Neubauer et al., 2004; reviewed in Chen et al., 2016).

As briefly listed, these are the major players that have been implicated in controlling the fate of SSCs/BMSCs, but there are other pathways initiated by factors such as insulin-like growth factor 1 (IGF-1) and PDGF (liberated from bone matrix during bone resorption), epidermal growth factor, and the transcription factor YAZ (reviewed in Chen et al., 2012, 2016; Cook and Genever, 2013; Lin and Hankenson, 2011). There are likely to be more regulators identified in the future.

Epigenetic controls

It is thought that epigenetic changes induced by signaling pathways operating in SSCs/BMSCs play a major role in fate decisions and stabilization of the osteogenic or adipogenic phenotype (Meyer et al., 2016). Modification of the conformation of chromatin (defined as DNA with bound protein) has an impact on transcription, with open chromatin (euchromatin) being accessible and condensed chromatin (heterochromatin) being inaccessible to transcriptional machinery, transcription factors, and other cofactors. Changes in chromatin architecture are brought about by DNA and histone modification. DNA methylation at CpG dinucleotides and CpG islands by methyltransferases is usually suppressive in nature. In addition to DNA methylation, chromatin structure is also influenced by modifications made to histones bound to DNA, such as methylation and acetylation (and there are others), that occur posttranslationally. Histones 3 and 4 are commonly methylated at specific sites by histone methyltransferases (HMTs). H3K4me3 is usually associated with euchromatin and gene activation, whereas H3K9me3 and H3K27me3 are usually associated with heterochromatin and gene repression. These methyl groups can be removed by histone demethylases (HDMs), and the changes in methylation are very dynamic, promoting flexibility. As an example, it has been demonstrated that formation of H3K27me3 by the

HMT EZH2 promotes adipogenesis of SSCs, whereas its removal by the HDM KDM6A promotes osteogenesis (Hemming et al., 2014). Histone acetylation by histone acetyltransferases and deacetylation by deacetylases (HDACs) is also dynamic. H3K9ac and HRK16ac are generally found in euchromatin and are indicative of transcriptional activation, whereas deacetylation leads to gene inactivation. While use of the HDAC inhibitor trichostatin A was thought to improve osteogenic differentiation of SSCs, it was determined that it profoundly decreased cell proliferation, and did not improve their osteogenic capacity upon in vivo transplantation (de Boer et al., 2006). Further work is needed to demonstrate what role histone acetylation and deacetylation plays in SSC/BMSC cell fate.

MicroRNAs

There are three forms of small noncoding RNAs: short-hairpin RNAs (shRNAs), microRNAs (miRs), and piwi RNAs. shRNAs are generally synthetic, and introduced exogenously (or created by processing of foreign dsRNAs), and piwi RNAs are primarily expressed in germ-line cells (reviewed in Carthew and Sontheimer, 2009; Ha and Kim, 2014); consequently, the role of miRs in controlling cell fate will be briefly summarized. miRs represent a way in which protein expression can be rapidly modified by either blocking translation or inducing the degradation of target mRNAs (reviewed in Jonas and Izaurralde, 2015). Interestingly, regulators of skeletal homeostasis such as BMPs and TGFβs are known to regulate miR expression and processing (reviewed in Lian et al., 2012). Numerous studies have been published indicating that miRs can control cell fate by downregulating the protein level of Runx2 or PPARγ, thereby enhancing adipogenesis or osteogenesis, respectively. Members of the miR-320 family were found to increase during adipogenic differentiation of SSCs/BMSCs by decreasing levels of Runx2 (among other genes) (Hamam et al., 2014). Conversely, miR-20a promotes osteogenesis by targeting PPARγ, as well as inhibitors of the BMP signaling pathway (Zhang et al., 2011). In addition, miR26a was found to decrease in SSCs during rapid bone loss in mice induced by ovariectomy. Overexpression of miR-26a was found to increase osteogenesis by SSCs by reducing levels of Tob1, which is a negative regulator of the BMP/Smad signaling pathway (Li et al., 2015). These are just a few examples, and others can be found in a 2014 review (Clark et al., 2014).

Cell–cell and cell–substrate interactions, cell shape, and mechanical forces

SSCs/BMSCs are not alone in the bone/marrow organ, and their interaction with other cell types undoubtedly influences fate. As already described, interaction with endothelial cells keeps them in a primordial state, and a study has shown that this is due to repression of Osterix (Meury et al., 2006). They also interact with HSCs; however, how HSCs and other hematopoietic cells influence SSC fate is not well known at this time, owing to the rather recent recognition by hematologists that SSCs are members of the HSC niche (reviewed in Ugarte and Forsberg, 2013).

Cell–matrix interactions occur primarily through: (1) integrins (which bind to many of the extracellular matrix components of bone), (2) discoidin domain receptors and urokinase plasminogen activator receptors, which bind to collagens, and (3) other cell surface molecules such as CD44, which binds to osteopontin (a major component of bone matrix) and hyaluronan. Of note, bone marrow is characterized by a preponderance of cell–cell interactions rather than cell–matrix interactions. Marrow contains thin reticular fibers composed primarily of type III collagen, and high levels of hyaluronan, which is gellike in nature (reviewed in Kuter et al., 2007). However, there is no doubt that after isolation from marrow, substrate has a profound influence on cell fate. For example, binding of αVβ1 to osteopontin inhibited adipogenic differentiation and stimulated osteogenic differentiation of murine SSCs, via downregulation of C/EBP expression (Chen et al., 2014). Modulation of cell shape also has an impact on fate. In a study where cell shape was controlled by plating at different densities, it was found that if cells were plated at low density and allowed to spread, the cells were directed toward osteogenesis, whereas plating at high densities, such that the cells remained rounded, induced adipogenesis. These phenomena were found to be mediated by the small GTPase RhoA, which is a regulator of the cytoskeleton (McBeath et al., 2004). There are a number of different methods by which substrates can be patterned, not only in shape, but in their surface character (D'Arcangelo and McGuigan, 2015). Patterns that promoted cytoskeletal contraction via JNK and ERK1/2 activity induced osteogenic differentiation, whereas when cytoskeletal contraction was not supported by a particular pattern, adipogenesis predominated (Kilian et al., 2010). Substrate elasticity and stiffness and the resulting mechanical forces sensed by SSCs/BMSCs control fate as well, with stiffer substrates generally favoring osteogenesis and softer substrates favoring adipogenesis. How substrate interactions control cell fate is extensively reviewed by Guilak et al. (2009). However, again the reader is cautioned that many of these studies purport to show differentiation of SSCs/BMSCs into nonskeletal phenotypes based on morphology and expression of a few markers, without demonstration of functionality. Last, matrix remodeling has a profound effect on the fate of SSCs. A dramatic example is found in the global deletion

of the membrane-type matrix metalloproteinase MT1-MMP (which is a true collagenase), in mice. Although mice appear normal at birth, there is a rapid decrease in growth, and by 40 days, they exhibit severe dwarfism and multiple skeletal defects. Transplantation of SSCs/BMSCs from the mutant mice revealed an almost complete inability to re-form a bone/marrow organ, indicating that MT1-MMP activity is essential for SSC self-renewal (Holmbeck et al., 1999). This mouse model is a direct phenocopy of the human vanishing bone disease Winchester syndrome, now known to be caused by an inactivating mutation in MT1-MMP (Evans et al., 2012).

Isolation of SSCs/BMSCs

While the multipotent stem cell found in marrow is most properly called a bone marrow stromal stem cell or an SSC (reviewed in Bianco and Robey, 2004, 2015; Robey, 2017), it has also gone by the name of "mesenchymal stem cell," based on its ability to re-create bone tissues that originate primarily from embryonic mesenchyme (reviewed in Caplan, 2005). However, not all embryonic mesenchyme forms bone. Furthermore, mesenchyme is an embryonic tissue that forms not only connective tissues, but also blood and blood vessels (MacCord, 2012). No postnatal cell, including any kind of "MSC," has been found to form all three of these tissues. But by applying some of the techniques developed for the isolation and characterization of SSCs/BMSCs, numerous studies purported to identify "MSCs" with the ability to form cartilage, bone, and fat in virtually all connective tissues and beyond. However, the true differentiation capacity and ability to self-renew of non−bone marrow "MSCs" have often not been determined using rigorous assays, leading one to believe that "MSCs" from any tissue are equivalent to SSCs/BMSCs. Furthermore, while some non−bone marrow "MSCs" may form bone, usually after treatment with a BMP, or genetic modification, most, if not all, lack the ability to support the formation of marrow. Few publications on nonmarrow "MSCs" comment on the ability to support hematopoiesis; however, examination of the histological results of in vivo transplantation assays highlight the fact that "MSCs" from adipose tissue (Hicok et al., 2004), dental pulp (Gronthos et al., 2000), periodontal ligament (Miura et al., 2003), and muscle (Sacchetti et al., 2016), as examples, often do not form bone based on rigorous criteria as presented in Phillips et al. (Phillips et al., 2014), and do not support the formation of hematopoietic marrow. In evaluating the results of in vivo transplantation with appropriate scaffolds, it is critical to determine that bone with identifiable osteocytes and osteoblasts of donor origin is formed, rather than dystrophic calcification, which can arise in pathological conditions such as some forms of heterotopic ossification (reviewed in Xu et al., 2018).

SSCs/BMSCs can be isolated from iliac crest aspirates, core biopsies, and surgical waste (Robey, 2011; Robey et al., 2014). While aspirates are less invasive than core biopsies, aspirates are contaminated with large amounts of peripheral blood when large volumes are aspirated, even with frequent repositioning of the aspiration needle, and excess peripheral blood can have a negative impact on the growth of BMSCs (Kharlamova, 1975). When core biopsies and surgical waste are available, repeated washing releases high numbers of cells (reviewed in Bianco et al., 2006). Cells from periosteal tissue, generated via enzymatic treatment or by explant cultures (for examples, see O'Driscoll and Fitzsimmons, 2001; Duchamp de Lageneste et al., 2018), also contain SSCs, but they are not identical to those found in bone marrow.

Characterization of SSCs/BMSCs

The definition of a stem cell is often variable, based on properties that are specific to the tissue from which a stem cell has been isolated. However, the two critical definitions of a stem cell are that the progeny of a single cell are able to re-create the functional parenchyma of a tissue (potency) and that the single cell can self-renew (reviewed in Ramalho-Santos and Willenbring, 2007); i.e., that its divisions are controlled in such a way that the stem cell is maintained within the tissue (Fig. 2.5).

Potency

Rigorous potency assays are critical in defining the differentiation potential of a stem cell and are based on clonal analyses rather than the BMSC population as a whole (Fig. 2.1). Studies by a number of groups (Friedenstein et al., 1974; Gronthos et al., 1994; Kuznetsov et al., 1997; Sacchetti et al., 2007; Sworder et al., 2015) characterized the differentiation capacity of clonal strains by combination of single-colony-derived strains with an appropriate scaffold and transplantation into immunocompromised mice in vivo. From these studies, it was determined that only ∼10% of the CFU-F-derived clonal strains were able to form a complete ossicle composed of bone, stroma, and marrow adipocytes of donor origin and hematopoiesis of recipient origin (multipotent clones), whereas ∼50% of the clones formed only bone and fibrous tissue of donor origin and did not support hematopoiesis (osteogenic clones), and the remainder formed only fibrous tissue

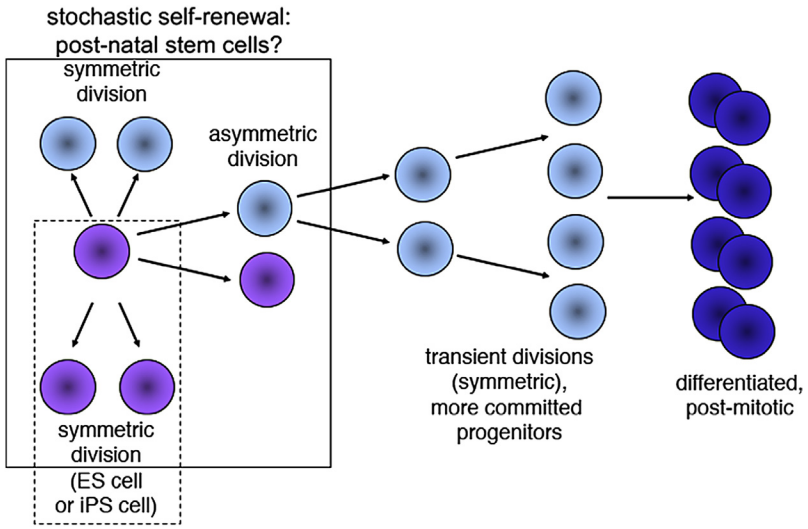

FIGURE 2.5 The kinetics of stem cell self-renewal. A defining feature of stem cells is the ability to self-renew, which is dependent on the type of cell division. Three patterns of stem cell division are possible: (1) asymmetric division in which one daughter cell remains a stem cell and the other is a committed transiently amplifying cell that ultimately differentiates and is postmitotic, (2) symmetric division in which both daughter cells remain as stem cells (as is exemplified by embryonic stem cells and pluripotent stem cells), and (3) symmetric division in which both daughter cells are committed transiently amplifying cells. The exact method by which postnatal stem cells are maintained within a given tissue is not well known, and it has been postulated that postnatal stem cells toggle from one type of division to another, based on the microenvironment and the needs of the tissue (Watt and Hogan, 2000). *ES*, embryonic stem; *iPS*, induced pluripotent stem. *Modified from Bianco, P., Robey, P.G., Penessi, G., 2008a. Cell source. In: de Boer, J., van Blitterswijk, C., Thomsen, P., Hubbell, J., Cancedda, R., de Bruijn, J.D., Lindahl, A., Sohler, J., Williams, D.F. (Eds.), Tissue Engineering. Elsevier, Amsterdam, pp. 279–306.*

(fibroblastic clones). These results indicate that while all of the multipotent clones originated from a single CFU-F, not all CFU-Fs are in fact multipotent. Based on the combination of clonal analysis and in vivo transplantation, one in five of the original CFU-Fs is multipotent, which is the closest approximation to date of the number of SSCs in the total BMSC population.

It must be noted that in vivo transplantation is the gold standard by which to evaluate osteogenic, stromagenic. and adipogenic capacity. Although in vitro assays are often used, they are highly prone to artifact. For the osteogenesis assay, alizarin red S cannot distinguish between dystrophic calcification induced by dead and dying cells versus matrix mineralization. In addition, if the cells make the enzyme alkaline phosphatase, the enzyme cleaves β-glycerophosphate that is in the osteogenic differentiation medium, and when the phosphate concentration in the medium becomes high enough, calcium phosphate precipitates, and it too stains with alizarin red S, but it is not hydroxyapatite. Of interest, there are a number of immortalized cell lines that are used to study the support of hematopoiesis in vitro. However, in vivo transplantation of several of these lines did not result in bone formation, or support hematopoiesis (Chang and Robey, unpublished results). In the adipogenic assay, many cells take up lipid from the serum in the medium and do not synthesize lipids de novo. From these findings, it is clear that in vivo transplantation with an appropriate scaffold is the gold standard by which to assess osteogenic, stromogenic, and adipogenic differentiation.

Conversely, the current gold standard for cartilage formation is the in vivo pellet culture as developed by Johnstone et al. (1998) and Barry et al. (Barron et al., 2015). However, the results of this assay are often misinterpreted. For the chondrogenic pellet culture, one must see bona fide chondrocytes lying in lacunae, surrounded by extracellular matrix that stains purple with toluidine blue (metachromasia). Alcian blue is not specific enough (osteoid stains lightly with Alcian blue), and many reports show pellets of dead cells that stain lightly with Alcian blue. With continued culture of cartilage pellets, the outer surface becomes osteogenic in nature, reminiscent of endochondral bone formation (Muraglia et al., 2003). If cartilage pellets are transplanted in vivo, without any additional scaffold, they remodel into bone either through a hypertrophy pathway (Scotti et al., 2013) or directly into a bone/marrow organ (Serafini et al., 2014). These results harken back to what is seen during development (modeling) and postnatal homeostasis (remodeling): under normal circumstances, SSCs/BMSCs do not form stable cartilage, although they may arise by conversion of a hypertrophic chondrocyte into a pericyte. However, it has been shown that SSCs/BMSCs may be maintained in vivo with an appropriate scaffold, perhaps due to a reawakening of the chondrogenic memory (Kuznetsov et al., 2019).

Markers

Based on their remarkable ability to form cartilage (at least temporarily), and a bone marrow/organ, there have been extensive studies on the characterization of the cell surface markers of human BMSCs, in hopes of identifying a signature that would be useful in isolating SSCs away from more committed BMSCs (reviewed in Bianco et al., 2006; Boxall and Jones, 2012). The consensus is that these cells are uniformly negative for hematopoietic markers such as CD14/LPS receptor, CD34/hematopoietic progenitor cell antigen, and CD45/leukocyte common antigen, and are devoid of many (CD31/PECAM1), but not all, endothelial markers. They are positive for a long list of markers, including (but not limited to) CD13/aminopeptidase N, CD29/ITGB1, CD44/phagocytic glycoprotein 1, CD49a/ITGA1, CD73/ecto-5′-nucleotidase, CD90/Thy-1, CD105/endoglin (also an endothelial marker), CD106/VCAM-2, CD166/ALCAM, Stro1/heat shock protein cognate 70 (a pericyte marker; Fitter et al., 2017; Simmons and Torok-Storb, 1991), and CD146/MCAM (also an endothelial marker) and CD271/LNGFR (Tormin et al., 2011), and there are others. However, these markers are not specific for SSCs/BMSCs and are found on virtually all fibroblastic and/or pericytic cells from many tissues, with some variation depending on the tissue source (Bianco et al., 2008b, 2013). As of this writing, there is no single cell surface marker that can be used to unequivocally identify an SSC, although combinations of markers such as CD146 (Sacchetti et al., 2007) and CD271 (Tormin et al., 2011) may be useful in enriching for SSCs (Robey et al., unpublished results). In addition, cell sorting is best applied to freshly isolated cells, rather than ex vivo-expanded cells. It is known that the expression of many markers changes with time and culture. For example, Stro-1 is known to rapidly decrease with time in culture (Bianco et al., 2008b, 2013).

The aforementioned markers pertain to human cells and in some cases to murine cells. However, there are some significant differences. For example, selection of $CD34^{-}/CD45^{-}/CD146^{+}$ human cells isolates all of the CFU-Fs, whereas murine cells with this phenotype are not CFU-Fs. Selection for CD106/VCAM-1 isolates murine CFU-Fs, but CD146 does not (Chou et al., 2012). With the ability to generate various reporter mice for proper lineage tracing, a number of studies have suggested that Nestin-GFP, Mx1, Lepr, PDGFRα, gremlin (reviewed in Chen et al., 2017, 2018) and CD164/podoplanin (Chan et al., 2018) are potentially relevant markers of murine SSCs.

Determination of skeletal stem cell self-renewal

Friedenstein and Owen, and others that followed, clearly demonstrated that BMSCs fulfilled the first criterion of a stem cell, e.g., they are able to re-create a functional parenchyma (a bone/marrow organ). However, determination of the precise origin and identity came later, along with evidence of self-renewal with the adaptation of a transplantation assay, as has been used by hematologists to determine the presence of HSCs (Sacchetti et al., 2007).

During mitosis, there are three fates for a stem cell: (1) the stem cell divides asymmetrically, and one daughter is maintained as a stem cell, the other as a transiently amplifying cell; (2) the stem cell divides symmetrically, and both daughters remain as stem cells, as in proliferation of embryonic and induced pluripotent stem cells in vitro; or (3) the stem cell divides symmetrically, but both daughters are transiently amplifying cells, with ultimate loss of the stem cell if this type of symmetrical division persists (Fig. 2.5). The allocation of stem cells among these types of divisions during embryonic development, postnatal growth, and homeostasis in adulthood is not well understood. It may be that all three types of divisions are operative under different circumstances, i.e., toggling from one type of division to another (Watt and Hogan, 2000).

Based on these types of cell divisions, it is clear that extensive proliferation is not evidence of self-renewal, as is often claimed in the literature. Using clonal analysis and the transplantation assay (which is key for the demonstration of self-renewal in the hematological system), evidence of self-renewal is linked with: (1) the isolation of a single cell with an identifiable phenotype whose progeny re-create a functional tissue and (2) reisolation of a single cell from the re-created functional tissue with the same identifiable phenotype. By comparing populations of bone-forming cells that were not able to support hematopoiesis to SSCs/BMSCs by fluorescence-activated cell sorting (FACS) for various different markers, it was determined that CD146 (also known as MCAM) was highly expressed by BMSCs, but not by normal human trabecular bone cells. Immunohistochemistry of human marrow identified the $CD146^{+}$ cells as pericytes. Clones established from freshly isolated human marrow were homogeneously positive for CD146, and when clonal strains were transplanted along with scaffolds into mice, again, ~10% were multipotent and able to form a bone/marrow organ. In those transplants, using an antibody specific for human CD146, the only human $CD146^{+}$ cells were pericytes on marrow sinusoids. Human osteocytes and osteoblasts, as identified by staining with antibody specific for human mitochondria, were not, indicating that ex vivo-expanded human $CD146^{+}$ cells were not only able to differentiate into osteogenic cells, but also able to self-renew into pericytes. Furthermore, human cells isolated by collagenase digestion of the transplants by

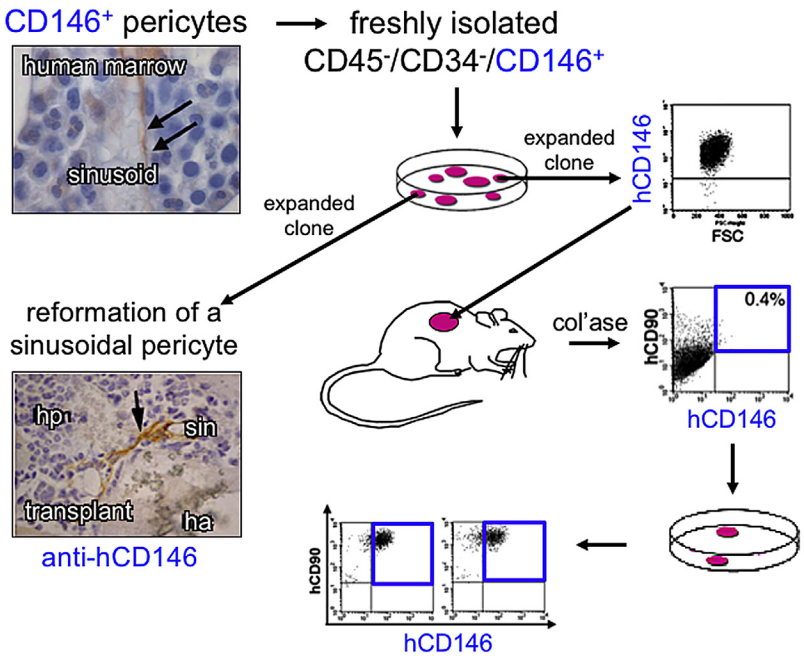

FIGURE 2.6 Skeletal stem cell self-renewal. Based on the use of cloned cells, an antibody specific for human CD146, and in vivo transplantation, it was determined that the multipotent subset of bone marrow stromal cells (BMSCs) does self-renew and contains bona fide skeletal stem cells (SSCs). It was first determined that CD146 is a marker of BMSCs that are able to support hematopoiesis (a defining feature of SSCs) and that these cells are sinusoidal pericytes. Freshly isolated human bone marrow $CD45^{-}/CD34^{-}/CD146^{+}$ cells are clonogenic. When a subset of individual $CD146^{+}$ clones (~1:5) is transplanted, they once again form a bone/marrow organ (ectopic ossicle) and human $CD146^{+}$ pericytes. Human $CD146^{+}$ cells can be reisolated from the ossicle as $CD146^{+}$ CFU-Fs, providing definitive evidence of self-renewal. *ha*, hydroxyapatite/tricalcium phosphate; *hp*, hematopoiesis; *sin*, sinusoid. *Modified from Sacchetti, B., Funari, A., Michienzi, S., Di Cesare, S., Piersanti, S., Saggio, I., Tagliafico, E., Ferrari, S., Robey, P.G., Riminucci, M., Bianco, P., 2007. Self-renewing osteoprogenitors in bone marrow sinusoids can organize a hematopoietic microenvironment. Cell 131, 324–336.*

way of magnetic cell sorting with anti-human-specific CD90 were clonogenic, and $CD146^{+}$, indicative of self-renewal of the CFU-F (Sacchetti et al., 2007) (Fig. 2.6).

The role of SSCs/BMSCs in postnatal bone turnover and remodeling

Bone turnover/remodeling is initiated by many factors, such as PTH, which is released from the parathyroid gland when the calcium-sensing receptor detects a decrease in serum calcium, and when there is a need to replace bone that has become microdamaged through mechanisms that are not yet clear. Formation of receptor activator of NF-κB (RANK)-expressing osteoclast precursors of the monocyte/macrophage series, as well as T cells that influence osteoclast formation (Li et al., 2011), is supported by SSCs/BMSCs by providing a "bed" (στρώμα (Greek)—*stróma*) upon which they are formed. SSCs/BMSCs express a long list of hematopoiesis-associated cytokines and growth factors (Gene Ontology categories "hematological system development and function" and "hematopoiesis" are highly overrepresented in multipotent SSC/BMSC clonal lines; data are in GEO GSE64789; Sworder et al., 2015). SSCs/BMSCs also express high levels of macrophage colony-stimulating factor and RANK ligand (RANKL), both of which are essential for osteoclast formation, and osteoprotegerin (OPG), which serves as a decoy receptor for RANKL, preventing osteoclast formation. Osteoclast formation and bone resorption are dependent on the balance of RANKL and OPG expressed by BMSCs and more mature osteoblastic cells, and BMSCs have long been thought to play a major role in osteoclast formation (reviewed in Boyce and Xing, 2007). Based on mouse models with conditional or cell/tissue-specific deletion of RANKL, it has been proposed that osteocytes also control osteoclast formation based on their expression of RANKL. However, it appears that the $RANKL^{+}$ cell type that controls osteoclastogenesis may be site specific. For example, mice with RANKL deletion in mature osteoblasts and osteocytes using a DMP1-Cre driver maintain tooth eruption, which requires bone resorption to occur, whereas the long bones exhibit an osteopetrotic-like phenotype (reviewed in Sims and Martin, 2014; Xiong and O'Brien, 2012). Further studies are needed to determine the contributions of SSCs/BMSCs, more mature osteoblastic cells, and osteocytes to initiating osteoclast formation throughout the skeleton.

Subsequent to the formation of osteoclasts and dissolution of mineralized matrix, a plethora of growth factors, buried within bone due to their affinity for carbonate-rich apatite, is liberated, including BMPs, PDGF, IGF-1 and IGF-2, and TGFβs. Consequently, PTH, the released factors, as well as those synthesized by local cells (Wnt10b by $CD8^+$ cells, FGF and vascular endothelial growth factor by BMSCs), mediate the reversal stage, which is marked by a cessation in bone resorption and creation of a microenvironment conducive for bone formation, thereby coupling bone resorption with bone formation (reviewed in Crane and Cao, 2014; Sims and Martin, 2014). It is thought that through osteoclastic action, active TGFβ is released and establishes a gradient from the resorption site through the marrow to the pericytes located on a nearby blood vessel. This gradient has two effects. Due to the high concentration of TGFβ at the site of resorption, it inhibits migration of osteoclastic precursors into the area; however, the gradient initiates migration of SSCs/BMSCs into the area in need of restoration, but does not induce differentiation (Tang et al., 2009). Upon arrival in the resorption bay, BMSCs are induced to osteogenic differentiation by the interplay of the TGFβ/BMP, Wnt, and IGF-1 signaling pathways. Interestingly, PTH, in addition to initiating bone resorption, also plays a role in bone formation. PTH bound to its receptor, PTHR1, complexes with Lrp6 (Wnt coreceptor), which leads to stabilization of β-catenin and pSmad1 signaling, along with stimulating cAMP-mediated signaling. The PTH−PTHR1 complex can also bind to the TGFβRII receptor, leading to pSmad2/3 signaling (reviewed in Crane and Cao, 2014). IGF-1 signaling activates mTOR via the PI3K−Akt pathway and induces osteogenic differentiation of BMSCs. Alterations in any of these pathways due to mutation, or alterations in levels of expression due to changes in the microenvironment, can have significant consequences on the balance of bone resorption and formation necessary for skeletal homeostasis (reviewed in Crane and Cao, 2014; Sims and Martin, 2014).

Skeletal stem cells in disease

Based on the fact that SSCs/BMSCs are essential for new bone formation following injury, and the fact that they, in part, control osteoclast formation, these cells are important mediators of skeletal homeostasis. As such, it was hypothesized that any genetic (intrinsic) change or change in their microenvironment (extrinsic) that has an impact on their normal biological activity would result in a skeletal disorder. Furthermore, due to their key role in supporting hematopoiesis and as a component of the HSC's niche (Ugarte and Forsberg, 2013), it was also theorized that there may be some hematological diseases or disorders that are caused, or worsened, by dysfunction of SSCs/BMSCs. Support for these notions came from both genetic (intrinsic) and acquired (extrinsic) diseases that affect bone and hematopoiesis.

Fibrous dysplasia of bone and the McCune−Albright syndrome

The genetic disease, McCune−Albright syndrome (MAS; OMIM: 174800) is characterized by the triad of skin hyperpigmentation (café au lait spots with the "coast of Maine" profile), hyperactive endocrinopathies (renal phosphate wasting, precocious puberty, growth hormone excess, hyperthyroidism, hyperparathyroidism, etc.), and fibrous dysplasia of bone (FD). Patients with FD/MAS are somatic mosaics (the mutation occurs after fertilization) with activating missense mutations of *GNAS*, which codes for Gsα, leading to overproduction of cAMP. FD lesions are characterized by the replacement of normal bone and marrow with woven, poorly organized, and undermineralized bone and replacement of marrow (hematopoiesis and marrow adipocytes) with a fibrotic tissue (reviewed in Boyce et al., 1993) (Fig. 2.7). This fibrotic tissue was found to be composed of a high proportion of mutant BMSCs (Riminucci et al., 1997). The initial effects of the mutation are to dramatically increase their proliferation and to inhibit their ability to form hematopoiesis-supporting stroma and marrow adipocytes. Furthermore, their differentiation into mature osteoblastic cells is severely compromised, as characterized by their retracted morphology and abnormal synthesis and organization of bone matrix, resulting in the formation of Sharpey's fibers (Bianco et al., 2000; Riminucci et al., 1999). The abnormal bone matrix is osteomalacic, due to hypophosphatemia caused by excess production of the phosphate-regulating hormone FGF-23 by the mutated osteogenic cells (Riminucci et al., 2003a). The abnormal composition of the matrix may also play a role in the undermineralization noted in these lesions.

Studies utilizing the fibrotic marrow from FD lesional bone showed that there was a higher colony-forming efficiency compared with normal bone marrow (Fig. 2.7). The presence of transiently amplifying cells present in the FD sample most likely explains the increase in colony-forming efficiency (Kuznetsov et al., 2008).

When FD BMSCs were transplanted along with hydroxyapatite/tricalcium phosphate ceramic particles into immunocompromised mice, they formed a fibrous dysplastic ossicle that completely recapitulated the nature of the FD

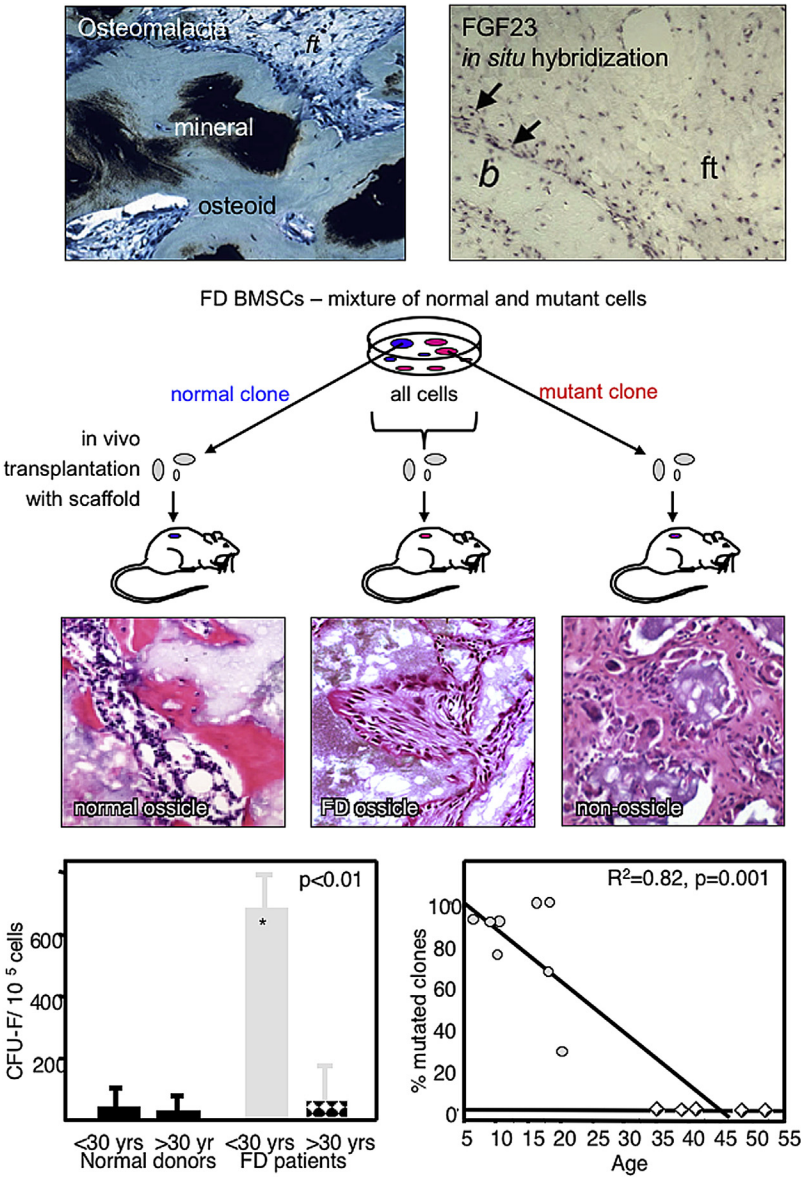

FIGURE 2.7 Fibrous dysplasia of bone/McCune–Albright syndrome (FD/MAS): a disease of skeletal stem cells. FD/MAS is a somatic mosaic disease caused by activating mutations of Gsα. Focal lesions are characterized by replacement of normal bone and marrow by highly disorganized and undermineralized bone and a fibrotic marrow devoid of hematopoiesis and marrow adipocytes. The fibrotic marrow is composed of a mixture of normal stromal cells, which are capable of forming normal bone in in vivo transplants, and mutated stromal cells, which on their own are not capable of surviving. It is only when normal and mutant cells are transplanted together that an FD tissue is formed. Colony-forming efficiency shows that in young patients with FD/MAS, there is a large increase compared with normal donors; however, with age colony-forming efficiency decreases dramatically, suggesting that colony-forming unit–fibroblasts (*CFU-Fs*) from young patients are, in fact, transiently amplifying cells rather than stem cells. Determination of the number of mutant CFU-Fs as a function of age also indicates that there is a dramatic decrease, leading to "normalization" due to the loss of mutated skeletal stem cells/transiently amplifying cells. *b*, bone; *BMSC*, bone marrow stromal cell; *FGF23*, fibroblast growth factor 23; *ft*, fibrous tissue. Arrows point out high levels of FGF23 expression by disfunction osteogenic cells on the bone surface. *Modified from Riminucci, M., Collins, M.T., Fedarko, N.S., Cherman, N., Corsi, A., White, K.E., Waguespack, S., Gupta, A., Hannon, T., Econs, M.J., Bianco, P., Gehron Robey, P., 2003a. lesion: abnormal woven and undermineralized bone, Sharpey's fibers, and lack of marrow formation (Bianco et al., 1998) (Fig. 2.7). In addition to transplantation of the total FD BMSC population, individual colonies were also evaluated. Clones were genotyped prior to transplantation, and as expected, clones with a normal genotype made a normal bone/marrow organ. Interestingly, mutant clones failed to survive transplantation; no bone was formed and human cells were not present (Bianco et al., 1998) (Fig. 2.7). This finding supports Happle's hypothesis that the mutation is embryonic lethal (Happle, 1986); that is, mutant cells would survive only when in combination with wild-type cells. Of note, there is no documented case in which FD/MAS was inherited; all cases are examples of de novo mutations after fertilization.

Evidence that FD is a "stem cell" disease (Riminucci et al., 2006) comes from the observation that as FD patients age, they "normalize" (Kuznetsov et al., 2008). Bone biopsies from patients of increasing age showed very high levels of apoptosis, up until approximately 30 years of age. Biopsies of older patients showed decreasing amounts of osteoid and increasing amounts of apparently normal bone and marrow. Marrow samples also showed a decrease in not only colony-forming efficiency, moving toward the normal level with increasing age, but also in the percentage of mutant cells in the total BMSC population, and a near-complete absence of mutant clones (Fig. 2.7). Transplants of BMSCs from older patients also showed increasingly normal ossicles, roughly correlated with age. From these observations, it was hypothesized that mutated SSCs were not able to undergo self-renewing types of division, and with time, transiently amplifying mutant cells differentiated and were ultimately cleared by apoptosis, leaving wild-type SSCs to undergo normal bone formation, albeit on an abnormal preexisting structure. Consequently, it can be reasoned that the impact of the mutation occurs at several levels in the skeletal lineage: (1) the mutation inhibits the self-renewal of mutant SSCs, (2) it causes extensive proliferation of mutant SSCs/BMSCs leading to premature apoptosis, and (3) it causes the derangement of BMSC differentiation into osteogenic, stromogenic, and adipogenic lineages.

Inherited forms of bone marrow failure

Inherited diseases of bone marrow failure are characterized by the inability to make normal numbers of all or specific types of blood cells (pancytopenia, or anemia, leukopenia, and thrombocytopenia) (Khincha and Savage, 2013). There are over 40 genes that have been reported to be mutated in association with these diseases (Ballew and Savage, 2013). Interestingly, many of these genes are not specific for hematopoietic cells based on the fact that patients with these diseases often have multiorgan manifestations. Dyskeratosis congenita (DC) is one such disease that is characterized by the triad of oral leukoplakia, nail dystrophy, and abnormal skin pigmentation, and also severe aplastic anemia, which is the main cause of death. These patients often have pulmonary fibrosis; stenosis of the esophagus, urethra, and/or lacrimal ducts; liver disease; premature graying of hair; and osteopenia (Ballew and Savage, 2013). Mutations have been detected in subunits of telomerase (*DKC1*, *TERT*, *TERC*, *NOP10*, *NHP2*), and in other genes involved in telomere biology (*WRAP53*, *TINF2*, *CTC1*, *RTEL1*). DC can be inherited in an X-linked recessive, autosomal dominant, or autosomal recessive fashion (Ballew and Savage, 2013; Nelson and Bertuch, 2012; Walne et al., 2013). In addition, a small proportion of patients with acquired aplastic anemia but without the other symptoms of DC have been found to have germ-line mutations in genes related to the telomerase complex (Alter et al., 2012; Yamaguchi et al., 2005). Based on these findings, patients with these various diseases and disorders have been grouped together as having telomere biology disorders (TBDs), and present with a very broad clinical spectrum ranging from limited bone marrow aplasia to a severe multiorgan phenotype as in DC.

Bone marrow failure caused by mutations in telomere biology-related genes is almost certainly caused, in part, by an intrinsic dysfunction of HSCs, due to short telomeres and a decrease in their ability to proliferate. However, the HSC's microenvironment (the niche) also controls the normal balance between quiescence and proliferation, self-renewal and differentiation (Schofield, 1978). As shown by Friedenstein et al., BMSCs are able to re-create the hematopoietic microenvironment upon in vivo transplantation into mice (Friedenstein et al., 1974; Owen and Friedenstein, 1988). Mature osteoblastic cells (Calvi et al., 2003), endothelial cells (Kiel et al., 2005), and BMSCs expressing CXCL12 (Omatsu et al., 2010; Sacchetti et al., 2007, 2016; Sugiyama et al., 2006), CD146 (Sacchetti et al., 2007), Nestin-GFP (Mendez-Ferrer et al., 2010), LEPR (Ding and Morrison, 2013), and others (reviewed in Ugarte and Forsberg, 2013) have been suggested to be constituents of the hematopoietic niche. In the quest for an identifiable niche-maintaining cell, current research is directed toward perivascular SSCs/BMSCs (Mendez-Ferrer et al., 2010; Omatsu et al., 2010; Pinho et al., 2013; Raaijmakers et al., 2010; Sacchetti et al., 2007, 2016). Thus, understanding the biological properties of SSCs/BMSCs has important implications not only for skeletal physiology and disease, but also for understanding the regulation of HSC physiology and dysregulation of hematopoiesis in blood disorders.

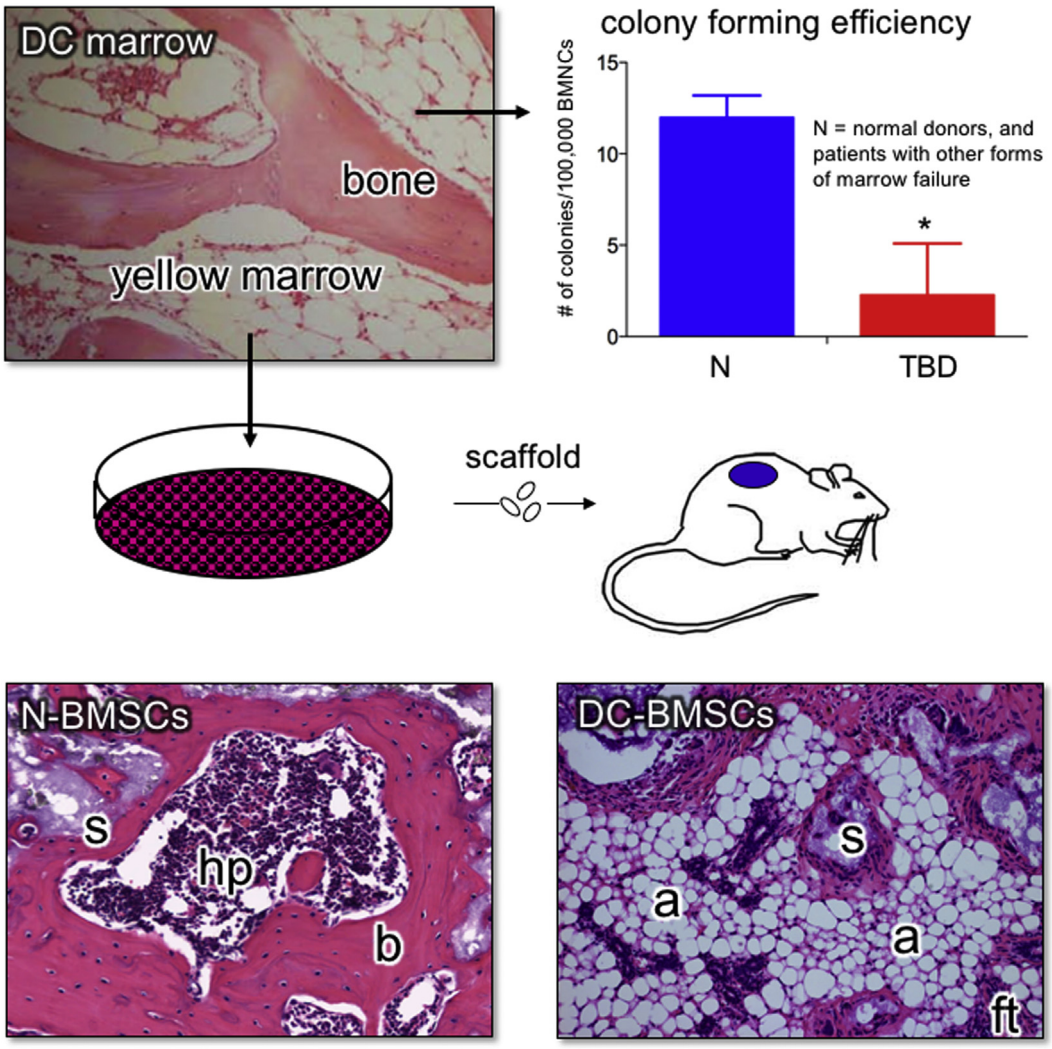

FIGURE 2.8 **Bone marrow failure: the role of skeletal stem cells.** A form of genetically acquired bone marrow failure syndromes is associated with mutations in genes that regulate telomere length, and they have been collectively termed telomere biology disorders (*TBDs*). Dyskeratosis congenita (*DC*) is one such TBD. Iliac crest biopsies from DC patients show predominately yellow marrow and demonstrate a dramatic decrease in colony-forming efficiency compared with normal donors. When DC bone marrow stromal cells (*BMSCs*) are expanded and transplanted, ectopic ossicles show a remarkable similarity to iliac crest biopsies: formation of a yellow marrow, completely devoid of hematopoiesis. *a*, adipocytes; *b,* bone; *BMNCs, bone marrow mono nucleated cells; ft*, fibrous tissue; *hp*, hematopoiesis; *s*, scaffold. *Modified from Balakumaran, A., Mishra, P.J., Pawelczyk, E., Yoshizawa, S., Sworder, B.J., Cherman, N., Kuznetsov, S.A., Bianco, P., Giri, N., Savage, S.A., Merlino, G., Dumitriu, B., Dunbar, C.E., Young, N.S., Alter, B.P., Robey, P.G., 2015. Bone marrow skeletal stem/progenitor cell defects in dyskeratosis congenita and telomere biology disorders. Blood 125, 793–802.*

By using BMSCs isolated from TBD patients to study the biological properties of TBD BMSCs, coupled with in vivo transplantation assay, it was found that SSCs contribute to the hematological phenotype in patients with TBD (Balakumaran et al., 2015) (Fig. 2.8). TBD BMSCs exhibited a drastically reduced colony-forming efficiency, as well as reduced telomerase activity. TBD BMSCs spontaneously differentiated into adipocytes and fibrotic cells even when cultured in osteogenic medium. In addition, they displayed increased senescence in vitro. Unlike normal BMSCs, upon in vivo transplantation into mice, TBD BMSCs failed to form bone or to support hematopoiesis. Knocking down *TERC* (a TBD-associated gene) in normal BMSCs using si*TERC*-RNA recapitulated the TBD BMSC phenotype as exemplified by reduced secondary colony-forming efficiency and growth rate, and accelerated senescence in vitro. Microarray profiles of control and si*TERC* BMSCs showed decreased hematopoietic factors at the mRNA level and decreased secretion of factors at the protein level. These findings are consistent with the notion that defects in SSCs/BMSCs, along with defects in HSCs, contribute to bone marrow failure in TBD patients. SSCs/BMSCs may be a target for drug treatment in some hematological diseases and disorders.

Role of SSCs/BMSCs in acquired inflammation

Changes noted in the ability of SSCs/BMSCs to support hematopoiesis as a function of an intrinsic (genetic) change in TBDs also led to the question whether extrinsic changes would influence the ability of SSCs/BMSCs to support hematopoiesis. Inflammation alters hematopoiesis, often by decreasing erythropoiesis and enhancing myeloid output. The mechanisms behind these changes and how the bone marrow stroma contributes to this process are not well known. These questions were studied in the setting of murine *Toxoplasma gondii* infection (Chou et al., 2012). The data revealed that infection alters early myeloerythroid differentiation, blocking erythroid development beyond the pre-megakaryocyte/erythroblast stage (erythroid crash), while expanding the granulocyte/monocyte precursor population (Fig. 2.9). The effects of infection in animal models deficient in cytokines known to regulate erythropoiesis were examined. The results indicated that in mice deficient in interleukin-6 (IL-6), the decrease in erythropoiesis was partially rescued, and it was also noted that in normal infected mice, serum IL-6 was elevated. From these results, IL-6 was found to be a critical mediator of the erythropoiesis, independent of hepcidin-induced iron restriction. Comparing bone marrow with the spleen showed that the hematopoietic response to infection was driven by the local bone marrow microenvironment. By using bone marrow transplantation to create bone marrow chimeras (IL-6-deficient marrow into normal recipients and vice versa), it was

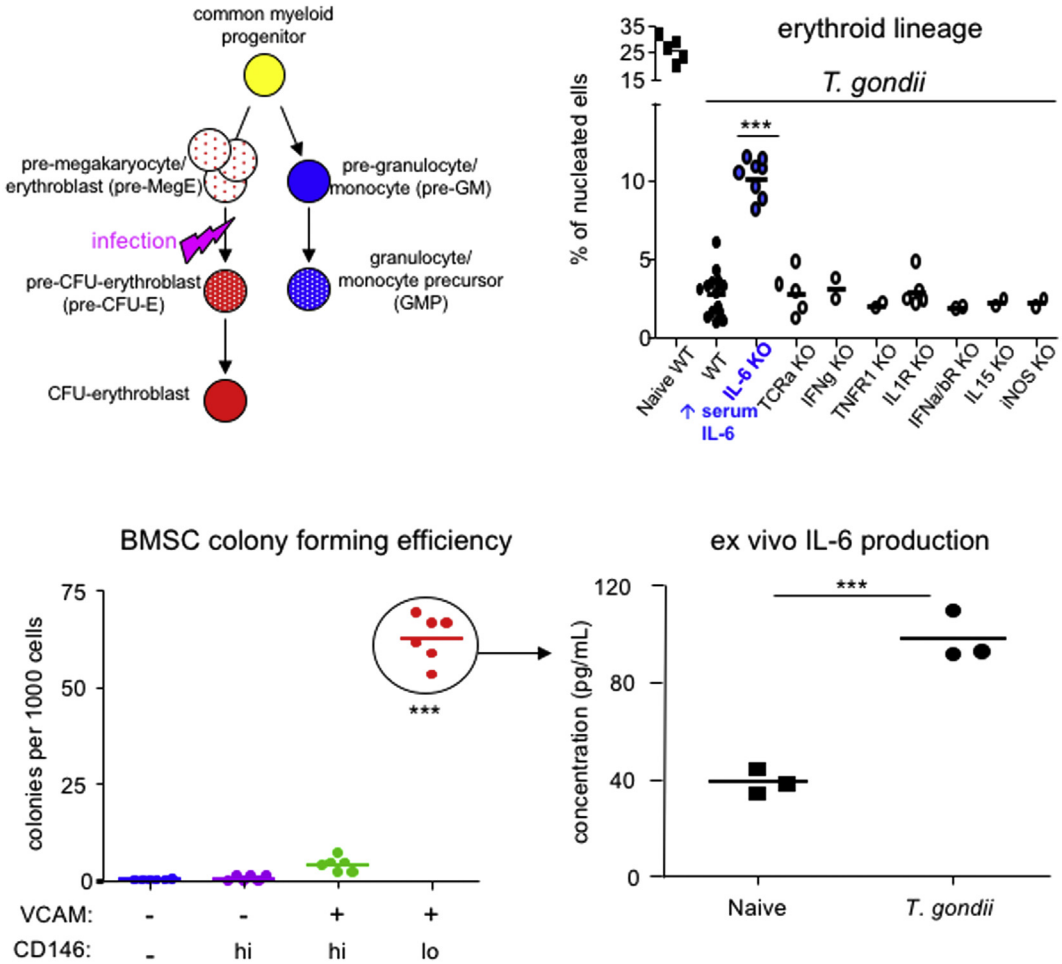

FIGURE 2.9 Skeletal stem cells/bone marrow stromal cells (SSC/BMSCs) in the sculpting of hematopoiesis. *Toxoplasmosis gondii* infection causes a crash in erythropoiesis due the blockade in differentiation of pre-megakaryocytes/erythroblasts into more differentiated cell types and a redirection of the common myeloid progenitor into the lymphoid series. Using mouse models deficient in various cytokines known to modulate erythropoiesis, it was determined that interleukin-6 (*IL-6*) deficiency partially rescued the erythroid crash and that IL-6 was increased in wild-type (*WT*) mice infected with *T. gondii*. Colony-forming unit (*CFU*)—fibroblasts ($CD45^-/Ter119^-/VCAM^+$) were isolated from naïve (uninfected) mice and infected mice, and were found to be the source of IL-6 induced by *T. gondii.* These results suggest that SSCs/BMSCs respond to external stimuli to modulate hematopoietic output and composition. *KO*, knockout. *Modified from Chou, D.B., Sworder, B., Bouladoux, N., Roy, C.N., Uchida, A.M., Grigg, M., Robey, P.G., Belkaid, Y., 2012. Stromal-derived IL-6 alters the balance of myeloerythroid progenitors during Toxoplasma gondii infection. J. Leukoc. Biol. 92, 123–131.*

demonstrated that radioresistant cells (BMSCs) were the relevant source of IL-6 in vivo. Finally, direct ex vivo sorting revealed that CD106/VCAM$^+$ colony-forming BMSCs significantly increased IL-6 secretion after infection (Fig. 2.9). These data suggest that SSCs/BMSCs regulate the hematopoietic changes during inflammation via IL-6 (Chou et al., 2012) and support the notion that extrinsic factors have an impact on stromal cell activity to sculpt hematopoietic output in response to microenvironmental changes.

Skeletal stem cells in tissue engineering

Based on their remarkable ability to form a complete bone/marrow organ, it is no wonder that many have pursued the use of SSCs/BMSCs in tissue engineering. Tissue engineering is typically described as the use of cells, growth factors, and/or cytokines and scaffolds, either alone or in various combinations, to restore tissue function lost due to trauma, tumor removal, and genetic and acquired diseases (Fig. 2.10). For skeletal tissue engineering, there are a number of parameters that affect outcome: the source of cells; the ex vivo expansion conditions, including the use of exogenous growth factors

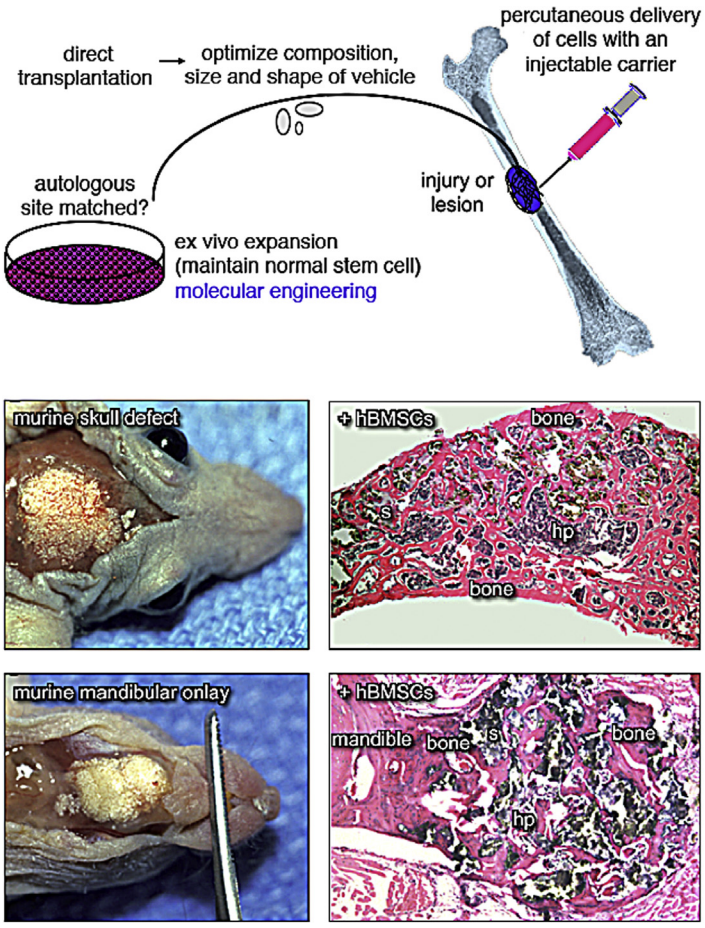

FIGURE 2.10 Skeletal stem cells in bone tissue engineering. In using skeletal stem cells/bone marrow stromal cells (SSCs/BMSCs), appropriate cell sources (e.g., autologous skeletal-derived cells such as bone marrow stromal cells) are needed. Ex vivo expansion conditions must maintain the SSC within the population to ensure that bone turnover can occur as needed. Culture of SSCs/BMSCs also offers the opportunity for molecular engineering to correct genetic defects (Piersanti et al., 2010). Ex vivo-expanded cells must be combined with an appropriate scaffold that will not only be osteoconductive, but also maintain the existence of SSCs. It may be possible to inject lesions directly, but an injectable carrier is needed to prevent their loss to the circulation and to hold them in place. Preclinical studies have been performed in mice to re-create jawbone and cranial bone (and also in dogs; Mankani et al., 2006a). *hp*, hematopoiesis; *s*, scaffold. *Modified from Bianco, P., Robey, P.G., Penessi, G., 2008a. and/or cytokines; and the nature of the scaffold. It also must be mentioned that the microenvironment (e.g., gender and age of the recipient, presence or absence of bacterial infection, inflammation, etc.) in which such constructs are placed will have an impact on the outcome of tissue engineering approaches.

Cell sources

By far and away, BMSCs have been the most studied cell population for the use of skeletal tissue regeneration. As shown by clonal analyses, BMSCs, if properly expanded, have a subpopulation of SSCs that are multipotent and able to form a bone/marrow organ. Based on the fact that the SSC is a pericyte on the abluminal side of marrow sinusoids, the presence of marrow in a transplant of BMSCs is indicative of the presence of SSCs. However, that is not to say that more mature populations of osteogenic cells are not useful. There are instances in which building new bone will fit that bill, and mature osteogenic cells isolated from trabecular bone and BMSCs grown in basic FGF make copious amounts of bone, but do not support hematopoiesis (Sacchetti et al., 2007). However, based on the fact that more committed osteogenic cells will eventually disappear and will need to be replaced during bone turnover, it is clear that an SSC is required. Furthermore, based on the fact that differentiated osteogenic cells begin to express histocompatibility antigens, cells used for skeletal tissue regeneration must be autologous and would ultimately be rejected if allogeneic unless immunosuppression is employed, which is not without serious side effects (Robey, 2011).

Finally, it is known that bone arises from three different embryonic specifications during development: paraxial mesoderm, lateral plate mesoderm, and neural crest. It is known that there are subtle histological differences and growth differences of bone from different origins (Akintoye et al., 2006), and studies suggest that there are also differences in the patterns of gene expression (Kidwai et al., unpublished results). Consequently, it is not yet known if SSCs from one embryonic source can substitute for those from another embryonic source. Studies in which iliac crest (appendicular lateral plate mesoderm) was used to build up alveolar bone (neural crest) showed rapid resorption of the iliac crest, suggesting a potential incompatibility (Burnette, 1972). Study of pluripotent stem cells (human embryonic stem cells [ESCs] and human induced pluripotent stem cells [iPSCs]) provides a way to dissect out the regulatory pathways that govern the discrete stages of human bone development operative in the three distinct embryonic sources. Many studies have aimed at differentiating ESCs or iPSCs into SSCs (see Phillips et al., 2014, for examples). However, this and other studies did not attempt to determine from which embryonic specification the cells originated. Studies are under way that are designed to take pluripotent stem cells stepwise through specific stages of bone development (primitive streak, mesendoderm, paraxial and lateral mesoderm, and neural crest) (Kidwai et al., unpublished results).

Scaffolds

There have been a large number of preclinical studies, and a number of small human trials, showing the efficacy of using ex vivo-expanded SSCs/BMSCs in conjunction with an appropriate scaffold for direct orthotopic delivery into large segmental defects (reviewed in Chatterjea et al., 2010; Winkler et al., 2018) (Fig. 2.10). In some approaches, cells are precultured on a scaffold prior to transplantation. However, it is not clear that this is an advantage, especially if osteogenesis is induced, which may preclude the cell population's ability to maintain the SSC. In addition, the nature of the scaffold plays a major role in the performance of the cell population. While many synthetic and natural scaffolds have been fabricated, as of this writing, 3D scaffolds that contain ceramics (usually hydroxyapatite/tricalcium phosphate) as part of their formulation (reviewed in Oh et al., 2006) appear to be the most reliable with respect to the formation of bone and the support of hematopoiesis when seeded with SSCs/BMSCs. However, many of these scaffolds are resorbed very poorly and can persist for long periods of time in vivo. Consequently, scaffolds composed of polymers such as PLGA (poly(lactic-*co*-glycolic acid)) and PCL (poly(ε-caprolactone)), with and without calcium phosphate components or further functionalization, have been developed (reviewed in Kretlow and Mikos, 2007; Rezwan et al., 2006). However, it is not clear that these scaffolds also maintain the SSC/BMSC population's ability to support hematopoiesis. Of note, many studies to identify new scaffolds rely on in vitro assays to evaluate the performance of newly developed scaffolds; however, these assays do not adequately determine osteogenesis or support of hematopoiesis, and in vivo transplantation is required.

In addition to the use of 3D scaffolds, it would also be of benefit to develop techniques for the use of injectable scaffolds that would hold cells in place and support their differentiation, and thereby avoid the need for open surgery (Mankani et al., 2008) (Fig. 2.10). Injection of concentrated bone marrow aspirates has been shown to be beneficial in the treatment of avascular necrosis (Hernigou et al., 2005), but it would be of interest to determine if their efficacy could be enhanced through the use of an injectable carrier. It could also be envisioned that this approach would be useful for the treatment of unicameral bone cysts and nonunions.

Skeletal stem cells and regenerative medicine

It is thought that either systemic infusion of SSCs/BMSCs into the circulation or direct injection into a diseased area has a beneficial effect in treating not only skeletal diseases and disorders, but also a long list of diseases (e.g., graft vs. host disease, cardiovascular disease, osteoarthritis, multiple sclerosis, etc.) (reviewed in Galipeau and Sensebe, 2018). Initially it was thought that SSCs/BMSCs could transdifferentiate into cells outside of the skeletal lineage based on expression of a limited set of markers characteristic of a nonskeletal tissue. However, more rigorous assays have shown that SSCs/BMSCs do not functionally differentiate into nonskeletal tissues without extensive treatment with chemicals or molecular engineering to express tissue-specific transcription factors (reviewed in Bianco et al., 2013). Furthermore, it is known that cells are rapidly cleared from the circulation when injected systemically, and are even rapidly cleared upon direct injection (when they are not attached to a scaffold or carrier) (Bianco and Cossu, 1999; Bianco et al., 2008b). It has been proposed that even though the cells do not seem to home to sites of disease or injury, or to survive long term, they secrete growth factors, cytokines, and/or extracellular vesicles that exert paracrine, immunomodulatory, and/or immunosuppressive effects on recipient cells that initiate an endogenous repair process (reviewed in Galipeau and Sensebe, 2018). While some studies, such as the treatment of certain symptoms of acute graft versus host disease, show that there may be some beneficial effect (Le Blanc and Ringden, 2007), the results of the vast majority of studies have been equivocal (reviewed in Galipeau and Sensebe, 2018). However, it has not been determined that these putative effects are mediated by the subpopulation of SSCs within the BMSC population, and this is unlikely to be the case, based on the fact that SSCs are very rare. Any potential effect is mediated by the BMSC population as a whole, and cannot rightly be called a stem cell therapy at the time of writing. Furthermore, their rapid disappearance in the lungs and the distance of their demise from the site of disease or injury make a mechanism of action obscure.

Stem cell and non–stem cell functions of skeletal stem cells

As described earlier, the regeneration of bone and maintenance of a stem cell on the abluminal side of the marrow sinusoid is of utmost importance in maintaining skeletal homeostasis throughout life (Robey, 2011). However, SSCs/BMSCs also perform other functions that do not rely on their stem/progenitor cell status, that is, not on their potency or their ability to self-renew. For example, based on their pericytic nature, they produce factors that guide the formation of microvessels in conjunction with endothelial cells. In vitro, a mixture of SSCs/BMSCs and endothelial cells plated on Matrigel forms networks with branches, with endothelial cells on the interior, surrounded by SSCs/BMSCs on the exterior. Likewise, when SSCs/BMSCs are cotransplanted in vivo along with human umbilical vein endothelial cells in Matrigel (conditions that are not conducive for bone formation), they again form an extensive capillary-like network after about 3 weeks, and after 8 weeks, a mature thick-walled structure forms with endothelial cells surrounded by pericytes derived from the SSCs/BMSCs. These capillary-like structures are functional based on the presence of recipient blood cells inside their lumens due to anastomosis of the nascent structures with the recipient vasculature (Sacchetti et al., 2016). Furthermore, SSCs/BMSCs support hematopoiesis, one of their defining features, and are thought to be a part of the HSC niche that controls the activities of the HSC (Bianco, 2011). In addition, there is evidence that SSCs/BMSCs play a major role in shaping the composition of hematopoiesis, as presented earlier (Chou et al., 2012). As such, SSCs/BMSCs can be targets for therapeutics designed to control the quantitative and qualitative aspects of hematopoietic cells.

Last, SSCs/BMSCs provide a tool by which to study human skeletal disease. There are many instances in which a mutation associated with a human disease does not re-create the same phenotype when introduced into a mouse. For example, Meunke syndrome is caused by autosomal dominant activating mutations of FGFR3 and is characterized by craniosynostosis, ocular and hearing abnormalities, and fusion or missing bones in the hands and/or feet (Doherty et al., 2007). However, the same mutation in heterozygous mice does not exhibit Meunke syndrome, and only when the mice are homozygous for the mutation do they exhibit some, but not all, of the phenotypic features (Nah et al., 2012). The use of SSCs/BMSCs from human patients with monogenetic disease, or the introduction of mutation with the use of CRISP/Cas9 or other types of genetic engineering, can provide valuable tools with which to elucidate the pathogenetic mechanisms at play by using appropriate in vitro assays and in vivo transplantation assays as described earlier. For example, by studying normal BMSCs transduced with the R201C activating Gsα mutation, it was noted that mutant BMSCs highly overexpress RANKL, an essential factor for osteoclast formation (Piersanti et al., 2010). This finding provided an explanation for the florid increase in osteoclastogenesis during the establishment of expansile lesions (Riminucci et al., 2003b). Furthermore, it suggested the use of denosumab (a humanized anti-RANKL antibody) to treat expansile disease, as has been reported (Boyce et al., 2012). Alternatively, using mutant SSCs/BMSCs to create an ectopic bone/marrow organ provides a model for testing new therapeutics to prevent the formation of diseased bone. The ectopic bone/marrow organ may be useful in

other diseases for which an appropriate animal model does not exist. Finally, the use of SSCs/BMSCs to create cartilage pellets may be helpful in screening small-molecule libraries for factors that prevent hypertrophy.

Summary

It is now clear that the bone/marrow organ contains a multipotent SSC that is able to re-create cartilage, bone, hematopoiesis-supportive stroma, and marrow adipocytes, and is able to self-renew. As such, these cells are central mediators of skeletal homeostasis. In the postnatal organism, fate choices of SSCs into chondrogenic (rarely), osteogenic, stromagenic, and adipogenic progeny are highly influenced by changes in the microenvironment in which they reside, and are mediated by numerous signaling pathways and genomic and epigenetic processes. Mutations (intrinsic changes) that affect their normal biological functions can have a profound effect on the skeleton and even on hematopoiesis based on their presence and activity in the HSC niche. In addition, changes in the microenvironment (extrinsic) that have an impact on SSC/BMSC function can also lead to skeletal and hematological diseases and disorders. Last, SSCs are an essential ingredient for any process aimed at enduring bone regeneration by the cells themselves due to their ability to mediate bone turnover.

Acknowledgments

The authors would like to acknowledge all of the genuinely seminal contributions of Professor Paolo Bianco to the evolution of the field of skeletal stem cell biology. He was truly a pioneer. The authors would also like to acknowledge all of the members, past and present, of the Skeletal Biology Section, NIDCR, and the Stem Cell Lab, Department of Molecular Medicine, Sapienza University of Rome.

The authors declare that they have no conflicts of interest. This work was supported by the DIR, NIDCR, of the IRP, NIH, DHHS, to P.G.R., and by Telethon (grant GGP15198), the EU (PluriMes consortium, FP7-HEALTH-2013-INNOVATION-1−G.A. 602423), and Sapienza University of Rome to M.R.

Chapter 3

Bone marrow and the hematopoietic stem cell niche

Laura M. Calvi

Department of Medicine and Wilmot Cancer Center, University of Rochester Medical Center, Rochester, NY, United States

Chapter outline

Introduction

In the adults of land-dwelling vertebrates, the skeleton is the obligate site for normal hematopoiesis during homeostasis. Throughout the life of an organism, hematopoiesis maintains the blood components necessary for oxygenation (erythropoiesis), clotting (megakaryopoiesis/thrombopoiesis), and immunity (myelopoiesis and lymphopoiesis). Since differentiated cells have varying life spans, from hours (in the case of neutrophils) to years (in the case of memory T cells and hematopoietic stem cells [HSCs]), a large component of the hematopoietic system is continually replaced by intermediate committed precursors derived from progenitors that may give rise to more than one differentiated lineage. Progenitors and precursors have limited self-renewal capacity and derive from HSCs, tissue-specific stem cells that persist throughout the life of an organism. While these stem cells are primarily quiescent, they are recruited when there is increased demand for blood products. Given their ability to regenerate the entire hematopoietic system and their relative accessibility, HSCs have been extensively studied as a model system for stem cell behavior. Clinically, HSCs are commonly used in the setting of stem cell transplantation for the treatment of hematologic malignancies and other disorders; therefore, extensive research has focused on understanding their regulation for regenerative purposes. In addition to cell-autonomous programs, a highly complex and dynamic microenvironment in the bone marrow contributes to the support and regulation of HSCs. The components of this system are likely to represent important potential therapeutic targets if their regulation and impact on HSCs are understood. Moreover, since bone and marrow are components of the same organ, dysfunction in bone may contribute to hematopoietic failure and vice versa. Here we present a historical prospective on the concept of the bone marrow microenvironment as a regulatory component for hematopoiesis, and describe the data supporting the role of niche constituents in the regulation of HSCs.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00003-8

The niche concept: a historical prospective

In the 1960s and early 1970s the ability to transplant bone marrow cells that could regenerate the hematopoietic system (McCulloch and Till, 1960) and the development of in vivo and cell culture methods that could detect and study hematologic progenitor cells as colony-forming unit cells (Becker et al., 1963; Senn et al., 1967) initiated studies aimed at defining immature cells responsible for sustaining hematopoiesis and their regulation. Based on divergent observations of spleen colony-forming cells compared with in vivo HSCs, the stem cell niche concept was initially proposed in 1978 by Schofield (Schofield, 1978). This investigator single-handedly postulated that the "virtual immortality" of HSCs in the bone marrow may be conferred by association with other cells capable of preventing their maturation, maintaining their reconstitution capacity (Schofield, 1978). At the same time, studies suggested that the distribution of HSCs followed a hierarchical organization, with the most primitive cell populations being found at the endosteal surface of bone (Gong, 1978). Analogous to the niche in ecology, niches conceptually represent the microenvironmental conditions that support specific stem cell populations. Schofield proposed that niche cells would be found in close proximity to supported stem cells, so as to form a relatively "fixed" unit, and that they would provide signals that could modify stem cell fate choices, including bestowing stem cell potential to more differentiated daughter cells (Schofield, 1978). While this innovative idea was stimulated by observations in hematopoiesis, the niche was first demonstrated in the *Drosophila* gonad, where elegant studies showed that niche occupancy could alter cell fate and induce stem cell behavior in progenitor populations (Kiger et al., 2000; Tran et al., 2000; Xie and Spradling, 2000). Since these initial studies, niches have been defined in colonial chordates (Rosental et al., 2018), *Caenorhabditis elegans* (Austin and Kimble, 1987), zebrafish (Tamplin et al., 2015), and murine models for many tissue-based stem cells (Tumbar et al., 2004; Bjerknes and Cheng, 2001), including, most recently, the hematopoietic system. In the bone marrow, many challenges initially delayed identification of niches and critical populations within them. These challenges included the technical difficulties involved in the examination of the boundary between the hard bone tissue and the soft bone marrow, difficulty in direct visualization of the marrow, apparent anatomic disorganization of marrow populations, rarity of HSCs, lack of histologic distinguishing features of these populations, and limited definition of mesenchymal cell populations. However, the regulatory niche, if comprehensively defined, offers the potential for indirect stem cell manipulation and could therefore be a very powerful therapeutic target. In addition, understanding of the critical component of the niche is necessary to design adequate supportive conditions for HSCs ex vivo. For these reasons, definition of the HSC niche has been the focus of intense research efforts since the beginning of the 21st century.

Hematopoietic stem cell microenvironments in the embryo and perinatal period

While in the adult HSCs are found primarily in bone, stem cells with the ability to generate all hematopoietic lineages initially arise in the hemogenic endothelium within the aorta−gonad−mesonephros (AGM) (Ivanovs et al., 2011; Muller et al., 1994; Medvinsky and Dzierzak, 1996; Medvinsky et al., 2011; de Bruijn et al., 2000) as a result of endothelial-to-hematopoietic cell transition (Jaffredo et al., 1998; Bertrand et al., 2010; Boisset et al., 2010; Kissa and Herbomel, 2010; de Bruijn et al., 2002). Additional studies have shown that HSCs may develop not only in the AGM but also in the placenta (Gekas et al., 2005; Ottersbach and Dzierzak, 2005; Rhodes et al., 2008). The role of the placenta as a supportive microenvironment for HSCs has also been demonstrated in humans (Robin et al., 2009). From the AGM and the placenta, HSCs migrate to the fetal liver (murine embryonic day 1, E11), where they are supported by portal vessels (Khan et al., 2016). In the liver, HSCs dramatically expand prior to seeding the bone marrow (Morrison et al., 1995; Bowie et al., 2007; Ema and Nakauchi, 2000). HSC activity is first detected in the bone marrow at E16.5 (Coskun et al., 2014). Contemporary analyses of skeletal and hematopoietic development have shown that, in the mouse, this transition to the bone marrow corresponds to fetal long bone vascularization and incipient osteogenesis (Coskun et al., 2014). Notably, at E16.5, in the long bones osteoblasts are primarily found at the bone collar/periosteum, suggesting that at this developmental stage marrow vascular or mesenchymal populations may drive HSC homing. However, mice with genetic deletion of the transcription factor Osterix ($Sp7^{-/-}$ mice), which lack osteoprogenitors and their progeny, while their marrow vasculature is intact, have bone marrow HSCs that cannot properly home and engraft (Coskun et al., 2014), highlighting the importance of the osteogenic niche in the perinatal time. HSCs continue to migrate to the bone marrow through the first postnatal week, at a time when liver portal vessels are remodeled (Khan et al., 2016), while osteoblastic cell populations are rapidly expanding (Coskun et al., 2014). Once in the bone marrow, during the first 3 weeks of life, HSCs proliferate extensively while bone and marrow grow (Bowie et al., 2006). Subsequently, HSCs become primarily quiescent (Wilson et al., 2008), although the degree of their contribution to daily hematopoiesis remains disputed (Sun et al., 2014; Sawai et al., 2016; Busch et al., 2015).

The adult bone marrow niche

The discovery of cell surface markers that could more easily enrich for and prospectively isolate cells with HSC function using few stains (Kiel et al., 2005; Oguro et al., 2013), combined with advances in tissue imaging, reviewed in Tjin et al. (2018), and the availability of genetic models that could target cellular subsets, reviewed in Kfoury and Scadden (2015), is revolutionizing our understanding of the bone marrow microenvironment. We next summarize bone marrow cell populations that have been shown to contribute to the regulation and support of HSCs.

Mesenchymal stromal/stem cell populations

The definition and identification of mesenchymal stem/stromal cells (MSCs) remain a disputed topic in the bone field; however, niche studies have highlighted specific subsets of these populations that are able to support and modulate HSCs (Mendez-Ferrer et al., 2010). These studies have been performed primarily in the mouse, while the definition of MSCs and their role as HSC niches in the human bone marrow remain poorly understood. By using genetic models in which a key supportive molecule, stromal cell-derived factor 1 (SDF1, also known as C-X-C motif chemokine 12, or CXCL12) or stem cell factor (SCF) (Greenbaum et al., 2013; Ding and Morrison, 2013; Zhou et al., 2017), is genetically deleted in different mesenchymal subsets, and then quantifying HSCs, a number of marrow MSC populations have been reported as participating in HSC support. HSC-supportive cells have also been described, based on their degree of CXCL12 expression, as CXCL12-abundant reticular (or CAR) cells (Sugiyama et al., 2006). A number of populations identified based on either genetic labeling or flow cytometric expression have been shown to support HSCs: nestin−green fluorescent protein (GFP)-positive cells (Mendez-Ferrer et al., 2010), leptin receptor-positive cells (Zhou et al., 2017), paired related homeobox 1 (Prx1)-targeted cells (Greenbaum et al., 2013), and cells identified by their expression of integrin αV (CD51), the platelet-derived growth factor receptor α (Pinho et al., 2013), or CD51 and the cell surface marker Sca1 (Morikawa et al., 2009). Notably, there is evidence that some cell populations, for example, nestin−GFP$^+$ cells, are still heterogeneous (Kunisaki et al., 2013) and that they do not represent multipotent MSCs, since they cannot differentiate to adipocytes (Zhou et al., 2014; Itkin et al., 2016). In addition, there is probably a hierarchy in the organization of these populations. For example, Prx1$^+$ MSCs are able to generate leptin receptor-positive and CAR cells (Zhou et al., 2014; Omatsu et al., 2010), and deletion of the leptin receptor in Prx1$^+$ cells expands osteolineage populations while inhibiting adipocytes (Yue et al., 2016).

More recent data have suggested that the location of supporting cell populations may also have an impact on their ability to functionally influence HSCs. Studies have shown that perivascular cell populations in fact express the highest level of CXCL12 (Ding and Morrison, 2013). Some studies show that nestin−GFP$^+$ cells are distributed along arterioles and sinusoidal structures within the bone marrow (Kunisaki et al., 2013), and at these different locations they provide differential support to HSCs (Asada et al., 2017). Nestin−GFP$^+$ cells at arteriole sites express the pericyte marker neural/glial antigen 2 (NG2), and appear to play a role in the maintenance of HSCs (Pinho et al., 2018). These findings have been debated, as another study has suggested that niches at sinusoidal sites provide a quiescent niche for HSCs (Acar et al., 2015). As we will discuss later, these discrepancies are probably due not only to different experimental models (Joseph et al., 2013), but also to heterogeneity of HSC populations.

Adipocytes

Marrow adipocytes are differentiated from MSC populations (Horowitz et al., 2017). They are rare populations in the juvenile marrow but increase during aging and especially in the setting of myeloablation and anorexia (Calvo et al., 1976; Abella et al., 2002). Studies have suggested that marrow adipocytes have different characteristics compared with adipocytes in other depots and may be heterogeneous (Scheller et al., 2015); however, the lack of a genetic approach to target marrow compared with other adipocyte depots has as of this writing represented a challenge to support these claims. The contribution of marrow adipocytes to the support of HSCs is an area of debate, as is their impact on bone (Doucette et al., 2015; Ambrosi et al., 2017). Initial studies using genetic murine models and pharmacologic tools suggested that adipocytic populations may inhibit HSCs (Naveiras et al., 2009). More recently, Ambrosi et al. presented data that correlate age- and diet-dependent increases in adipocytes with hematopoietic and skeletal stem cell dysfunction (Ambrosi et al., 2017), while Zhou et al. found that adipocytes secrete SCF and promote the regeneration of HSCs (Zhou et al., 2017). While some of these discrepancies have been attributed to differential effects in different bones (Zhou et al., 2017), these data may also tap into the reciprocal relationship of osteolineage and adipocytic cells, long shown in vitro (Ge et al., 2016), and also into the emerging concept that adipocytes may represent a local energy depot to support the

metabolically demanding daily hematopoiesis (Tabe et al., 2017). The ability to target specifically marrow adipocytes genetically will no doubt provide clarity to this important area of investigation, especially as it may modulate skeletal and hematopoietic regeneration, as well as contributing to a supportive microenvironment in the setting of leukemia (Tabe et al., 2017).

Osteoblastic cells

Since bone is the required site for hematopoiesis in adulthood, cells in the osteoblastic lineage were the first candidates as HSC-supportive niche cells. Initial in vitro studies demonstrated that cells of osteoblastic lineage, derived from mice or humans, could provide support to hematopoietic stem and progenitor cells (Taichman and Emerson, 1994; Taichman et al., 1996). Subsequently, data showed that genetic manipulation of osteoblastic populations could expand HSCs, providing the first evidence for the existence of a regulatory hematopoietic microenvironment (Calvi et al., 2003; Zhang et al., 2003). Additional experiments in which osteoblastic populations were ablated in adulthood also demonstrated loss of hematopoietic populations (Visnjic et al., 2004), although lymphocytes were lost prior to HSCs. Moreover, studies using bone marrow samples from patients showed that HSCs are found proximal to endosteal surfaces (Guezguez et al., 2013). In addition, direct imaging of the niche in the calvarial space demonstrated homing of HSCs preferentially to the endosteum (Lo Celso et al., 2009; Xie et al., 2009), even in the absence of myeloablative conditioning (Ellis et al., 2011), with hierarchical organization placing HSCs proximal to the endosteum compared with progenitor cells (Lo Celso et al., 2009). In a genetic model, depletion of osteocalcin-expressing osteolineage cells inhibits mobilization of HSCs (Asada et al., 2013; Ferraro et al., 2011). Finally, when *Sp7*, the gene encoding the transcription factor Osterix, is conditionally deleted, with resulting loss of osteoblastic differentiation, hematopoiesis is almost completely eliminated from the metaphyseal region (Zhou et al., 2010). However, the importance of osteoblastic populations in support of HSCs has been questioned by studies showing that, while the majority of hematopoietic cells reside in the metaphyseal regions, enriched with trabecular bone (Nombela-Arrieta et al., 2013; Guezguez et al., 2013), only a small subset of HSCs are found in direct proximity to osteoblasts (Lo Celso et al., 2009; Kiel et al., 2005, 2009; Sugiyama et al., 2006; Acar et al., 2015), pointing instead to perivascular sites as more frequent niches for HSCs. Later studies clearly demonstrated the close proximity of important endothelial structures to the endosteum, and their interaction with osteoblastic cells, suggesting that these populations collaborate in the support and regulation of HSCs (Kusumbe et al., 2014, 2016; Ramasamy et al., 2014; Xu et al., 2018). Skepticism regarding the role of osteolineage cells in HSC regulation was also supported by studies targeting deletions of two key pro-HSC signals, the chemokine CXCL2 (also known as SDF1) and the growth factor SCF, which demonstrated regulation of HSC numbers and function when removed from mesenchymal stem and progenitor cells but not from osteoblastic populations (Ding and Morrison, 2013; Greenbaum et al., 2013). However, these models reflect primarily the impact of these two factors on HSC numbers and function, and therefore limit the scope of the evaluation of the niche.

Numerous studies provide interesting evidence that osteoblastic cell populations support specifically the common lymphoid progenitor and/or the lymphoid lineage within the bone marrow (Zhu et al., 2007; Ding and Morrison, 2013; Wu et al., 2008), supporting the concept that there may be multiple niches within the bone marrow to support not just HSCs, but also other progenitor populations that are more specialized. For example, data have shown that thymus-seeding progenitors are supported by the Notch ligand Delta-like 4, produced by osteocalcin-expressing osteoblastic cells (Yu et al., 2015).

Within the osteoblastic lineage, there is also evidence that differentiation stage may contribute differentially to HSC support. Data from in vitro studies in which the differentiation stage of osteoblastic populations was controlled showed decreasing support of HSCs with osteoblastic maturation (Cheng et al., 2011; Nakamura et al., 2010). These findings are also supported by proximity-based isolation of endosteal osteoblastic populations found close to HSCs in vivo (Silberstein et al., 2016). Data have shown that genetic disruption of osteoprogenitor cells initiates bone marrow failure and pre-leukemia, while the same defect targeted to osteocalcin-positive populations does not (Raaijmakers et al., 2010). Moreover, while targeting of a constitutively active parathyroid hormone (PTH) receptor to osteoblastic cells expanded HSCs (Calvi et al., 2003), targeting the same construct to osteocytes did not (Calvi et al., 2012), despite similar degrees of osteoblastic expansion. A key PTH-regulated molecule that is produced by osteocytes is sclerostin, the protein encoded by the *Sost* gene, which is known to be downregulated by PTH. Notably, consistent with the data from mice with targeting of the PTH receptor to osteocytes, $Sost^{-/-}$ mice also demonstrate the bone anabolic effect of PTH but not the expansion in HSCs (Cain et al., 2012). Therefore, expansion of osteoblasts alone is not sufficient to expand HSCs, as also shown by treatment with strontium (Lymperi et al., 2008), and osteocyte activation alone does not increase HSCs. However, when osteocytes were depleted in adult mice, lymphopoiesis was disrupted, and mobilization of HSCs induced by granulocyte

colony−stimulating factor (G-CSF) was inhibited (Asada et al., 2013). These data suggest that these populations of terminally differentiated osteoblasts that are embedded in matrix contribute to some aspects of HSC regulation. Interestingly, targeted deletion of $G_s\alpha$ in osteocytes induces a myeloproliferative disorder and splenomegaly through the microenvironment, in a G-CSF-dependent manner (Fulzele et al., 2013). Together these data suggest that cells in the osteoblastic lineage contribute to hematopoietic regulation in a differentiation-dependent manner. One limitation of these data is the unexpected targeting of CAR cells by the DMP-1 promoter (Zhang and Link, 2016). Further data are required to define mechanistically the contributions of these osteolineage populations to the regulation of HSCs and their progeny.

While the importance of osteoblastic cells in normal HSCs remains a hotly debated issue, the role of osteoblastic cells in hematologic malignancies is supported by extensive experimental data. In a murine model of myeloproliferative neoplasia there was an expansion of osteolineage populations that were, however, defective in their ability to support normal HSCs, enhancing clonal hematopoietic populations (Schepers et al., 2013). Numerous models of leukemia have shown its ability to disrupt osteoblastic populations, for example, in a model of blast crisis acute myeloid leukemia (Frisch et al., 2012) and in the MML-AF9 model of acute myeloid leukemia (Silva et al., 2010; Duarte et al., 2018). Loss of osteoblasts accelerated leukemia progression (Silva et al., 2011), and osteoblasts could inhibit leukemia cell engraftment and disease progression (Krevvata et al., 2014). In some cases, activation of the normal niche was able to decrease transformation of preleukemic clones to leukemia (Krause et al., 2013), pointing to the potentially protective role of normal niches.

Osteoblastic cells are also important for the ability of HSCs to recover from radiation injury (Dominici et al., 2009). In this setting, rapid expansion of endosteal osteoblasts required insulin-like growth factor 1 (IGF1) (Caselli et al., 2013). In elegant studies using proximity-based single-cell profiling in the setting of radiation conditioning, Silberstein et al. were able to define characteristics of endosteal osteoblastic populations proximal to HSCs, and identified secreted signals that regulate HSCs, including the secreted RNase angiogenin, interleukin 18, and the adhesion molecule Embigin (Silberstein et al., 2016). Interestingly, these studies were performed in neonatal calvaria, to avoid decalcification, and therefore whether these cell populations contribute to the support and regulation of adult HSCs remains untested. However, the novel signals identified by this approach were found to be important for hematopoietic stem and progenitor cell regulation, strongly implicating osteolineage populations in hematopoietic recovery after myeloablation (Silberstein et al., 2016). Notably, in the case of angiogenin, the same signal had differential effects on stem cell populations and progenitors, indicating a role for osteolineage populations in a coordinated response of the hematopoietic system to acute injury, in which angiogenin maintains HSC quiescence while enhancing progenitor cell proliferation (Goncalves et al., 2016).

Lessons learned from the dissection of mesenchymal osteoblastic components and their matrix were instrumental in attempts at recapitulating a supportive HSC niche ex vivo, as was shown in initial studies describing a biomimetic microenvironment using human cell populations (Bourgine et al., 2018).

Endothelial cells

Initial studies identifying HSCs as lineage$^-$, CD150$^+$, CD48$^-$, and CD41$^-$ cells showed that 60% of these cells were found in proximity to sinusoidal endothelial structures in the adult marrow at homeostasis (Kiel et al., 2005, 2007), suggesting that endothelial cells may contribute to HSC regulation. However, deletion of *CXCL12*, *Jagged1,* or *SCF* in endothelial populations did not have an impact on HSC maintenance although deletion of *Jagged1* in endothelial cells may impact HSF self-renewal (Ding et al., 2012; Greenbaum et al., 2013; Poulos et al., 2013; Ding and Morrison, 2013). However, the endothelium is clearly critical for recovery of HSCs after myeloablation (Hooper et al., 2009; Kobayashi et al., 2010; Butler et al., 2010; Winkler et al., 2012). Just as in the mesenchymal osteoblastic lineage, the heterogeneity of marrow endothelial structures is emerging (Kusumbe et al., 2014; Ramasamy et al., 2014). Vascular heterogeneity clearly imparts differential effects on hematopoiesis (Itkin et al., 2016), to some extent as a result of differential permeability of sinusoids compared with arteriolar structures. Moreover, coupling of vascular with mesenchymal osteolineage populations is being uncovered (Xu et al., 2018; Kusumbe et al., 2016). These data strongly suggest that different niche components are interdependent in their regulation of HSCs.

Hematopoietic cells

The progeny of HSCs are also recognized for their ability to regulate HSCs. In particular, megakaryocytes, marrow macrophages, senescent neutrophils, osteoclasts, and regulatory T cells have been demonstrated to regulate HSCs, either directly or through their ability to modulate the behavior of other niche cells.

Megakaryocytes

Megakaryocytes are the hematologic progenitors that give rise to platelets in the bone marrow when associated with endothelial structures. Several groups have shown that megakaryocytes are direct regulators of HSC quiescence. In the bone marrow, HSCs are often found in close proximity to megakaryocytes (Bruns et al., 2014). Moreover, signals derived from megakaryocytes, including the chemokine CXCL4 (also known as platelet factor 4), Thrombopoietin, and transforming growth factor β1 (TGFβ1), have been shown to mediate the quiescence of HSCs, at least at homeostasis (Bruns et al., 2014; Nakamura-Ishizu et al., 2014, 2015; Zhao et al., 2014). Megakaryocytes also promote murine osteoblastic expansion after radioablation (Olson et al., 2013), and provide a supportive niche preferentially for platelet- and myeloid-biased HSCs (Pinho et al., 2018). The study shows that cells contributing to HSC support can also have an impact on their fate, since deletion of megakaryocytes could induce myeloid- and platelet-biased HSCs to give balanced lineage contribution upon transplantation.

Macrophages

Macrophages are key regulators of both innate and adaptive immunity, and are critical for tissue homeostasis through their capacity to engulf debris, pathogens, and apoptotic cells. Macrophages are highly heterogeneous within different tissues and are derived both from the yolk sac and from the differentiation of monocytes derived from bone marrow (Heideveld and van den Akker, 2017). In the bone marrow, specialized macrophage activities include the engulfment of senescent neutrophils (Casanova-Acebes et al., 2013) and erythropoiesis through their contribution to erythroblastic islands (Bessis, 1958; Chow et al., 2013). Supporting a role for macrophages in the bone marrow niche, HSC dormancy is regulated through the interaction of CD234/Duffy antigen receptor for chemokines expressed on macrophages with CD82/KAI1 expressed on HSCs (Hur et al., 2016). Several lines of evidence demonstrate that marrow macrophages play an important role in trafficking of HSCs to and from the bone marrow. Macrophages regulate the retention of hematopoietic stem and progenitor cells in the bone marrow (Chow et al., 2011; Winkler et al., 2010), and specifically the release of HSCs from the niche, also known as mobilization, induced by G-CSF (Christopher et al., 2011). Interestingly, some of these actions appear to be through their ability to modulate mesenchymal and osteoblastic cell populations. For example, a subset of $CD169^+$ macrophages was found to maintain HSCs in the marrow by regulating MSC production of CXCL12 (Chow et al., 2011). In addition, a population of marrow macrophages marked by smooth muscle actin expresses cyclooxygenase 2 and produces prostaglandin E2 (Ludin et al., 2012). This macrophage population supports HSCs and is expanded by radiation (Ludin et al., 2012) and, on a daily basis, by circadian bursts of darkness-induced norepinephrine that induces melatonin through tumor necrosis factor (Golan et al., 2018). More recently, studies have begun to show that macrophages are also important for homing and engraftment of HSCs. For example, in the zebrafish caudal hematopoietic tissue (equivalent to the mammalian fetal liver), vascular cell adhesion molecule-positive macrophages were found to patrol the venous plexus, interact with HSCs through integrin α4, and regulate HSC retention (Li et al., 2018). In the mammalian bone marrow, a population of $CD169^+$ macrophages located within perivascular and endosteal regions was resistant to conditioning radiation and was found to promote long-term engraftment of HSCs (Kaur et al., 2018). A subset of marrow macrophages found in close proximity to the endosteum, also known as osteomacs, has been shown to regulate osteoblastic function (Chang et al., 2008) and also contribute to support of HSCs through their synergy with osteoblasts and megakaryocytes (Mohamad et al., 2017). Finally, a recent study demonstrated that marrow macrophages from aged mice become defective, with increased inflammatory signals and decreased phagocytic capacity, and that they determine HSC megakaryocytic skewing likely through Interleukin 1 β (Frisch et al 2019 JCI Insight. 2019 Apr 18;5. pii: 124213. doi: 10.1172/jci.insight.124213.PMID: 30998506).

Neutrophils

Neutrophils are hematopoietic cells characterized by segmented nuclei and the presence of granules critical for innate immunity. Neutrophils are very short lived and highly mobile, and represent the "first responder" population in immune and injury responses (Nathan, 2006). They are produced in the bone marrow, where they are preferentially found in close proximity to CAR cells rather than endothelial cells (Evrard et al., 2018). Mature and immature neutrophils exit the bone marrow to the circulation and tissues and senesce rapidly (Evrard et al., 2018). Following a circadian rhythm, a large number of senescent neutrophils expressing the CXCL12 receptor CXCR4 home daily to the bone marrow (Casanova-Acebes et al., 2013). In the bone marrow, senescent neutrophils are phagocytosed by macrophages and indirectly modulate microenvironmental CXCL12 levels (Casanova-Acebes et al., 2013), influencing signals that not only guide senescent neutrophils but also support HSCs.

T cells

High-resolution imaging of the HSC niche after transplantation showed colocalization of hematopoietic stem and progenitor cells with regulatory FoxP3 T cells (T regs) at the endosteum, and demonstrated that depletion of T regs resulted in the loss of HSCs (Fujisaki et al., 2011). These data support the hypothesis that T regs are necessary for the maintenance of allogeneic HSCs after transplantation. Follow-up studies identified a subset of CD150high T regs in the niche that maintain HSC quiescence (Hirata et al., 2018). Transcriptional analysis of these cells found increases in CD39 and CD73, cell surface ectoenzymes that generate extracellular adenosine (Hirata et al., 2018). The authors went on to demonstrate that adenosine is required to mediate the beneficial effects of CD150high T regs, and that adaptive transfer of these cells improves allogeneic engraftment of HSCs (Hirata et al., 2018). In addition to demonstrating the participation of T regs in the regulation of adult HSCs, these data provide strong evidence that definition and targeting of the niche can have a significant impact under clinically relevant conditions.

Osteoclasts

Osteoclasts, key specialized cells that resorb bone, are hematopoietically derived and play a crucial role in the maintenance of skeletal homeostasis. Osteoclasts, as key cells that resorb bone, are necessary for the formation of the bone marrow cavity in the embryo (Mansour et al., 2012). In addition, the ability of osteoclasts to resorb bone may also regulate HSCs through the release of matrix components and minerals. Data using HSCs from mice that lack the calcium sensor have suggested that HSCs preferentially home to regions of high calcium in the marrow (Adams et al., 2006). Similarly, TGFβ is a known matrix factor that can be released by osteoclastic bone resorption that also has been shown to induce quiescence in stem cell populations (Yamazaki et al., 2009).

Neuronal regulation of the hematopoietic stem cell niche

With improvements in the ability to prospectively isolate HSCs, experimentalists observed that the frequency of marrow HSCs is regulated by a circadian rhythm. Studies had uncovered how neuronal innervation of the marrow by the sympathetic nervous system (SNS) plays a role in mobilization of HSCs (Katayama et al., 2006). The same laboratory later discovered that the SNS is responsible for this circadian mobilization of HSCs through β-adrenergic signals (Mendez-Ferrer et al., 2008). Unexpectedly, β-adrenergic receptor agonists induced expression of the vitamin D receptor (VDR) in osteoblasts, and mice lacking the VDR had impairment in G-CSF-mediated osteoblastic inhibition and mobilization of HSCs, suggesting that the VDR is a modulator of HSC trafficking (Kawamori et al., 2010). Neuronal regulation of the hematopoietic stem cell niche is modulated by aging (Maryanovich et al., 2018), chemotherapy (Hanoun et al., 2014), and myeloproliferative syndromes (Arranz et al., 2014), although the mechanisms by which these conditions alter the SNS remain poorly understood. In addition to these direct effects, nonmyelinating marrow Schwann cells have been shown to induce HSC quiescence through their production of TGFβ (Yamazaki et al., 2011). Therefore, neuronal signals are clearly an important target for the manipulation of niches and the HSCs they support.

Hormonal regulation of the hematopoietic stem cell niche

The impact of hormones on the niche indicates that the niche is a dynamic system that is physiologically regulated and therefore represents a homeostatic mechanism to regulate and maintain HSCs. It is likely that these are simply examples of many systemic signals that can regulate HSCs through their niche.

Parathyroid hormone

Studies have demonstrated how constitutive activation of the PTH receptor 1 in osteolineage cells could expand HSCs, and how pharmacologic treatment with anabolic doses of PTH expands HSCs (Calvi et al., 2003; Bromberg et al., 2012; Adams et al., 2007; Itkin et al., 2012). Taking advantage of the use of teriparatide (recombinant PTH1-34) for the treatment of osteoporosis, Yu et al. collected blood from patients with osteoporosis undergoing treatment with teriparatide and quantified circulating HSCs (Yu et al., 2014). This study showed an increase in circulating HSCs in patients receiving anabolic treatment, a first demonstration of the impact of PTH on HSC regulation in humans. Since the bone marrow was

not tested in this patient population, it is not known whether the increase in circulating HSCs was due to increases in their marrow populations or to mobilization to the periphery. Notably, the physiologic role of PTH or PTH-related protein acting through PTH receptor 1 in the niche is poorly understood.

Insulin-like growth factor 1

IGF1 is produced in the liver and by osteoblasts, and its increase in osteoblastic cells after radiation injury appears to have a beneficial impact on the recovery of the hematopoietic systems (Caselli et al., 2013). Since expression of IGF1 is increased with PTH treatment, it is possible that some of the PTH effects on the niche may be mediated by IGF1.

Niche heterogeneity for heterogeneous hematopoietic stem and progenitor cells

From the studies presented thus far, it is clear that, rather than a single niche cell population, the bone marrow microenvironment is heterogeneous and dynamic (Fig. 3.1). Developments in the understanding of hematopoietic stem and progenitor cells now suggest that rather than omnipotent undifferentiated stem cells, there may be functional heterogeneity of HSCs as well. Single-cell transplantation studies have shown that individual HSCs are biased toward myeloid or lymphoid differentiation (Dykstra et al., 2007; Muller-Sieburg et al., 2002; Wilson et al., 2015). This heterogeneity changes with development and with aging (Benz et al., 2012), and appears to be epigenetically imposed (Yu et al., 2017). Evidence of megakaryocytic-biased HSCs has also been shown by numerous laboratories (Sanjuan-Pla et al., 2013; Gekas and Graf, 2013; Shin et al., 2014). This heterogeneity may explain the conflicting data regarding localization of hematopoietic stem and progenitor cells in association with endosteal, periarteriolar, or perisinusoidal sites, or in association with megakaryocytes (as discussed earlier). Initial data to support this contention were provided by the Frenette laboratory, showing that lineage-biased HSCs are regulated by distinct niches, with platelet- and myeloid-biased HSCs

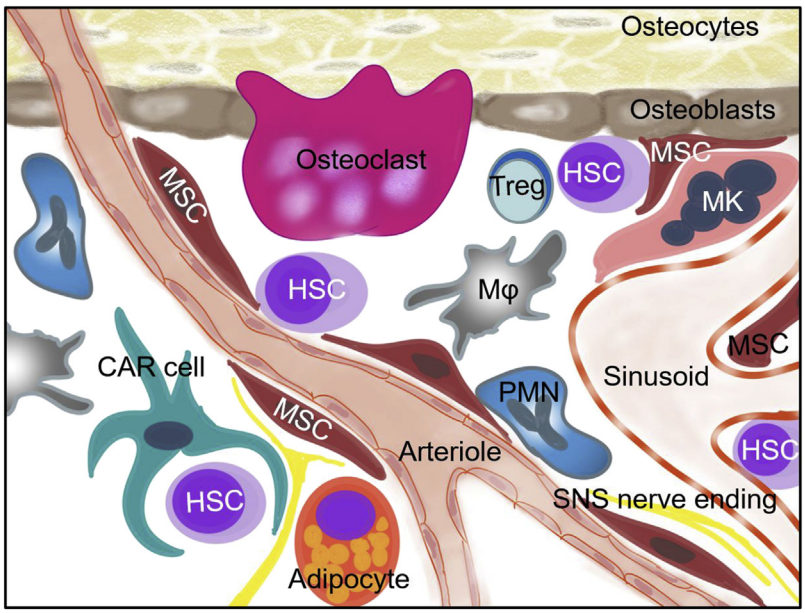

FIGURE 3.1 Heterogeneity of the hematopoietic stem cell niche in the bone marrow. Hematopoietic stem cells (HSCs) are found in close anatomic proximity to multiple regulatory populations in the bone marrow. A diagrammatic representation of the interactions of mesenchymal stroma cells (MSCs), HSCs, and other components of the bone marrow microenvironment is shown. Mesenchymal populations identified as HSC-regulating niche cells through genetic studies include subsets of MSCs (shown in *brown*), found in endosteal and more commonly perivascular locations, with CXCL12-abundant reticular (CAR) cells and leptin receptor-positive cells found primarily in perisinusoidal locations, while nestin−GFP^{+} cells are found primarily in periarteriolar sites. Multiple hematopoietic cells, including macrophages (Mφs), neutrophils (PMNs), megakaryocytes (MKs), osteoclasts, and regulatory T cells (T regs) contribute to HSC regulation. Sympathetic nervous system innervation modulates the circadian mobilization of HSCs in the circulation through its action on the niche.

found in association with and regulated with megakaryocytes, while $NG2^+$ arteriolar niche cells selectively regulate lymphoid-biased HSCs (Pinho et al., 2018).

Conclusions

As the data reviewed here show, our understanding of the HSC and progenitor microenvironment has evolved as our tool kit for their analysis has expanded, and it is likely to continue to increase as our ability to identify rare hematopoietic and mesenchymal populations in both murine models and humans improves. Progress in the definition of the HSC niche has already provided targets that may accelerate hematopoietic recovery and positively influence skeletal disease, especially if there are reciprocal interactions between skeletal stem cells and HSCs and/or their progenies. Moreover, given the potential for microenvironmental contribution to the support of either normal or malignant hematopoiesis, signals regulating interactions between bone microenvironmental populations and cancer cells could provide novel targets for the treatment of metastatic malignancy or primary malignancies in the bone and bone marrow.

Acknowledgments

The author wishes to thank the members of the Calvi, Becker, and Liesveld laboratories for helpful suggestions. This work was supported in part by the National Institutes of Health, National Cancer Institute, and National Institute on Aging awards CA166280 and AG046293; the University of Rochester Core Center for Musculoskeletal Biology and Medicine award AR061307 from the National Institute of Arthritis and Musculoskeletal and Skin Diseases; the Department of Defense (Award W81XWH1810485 to LMC) and the University of Rochester CTSA award UL1 TR002001 from the National Center for Advancing Translational Sciences.

Chapter 4

The osteoblast lineage: its actions and communication mechanisms

Chapter outline

Introduction

The skeleton is a metabolically active organ in which the organizational pattern of its mineral and organic components determines its successful mechanical function. This is achieved by a combination of dense, compact (cortical) bone and cancellous (trabecular) bone, reinforced at points of stress (Chapter 11). Bone itself is a heterogeneous compound material. The mineral phase of bone, in the form of modified hydroxyapatite crystals, contributes about two-thirds of its weight. The remaining organic matrix consists largely of type I collagen (~90%), with small amounts of lipid (~2%), noncollagenous proteins (~5%), and water. Noncollagenous proteins within the bone matrix include signaling molecules (such as transforming growth factor β and insulin-like growth factor I) and regulators of mineralization (such as osteocalcin and dentin matrix protein 1 [DMP1]).

The word "osteoblast" has been used traditionally to describe those cells in bone responsible for bone collagen matrix production. However, we now know there are multiple stages within the osteoblast lineage, and they perform a much wider range of functions; in fact, these cell types within the lineage, when fully delineated, will merit naming in ways to reflect those functions. In addition to regulating mineralization and osteoclastogenesis directly, the lineage also produces paracrine and autocrine factors (cytokines, growth factors, prostanoids, proteinases), thereby forming communication systems profoundly influencing not only bone formation, but also bone resorption and hematopoiesis (see Chapter 3). To this is added the discoveries revealing bone as an endocrine organ, with cells of the osteoblast lineage being sources of circulating hormones such as fibroblast growth factor 23 (FGF23) and osteocalcin. These two hormones will be discussed in detail in Chapters 64 and 25, respectively.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00004-X

Our approach in this chapter is to recognize the mixture of cells comprising the osteoblast lineage. We will consider their range of functions influencing bone structure and strength, without confining the discussion to only those particular cells in the lineage traditionally called osteoblasts because of their ability to produce the bone matrix.

The stages of the osteoblast lineage

The osteoblast lineage consists of a number of stages of differentiation through the mesenchymal lineage. These functions are identifiable by the morphology and location of the cells as well as their gene expression and synthetic capabilities (Fig. 4.1). We will describe each stage of the lineage in turn: mesenchymal precursors, committed preosteoblasts, mature matrix-producing osteoblasts, osteocytes, and bone-lining cells.

Mesenchymal precursors

A detailed discussion of the stem cells of bone will be provided in Chapter 2, but some matters most directly relevant to osteoblasts will be discussed briefly here.

Osteoblasts are derived from stromal mesenchymal cells present in the bone marrow. In vitro, these multipotent precursors are capable of differentiating into osteoblasts, chondrocytes, adipocytes, or myocytes (reviewed in Bianco et al., 2008; Bianco et al., 2010). In vivo their location in the marrow is required for their ability to differentiate into osteoblasts (Sacchetti et al., 2016). Our understanding of these pathways owes much to the work of Alexander Friedenstein and Maureen Owen (Friedenstein, 1976). Their seminal work identified the existence of osteogenic stem cells within the bone marrow stroma. This was achieved when intraperitoneal transplantation of diffusion chambers containing bone marrow cells in rabbits gave rise to a mixture of tissues, including bone and cartilage (Friedenstein, 1976). This diversity of differentiation led Bianco et al. (Bianco et al., 2008) to propose renaming their "osteogenic stem cells" to "skeletal stem cells" (SSCs). The ability of these cells to form bone depended on their location in the marrow: those bone marrow cells taken from close to the endocortical surface of the femora were more osteogenic than cells taken from the central marrow or the intermediate region (Ashton et al., 1984; Bab et al., 1984). Furthermore, when marrow cell distribution was correlated with the colony-forming efficiency of the cells in vitro, stromal fibroblasts from the endocortical surface formed four times as many colonies as the same number of core cells. These observations served to establish Friedenstein's concept of the CFU-F (colony-forming unit—fibroblastic), which he proposed was a self-renewing multipotential stem cell population. An elegant extension of this involved establishing single stromal cell colonies, transplanted under the renal capsule of mice, where they formed plaques containing bone, with the host cells establishing hemopoiesis and excavating a marrow cavity (reviewed in Owen and Friedenstein, 1988). This experiment also provided the first evidence that stromal or osteoblast lineage cells could promote osteoclast recruitment from circulating precursors. Direct evidence for stromal or osteoblast lineage regulation of osteoclast formation was obtained some years later by coculture of osteoblast lineage cells with hemopoietic cells (Takahashi et al., 1988; Udagawa et al., 1989), and is reviewed in Chapter 5.

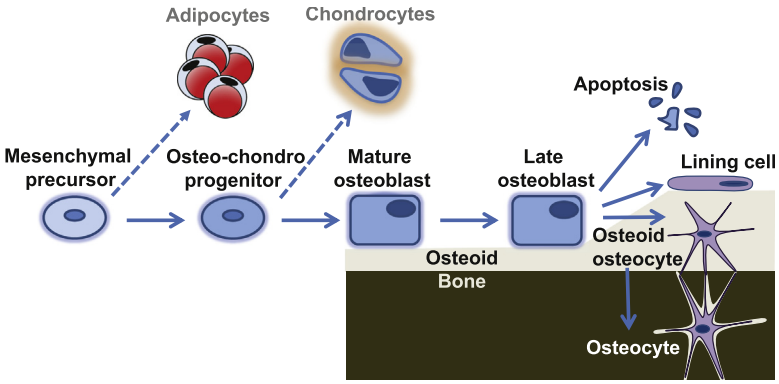

FIGURE 4.1 Stages of differentiation of the osteoblast lineage. Multipotent, replicating mesenchymal precursors, capable also of adipocyte differentiation, become more committed to be replicating osteo-chondro progenitors (osteoblast progenitors). These cells are capable of either chondrocytic or osteoblastic differentiation. When they reach the mature osteoblast stage, they reside on the bone surface above a layer of newly produced collagen-containing osteoid, and continue to differentiate. When they have completed the process of osteoid production, osteoblasts undergo one of three possible fates: (1) cell death through apoptosis; (2) remaining on the bone surface as flattened bone-lining cells, not actively producing osteoid; or (3) becoming embedded in the osteoid as "osteoid osteocytes," gradually becoming encased in mineralized bone, forming a network throughout the bone matrix, and remaining there as osteocytes.

These and subsequent studies using rigorous differentiation assays and CFU-F cells to show multipotency identified an SSC subset capable of forming skeletal tissue within bone marrow stroma. SSCs are rare in the marrow stromal cell population and need to be defined by rigorous clonal and differentiation assays. As an alternative some laboratories turned to the nonhemopoietic adherent cells of the bone marrow, which became known commonly as "mesenchymal stem cells" (MSCs). MSCs could be isolated from many tissues (da Silva Meirelles et al., 2006) and have been claimed to also be capable of forming osteoblasts in vitro. However, such studies have to be viewed with some reservation. The commonly used "osteogenesis assay," often used to confirm osteoblast differentiation, assesses mineral deposition by cells cultured in ascorbic acid and β-glycerophosphate. However, mineral stains rarely distinguish between collagen-containing nodule formation and diffuse mineral deposited by dead or dying cells (Orriss et al., 2014). It should be noted that any cell rich in alkaline phosphatase, including non−osteoblast lineage cells, like chondrocytes, can generate phosphorus by cleaving β-glycerophosphate, resulting in calcium phosphate precipitates, without expressing osteoblast marker genes or producing collagen-rich matrix. The International Society of Cell and Gene Therapy now recommends the term "mesenchymal stromal cells," which reflects only their in vitro properties, without clonal analyses or in vivo studies (Dominici et al., 2006). These caveats were summarized succinctly in a 2017 review (Robey, 2017).

A critical question remains as to whether other stromal cells derived from other sources can generate bone organoids (ossicles) supporting hemopoiesis in vivo. A comparison of stromal cells from bone marrow, white adipose tissue, umbilical cord, and skin led to the conclusion that only bone marrow−derived MSCs have this property (Reinisch et al., 2015). However, a different conclusion was reached when cord blood-borne fibroblasts (CB-BFs) were isolated. These CB-BFs, a rare population of cells, could generate complete ossicles in vivo with a functional hematopoietic stem cell niche, and did so through an endochondral bone formation program (Pievani et al., 2017). This outcome required as a starting point the CB-BF population rather than unselected MSCs from cord blood.

Further advances in understanding the osteoblast progenitor have come through cell lineage tracing methods. These studies localized osteoblast progenitors to vascular structures in the marrow, and suggested the same precursors may also give rise to cells forming the blood vessel and pluripotent perivascular cells (Doherty et al., 1998; Modder and Khosla, 2008; Otsuru et al., 2008). Support for this comes from mice with the smooth muscle α-actin (SMAA) promoter used to direct green fluorescent protein (GFP) to smooth muscle and pericytes; strong osteogenic differentiation was evident in cells positive for SMAA−GFP (Kalajzic et al., 2008). This indicates the capacity of SMAA to mark an osteoblast progenitor population, and reinforced earlier studies proposing the pericyte as an osteoblast progenitor during bone remodeling (Brighton et al., 1992; Doherty et al., 1998). It should be noted that pericytes appear to behave in an organ-specific manner, dictated by their anatomy and position (Bianco et al., 2008). For example, pericytes isolated from muscle generate myocytes in vitro (Dellavalle et al., 2007). Notably, only marrow-residing pericytes appear capable of becoming osteoblasts under normal conditions (Sacchetti et al., 2016). In pathological conditions, there are clearly osteoblast precursor populations resident in other tissues capable of forming bone, including the heterotopic ossifications observed after spinal cord injury (Genet et al., 2015). The generation of osteoblasts from bone marrow−specific pericytes illustrates the importance of the microenvironment in determining differentiation, probably by the generation and influence of local factors. Lineage tracing studies also suggest that bone-lining cells can form a population of osteoblast precursors (see "Bone-lining cells") (Matic et al., 2016).

Commitment of osteoblast progenitors (preosteoblasts)

For many years the "osteoblast phenotype" was studied in rodent cell culture systems, including stable and transformed cell lines, osteogenic sarcoma cell lines, and organ cultures. The limited characterization possible when cells were first grown from rodent bone fragments (Peck et al., 1964) was extended when methods were established to culture cells obtained from newborn rodent calvariae by enzymatic digestion (Luben et al., 1976). At the same time, cells were cultured from osteogenic sarcomata; these, and the clonal cell lines derived from them, were enriched in a number of osteoblastic properties (Majeska et al., 1980; Partridge et al., 1983). The concepts of the osteoblast phenotype developed in these rodent culture systems were extrapolated to adult bone in vivo. Limitations were not always realized, in particular the heterogeneity of primary rodent cultures and the identity of osteosarcoma cells, not as true osteoblasts, but as tumor cells enriched in some osteoblastic features. Nevertheless, these systems have provided useful foundational knowledge, particularly in studying osteoblast lineage intracellular signaling responses to hormones, growth factors, and cytokines (Crawford et al., 1978; Partridge et al. 1981, 1982; Livesey et al., 1982).

Stromal lineage commitment depends on the expression of key transcription factors that, on induction, initiate a cascade of events culminating in differentiation. These are discussed in depth in Chapter 7. Among the transcription factors regulated, osteoblast differentiation requires expression of Runx2 (Komori et al., 1997; Otto et al., 1997) and Osterix

(Nakashima et al., 2002) to commit progenitors to preosteoblasts. Other transcription factors, including ATF4 (Yang et al., 2004), AP-1 (Sabatakos et al., 2000), C/EBPβ, and C/EBPδ (Gutierrez et al., 2002), promote their transition to functional osteoblasts. Alternatively, commitment toward adipocytic differentiation requires expression of other transcription factors, including peroxisome proliferator-activated receptor (PPARγ) (Barak et al., 1999) and C/EBPα (Tanaka et al., 1997).

Because osteoblasts and adipocytes are derived from common progenitors, lineage commitment of precursor cells to osteoblasts results in a proportional decrease in adipogenesis. This inverse relationship is observed in cell culture (Walker et al., 2010; Poulton et al., 2012), and has been described in genetically altered mouse models, both where high osteoblast activity is associated with low marrow adipocyte volume (Sabatakos et al., 2000) and where low osteoblast numbers are associated with high marrow adipocyte volume (Sims et al., 2000; Walker et al., 2010; Poulton et al., 2012). Such reciprocal regulation is also observed clinically: high marrow adiposity is associated with age-related osteoporosis (Justesen et al., 2001) and observed in preclinical models of induced bone loss, such as ovariectomy (Martin et al., 1990) and immobilization (Ahdjoudj et al., 2002). Understanding the relationship between osteoblasts and adipocytes and how its dysregulation contributes to bone loss will provide key information required to improve treatments for skeletal disorders in adult bone metabolism.

The effects of pharmacological parathyroid hormone (PTH) provide another example of the reciprocal regulation of osteoblast/adipocyte commitment. Intermittent administration of amino-terminal preparations of PTH increases bone mass in part by promoting the differentiation of committed osteoblast precursors (Dobnig and Turner, 1995), decreasing osteoblast apoptosis (Manolagas, 2000), and suppressing production of sclerostin by osteocytes (Keller and Kneissel, 2005). Intermittent PTH treatment is also associated with reduced marrow adipocyte numbers in vivo (Sato et al., 2004). Similar observations of reduced osteoprogenitor recruitment and increased marrow adiposity have been noted in mice haploinsufficient for PTH-related protein (PTHrP) (Amizuka et al., 1996; Miao et al., 2005), and increased formation of adipocytes has been noted after cessation of PTH treatment in mice (Balani and Kronenberg, 2018). What is particularly interesting is recent evidence obtained through lineage tracing in mice indicating direct actions of PTH(1−34) through the PTH receptor (PTHR1) on very early osteoblast precursors, favoring osteoblast commitment at the expense of adipocytes (Balani et al., 2017); this is surprising because earlier studies of receptor activation in vitro indicated that responsiveness to PTH required more mature osteoblasts (Allan et al., 2008). The new data suggest that PTHR1 responsiveness is active earlier in the osteoblast lineage. This is consistent with very early work showing suppression of preadipocyte differentiation in vitro by PTHrP (Chan et al., 2001). In support of this, mice with PTHR1 deletion targeted to the osteoblast lineage, including early precursors (using Prx1-Cre), exhibited low bone formation and high marrow fat (Fan et al., 2017). This was associated with altered expression of ZFP467, a transcriptional cofactor, previously described to enhance adipocyte and blunt osteoblast differentiation, which is downregulated in osteoblast lineage cells by PTH or interleukin-6 (IL-6) family cytokine treatment (Quach et al., 2011). Transfection of ZFP467 into mouse calvarial cells substantially increased their transformation into adipocytes when transplanted into marrow (Quach et al., 2011).

A further link between the osteoblast and adipocyte lineages is provided by the finding that knockout of the leptin receptor (LepR) from limb bone marrow stromal cells by crossing *Prrx1.Cre* and *LepR*$^{fl/fl}$ mice revealed that the LepR also mediates local actions on very early SSC precursors to promote adipogenesis and inhibit bone formation (Yue et al., 2016). Such a role for the LepR is opposite to that described above for PTHR1 (Balani et al., 2017; Fan et al., 2017); whether there is any physiological connection between the two is not known.

Osteoblasts and chondrocytes are also derived from a common precursor (sometimes termed an "osteo-chondro progenitor"), and while this does not need to be considered in adult bone remodeling, the commitment of precursors to either of these lineages is important in developmental biology, fracture healing, and approaches being developed for joint cartilage repair. For example, the osteoblast commitment genes *Osterix* and *Runx2* both promote the final stage of chondrocyte differentiation (hypertrophy) preceding vascular invasion in endochondral ossification. This progression through to hypertrophy is blocked in both *Runx2*- (Inada et al., 1999; Kim et al., 1999) and *Osterix*-null mice (Nishimura et al., 2012). These two transcription factors appear to interact directly with each other to promote chondrocyte hypertrophy (Nishimura et al., 2012). In addition, overexpression of *Runx2* promotes chondrocyte hypertrophy, while knockdown reduces it and promotes adipogenesis (Enomoto et al., 2000; Takeda et al., 2001; Ueta et al., 2001). Although reciprocal regulation of chondrogenesis and osteoblastogenesis from the same common precursor has been suggested (Komori, 2018), mechanisms controlling this have not yet been identified. So, too, the question of whether hypertrophic chondrocytes also represent partially committed osteoblast precursors capable of transdifferentiating into osteoblasts continues to be investigated (Yang et al., 2014).

Mature "bone-forming" osteoblasts

Mature osteoblasts synthesize the organic components of bone and contribute to the events resulting in its mineralization. This is discussed in additional detail in Chapter 11.

Mature matrix-producing osteoblasts are recognized as groups of plump, cuboidal mononuclear cells lying on the unmineralized matrix (osteoid) they have synthesized. These cells do not operate in isolation, and in vivo are rarely seen even in small groups of two or three cells. Rather, active bone-forming surfaces are lined by a seam of osteoid, on the surface of which resides a team of osteoblasts with similar morphologic characteristics, including similar nuclear–cytoplasmic alignment, and extensive sites of contact between team members (Fig. 4.2). Formation of mineralized nodules in vitro also depends on a critical mass of differentiated osteoblasts, which form a cobblestone layer before matrix deposition occurs (Ecarot-Charrier et al., 1983; Abe et al., 1993). Matrix-producing osteoblasts communicate with one another, with adjacent bone-lining cells (Doty, 1981), and with osteocytes below the surface through gap junctions and direct cell–cell contact. This requirement of cell–cell contact between matrix-producing osteoblasts emphasizes the importance of juxtacrine and paracrine control mechanisms for osteoblast differentiation and bone formation.

Osteoblasts do not produce "bone" per se, but synthesize a collagen-rich osteoid matrix, which becomes gradually mineralized over time. This process of mineralization is controlled by noncollagenous proteins produced by late-stage osteoblasts and osteocytes. The ability of osteoblasts to produce large quantities of protein is clearly shown by their dense endoplasmic reticulum (Fig. 4.2).

When osteoid is deposited by osteoblasts, it has two potential forms depending on its collagen orientation and speed of production. Within the osteoblast Golgi, procollagen molecules that make up osteoid are biochemically modified to form collagen triple helices, which are released by exocytosis into the extracellular space (Leblond, 1989). During bone

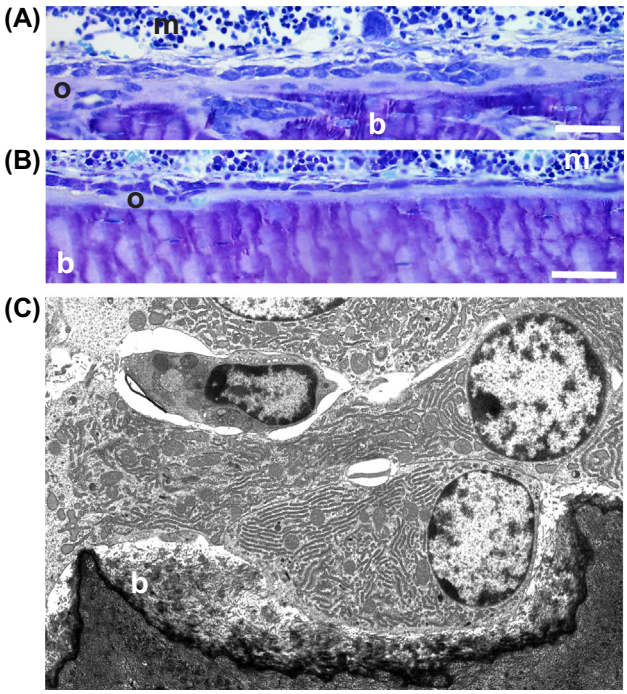

FIGURE 4.2 The appearance of matrix-producing osteoblasts by (A and B) light microscopy and (C) transmission electron microscopy. EphrinB2 signaling in osteoblasts promotes bone mineralization by preventing apoptosis. FASEB J. 28 (10), 4482–4496.*

development and fracture healing, woven bone is deposited rapidly: this contains disordered collagen fibers. During adult bone remodeling, the more slowly deposited, and mechanically stronger, lamellar bone has collagen fibers oriented in perpendicular planes in adjacent lamellae (Giraud-Guille, 1988). How osteoblasts are instructed to form either of these two substances is not known. One clue comes from ultrahigh-voltage electron microscopy studies showing initial sparse and random deposition of collagen fibers, followed, with increasing distance from the surface osteoblasts, by thickening and a shift to being oriented parallel to the direction of growth (Hosaki-Takamiya et al., 2016).

After collagen is deposited it becomes progressively mineralized by the accumulation of hydroxyapatite crystals. This mineralization process has two phases. Within ~5−10 days, osteoid undergoes rapid primary mineralization, and over subsequent weeks, months, and years, secondary mineralization occurs (Glimcher, 1998). Usually, the tissue reaches approximately 50%−70% of its final mineral content during primary mineralization (Boivin and Meunier, 2002; Ruffoni et al., 2007). During secondary mineralization, mineral continues to accumulate at a slower rate (Fuchs et al., 2008), crystals become larger (Glimcher, 1998), and carbonate is substituted for phosphate groups within the matrix (Vrahnas et al. 2016, 2018). As mineral is deposited, the surrounding collagen fibers of bone also change, becoming more cross-linked (Paschalis et al., 2004) and more compact (Vrahnas et al. 2016, 2018).

The processes of mineralization initiation, mineral accrual, and crystal maturation are controlled by a number of noncollagenous proteins expressed by osteoblasts and osteocytes (see Table 4.1). Some proteins promote mineralization, such as the many phosphate-regulating and SIBLING proteins including alkaline phosphatase; phosphate-regulating neutral endopeptidase, X-linked; DMP1; matrix extracellular phosphoglycoprotein; and bone sialoprotein/integrin-binding sialoprotein. The importance of these proteins is clearly illustrated by defective bone mineralization in genetic insufficiencies of these proteins in both humans and mice (Whyte, 1994; Quarles, 2003; Holm et al., 2015). Mineralization inhibitors, such as osteopontin/secreted phosphoprotein-1 (Addison et al., 2010), are also expressed by osteoblasts and osteocytes. The final level of mineralization achieved in the bone substance varies locally within the bone matrix, and depends on the species, sex, age, and anatomical location of the bone (Boskey, 2013).

Bone-lining cells

Bone-lining cells are the abundant flattened cells lining both endocortical and trabecular bone surfaces (Miller and Jee, 1987). These cells have much less synthetic function, little cytoplasm or endoplasmic reticulum, and somewhat less cytoplasmic basophilia and alkaline phosphatase activity. They nevertheless possess gap junctions and may communicate both with one another and, probably through the canaliculi, with osteocytes residing in the bone matrix.

Although long regarded as a "resting" or "quiescent" population, bone-lining cells express receptors for endocrine and paracrine agents in common with mature osteoblasts. Their contraction from the bone surface in response to PTH (Jones and Boyde, 1976) was suggested to be a means of allowing osteoclasts access to the bone surface (Rodan and Martin,

TABLE 4.1 Selected proteins expressed at specific stages of osteoblast differentiation

Committed osteoblast progenitors	Early osteoblasts	Intermediate osteoblasts	Late osteoblasts	Early osteocytes	Late osteocytes
Runx2 (Komori et al., 1997) Osterix (Nakashima et al., 2002)	Pro-a(1)I collagen (Rodan and Noda, 1991) Fibronectin (Stein et al., 1990)	Alkaline phosphatase (Aubin, 1998) Osteonectin (Aubin, 1998) Matrix gla-protein (Stein et al., 1990). Bone sialoprotein Chen et al. (1992) PTH receptor (Allan et al., 2008)	Osteocalcin (Stein et al., 1990) Osteopontin (Stein et al., 1990)	Matrix extracellular phosphoglycoprotein (Igarashi et al., 2002). Dentin matrix protein 1 (Toyosawa et al., 2001) Phosphate-regulating neutral endopeptidase, X-linked (Westbroek et al., 2002)	Sclerostin (van Bezooijen et al., 2004) Fibroblast growth factor 23 (Yoshiko et al., 2007).

Shown is the stage of differentiation at which the marker is most highly expressed. Note: these proteins are expressed at lower levels at other stages of differentiation.

1981). The emergence of bone-lining cells from quiescence has been highlighted much more recently in other ways. This includes reactivation to resume their bone-forming ability by contributing to the anabolic effects of PTH (Kim et al., 2012) and anti-sclerostin treatment (Kim et al., 2017). The ability of bone-lining cells to form active osteoblasts is not restricted to "reactivation." After osteoblast ablation, bone-lining cells have been shown to proliferate and differentiate into mature osteoblasts; marrow-derived precursors were not capable of this (Matic et al., 2016). Bone-lining cells may therefore also provide a source of osteoblast precursors capable of proliferation during adulthood.

Another suggested function for bone-lining cells is their ability to lift from the bone surface to generate a canopy over the basic multicellular unit (BMU) to enclose its activities on the bone surface (Hauge et al., 2001), as discussed in Chapter 10. Bone-lining cells have also been shown to express receptor activator of NF-κB ligand (RANKL) and M-CSF (CSF1), and may therefore also participate in stimulating osteoclastogenesis (Matic et al., 2016). This has been suggested to be particularly important in estrogen deficiency (Streicher et al., 2017).

Osteocytes

Osteocytes, the matrix-embedded cells of the osteoblast lineage, are considered major "controlling cells" or "orchestrators" of bone due to their extensive networks and ability to signal to other cells (Bonewald, 2011; Schaffler et al., 2014). At this stage of the lineage, osteocytes exhibit a distinct pattern of gene expression (Table 4.1), and a distinct phenotype and location. Osteocytes are osteoblasts that became entrapped within the bone matrix during bone formation. As they are trapped, they form extensive dendritic processes through a fluid-filled network of communicating channels, allowing them to sense and respond to mechanical strain and microdamage to bone. They are the most abundant cell in bone by far, forming a highly complex cellular communication network through the bone matrix with a total of ~3.7 trillion connections throughout the adult skeleton (Buenzli and Sims, 2015). The nature and functions of osteocytes are considered in detail in Chapter 6.

One major protein involved in the communication network of osteocytes to osteoblasts is sclerostin, an inhibitor of Wnt-stimulated osteoblast differentiation (Bonewald and Johnson, 2008); the influence of this pathway on bone formation will be considered later. Sclerostin is likely to be important in limiting the amount of bone laid down in modeling, and its production in response to loading (Galea et al., 2011) or to local factors such as prostaglandin E_2 (Genetos et al., 2011), IL-6 family cytokines (Walker et al., 2010), or PTHrP (Ansari et al., 2018) also regulates bone formation.

The process of osteoblast lineage differentiation

Although we have summarized the main subsets of osteoblast lineage cells (precursors, matrix-producing osteoblasts, bone-lining cells, and osteocytes), differentiation is likely to proceed subtly even within each subset, with a range of phenotypic properties likely within any group (i.e., they are probably not homogeneous).

The first approach used to study osteoblast differentiation in vitro was to use primary cultured cells derived from stromal precursors or cell lines such as MC3T3-E1 (Sudo et al., 1983) and Kusa subclones (Allan et al., 2003). These have been used extensively to define pathways of osteoblast differentiation and equate each stage of differentiation and its gene expression profiles with some function in bone. The functions carried out by any member of the lineage depend on its stage of differentiation, its pattern of gene expression, its location in bone, and the influence of local and humoral factors. Thus, it is not appropriate to use the presence or absence of a single gene to define whether a cell is, or is not, an osteoblast. Rather, the expression of multiple genes may be used to define approximately the particular stages of osteoblast lineage differentiation, as illustrated in Table 4.1. While these gene products are often considered osteoblast markers, many are not exclusively expressed by osteoblasts and can be found in other cell types in the body. As single-cell sequencing methods are applied to this question, more will be learned about specific stages of differentiation and potential "subpopulations" of the osteoblast lineage.

When it comes to analyzing mutant mice, or mice treated with agents modifying osteoblast function, attempts to identify changes in the distribution of cells throughout the lineage (i.e., whether there are more cells at the precursor or collagen-producing stage of differentiation) still require morphologic and functional assessment. For example, our work using an antagonist to the EphrinB2/EphB4 interaction in cultured osteoblast lineage cells resulted in low mRNA levels specifically for genes associated with late osteoblasts and osteocytes (Takyar et al., 2013); when cell lineage−specific blockade was assessed in vivo, the midpoint blockade of osteoblast differentiation was reflected in elevated early-stage markers of osteoblast differentiation and reductions in late-stage markers (Tonna et al., 2014), suggesting an EphrinB2/EphB4 checkpoint midway through the differentiation process. Additional histomorphometric data confirmed this: osteoid production was maintained, while the initiation of bone mineralization (which requires expression of late osteoblast and

osteocyte markers) was delayed, leading to a reduction in bone stiffness (Tonna et al., 2014). Thus, stage-specific changes in osteoblast differentiation can lead to changes in the process of bone mineralization, ultimately modifying bone strength.

Defining gene expression patterns at specific stages of osteoblast differentiation has been aided by the use of genetically modified mice with reporter genes under the control of specific promoters. These reporter genes allow sorting of specific populations by fluorescence-activated cell sorting (FACS), a method enabling microarray studies to define specific gene sets expressed by, for example, osteoblasts compared with osteocytes (Kalajzic et al., 2005; Paic et al., 2009). Such studies have led to the identification of gene products associated with bone dissolution expressed by osteocytes (Chia et al., 2015), and allowed purification of cells to confirm gene knockdown in genetically altered mice (Ansari et al., 2018).

Although cell sorting might be helpful for identifying the stages of osteoblasts present in cells isolated from rodents, there remain only very limited cell surface markers available to identify the stages of osteoblast differentiation in non–genetically modified bone. Efforts are being made to develop antibodies specific for SSCs and their progeny, but have to date been unsuccessful. In mice, when cells must be derived from bone by prolonged enzymatic digestion, cell surface markers are inevitably damaged; this hampers FACS analysis. This disadvantage does not apply to the analysis of hemopoietic cells, since they do not require enzymatic digestion; such analyses have been carried out successfully for many years. Despite this limitation, freshly isolated murine bone osteoblast progenitors, which are perhaps less firmly attached to the bone surface, can be separated broadly into early (Sca-1^{+}CD51^{-}) and relatively mature (Sca-1^{-}CD51^{+}) osteoblast progenitors, each of which consist of heterogeneous populations (e.g., Lundberg et al., 2007).

Histology and histomorphometry remain the gold standard for identifying and quantifying mature osteoblasts, osteocytes, and bone-lining cells, and rely on their distinct morphologies and locations; in this way increased osteoblast numbers or changes in the osteocyte network can be identified and compared with changes in osteoid deposition and the rate at which mineralization is initiated. It should be noted that cells very early in the lineage arising from SSCs cannot be recognized morphologically in bone without the use of specific markers. Identifying specific stages of differentiation has been challenging, and requires the use of immunohistochemistry and in situ hybridization. Such methods have been used to identify the presence of Runx2-positive precursors within the marrow space in pathological conditions (for example, Walsh et al., 2009). Needed above all else are markers of osteoblast development and methods of visualization for in situ applications to complement morphologic assessment. The method of laser scanning cytometry, in which image analysis, somewhat like cell sorting, can be carried out on immunostained tissue sections, is a promising approach (Fujisaki et al., 2011).

At their various stages of development, cells of the osteoblast lineage signal to one another

Osteoblast lineage precursors begin their differentiation in the BMU, during which they are likely to be in contact with (or at least in close proximity to) other osteoblast precursors and mature osteoblasts on the bone surface. Bone-lining cells and matrix-producing osteoblasts on the bone surface are also in contact, not only with one another, but also with the highly differentiated osteocytes within the bone matrix. Not surprisingly, therefore, the cells of the lineage exert their influence through communicating signals among its member cells. These may be through direct contact by gap junctions or by paracrine and autocrine signaling. Some influential signaling processes within the osteoblast lineage will be discussed as examples of interactions within the lineage contributing to differentiation and their abilities to form bone, and program the generation of osteoclasts.

An example of contact-dependent communication: EphrinB2/EphB4

We have drawn attention to the role of the contact-dependent interaction between the receptor tyrosine kinase EphB4 and its ligand EphrinB2 as an important checkpoint prior to the late stages of osteoblast differentiation (see earlier) (Takyar et al., 2013; Tonna et al., 2014). EphrinB2 is produced at constant levels throughout osteoblast differentiation in vitro (Allan et al., 2008). In contrast, EphrinB2, but not its receptor, was rapidly increased when cells were exposed in vitro to PTHrP or PTH (Allan et al., 2008). Acute treatment of mice or rats with PTH also results in a rapid increase in EphrinB2 mRNA production in bone (Allan et al., 2008). Osteoblast-specific deletion of EphrinB2 (*OsxCre.Efnb2*$^{f/f}$ mice) caused a mild osteomalacia with compromised bone strength due to impaired late-stage osteoblast differentiation and high levels of osteoblast apoptosis (Tonna et al., 2014). The impairment in osteoblast differentiation was interesting because the osteoblasts expressed all early markers of osteoblast commitment at normal levels, but showed low levels of osteoblast marker expression after the stage of PTHR1 expression. This led to normal osteoid production, but delayed mineralization and diminished bone strength, pinpointing a failure of osteoblasts to pass through the EphrinB2/EphB4 checkpoint to become late-stage osteoblasts and osteocytes. A new insight into such contact-dependent communication

processes came with deletion of EphrinB2 at a later stage of differentiation, in osteocytes. These *Dmp1Cre.Efnb2*$^{f/f}$ mice had brittle bones in which the maturing matrix incorporated mineral and carbonate more rapidly than controls, and strikingly, the osteocytes in the mutant mice exhibited a higher level of cellular autophagy (Vrahnas et al., submitted for publication). Thus EphrinB2-directed actions with differing outcomes can be recognized in these two stages of the osteoblast lineage.

Communication between different stages of differentiation: IL-6 cytokines

The IL-6 family cytokines have many roles in bone physiology mediated by the osteoblast lineage. The first function identified for these cytokines in bone was their ability to promote osteoclast formation in vitro. However, osteoclast formation by IL-6, IL-11, leukemia inhibitory factor (LIF), cardiotrophin 1 (CT-1), and oncostatin M (OSM) in vitro depends on the presence of osteoblast-lineage cells (Tamura et al., 1993), by virtue of their ability to produce RANKL in response to these cytokines (Richards et al., 2000; Palmqvist et al., 2002).

These cytokines also promote bone formation. IL-6, IL-11, CT-1, and OSM all promote osteoblast differentiation in vitro (Bellido et al., 1997; Song et al., 2007; Walker et al., 2008). OSM, CT-1, and LIF, all of which are produced by osteoblasts, stimulate bone formation in vivo (Cornish et al., 1993; Walker et al. 2008, 2010). OSM, CT-1, LIF, and IL-11 also inhibit adipocyte differentiation (Sims et al., 2005; Song et al., 2007; Walker et al. 2008, 2010; Poulton et al., 2012) and stimulate the transcription factors involved in osteoblast commitment described earlier (C/EBPβ and C/EBPδ), while inhibiting the adipogenic transcription factor PPARγ, indicating an influence of these cytokines on early osteoblast/adipocyte commitment; this is confirmed by the low bone formation, high marrow adipose phenotypes of the IL-11 receptor-, CT-1-, LIF-, and OSM receptor-null mice (Sims et al., 2005; Walker et al. 2008, 2010; Poulton et al., 2012). In addition, these cytokines, which are expressed at all stages of osteoblast differentiation, all strongly inhibit expression of sclerostin, confirming a direct action in osteocytes (Walker et al., 2010). Thus, they promote bone formation by direct actions at multiple stages of osteoblast differentiation.

Stage-specific roles of IL-6 family cytokines in the osteoblast lineage were studied further using two mouse models in which the common receptor subunit for these cytokines (gp130) was conditionally deleted either from the entire osteoblast lineage (*Osx1Cre*) or later in osteoblast/osteocyte differentiation (*Dmp1Cre*). Given the role of these cytokines in stimulating osteoclast formation, it was a surprise that no changes in osteoclast formation or RANKL expression were observed. Instead, the mice exhibited a low level of bone formation (Johnson et al., 2014). This indicated that the major physiological effect of these cytokines in the osteoblast lineage is not to support osteoclast formation, but to maintain bone formation (Johnson et al., 2014). Although these cytokines stimulate RANKL expression in the osteoblast lineage, that function is not required for the maintenance of normal bone mass, but may be required to generate osteoclasts specifically in pathological conditions; alternatively, the gp130-dependent support of osteoclast formation within the osteoblast lineage may occur prior to osteoblast commitment. Consistent with differing influences at specific stages of the osteoblast lineage, there was no effect of deletion of gp130 within the osteoblast lineage on marrow adipogenesis (Johnson et al., 2014), suggesting these cytokines also influence osteoblast−adipocyte commitment before the stage of *Osterix* expression. Ultimately, both mice showed the same structural phenotype, indicating that role of gp130 in the osteoblast lineage controlling bone structure is mediated by the osteocyte (Johnson et al., 2014).

Communication at different stages of differentiation: PTHrP/PTHR1

Another communication pathway among the osteoblast lineage is mediated by PTHR1, the G-protein-coupled receptor shared between the hormone PTH and the cytokine PTHrP.

The paracrine action of osteoblast lineage−derived PTHrP to promote bone formation and stimulate osteoclastogenesis has been demonstrated in mice globally deficient in PTHrP and in mice with PTHrP knockdown directed to mature osteoblasts and osteocytes using *ColI(2.3)Cre* (Miao et al., 2005). This revealed a mechanism analogous to the anabolic action of intermittent PTH treatment in osteoporosis (i.e., that local PTHrP retains trabecular bone mass by promoting bone formation). The communication by PTHrP within the lineage has been extended to osteocytes, since osteocyte-specific knockout of PTHrP also results in reduced bone formation and loss of bone mass and strength (Ansari et al., 2018), with the conclusion that osteocyte-derived PTHrP acts in a paracrine/autocrine manner on osteocytes and osteoblasts. Notably, deletion later in the lineage (with *Dmp1Cre*) did not result in reduced osteoclast formation (Ansari et al., 2018), indicating that PTHrP promotes bone formation through actions later in the osteoblast lineage than its actions to stimulate osteoclast formation, analogous to the aforementioned observations in gp130-deficient mice. This topic is considered in detail in Chapter 25.

Physical sensing and signaling by osteoblasts and osteocytes

Another possible signaling mechanism within the osteoblast lineage is their ability to "sense" changes on the bone surface. When rat calvarial cells were provided in vitro to bone slices with crevices made by osteoclasts, or mechanically excavated grooves, the cells made bone in those defects, filling them exactly to a flat surface (Gray et al., 1996). In this way, in bone remodeling, osteoblast filling of a BMU follows the dictates of the size of the resorption cavity made by the osteoclasts, and once the formation process is established, the participating cells themselves sense the spatial limits and fill the space. This may be achieved by the ability of osteoblast precursors to respond to changes in surface topography when the change is either much larger than the cell itself, as in the aforementioned study, or very much smaller than the cell. For example, in response to altered nanotopography, cells adhere to the surface and one another and proceed to differentiate (Dalby et al., 2006). This filling may then occur through chemical communication, possibly involving gap junctions both among matrix-producing osteoblasts and between osteoblasts and osteocytes (Doty, 1981). The changes brought about on the bone surface by cells in the reversal phase may also change the topography and thereby determine osteoblast function. The in vitro study of Gray used bone that did not contain osteocytes, so they are not necessary for osteoblasts to respond to topographic clues, at least in vitro.

Osteocytes also sense the need for new bone formation, in their case, by sensing mechanical strain within the lacuna−canalicular network. Osteocytes respond to these changes by modifying their production of a range of signaling proteins (Mantila Roosa et al., 2011). The most well defined of these modifications is their decreased production of the bone formation inhibitor sclerostin (Robling et al., 2006). This releases a brake on matrix-producing osteoblasts on the bone surface (Robling and Turner, 2009) such that bone formation is increased in response to load in regions under greatest strain, i.e., where new bone is needed. The properties of osteocytes and their actions in mechanotransduction are discussed in detail in Chapter 6; here we use it as an example of how different stages of the osteoblast lineage communicate with one another.

How does the osteoblast lineage promote osteoclast formation?

The first intercellular communication function ascribed to the osteoblast lineage arose when it was proposed that the osteoblast lineage controlled the formation of osteoclasts (Rodan and Martin, 1981). Cell culture methods established this to be the case (Takahashi et al., 1988) by showing that osteoclastogenic cytokines and hormones, such as IL-6, PTH, 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D$), and OSM, act first on osteoblast lineage cells to promote their production of a membrane-bound regulator of osteoclastogenesis. The essential product from the osteoblast lineage proved to be RANKL, a member of the tumor necrosis factor ligand family that acts upon its receptor RANK in the hematopoietic lineage (Yasuda et al., 1998). The interaction is restricted by a decoy soluble receptor, osteoprotegerin (OPG), also a product of the osteoblast lineage (Simonet et al., 1997). The essential physiological roles of these factors in osteoclastogenesis were established through genetic and pharmacological studies (Boyle et al., 2003).

It continues to be unclear which stage of the osteoblast lineage is most influential in providing RANKL to the osteoclast precursor population. Early studies indicated that RANKL was probably derived from cells relatively early in the osteoblast lineage (Udagawa et al., 1989; Kartsogiannis et al., 1999), which would be more likely to be in contact with the appropriate osteoclast precursor populations. Consistent with a role for pluripotent precursors as a source of RANKL, adipocytes have also been reported to support osteoclastogenesis (Kelly et al., 1998; Hozumi et al., 2009; Quach et al., 2011). It has also been suggested that bone-lining cells may make direct contact with osteoclast precursors (Streicher et al., 2017); this may particularly come into play when they lift from the bone surface to form the canopy prior to bone remodeling. Of all the cells of the osteoblast lineage, probably the least likely to play a part in the regulation of osteoclast formation are mature, bone-synthesizing osteoblasts.

It has also been proposed that osteocytes are a major source of RANKL for osteoclast precursors. This follows the findings that genetic deletion of RANKL causes osteoclast deficiency and osteopetrosis both when the deletion is targeted to the entire osteoblast lineage and (albeit less so) when it is targeted specifically to osteocytes (Nakashima et al., 2011; Xiong et al., 2011). Although genetic deletion of RANKL throughout the osteoblast lineage led to profound osteopetrosis, when genetic deletion of RANKL in that lineage was delayed until adulthood, a reduction of RANKL in the entire osteoblast lineage did not lead to osteopetrosis, leading the authors to suggest that it is only the osteocyte that provides RANKL for osteoclast formation. This finding was not reproduced by Fumoto et al., who achieved a similar level of delayed RANKL knockdown, albeit in younger mice, that resulted in osteopetrosis of the same severity as that in mice lacking RANKL in osteoblast lineage throughout life (Fumoto et al., 2013). Notable in the latter work, in direct contrast to the findings of Nakashima et al. (Nakashima et al., 2011), RANKL mRNA levels were higher in osteoblast-rich cell

preparations compared with osteocyte-rich preparations. In both those studies the cell preparations being compared were impure, and would have contained hematopoietic cells, such as RANKL-expressing T cells, and natural killer cells, which are also capable of promoting osteoclast formation (Horwood et al., 1999; Soderstrom et al., 2010), although the proportion of contamination in each population is unknown. When highly purified populations of osteoblasts and osteocytes were prepared, in which those hematopoietic cells were removed, the level of RANKL expression in non-osteocytic mesenchymal cells (osteoblasts and their precursors) was approximately double that of purified osteocytes (Chia et al., 2015). This is consistent with early in situ hybridization studies, in which few osteocytes were reported to express RANKL (Kartsogiannis et al., 1999). It also parallels two other studies using transgenic expression of marker genes to isolate specific populations of the osteoblast lineage, in which osteoclastogenic support of osteoprogenitors was compared with a mixed population of mature osteoblasts and osteocytes (Li et al., 2010), with purified hematopoietic-cell-free osteocytes (Chia et al., 2015), or with an osteocyte-like cell line (McGregor et al., 2019). In all three works, while osteoblast progenitors supported $1,25(OH)_2D_3$-induced osteoclastogenesis, no osteoclasts were formed when the more mature osteocyte populations were used.

One important concept to consider in the role of osteoblast lineage cells in supporting osteoclastogenesis is that direct contact between the RANKL-expressing osteoblast lineage cells and the RANK-expressing hemopoietic osteoclast precursors was absolutely required for osteoclast formation in vitro (Takahashi et al., 1988; Suda et al., 1992). While recombinant soluble RANKL certainly promotes osteoclast formation from precursors in vitro (Quinn et al., 2001), and in vivo (Tomimori et al., 2009), there remains no evidence for shedding of soluble RANKL in the interaction between osteoblast and hemopoietic lineages, nor any convincing evidence of a physiological role for circulating RANKL. This means it is important to consider the location of the osteoblast lineage cells most likely to support osteoclast formation; cells within or in direct contact with the marrow, such as osteoblast precursors and bone-lining cells, rather than embedded osteocytes, are more likely to come into contact with osteoclast precursors and, therefore, are more likely to support osteoclast formation in normal remodeling. It has been difficult to understand how osteocytes, from within the matrix, could control RANKL availability to osteoclast precursors in the bloodstream through a contact-dependent mechanism, but some mechanisms have been proposed. Early confocal laser scanning microscope images have shown that osteocytic processes extend to the vascular-facing surface of the osteoblast (Kamioka et al., 2001). It has also been suggested that osteocyte-derived exosomes may participate: their release induced by apoptosis can stimulate osteoclastogenesis (Kogianni et al., 2008), and live-cell imaging showed release of microvesicles into the vasculature (Kamel-ElSayed et al., 2015). However, such a mechanism does not overcome the requirement for direct contact between RANKL-producing stromal cells and osteoclast precursors in vitro.

Actions of the osteoblast lineage during the bone remodeling sequence

Osteoblast differentiation is promoted by signals from a range of cell types within the BMU during remodeling. From the perspective of this chapter, it is important to consider the stages of osteoblast differentiation that participate in the remodeling sequence. Of course, their major known function in the bone remodeling sequence is the formation of the appropriate quantity of bone, in response to signals from the bone-resorbing osteoclast, including factors released from the bone matrix or factors produced by the osteoclasts themselves, often termed "coupling factors." Among the many possibilities are CT-1, sphingosine-1-phosphate, Wnt 10b, BMP6, and others (Pederson et al., 2008; Walker et al., 2008; Lotinun et al., 2013; Weske et al., 2018). Osteoclast-derived inhibitors of osteoblast differentiation might also contribute to the outcome. Examples of such inhibitors are Semaphorin 4D (Negishi-Koga et al., 2011), which acts on its receptor Plexin B1 in osteoblastic cells. These factors influence osteoblast precursors, mature matrix-producing osteoblasts, and osteocytes. They are discussed in Chapter 10 and have been described in reviews (Sims and Martin 2014, 2015).

There are additional functions of the osteoblast lineage in remodeling that should also be considered; these are also described in Chapter 10 but are noted briefly here. It has been proposed that the initiation of remodeling may stem from two activities at two different stages of the osteoblast lineage: (1) a signal from osteocytes in response to microdamage within the bone matrix (Schaffler et al., 2014) and (2) the lifting of bone-lining cells to form a canopy over the BMU (Hauge et al., 2001). It has also been proposed that differentiating osteoblast lineage cells on the bone surface are responsible for the duration of the reversal phase (Abdelgawad et al., 2016).

Lessons in osteoblast biology from the Wnt signaling pathway

A major pathway regulating osteoblast differentiation and bone formation identified and defined since 2001 is the Wnt signaling pathway, which modifies bone formation by altering, among other steps, the transcriptional control of

osteoblasts. This new information has had a very great impact on the understanding of control mechanisms within the osteoblast lineage and the development of pharmacological approaches for skeletal fragility. These landmark findings arising out of human genetics are discussed and put into context in detail in Chapters 7 and 8. The implications of these findings for understanding the osteoblast lineage are discussed here.

Wnt signaling is specifically and powerfully inhibited by the action of sclerostin, a protein secreted by osteocytes and encoded by the *SOST* gene. The rare syndromes of skeletal enlargement, sclerosteosis, and van Buchem's disease were discovered to be caused by inactivating mutations in the *SOST* gene (Balemans et al. 2001, 2002). Genetically manipulated mouse models recapitulated the high bone mass observed in the human mutation syndromes (Loots et al., 2005). Within the cell, activation of canonical Wnt signaling leads to stabilization of β-catenin in the cytoplasm through inhibition of glycogen synthase kinase (GSK)-3β-mediated phosphorylation, resulting in accumulation of cytoplasmic β-catenin followed by its translocation to the nucleus and transcription of specific gene targets. Such activation in mesenchymal cells promotes osteoblast activity (Rawadi et al., 2003). Oral delivery of either a small-molecule inhibitor of GSK-3β (Kulkarni et al., 2006) or a less potent inhibitor, lithium chloride (Clement-Lacroix et al., 2005), each enhanced osteoblast differentiation in vitro and increased bone formation, bone mass, and strength in vivo.

It soon became clear that this pathway to control osteoblast differentiation offered appealing therapeutic prospects for the development of anabolic agents. The many possible targets used to increase Wnt/β-catenin signaling included extracellular agonists, inhibition of any of the several extracellular antagonists, and inhibition of GSK-3β. Many of these have been attempted in preclinical experiments, but the chosen approach that is now advanced in clinical development is blockade of sclerostin by treatment with neutralizing antibody.

The effects of the Wnt signaling pathway on bone are not restricted to direct actions on bone matrix production by osteoblasts, however. Mice prepared with a constitutively active β-catenin—and therefore constitutively active Wnt signaling—in the osteoblast lineage surprisingly showed no significant alteration in mature osteoblast numbers; instead the mice had a severe form of osteopetrosis, including failed tooth eruption (Glass et al., 2005). This phenotype appeared to be due to failure of osteoclast formation, caused by increased OPG production by osteoblast lineage cells in which active β-catenin was expressed. A similar osteopetrotic syndrome due to failed osteoclast development and increased OPG was observed in mice lacking the adenomatous polyposis coli protein (APC) in osteoblasts (Holmen et al., 2005). APC acts in a complex of proteins with GSK-3β to maintain the normal degradation of β-catenin. Its absence leads to accumulation of β-catenin, resulting in cell-autonomous activation of Wnt signaling in the osteoblast lineage.

As was predicted, inhibition of production or action of sclerostin resulting in enhanced Wnt canonical signaling led to increased bone mass in preclinical studies (Li et al., 2009; Kramer et al., 2010). In rodents and nonhuman primates, the tissue level mechanism by which anti-sclerostin increases bone is predominantly to promote bone formation on quiescent surfaces—thus a modeling effect. On preresorbed surfaces (remodeling) the amount of new bone formed is greater than that resorbed; this includes bone laid down over quiescent surfaces adjacent to remodeling sites. In the phase II and phase III clinical studies carried out with the humanized monoclonal antibody to sclerostin (romosozumab) (McClung et al., 2014; Cosman et al., 2016), romosozumab recapitulated the rapid increase in bone mineral density that had been seen in preclinical studies. In both clinical studies romosozumab treatment was associated with a transitory increase in the bone formation marker P1NP and a moderate but more sustained decrease in bone resorption markers. The latter effect remains unexplained but could be related to a change in the distribution of cells in the osteoblast lineage population. The profound increase in bone formation may shift the population such that there is a greater proportion of matrix-producing osteoblasts, and the push toward differentiation may lead to a lesser availability of less mature cells that stimulate RANKL production and therefore support osteoclast formation. Alternative explanations could be that Wnt signaling results in sufficient β-catenin activation to promote OPG production (*vide supra*), or that WISP1, induced by Wnt signaling (Holdsworth et al., 2018), inhibits osteoclast formation (Maeda et al., 2015).

The reason for the decrease in bone formation markers after an initial rise poses interesting questions concerning osteocyte/osteoblast interactions. Multiple studies using two different sclerostin antibodies in rats or mice identified a rapid increase in modeling-based bone formation and a transient increase in mineral apposition rate in remodeling sites that was not sustained with continued treatment (Ominsky et al., 2014; Stolina et al., 2014; Nioi et al., 2015; Taylor et al., 2016; Ma et al., 2017). Progressive increases were seen in mRNA levels of Wnt signaling antagonists *Sost* and *Dkk1* in osteoblastic cells, tibiae, and vertebrae. Supporting evidence was recently provided by Holdsworth et al. (Holdsworth et al., 2018), who showed that treatment of mice with anti-sclerostin increased expression in bone of transcripts for antagonists of Wnt signaling, including Sost, Dkk1, Dkk2, WIF1, SFRP2, SFRP4, SFRP5, and FRZB, as well as increased expression of WISP1, which inhibits osteoclast formation (Maeda et al., 2015). Thus, the intriguing possibility has been raised that the transience of anabolic action through sclerostin blockade is the result of self-regulation within the Wnt pathway.

Modulation of the program of osteoblast differentiation can also influence sclerostin expression by the osteoblast lineage. The transcription factor Osterix is absolutely required for osteoblast differentiation and is expressed at early stages of osteoblast commitment (Nakashima et al., 2002). Since sclerostin is expressed by osteoblasts that have reached the osteocytic stage, it was surprising to find that this early osteoblastic transcription factor also binds to the sclerostin promoter, thereby directly stimulating sclerostin expression (Yang et al., 2010). Whether this mechanism plays an important role in continued differentiation of the osteoblast lineage remains to be understood.

These aspects of anti-sclerostin action reveal a complexity of regulation that will undoubtedly be the focus of future attention. Ultimately, activation of Wnt signaling, by whatever means, induces osteoblast differentiation and osteoid formation, but the extent of these effects can be limited by built-in regulation, carried out by later cells of the lineage that produce inhibitors to block further Wnt signaling. They illustrate very well what crucial roles are played in the regulation of bone by cells of the osteoblast lineage; many are new roles revealed in the last 10 years. They draw attention to the fact that the mechanisms involved in sclerostin blockade are new to us, and they illustrate the lack of precision in using the word "osteoblast" as though it is being applied to a group of cells with common properties.

From paracrinology to endocrinology in bone: the secretory osteoblast lineage

The many constituent cells of the osteoblast lineage not only form bone, but also engage in paracrine and juxtacrine signaling among its members, as discussed earlier, as well as with hematopoietic cells in the regulation of osteoclast formation. This makes for a lineage of cells that carry out many functions that extend far beyond the matrix-producing role traditionally ascribed to osteoblasts. These additional functions of osteoblasts include support in physiology of the hematopoietic and immune systems (Calvi et al., 2003). In pathology, the osteoblast lineage also directs how cancer cells are housed, whether having their malignant progression enhanced, as in breast and prostate cancer (Sterling et al., 2011), or inhibited, as in multiple myeloma (Lawson et al., 2015). The osteoblast lineage can also play a central part providing an environment that favors cancer cell dormancy (reviewed in Croucher et al., 2016), in which the large population of lining cells could favor dormancy until changes in local events reawaken malignant cells.

A real surprise came with the realization that the osteoblast lineage also serves as a site of production and secretion of hormones. The first osteoblast lineage endocrine factor identified was FGF23, discovered as responsible for tumor-induced osteomalacia (Yamashita et al., 2000), and with missense mutations causing autosomal dominant hypophosphatemic rickets (Consortium, 2000). Its bone cell of origin was found to be the osteocyte (Liu et al., 2003). Then its hormonal nature was shown: circulating FGF23 acts on the kidney to promote phosphorus excretion and reduce 25(OH)D-1α-hydroxylase expression and hence circulating $1,25(OH)_2D_3$ (Shimada et al., 2004). FGF23 is reviewed in detail in Chapter 64.

Recognition of bone as an endocrine organ (Fukumoto and Martin, 2009) brings with it questions that relate to long-held views of regulatory mechanisms of hormone secretion from endocrine "glands." Usually a specific stimulus, e.g., low calcium for PTH, low glucocorticoid for adrenocorticotropic hormone, results in rapid response secretion of the appropriate hormone. In the case of FGF23, in which the cell source, predominantly osteocytes, is so widely distributed, there must be new endocrine mechanisms by which a need for FGF23 secretion by osteocytes is communicated. A high-phosphate diet increased FGF23 in rats and mice (Perwad et al., 2005), but the mechanism by which this increase occurred is not clear. The substantial increase in FGF23 mRNA and protein production following pharmacological administration of PTH(1−34) was blocked in mice with *Pthr1*-null bones (Fan et al., 2016). Given the evidence for the roles of paracrine PTHrP in osteoblast and osteocyte biology, this would support a view that locally generated PTHrP might regulate FGF23 secretion.

The questions become even more complex in the case of the second bone hormone discovered relatively recently, osteocalcin. Its endocrine role will be considered in detail in Chapter 86. Its direct relevance to this chapter is that it also is a product of the osteoblast lineage, specifically late osteoblasts and early osteocytes, secreted and stored as an abundant component of the bone matrix and with readily assayed circulating levels that can reflect both bone formation and bone resorption.

Osteocalcin is carboxylated at three glutamic acid residues through a vitamin K-dependent process, and is decarboxylated in the acid pH of the bone resorption lacuna to convert GlaOCN (osteocalcin) to GluOCN (undercarboxylated osteocalcin). The latter undercarboxylated and uncarboxylated forms are considered to be the hormonal forms capable of enhancing glucose uptake in muscle, insulin production and cell mass in the pancreatic β-cell, and insulin sensitivity in liver and adipose tissue (Lee et al., 2007; Ferron et al., 2010; Wei et al., 2014; Karsenty and Olson, 2016). These actions are thought to be mediated through the G-protein-coupled receptor family C group 6 member A, GPCR6A (Pi et al., 2011).

Mice with high osteoclast activity levels developed high circulating GluOCN and improved glucose tolerance and insulin sensitivity, while osteoclast suppression was associated with low GluOCN (Lacombe et al., 2013).

The effects of osteocalcin on energy production and utilization were not noted when osteocalcin (*Bglap*)-null mice were first prepared; at that time it was simply surprising to find that there was no striking bone phenotype (Ducy et al. 1996, 1997), although later studies revealed changed bone composition and strength (Boskey et al., 1998). The osteocalcin-null mice were later noted to have larger fat pads and mild hyperglycemia (Lee and Karsenty, 2008). The mice were also noted to breed poorly, and GluOCN was found to enhance male fertility by increasing testosterone production by Leydig cells (Oury et al., 2011). The reproductive role of osteocalcin will also be considered in Chapter 86.

Another feature of the osteocalcin-null mice (Ducy et al., 1997) was a noticeable passivity of behavior that translated into anxiety-like behavior and deficits in memory and learning that could be demonstrated experimentally (Oury et al., 2013). Although GPCR6A was found to be the receptor for osteocalcin in β-cells and myoblasts, the brain actions required a different receptor, since *Gpcr6a*-null mice had none of the behavioral abnormalities of osteocalcin deficiency, and *Gpcr6a* could not be detected at sites of action of osteocalcin in the brain (Khrimian et al., 2017). Rather, genetic experiments indicated that the receptor for osteocalcin in the brain is GPR158. Mice rendered deficient for *Gpr158* exhibited severe cognitive effects that could not be treated by undercarboxylated osteocalcin (Khrimian et al., 2017; Obri et al., 2018).

At the time of writing, these diverse effects of osteocalcin deficiency need confirmation in other species. Complete knockout of osteocalcin in the rat using CRISPR/Cas9 yielded rats with high trabecular thickness and trabecular bone volume, a phenotype not observed in the murine knockout. In addition, although a statistically significant increase in insulin sensitivity was noted in the osteocalcin-null rat, there were no changes in gonadal fat pad weight or body composition (Lambert et al., 2016).

These many effects of uncarboxylated osteocalcin and FGF23 as hormones are fascinating in pointing to an endocrine role for the osteoblast lineage that could never have been predicted. In the case of FGF23 the predominant cell of production is the osteocyte. It is not known whether there are osteocyte subpopulations that preferentially produce FGF23. Whether or not that is the case, FGF23 production is based on a large number of cells that are very widely distributed in the body. To serve as a hormone, mechanisms would be needed to ensure that FGF23 is secreted physiologically in response to signals that come from other organs (endocrine) or from neighboring cells in the same organ (paracrine).

Hormonal osteocalcin presents these same questions and others. Osteocalcin production in the osteoblast lineage is high at later stages of differentiation (e.g., Allan et al., 2003), and is generally regarded as a marker of "late" osteoblasts (Table 4.1). Expression of osteocalcin is also observed in the osteocyte cell line Ocy454 (Spatz et al., 2015), possibly at a lower level than in mature osteoblasts (Ansari et al., 2018). The few studies of osteocalcin localization by in situ hybridization and immunohistochemistry seem to point to either less production in osteocytes than in mature osteoblasts or production restricted to early osteocytes (Weinreb et al., 1990; Ikeda et al., 1992; Zhou et al., 1994). As with FGF23, questions about regulation are raised, such as, what are the immediate signaling mechanisms indicating the need for GluOCN secretion to facilitate energy utilization, reproductive activity, or cognitive activity? If acidification in resorption spaces is an important contributing mechanism, how could the levels be sufficiently tightly regulated for a hormone? Anabolic activity within the osteoblast lineage is associated with increased osteocalcin in the circulation, hence its role as a formation marker as well as a resorption marker, yet how does this modify glucose metabolism and brain function? Answers to these questions could uncover the osteoblast lineage at the center of a new endocrine system and illustrate an even more remarkable diversity in the influence of these cells.

Chapter outline

Introduction

We contributed a chapter with the title "Osteoclast generation" to *Principles of Bone Biology*, third edition, in 2008. Since then, our understanding of osteoclast differentiation and activation has greatly advanced. The previous chapter focused on the regulation of osteoclast differentiation by the receptor activator of NF-κB ligand/receptor activator of NF-κB/osteoprotegerin (RANKL/RANK/OPG) system. In this new chapter, we have added a section called "Function of osteoclasts" in addition to the regulation of osteoclastogenesis. In retrospect, the role of tumor necrosis factor receptor-associated factors (TRAFs) in osteoclast differentiation and activation was not adequately described in the previous chapter. Findings obtained since its publication have clarified the role of TRAFs in osteoclastogenesis. Studies have shown that the removal of endogenous inhibitory molecules from osteoclast precursors is particularly important for inducing osteoclast differentiation and function. We have attempted to summarize the regulatory mechanisms of osteoclastogenesis elucidated in the past decade in this chapter. In a PubMed search, the number of papers hit with the word "osteoclast" was 436 in 1997, when OPG was discovered, and this number increased to 1408 in 2017. Therefore, the identification of important studies has become more challenging. We did not describe the role of osteoclasts in functional coupling between bone resorption and bone formation; this is described in Chapter 10 (Sims and Martin). Since not all important findings on osteoclasts are introduced in this chapter, each reader will obtain a better understanding of osteoclasts by adding the findings that each considers important. We also describe our working hypothesis on osteoclast precursors in vivo in the final section of this chapter. We hope that the contents of this chapter will contribute to the reader's understanding of osteoclasts.

Function of osteoclasts

Morphological features of osteoclasts

Osteoclasts are multinucleated cells with a size of 20−100 μm, and are formed by the fusion of mononuclear pre-osteoclasts. Osteoclasts have a large number of pleomorphic mitochondria and a well-developed Golgi apparatus with a rough endoplasmic reticulum, indicating that active energy metabolism and protein synthesis are performed in these cells. Many lysosomes are present in osteoclasts, suggesting that the function of osteoclasts is related to protein degradation. The most characteristic feature of bone-resorbing osteoclasts is the presence of ruffled borders and clear zones (also called the sealing zones). Osteoclasts create resorption lacunae (also called Howship's lacunae) under ruffled borders. Resorption lacunae are acidic to promote the dissolution of bone minerals and proteins. The morphological features of a functioning osteoclast and the mechanisms underlying bone resorption are summarized in Fig. 5.1.

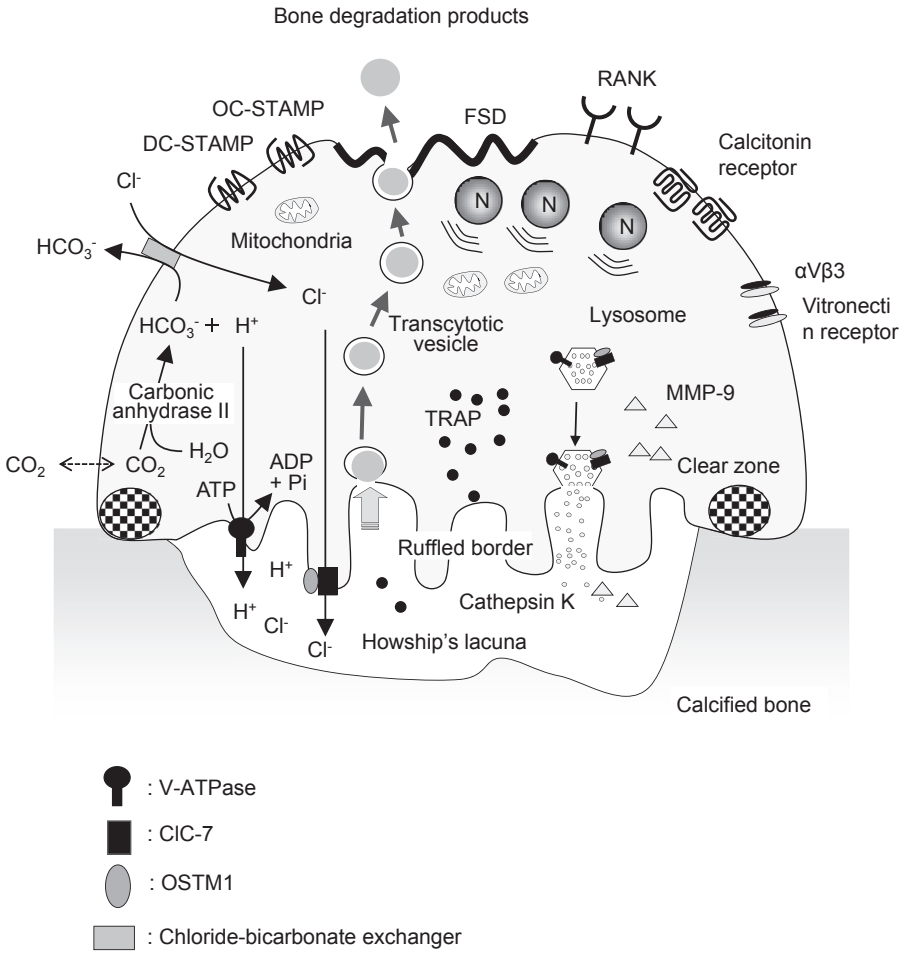

FIGURE 5.1 Schematic representation of a functioning osteoclast. Osteoclasts have several unique ultrastructural characteristics, such as multiple nuclei, abundant mitochondria, and numerous vacuoles and lysosomes. Functioning osteoclasts form ruffled borders and clear zones. The clear zone is recognized as a thick band of actin, isolating resorption lacunae from the surroundings. The resorbing area under the ruffled border is acidic. Vacuolar proton ATPase (*V-ATPase*) exists in the ruffled border and lysosomal membranes. Chloride channel 7 (*ClC-7*) and osteopetrosis-transmembrane protein 1 (*OSTM1*) colocalize in the ruffled border and lysosomal membranes. Matrix metalloproteinase-9 (*MMP-9*) and lysosomal enzymes containing cathepsin K are also secreted into resorption lacunae. Matrix degradation products are endocytosed from a ruffled border region into transcytotic vesicles and then secreted from the functional secretion domain (*FSD*) in the basolateral membrane. Protons are generated by carbonic anhydrase II. Passive chloride−bicarbonate exchangers expressed in the basolateral membrane simultaneously remove HCO_3^- and incorporate Cl^-. Osteoclasts also express large numbers of calcitonin receptors and αVβ3 vitronectin receptors. Dendritic cell-specific transmembrane protein (*DC-STAMP*) and osteoclast-specific transmembrane protein (*OC-STAMP*) are expressed in the osteoclast plasma membrane and play a role in the cell fusion of osteoclasts. Osteoclasts abundantly express calcitonin receptors and receptor activator of NF-κB (*RANK*). *TRAP*, tartrate-resistant acid phosphatase.

The cell membranes of bone-resorbing osteoclasts are divided into four distinct regions: the clear zone, ruffled border, and basolateral and functional secretion domain (FSD) regions (Väänänen and Laitala-Leinonen, 2008). The clear zone is named after its appearance as a bright area under an electron microscope, and this structure is also defined by a thick band of actin called actin rings. Clear zones are involved in the attachment of osteoclasts to bone surfaces and the isolation of resorption lacunae from the surroundings. The ruffled border, which is a foldlike structure formed by the invasion of the cell membrane into the cytoplasm, is the main functional site of bone resorption. Protons and lysosomal enzymes are secreted from ruffled borders into resorption lacunae for the degradation of minerals and matrix proteins. The degradation products of bone are taken up from the specific area of ruffled borders into transcytotic vesicles (Nesbitt and Horton, 1997; Salo et al., 1997; Mulari et al., 2003), are further digested in these vesicles, and are then released from the FSD by vesicular exocytosis.

Mechanism of bone resorption

Osteoclasts possess abundant amounts of carbonic anhydrase II, which is responsible for proton production (Sly et al., 1985). Vacuolar proton ATPase (V-ATPase) localizes to the ruffled border and secretes protons into resorption lacunae in an ATP hydrolysis-dependent manner (Blair et al., 1989; Li et al., 1999; Blair and Athanasou, 2004) (Fig. 5.1). V-ATPase is also detected in lysosomal membranes, and acidifies the inside of lysosomes. Cl^- is transported through chloride channel 7 (ClC-7) to the resorption lacunae to maintain an ionic equilibrium (Kornak et al., 2001). Osteopetrosis-transmembrane protein 1 (OSTM1) is a molecule that is essential for the localization and function of ClC-7 in lysosomes and ruffled borders (Ramírez et al., 2004). OSTM1 acts as the β subunit of ClC-7 (Lange et al., 2006). A mutation in the *OSTM1* gene has been reported in *gl/gl* (gray-lethal) osteopetrotic mice and in patients with hereditary osteopetrosis (Ramírez et al., 2004).

Resorption lacunae are maintained in an acidic environment of approximately pH 4, which favors the dissolution of bone minerals. Proton secretion into resorption lacunae leaves HCO_3^- inside osteoclasts. Passive chloride−bicarbonate exchangers are expressed in the basolateral membrane of osteoclasts and simultaneously remove and incorporate HCO_3^- and Cl^-, respectively (Teti et al., 1989; Wu et al., 2008). The degradation of type I collagen is also promoted under acidic conditions by cathepsin K, a lysosomal enzyme. Cathepsin K has been identified as an enzyme that is specifically expressed in osteoclasts (Tezuka et al., 1994b), and was confirmed to cleave type I collagen at acidic optimum pH (Bossard et al., 1996; Saftig et al., 1998). Matrix metalloproteinase-9 (MMP-9) is highly expressed in osteoclasts (Reponen et al., 1994; Tezuka et al., 1994a). MMP-9 is also secreted into resorption lacunae to digest bone matrix proteins. As described earlier, the degradation products of bone are taken up from the ruffled borders and are ultimately exocytosed to the intercellular space from the FSD. Thus, osteoclasts secrete acids and enzymes and simultaneously absorb degradation products. The flow of vesicles toward the ruffled borders is accompanied by microtubule- and microfilament-mediated vesicle transport (Abu-Amer et al., 1997; Teitelbaum and Ross, 2003; Jurdic et al., 2006). Small GTPases such as RAB7 and RAC are proposed to be involved in vesicle transport in osteoclasts (Zhao et al., 2001; Mulari et al., 2003; Teitelbaum, 2011).

Osteoclasts express a large amount of tartrate-resistant acid phosphatase (TRAP), and release it into blood when they resorb bone (Minkin, 1982). Therefore, TRAP staining is widely used to identify osteoclasts in bone tissues, and serum TRAP activity is measured to evaluate osteoclast number and function in vivo. However, the role of TRAP in bone resorption has not been fully elucidated. Osteoclasts abundantly express the vitronectin receptor, αVβ3 (Horton et al., 1985). This integrin is considered to be involved in the early adhesion of osteoclasts to bone (McHugh et al., 2000). Osteoclasts also abundantly express the calcitonin receptor, a GTP-binding-protein-coupled receptor (Chambers and Magnus, 1982; Nicholson et al., 1986). Calcitonin is secreted from parafollicular cells (C cells) in the thyroids of mammals. Calcitonin activates cAMP/protein kinase A and Ca^{2+}/protein kinase C signaling via a heterotrimeric GTP-binding protein in osteoclasts (Suzuki et al., 1996; Sexton et al., 1999). Calcitonin-induced signals inhibit the bone-resorbing activity of osteoclasts by disrupting the cytoskeletal organization of osteoclasts (Tanaka et al., 2006; Martin and Sims, 2015). RANK is also abundantly expressed on the membrane of osteoclasts (described later).

DC-STAMP/OC-STAMP

Dendritic cell-specific transmembrane protein (DC-STAMP), a seven-transmembrane protein, was discovered as a membrane protein expressed by dendritic cells. Osteoclasts also abundantly express DC-STAMP (Kukita et al., 2004; Yagi et al., 2005). Mononuclear preosteoclasts, but not multinucleated osteoclasts, have been detected in DC-STAMP-deficient mice. Macrophage-derived foreign-body giant cells are also absent in DC-STAMP-deficient mice. Thus, DC-STAMP is a molecule that is needed for the cell fusion of macrophage lineage cells, including osteoclasts and foreign-body giant cells.

Mononuclear preosteoclasts in DC-STAMP-deficient mice express all osteoclast markers and form clear zones and ruffled borders on bone slices. These findings suggest that osteoclastic differentiation is nearly completed by the differentiation of precursor cells into mononuclear preosteoclasts.

Another seven-transmembrane protein, osteoclast-specific transmembrane protein (OC-STAMP), has been identified (Miyamoto et al., 2012b). OC-STAMP-deficient mice showed features very similar to those of DC-STAMP-deficient mice. OC-STAMP-deficient mice express DC-STAMP, whereas no multinucleated osteoclasts are observed in OC-STAMP-deficient mice. Many mononuclear preosteoclasts are also found in OC-STAMP-deficient mice. These findings suggest that DC-STAMP and OC-STAMP both play an important role in the fusion of osteoclasts, but cannot compensate for each other. DC-STAMP-deficient mice and OC-STAMP-deficient mice both develop weak osteopetrosis with age. Thus, DC-STAMP and OC-STAMP are essential factors for the cell fusion of osteoclasts and macrophages, and the multinucleation of osteoclasts appears to be necessary for increasing bone-resorbing capacity. Studies have also shown that the fusion of osteoclasts and macrophages is different from each other in some way. Signal transducer and activator of transcription 6 signals induced by interleukin 4 (IL-4) were required for the cell−cell fusion of macrophages but not osteoclasts (Miyamoto et al., 2012a). DC-STAMP is proposed to play an imperative role in bone homeostasis (Chiu and Ritchlin, 2016). Further studies will unravel the role of this interesting molecule in bone biology.

Ruffled border formation

The fusion of exocytotic vesicles to membranes appears to be mediated by the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor complex assembly. The synaptotagmin family is also involved in the fusion of exocytotic vesicles. Synaptotagmin I was initially identified as a Ca^{2+} sensor that is abundantly expressed on synaptic vesicles and regulates the fusion step of synaptic vesicle exocytosis. In osteoclasts, synaptotagmin VII plays an essential role in the fusion of lysosomal vesicles to secrete lysosomal enzymes into resorption lacunae (Zao et al., 2008). The degradation of type I collagen by cathepsin K was markedly decreased in synaptotagmin VII-deficient osteoclasts.

Autophagy-related proteins such as autophagy-related protein 5 (ATG5), ATG7, ATG4B, and light-chain protein 3, are also involved in the ruffled border formation of osteoclasts (DeSelm et al., 2011). These findings provide suggestions on how to make ruffled borders in osteoclasts. Osteoclasts possess numerous acidified lysosomes bearing V-ATPase and ClC-7 in the cytoplasm. Bone-resorbing osteoclasts transfer and fuse acidified lysosomes to the side of the plasma membrane facing the bone surface (Mulari et al., 2003; Teitelbaum, 2007). The insertion of vesicles into the plasma membrane markedly increases the surface area of cells and delivers V-ATPase and ClC-7 to the plasma membrane. Osteoclasts form ruffled borders, making extracellular secondary lysosomes and resorbing bone.

Role of osteoblastic cells in osteoclastogenesis

Coculture system

The differentiation and activation of osteoclasts are strictly regulated by the mesenchymal cells of osteoblast lineage cells (referred to as osteoblastic cells), such as osteoblasts, osteocytes, and bone marrow−derived stromal cells. In 1981, Rodan and Martin (1981) proposed a concept that bone-resorbing factors act on osteoblastic cells, but not osteoclasts, to induce osteoclastic bone resorption based on the observation that osteoblastic cells express the receptors for bone-resorbing factors, including parathyroid hormone (PTH) and prostaglandin E_2 (PGE_2). By incorporating this hypothesis, a murine coculture system of osteoblastic cells and hematopoietic cells was established in 1988 (Takahashi et al., 1988). Osteoclasts were formed in a coculture treated with bone-resorbing factors. Osteoblastic cells were shown to strictly regulate osteoclast differentiation and activation in the coculture. Cell-to-cell contact between hematopoietic cells and osteoblastic cells was required to induce osteoclast formation and activation. Experiments using this coculture system established the concept that osteoblastic cells express osteoclast differentiation factor (ODF) as a membrane-associated factor for the induction of osteoclast differentiation (Suda et al., 1992). It was also established that osteoclasts differentiate from various types of monocyte−macrophage lineage precursors in the coculture (Udagawa et al., 1990). The role of osteoblastic cells in the differentiation and function of osteoclasts is summarized in Fig. 5.2.

Macrophage colony-stimulating factor

Macrophage colony-stimulating factor (M-CSF; also called colony-stimulating factor 1) was originally identified as a growth factor that specifically stimulates the development of macrophage colonies. The critical role of M-CSF in osteoclast

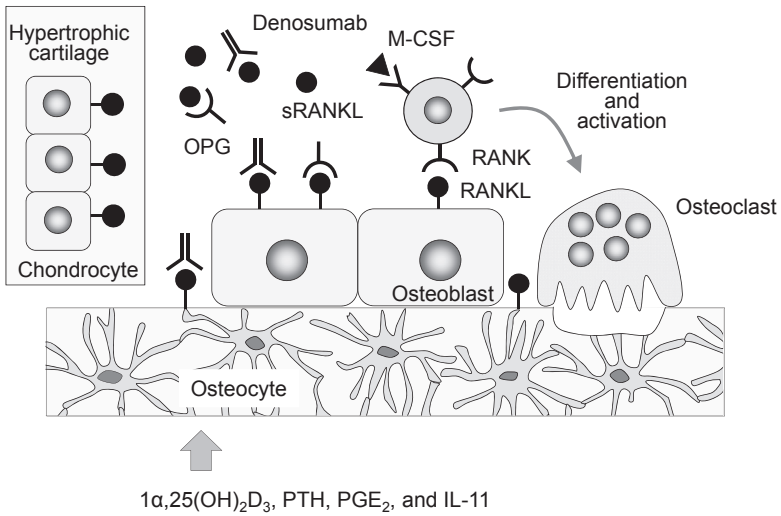

FIGURE 5.2 Schematic representation of osteoclast differentiation and activation. Receptor activator of NF-κB ligand (*RANKL*) expressed by osteoblasts, osteocytes, and hypertrophic chondrocytes supports osteoclast differentiation in the presence of macrophage colony-stimulating factor (*M-CSF*). Osteotropic factors such as 1α,25-dihydroxyvitamin D_3 (*1α,25(OH)$_2$D$_3$*), parathyroid hormone (*PTH*), prostaglandin E_2 (*PGE$_2$*), and interleukin 11 (*IL-11*) stimulate the expression of RANKL in the aforementioned cells. Osteoclast precursors express M-CSF receptor and RANK, and differentiate into osteoclasts in response to both cytokines. The membrane-associated and soluble (s) forms of RANKL support osteoclastogenesis. Osteoprotegerin (*OPG*) secreted by osteoblastic cells and other cells, and denosumab, an anti-RANKL antibody, inhibit osteoclast differentiation and activation by suppressing the RANKL−RANK interaction.

biology was established in a series of experiments on *op/op* (osteopetrosis) mice. Impaired bone resorption in *op/op* mice is associated with a marked reduction in the number of osteoclasts in skeletal tissues (Wiktor-Jedrzejczak et al., 1982). A point mutation in the coding region of the *M-CSF* gene was found in *op/op* mice, leading to the stop codon TGA, 21 bp downstream (Yoshida et al., 1990; Wiktor-Jedrzejczak et al., 1990). The administration of recombinant M-CSF to animals cured their osteopetrotic phenotype, confirming the essential role of this cytokine in the differentiation of osteoclasts (Felix et al., 1990; Kodama et al., 1991b). Hematopoietic cells derived from *op/op* mice differentiated into osteoclasts in a coculture with normal mouse-derived osteoblastic cells. On the other hand, *op/op* mouse-derived osteoblastic cells failed to support osteoclast formation in the coculture with normal hematopoietic cells (Kodama et al., 1991a; Takahashi et al., 1991). These findings further confirmed that M-CSF produced by osteoblastic cells is essentially involved in osteoclastogenesis.

Osteoprotegerin and RANKL

RANKL is a member of the tumor necrosis factor (TNF) superfamily (encoded by TNFSF11) (Anderson et al., 1997), which was originally identified as the T-cell-derived immunomodulatory cytokine, TNF-related activation-induced cytokine (TRANCE), in 1997 (Wong et al., 1997). RANKL is expressed in activated T cells and promotes the survival of dendritic cells by binding to RANK (encoded by *TNFRSF11a*), resulting in enhanced dendritic cell−mediated T cell proliferation. The discovery that RANKL is an essential factor for osteoclastogenesis was made by two independent groups at similar times. In 1997, Simonet et al. cloned a new member of the TNF receptor (TNFR) superfamily (encoded by *TNFRSF11b*) (Simonet et al., 1997). This protein lacked a transmembrane domain, indicating that it is a secreted member of the TNFR family. The hepatic expression of this protein in transgenic mice resulted in severe osteopetrosis. This protein was named "osteoprotegerin," reflecting its protection of bone. Tsuda et al. (1997) independently isolated a novel protein termed "osteoclastogenesis inhibitory factor" (OCIF) from the conditioned medium of a human fibroblast culture. The amino acid sequence of OCIF was identical to that of OPG (Tsuda et al., 1997; Yasuda et al., 1998a). OPG strongly inhibited osteoclast formation induced by 1α,25-dihydroxyvitamin D_3 (1α,25(OH)$_2$D$_3$), PTH, PGE_2, or IL-11 in the coculture. Using OPG as a probe, two groups simultaneously isolated a cDNA with an open reading frame encoding 316 amino acid residues from murine cell lines, and ODF and OPG ligand were found to be identical to RANKL (Yasuda et al., 1998b; Lacey et al., 1998). The expression of RANKL was induced in osteoblastic cells in response to 1α,25(OH)$_2$D$_3$, PTH, PGE_2, and IL-11. The combined treatment of hematopoietic cells with M-CSF and the soluble form of RANKL (sRANKL) induced osteoclast differentiation in vitro in the absence of supporting osteoblastic cells. Moreover, the targeted

disruption of RANKL or RANK induced severe osteopetrosis in mice due to a defect in osteoclast differentiation (Kong et al., 1999; Dougall et al., 1999). RANKL was also shown to activate osteoclast function. Loss-of-function mutations in the genes encoding *RANK*, *OPG*, and *RANKL*, and gain-of-function mutations in the *RANK* gene, were detected in humans (Kobayashi et al., 2009; Crockett et al., 2011). These findings confirmed the essential role of the RANKL–RANK pathway in osteoclast development and function both in vitro and in vivo.

Osteoclastogenesis supported by RANKL

Osteocytes are osteoblast-derived cells embedded in the bone matrix. Osteocytes are connected to one another by gap junctions via cellular processes. Studies have shown that osteocytes also regulate osteoclast formation through the production of RANKL (Nakashima et al., 2011; Xiong et al., 2011). The deletion of RANKL specifically in osteoblastic cells using *osterix*-Cre and *osteocalcin*-Cre resulted in osteopetrosis with impaired tooth eruption, a typical symptom of severe osteopetrosis (Xiong et al., 2011). On the other hand, when *RANKL* was deleted in an osteocyte-specific manner using *dentin matrix protein 1*-Cre, bone resorption was suppressed 6 months after birth and bone mass increased. These findings indicated that RANKL expressed by osteocytes plays an important role in the process of bone remodeling. In addition, hypertrophic chondrocyte-derived RANKL was shown to be important for bone development. An osteopetrotic feature was developed when RANKL was disrupted in hypertrophic chondrocytes using *type X collagen*-Cre mice (Xiong et al., 2011). RANKL was shown to be strongly expressed by T lymphocytes. However, osteopetrosis does not develop with a T-cell-specific *RANKL* deficiency. Based on these findings, it was concluded that RANKL expressed by osteoblasts, osteocytes, and hypertrophic chondrocytes is important for the regulation of bone resorption in mice.

RANKL is produced as an integral membrane protein, and is also cleaved to produce sRANKL (Lacey et al., 1998). Previous studies using the coculture system suggested that the membrane-bound form of RANKL is required for osteoclast formation. However, transgenic mice overexpressing sRANKL or mice injected with sRANKL exhibited increased resorption. To establish the relative importance of membrane-bound versus sRANKL, mice expressing only membrane-bound form of RANKL were produced. The membrane-bound form of RANKL was shown to exert almost all of the functions of RANKL in bone (Xiong et al., 2017).

The anti-RANKL antibody denosumab was developed to suppress excessive bone resorption. Denosumab is a fully humanized monoclonal antibody with affinity and specificity for human RANKL (Lacey et al., 2012). Denosumab blocks the binding of RANKL to RANK expressed on osteoclast precursors and osteoclasts, causing the suppression of osteoclast differentiation and activation. Denosumab is used in the treatment of patients at high risk of bone fractures, including women and men with osteoporosis, men with prostate cancer, and women with breast cancer. Furthermore, denosumab is used to prevent skeletal-related events in patients with bone metastases originating from solid tumors. The roles of RANKL, OPG, and denosumab in osteoclast differentiation and activation are summarized in Fig. 5.2.

RANKL is expressed not only in bone, but also in mammary glands, the lymph nodes, the thymus, and intestinal Peyer's patches (Lacey et al., 1998). Subsequent studies demonstrated that the RANKL–RANK signal is essentially involved in mammary gland development (Fata et al., 2000), lymph node formation (Kong et al., 1999; Yoshida et al., 2002), the elimination of self-reactive T cells in the thymus (Rossi et al., 2007; Akiyama et al., 2008), and microfold cell differentiation in Peyer's patches (Knoop et al., 2009; Kanaya et al., 2012). It was shown in 2017 that the membrane-bound form of RANKL plays an essential role in microfold cell differentiation in intestinal Peyer's patches (Nagashima et al., 2017).

Signal transduction in osteoclastogenesis

The M-CSF receptor FMS

Osteoclasts develop from monocytic precursors from the hematopoietic lineage. PU.1 induces the expression of the M-CSF receptor FMS and is critical for monocyte–macrophage lineage commitment (Tondravi et al., 1997; Zaidi et al., 2003). Signals via FMS are essential for the induction of osteoclast differentiation (Hamilton, 1997; Feng and Teitelbaum, 2013; Stanley and Chitu, 2014). The receptor FMS has a tyrosine kinase domain in the intracellular region. Signals mediated by FMS are required not only for the proliferation of osteoclast progenitors, but also for the differentiation of postmitotic osteoclast precursors (Tanaka et al., 1993). The binding of M-CSF to FMS induces the autophosphorylation of the receptor at several tyrosine residues within the cytoplasmic domain (Feng et al., 2002; Stanley and Chitu, 2014). This phosphorylation of tyrosine residues recruits signaling molecules such as growth factor receptor–bound protein 2 (GRB2) (Insogna et al., 1997) and phosphatidylinositol 3-kinase (PI3K) (Mandal et al., 2009) during osteoclastogenesis. M-CSF mainly activates two signaling pathways: extracellular signal-regulated kinase (ERK) through GRB2 and a serine/

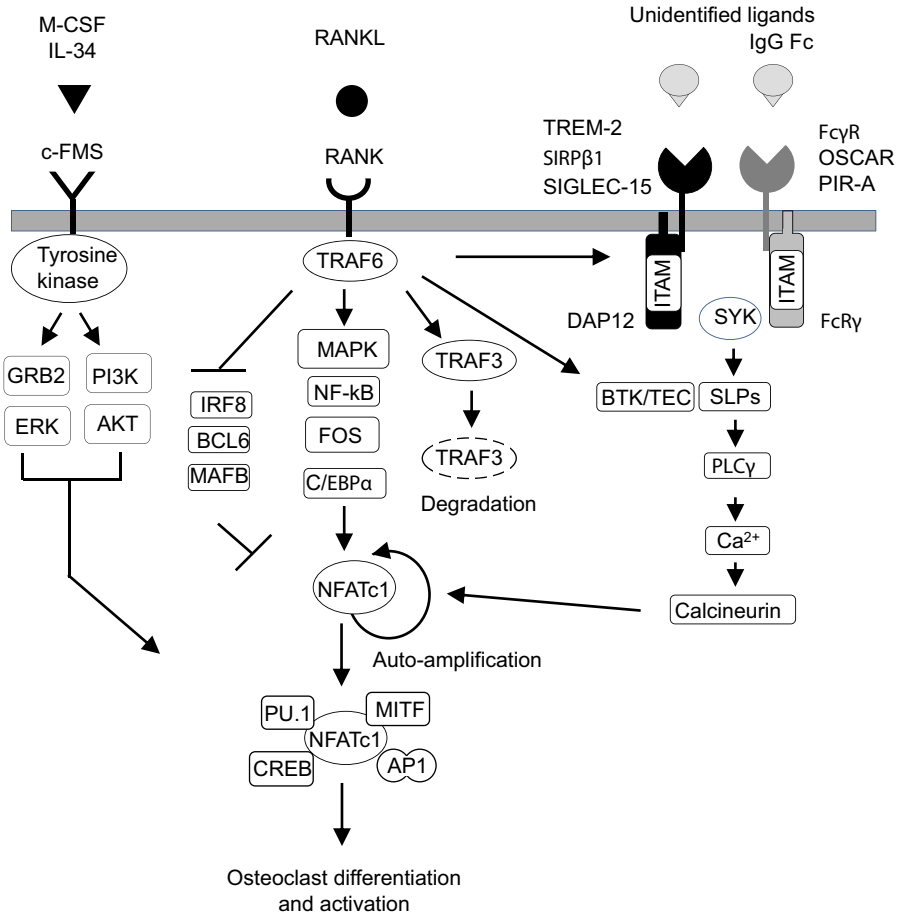

FIGURE 5.3 Signal transduction for osteoclast differentiation and activation. When M-CSF binds to the receptor FMS, the signaling pathways of GRB2−ERK and PI3K−AKT are activated. IL-34 is the second ligand for FMS and induces the same signals as M-CSF. TRAF6 acts as the main adaptor molecule of RANK signaling. TRAF6-mediated signals activate downstream targets such as MAPK, NF-κB, JNK, FOS, and C/EBPα, and ultimately induce the autoamplification of NFATc1. In addition, RANK signals suppress the expression of inhibitory molecules such as IRF8, BCL6, and MAFB. ITAM signaling via immunoglobulin-like receptors is an additional signal that regulates osteoclast differentiation and function. The adaptor proteins DAP12 and FcRγ possess the ITAM sequence and induce ITAM signals. RANK signals also activate ITAM signals. ITAM signals activate SYK, which, in turn, phosphorylates the tyrosine residues of SLPs. RANK signaling activates BTK and TEC. A signaling complex of BTK/TEC and SLPs is formed and activates PLCγ. Activated PLCγ induces the mobilization of intracellular Ca^{2+}, which activates calcineurin to induce the dephosphorylation and autoamplification of NFATc1. Amplified NFATc1 induces the transcription of osteoclast-associated genes in cooperation with PU.1, CREB, and MITF. These signaling cascades induce the differentiation and activation of osteoclasts. *AKT*, serine/threonine kinase; *BCL6*, B cell leukemia/lymphoma 6; *C/EBPα*, CCAAT/enhancer binding protein α; *c-FMS*, M-CSF receptor; *CREB*, cAMP-responsive element binding protein; *DAP12*, DNAX activation protein 12; *ERK*, extracellular signal-regulated kinase; *FcγR*, Fcγ receptor; *FcRγ*, Fc receptor common γ subunit; *GRB2*, growth factor receptor−bound protein 2; *IgG Fc*, immunoglobulin G Fc region; *IL-34*, interleukin-34; *IRF8*, interferon regulatory factor 8; *ITAM*, immunoreceptor tyrosine-based activation motif; *MAPK*, mitogen-activated protein kinase; *M-CSF*, macrophage colony-stimulating factor; *MITF*, microphthalmia-associated transcription factor; *NF-κB*, nuclear factor κB; *NFATc1*, nuclear factor of activated T cells 1; *OSCAR*, osteoclast-associated receptor; *PI3K*, phosphatidylinositol 3-kinase; *PIR-A*, paired immunoglobulin-like receptor A; *PLCγ*, phospholipase Cγ; *RANK*, receptor activator of NF-κB; *RANKL*, receptor activator of NF-κB ligand; *SIGLEC-15*, sialic acid-binding immunoglobulin-like lectin 15; *SIRPβ1*, signal-regulatory protein β1; *SLP*, SRC homology 2 domain-containing leukocyte protein; *SYK*, spleen tyrosine kinase; *TRAF*, tumor necrosis factor receptor-associated factor; *TREM-2,* triggering receptor expressed on myeloid cells 2.

threonine kinase, AKT, through PI3K (Feng and Teitelbaum, 2013; Stanley and Chitu, 2014). Both signaling pathways are considered to be involved in M-CSF-supported osteoclastogenesis. Signals mediated by GRB2 and PI3K are involved in the regulation of cytoskeletal organization in osteoclasts as well as osteoclast differentiation. Signal transduction that induces osteoclast differentiation and activation is summarized in Fig. 5.3.

M-CSF-deficient *op/op* mice exhibit monocytopenia and osteopetrosis (Wiktor-Jedrzejczak et al., 1982). However, several unusual phenomena have been observed in *op/op* mice. Osteoclasts are completely absent in young *op/op* mice, but appear in aged mice (Begg et al., 1993). The osteopetrotic characteristics of FMS-deficient mice are more severe than those

of *op/op* mice (Dai et al., 2002). F4/80-positive macrophages exist in the splenic red pulp in *op/op* mice as well as in wild-type mice, and their number is regulated by a mechanism independent of M-CSF (Cecchini et al., 1994; Yamamoto et al., 2008). These phenomena may be explained by the discovery of IL-34, a second ligand for FMS (Lin et al., 2008; Nakamichi et al., 2013; Stanley and Chitu, 2014). The amino acid sequence of IL-34 is different from that of M-CSF; however, IL-34 binds to FMS and induces the same effects as M-CSF. IL-34 cannot substitute for M-CSF in vivo because its localization differs from that of M-CSF. IL-34 is strongly expressed in the spleen, but not in bone. On the other hand, M-CSF is strongly expressed in bone and the spleen. Osteoclast precursors were previously shown to be present in the spleen, but not in bone in *op/op* mice (Nakamichi et al., 2012). Splenectomy blocked M-CSF-induced osteoclastogenesis in *op/op* mice. Osteoclasts appeared in aged *op/op* mice with the upregulation of IL-34 expression in bone. Splenectomy in *op/op* mice also blocked the age-associated appearance of osteoclasts. These findings suggest that IL-34 plays a pivotal role in maintaining the splenic reservoir of osteoclast precursors, which are transferred from the spleen to bone via the bloodstream in response to diverse stimuli, in *op/op* mice. The administration of FYT720, a sphingosine-1-phosphate agonist, has also been shown to promote the egress of osteoclast precursors from hematopoietic tissues into the bloodstream (Ishii et al., 2009). These findings suggest that some osteoclast precursors are circulating in the bloodstream.

RANK

RANK-mediated signals are also essential for the induction of osteoclast differentiation and function (Fig. 5.3). When RANKL binds to RANK, RANK recruits TRAFs, which are adapter molecules that induce osteoclastogenesis (Wong et al., 1998). TRAFs 1, 2, 3, 5, and 6 are recruited to the cytoplasmic tail of RANK. Among them, the TRAF6-mediated signal is considered to induce osteoclast differentiation and function because TRAF6-deficient mice show severe osteopetrosis with a decreased number of osteoclasts (Lomaga et al., 1999; Naito et al., 1999; Walsh et al., 2015). Osteoclast precursors from TRAF6-deficient mice fail to differentiate into osteoclasts even in the presence of RANKL (Gohda et al., 2005). RANK-mediated signals activate downstream signals such as p38 mitogen-activated protein kinase (MAPK), Jun N-terminal kinase (JNK), and FOS (Wagner and Eferl, 2005; Takayanagi, 2007). These signals ultimately induce the expression of the transcription factor nuclear factor of activated T cells 1 (NFATc1), a master transcription factor that plays a pivotal role in osteoclastogenesis (Ishida et al., 2002; Takayanagi et al., 2002). This robust induction of NFATc1 is based on an autoamplifying mechanism affected through the persistent calcium signal−mediated activation of NFATc1. NFATc1 binds to NFAT-binding sites on its own promoter, constituting a positive feedback loop. In the nucleus, NFATc1 cooperates with other transcription factors, such as PU.1, cAMP-responsive element binding protein, and microphthalmia-associated transcription factor, to induce various osteoclast-specific genes (Sato et al., 2006; Okamoto et al., 2017). *CCAAT/enhancer* binding protein α (C/EBPα) is a key molecular determinant in myeloid lineage commitment. C/EBPα is strongly expressed in osteoclasts and has been identified as a critical *cis*-regulatory element-binding protein in the cathepsin K promoter (Chen et al., 2013). C/EBPα-deficient mice exhibit severely blocked osteoclastogenesis, suggesting that C/EBPα is a key regulator of osteoclast lineage commitment. Peroxisome proliferator-activated receptor γ is also reported to be important for osteoclast differentiation (Okazaki et al., 1999; Wan et al., 2007).

On the other hand, it is important for osteoclastogenesis to exclude factors that inhibit osteoclast differentiation. Interferon regulatory factor 8 (IRF8), a transcription factor expressed in immune cells, is a key inhibitory molecule for osteoclastogenesis (Zhao et al., 2009). IRF8 was found to inhibit osteoclast formation under physiological and pathological conditions, and was downregulated in response to a RANKL stimulation. RANKL also upregulates the expression of the transcription factor B-lymphocyte-induced maturation protein-1 (BLIMP1) (Nishikawa et al., 2010). BLIMP1 then suppresses the expression of other inhibitory transcription factors, such as B cell leukemia/lymphoma 6 and MAFB (Miyauchi et al., 2010). Thus, RANK signaling induces the downregulation of negative regulators together with the upregulation of positive regulators for osteoclastogenesis (Fig. 5.3).

Tumor necrosis factor receptors

TNFα together with M-CSF has been shown to induce osteoclastogenesis in the absence and presence of RANKL (Kobayashi et al., 2000; Zhang et al., 2001). Osteoclast formation induced by TNFα was inhibited by the addition of respective antibodies against TNFR type I (TNFRI, p55) and TNFR type II (TNFRII, p75), but not by OPG. This finding suggests that TNFα stimulates osteoclastogenesis via TNFRs. Osteoclast precursors obtained from RANK- or TRAF6-deficient mice differentiate into osteoclasts when stimulated with TNFα in the presence of cofactors such as transforming growth factor β (Kim et al., 2005). However, the osteoclastogenesis-inducing ability of TNFα is markedly weaker than that of RANKL. Studies have revealed the mechanisms by which TNF induces the differentiation of osteoclasts

(Boyce et al., 2015). When osteoclast precursors prepared from IRF8-deficient mice were used in an osteoclast formation assay, TNFα induced osteoclastogenesis as strongly as RANKL. Recombinant recognition sequence binding protein at the Jκ site (RBP-J) is a DNA-binding protein that functions as a transcriptional repressor or activator depending on the partner proteins. RBP-J strongly suppressed TNFα-induced osteoclastogenesis and inflammatory bone resorption (Zhao et al., 2012). In the absence of RBP-J, TNFα effectively induced osteoclastogenesis and bone resorption in RANK-deficient mice (Yao et al., 2009). In contrast to TRAF6, TRAF3 inhibits osteoclast formation by moderating nuclear factor κB (NF-κB) signaling (Xiu et al., 2014). TRAF3 suppresses the conversion of NF-κB p100 (inhibitory form) into NF-κB p52 (active form) through the degradation of NF-κB-inducing kinase, suggesting that TRAF3 signals induce the accumulation of inhibitory NF-κB p100. RANKL induced the degradation of inhibitory TRAF3 and NF-κB p100 in osteoclast precursors. In contrast, TNFα increased the expression of TRAF3 in osteoclast precursors (Yao et al., 2017). TNFα induced osteoclast formation to the same level as RANKL when NF-κB p100 or TRAF3 was deleted in RANK-deficient osteoclast progenitors. A TNFα injection strongly induced osteoclastogenesis in vivo in mice deficient in RANK together with NF-κB p100 (Yao et al., 2009; Boyce et al., 2015). These findings suggest that TNFα induces osteoclast formation at a similar level compared with RANKL through TNFR under specific conditions, and also that RANKL efficiently eliminates endogenous inhibitory molecules in osteoclast precursors.

ITAM costimulatory signals

Calcium signals

Immunoreceptor tyrosine-based activation motif (ITAM) signaling via immunoglobulin-like receptors is an additional signal regulating osteoclast differentiation and function (Koga et al., 2004; Mocsai et al., 2004; Humphrey and Nakamura, 2016, Okamoto et al., 2017). The adaptor proteins DNAX activation protein 12 (DAP12) and Fc receptor common γ subunit (FcRγ) possess the ITAM sequence (Fig. 5.3). DAP12 is coupled with triggering receptor expressed on myeloid cells 2, signal-regulatory protein β1, and sialic acid-binding immunoglobulin-like lectin 15 (SIGLEC-15), while FcRγ is coupled with osteoclast-associated receptor (Kim et al., 2002; Barrow et al., 2011) and paired immunoglobulin-like receptor A as well as Fcγ receptor (FcγR). DAP12- and FcRγ-mediated ITAM signals activate spleen tyrosine kinase (SYK). RANK-mediated signals also activate ITAM signals as well as MAPK, NF-κB, and FOS signaling. Activated SYK then phosphorylates the tyrosine residues of SRC homology 2 domain-containing leukocyte protein (SLP) adapter molecules such as B cell linker and SLP-76 (Shinohara et al., 2008; Lee et al., 2008). TEC and BTK are tyrosine kinases that belong to the TEC family. RANK signaling activates BTK and TEC by tyrosine phosphorylation. Mice lacking both BTK and TEC showed severe osteopetrosis caused by a defect in bone resorption. ITAM and RANK signaling results in the formation of a signaling complex of BTK/TEC and SLPs. This complex activates phospholipase Cγ (PLCγ), thereby increasing the mobilization of intracellular Ca^{2+}. This increase in intracellular Ca^{2+} activates calcineurin, a Ca^{2+}-dependent serine/threonine phosphatase. Calcineurin induces the dephosphorylation of NFATc1 and promotes its nuclear translocation to enhance the autoamplification of NFATc1. Amplified NFATc1 then induces the transcription of osteoclast-associated genes. Thus, the ITAM signal cooperates with the RANK-mediated signal to induce NFATc1.

Mice lacking both FcRγ and DAP12 exhibit severe osteopetrosis due to impaired osteoclast differentiation, confirming that ITAM signaling is an essential signal promoting osteoclast differentiation. Patients with Nasu−Hakola disease, a rare recessive genetic disease found in Japanese and Finnish people, have cyst formation at the limb epiphysis and exhibit multiple pathological fractures (Humphrey and Nakamura, 2016). Point mutations and defects in the *DAP12* gene have been reported in this disease.

Osteoclast differentiation is also induced from osteoclast precursors deficient in inositol 1,4,5-trisphosphate receptor type 2, which is essential for calcium mobilization. Therefore, there appears to be an osteoclast differentiation pathway that is not dependent on calcium ions (Kuroda et al., 2008; Oikawa et al., 2013). Several common pathways of bone metabolism and the immune system have been elucidated, and the term "osteoimmunology" has been proposed and widely used to obtain a clearer understanding of the regulation of osteoclastogenesis.

SIGLEC-15 and FcγR

Studies have revealed that SIGLEC-15 and FcγR play important roles in osteoclastic bone resorption (Fig. 5.4). SIGLEC family members are sialic acid-binding receptors that are primarily expressed by immune cells. SIGLEC-15 is the only SIGLEC highly conserved throughout vertebrate evolution (Angata et al., 2007). SIGLEC-15 was identified as a gene that is strongly expressed in human osteoclastoma (giant cell tumor of bone) (Hiruma et al., 2011) and also as a gene product

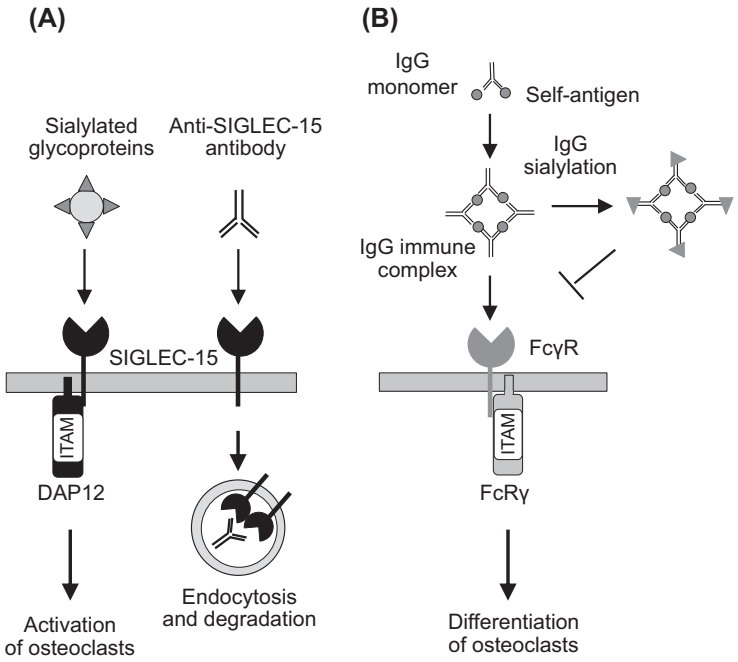

FIGURE 5.4 SIGLEC-15- and FcγR-mediated signaling. (A) Sialic acid-binding immunoglobulin-like lectin 15 (*SIGLEC-15*)-mediated signals. SIGLEC-15 is a sialic acid-binding receptor associated with DNAX activation protein 12 (*DAP12*). It activates spleen tyrosine kinase via DAP12 and promotes the bone resorptive function of osteoclasts. Osteoclasts lacking SIGLEC-15 cannot form actin rings. When an anti-SIGLEC-15 antibody is administered to mice, bone mass increases due to the suppression of bone resorption. Binding of the antibody to SIGLEC-15 induces the dimerization of SIGLEC-15, rapid internalization, and lysosomal degradation. **(B) Fcγ receptor (*FcγR*)-mediated signals.** Although immunoglobulin G (*IgG*) antibodies generally exist as monomers, IgG immune complexes (ICs) are formed in inflammation and autoimmune diseases. IgG ICs promote osteoclast formation via FcγR. The Fc portion of the IgG antibody undergoes sugar chain modifications, and sialic acid is added to a part of its end. Sialylated IgG ICs attenuate its ability to bind to FcγR. *FcRγ*, Fc receptor common γ subunit; *ITAM*, immunoreceptor tyrosine-based activation motif.

induced by NFATc1 (Ishida-Kitagawa et al., 2012). SIGLEC-15 associates with DAP12. SIGLEC-15-deficient mice exhibited osteopetrosis with the suppression of osteoclastic bone resorption. TRAP-positive osteoclasts were detected in SIGLEC-15-deficient mice at levels similar to those in wild-type mice, suggesting that SIGLEC-15 plays a role in osteoclast function (Hiruma et al., 2013; Kameda et al., 2013, 2015). Osteoclasts derived from SIGLEC-15-deficient mice could not form actin rings. In an antigen-induced arthritis model, the degree of periarticular bone loss in the proximal tibia is significantly lower in SIGLEC-15-deficient mice than in wild-type mice (Shimizu et al., 2015). When an anti-SIGLEC-15 neutralizing antibody was administered to mice, bone mass increased due to the suppression of bone resorption (Stuible et al., 2014; Fukuda et al., 2017). The binding of a neutralizing antibody to SIGLEC-15 induces the dimerization of the receptor, rapid internalization, and lysosomal degradation. SIGLEC-15-deficient mice also show resistance to bone loss by ovariectomy. SIGLEC-15-mediated signals activate PI3K and AKT together with PLCγ in osteoclasts. The ligand of SIGLEC-15 is proposed to be a glycoprotein having sialic acid that has not yet been identified. SIGLEC-15 may be a major target for the treatment of bone diseases with excessive bone resorption.

Autoantibody production and IgG immune complex (IC) formation are frequently observed in autoimmune diseases associated with bone loss. Studies have demonstrated that, under pathological conditions such as autoimmune diseases associated with hypergammaglobulinemia, IgG ICs enhance osteoclast formation through FcγR and promote bone resorption (Fig. 5.4) (Negishi-Koga et al., 2015; Harre et al., 2015). The Fc portion of the IgG antibody undergoes various sugar chain modifications. Sialic acid is added to the sugar chain terminal of the Fc portion. This sialylated IgG attenuates its ability to bind to FcγR. The desialylated, but not sialylated, human IgG IC promoted osteoclast formation in vitro. The relationship between the sialylation status of IgG and bone mass was examined in patients with rheumatism. Bone mass was found to decrease as the sialylation rate of IgG in these patients became lower. The administration of the sialic acid precursor *N*-acetyl-D-mannosamine to animals promotes the sialylation of IgG ICs, and suppresses IgG IC-enhanced osteoclast formation. These results demonstrate that ITAM costimulatory signals are important for regulating osteoclast differentiation and function.

WNT signals

Canonical WNT signals

WNT proteins activate β-catenin-dependent canonical and β-catenin-independent noncanonical signaling pathways. In the absence of WNT ligands, β-catenin is phosphorylated by a degradation complex composed of axin, adenomatous polyposis coli, glycogen synthase kinase 3β, and casein kinase 1. Phosphorylated β-catenin is degraded by the ubiquitin proteasome, and cytosolic β-catenin is then maintained at a low level. When the WNT ligand binds to a receptor complex composed of frizzled receptor and low-density lipoprotein receptor-related protein 5/6, the activity of the degradation complex is suppressed, and β-catenin then accumulates in the cytoplasm. Accumulated β-catenin translocates to the nucleus. Nuclear β-catenin together with the transcription factors T cell factor and lymphoid enhancer factor (LEF) induces the transcription of the target gene.

Glass et al. (2005) showed the importance of WNT/β-catenin signals in bone resorption in vivo using genetic approaches. Mice expressing the constitutively active form of β-catenin in mature osteoblasts had an increased bone mass with impaired osteoclast formation. The expression of OPG was increased in the long bones of these mice. The LEF-1 binding sequence is found in the promoter region of the *OPG* gene, and the LEF-1/β-catenin complex induces the expression of OPG. Thus, the activation of WNT/β-catenin signals induces the expression of OPG in mature osteoblasts and markedly inhibits bone resorption. The roles of β-catenin-dependent canonical WNT signaling and β-catenin-independent noncanonical WNT signals that regulate osteoclast differentiation and activation are summarized in Fig. 5.5 (Kobayashi et al., 2016).

WNT3A, a typical canonical WNT ligand, inhibited $1\alpha,25(OH)_2D_3$-induced osteoclast formation in a coculture, but not RANKL-induced osteoclast formation in osteoclast precursor cultures (Yamane et al., 2001). This finding indicates that WNT3A suppresses osteoclastogenesis through the expression of OPG in osteoblasts. The concept that WNT/β-catenin signals inhibit osteoclastogenesis through the expression of OPG was confirmed in a study using OPG-deficient mice (Kobayashi et al., 2015). WNT3A did not inhibit $1\alpha,25(OH)_2D_3$-induced osteoclast formation in a coculture of normal bone marrow cells with OPG-deficient osteoblastic cells.

Moverare-Skrtic et al. (2014) reported important roles for WNT16 in bone mass. WNT16 mRNA was strongly expressed in cortical bone among the various tissues tested, including trabecular bone, suggesting that WNT16 regulates bone formation and resorption in cortical bone. WNT16-deficient mice showed a marked decrease in cortical bone, but not in cancellous bone. WNT16 induced the expression of OPG through the activation of WNT/β-catenin signaling in MC3T3-E1 osteoblastic cells. Furthermore, osteoclast formation was enhanced in cocultures of WNT16-deficient osteoblastic cells with bone marrow cells, suggesting that WNT16 induced OPG through the activation of WNT/β-catenin signals in osteoblastic cells. WNT16 has also been shown to affect osteoclast precursors by activating noncanonical WNT signals. This topic is discussed later.

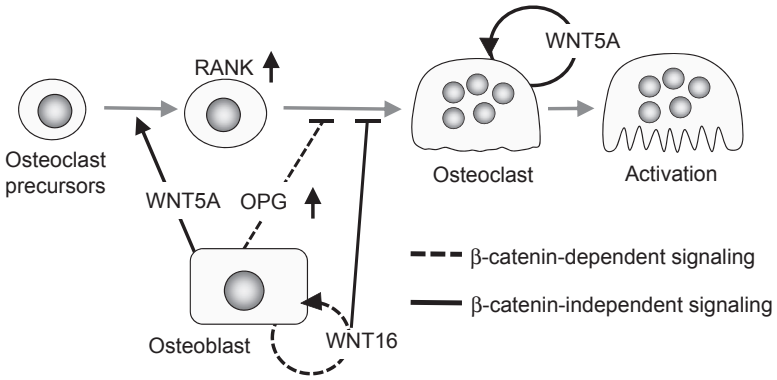

FIGURE 5.5 Regulation of osteoclast differentiation and activation by WNT signals. WNT proteins activate β-catenin-dependent canonical and β-catenin-independent noncanonical signaling pathways. Mice expressing constitutively active β-catenin in mature osteoblasts exhibit an increased bone mass with impaired osteoclast formation. Canonical WNT signals in osteoblastic cells enhance the expression of osteoprotegerin (*OPG*) and inhibit bone resorption. WNT16 is strongly expressed in cortical bone. WNT16 suppresses osteoclast differentiation through the β-catenin-dependent canonical pathway, which enhances OPG production, in osteoblastic cells. WNT16 also acts on osteoclast precursors and inhibits osteoclastic differentiation through noncanonical WNT signaling. WNT5A is a typical ligand for noncanonical WNT signals. WNT5A secreted by osteoblastic cells promotes receptor activator of NF-κB (*RANK*) expression in osteoclast precursors through receptor tyrosine kinase orphan receptor 2 and promotes their osteoclastic differentiation. WNT5A expressed by osteoclasts also induces osteoclast resorptive activity.

The roles of WNT/β-catenin signals in osteoclast precursors have also analyzed. Wei et al. (2011) developed mice expressing a constitutively active form of β-catenin (CA β-cat) or deleted the *β-catenin* gene (Δβ-cat) in osteoclast lineage cells. Both mice with CA β-cat and Δβ-cat osteoclast lineage cells exhibited osteopetrotic phenotypes due to decreased bone resorption. This study showed that β-catenin signals are required for the proliferation of osteoclast precursors, while the sustained activation of β-catenin signals inhibits the differentiation of precursors into osteoclasts. These findings suggest that finely balanced β-catenin signals in osteoclast precursors regulate osteoclastogenesis (Fig. 5.5).

Noncanonical WNT signals

WNT5A is a typical ligand that activates β-catenin-independent noncanonical WNT signals (Mikels et al., 2009) (Fig. 5.5). Receptor tyrosine kinase orphan receptor 1/2 (ROR1/2), coreceptors of WNT proteins, mainly mediate the action of WNT5A. WNT5A secreted by osteoblastic cells promotes osteoclast formation through ROR2, but not ROR1 (Maeda et al., 2012). The conditional deletion of ROR2 in osteoclast precursors and that of WNT5A in osteoblastic cells resulted in impaired osteoclast formation, suggesting that WNT5A−ROR2 signals between osteoblastic cells and osteoclast precursors promote osteoclast differentiation. WNT5A upregulated the expression of RANK in osteoclast precursors through the activation of JNK, thereby enhancing RANKL-induced osteoclast formation.

WNT16 suppressed osteoclast differentiation through the activation of β-catenin-dependent canonical pathways in osteoblastic cells. In contrast, the treatment of osteoclast precursors with WNT16 did not activate WNT/β-catenin signals, but suppressed RANKL-induced NF-κB activation and NFATc1 expression in osteoclast precursors (Moverare-Skrtic et al., 2014; Gori et al., 2015). Furthermore, WNT4 was also reported to inhibit RANKL-induced activation of NF-κB, which in turn suppressed osteoclast formation in a β-catenin-independent manner (Yu et al., 2014). WNT3A activated protein kinase A signals and suppressed the nuclear translocation of NFATc1 in osteoclast precursors, thereby inhibiting osteoclast formation (Weivoda et al., 2016). Thus, WNT16, WNT4, and WNT3A inhibit osteoclast formation through β-catenin-independent noncanonical WNT signals.

The expression of WNT5A and ROR2 was increased in osteoclast precursors during osteoclastic differentiation, suggesting that WNT5A regulates osteoclast function as well as osteoclast differentiation (Uehara et al., 2017). Osteoclast-specific *ROR2* conditional knockout (ROR2 cKO) mice exhibited impaired bone resorption with defects in actin ring formation, but with normal osteoclast formation. The overexpression of the constitutively active form of RHOA, but not that of RAC1, a small GTPase of the RHO family, rescued the impaired bone-resorbing activity of *ROR2* cKO osteoclasts. Osteoclasts strongly expressed protein kinase N3 (PKN3), a RHO effector. *PKN3*-deficient mice exhibited the high bone mass phenotype with the impaired bone-resorbing activity of osteoclasts. SRC activity was weaker in *ROR2* cKO and PKN3-deficient osteoclasts than in wild-type osteoclasts. These findings indicate that WNT5A promotes the bone-resorbing activity of osteoclasts through the ROR2−RHOA−PKN3−SRC signaling axis. The WNT5A−ROR2 signal was also found to promote the invasion of osteosarcoma cells through the activation of SRC and expression of MMP13. These findings suggest that the WNT5A−ROR2 signal plays a role in the degradation of extracellular matrices by activated osteoclasts (Fig. 5.5). Thus, the WNT5A−ROR2 signal in osteosarcomas as well as osteoclasts is critical for degrading extracellular matrices.

Induction of osteoclast function

Adhesion signals

For osteoclasts to become polarized, adhesion signals and cytokine signals need to be simultaneously transmitted into osteoclasts. The induction of osteoclast function begins with the adhesion of osteoclasts to the bone matrix via vitronectin receptors (αVβ3). Adhesion signals transmitted into osteoclasts are summarized in Fig. 5.6. Vitronectin receptors recognize the RGD sequence of extracellular matrix proteins in bone. The targeted disruption of SRC in mice induced osteopetrosis (Soriano et al., 1991). It was also revealed that osteoclasts express high levels of SRC and that SRC-deficient osteoclasts have defects in ruffled border formation (Tanaka et al., 1992; Boyce et al., 1992). Proline-rich tyrosine kinase 2 (PYK2) was identified as a major adhesion-dependent tyrosine kinase in osteoclasts. In osteoclasts derived from SRC-deficient mice, the tyrosine phosphorylation and kinase activity of PYK2 were markedly reduced (Duong et al., 1998). The adaptor molecule, p130 CRK-associated substrate ($p130^{CAS}$), is highly phosphorylated on tyrosine residues and is stably associated with the oncogene products CRK and SRC. Similar to PYK2, $p130^{CAS}$ is highly tyrosine phosphorylated upon osteoclast adhesion to extracellular matrix proteins (Nakamura et al., 1998; Lakkakorpi et al., 1999). $p130^{CAS}$ is not tyrosine

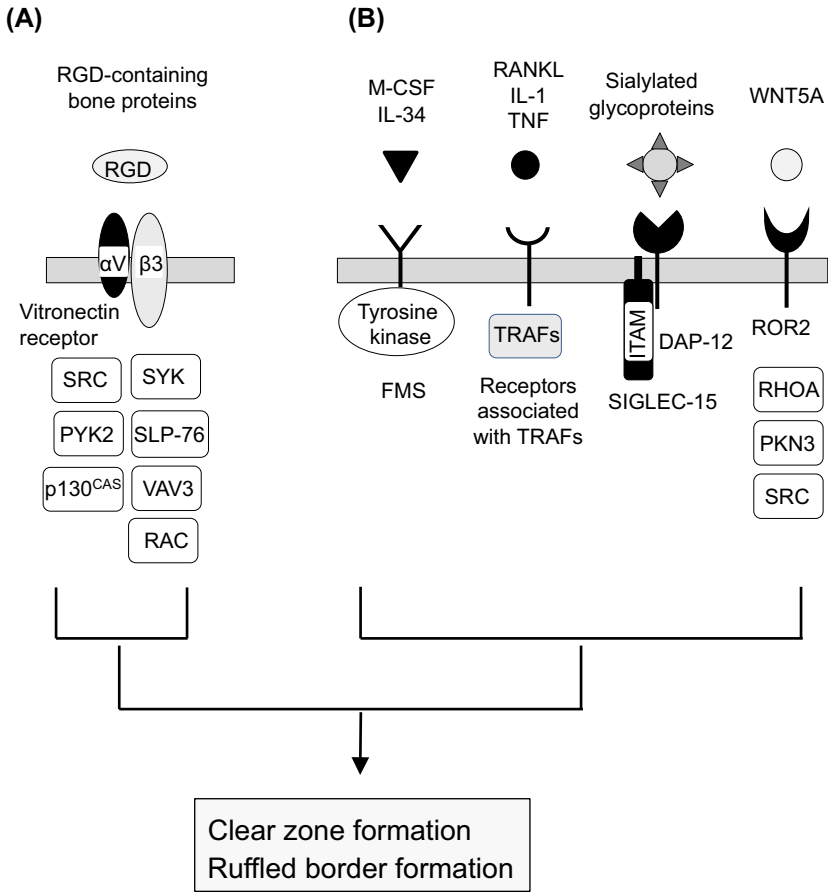

FIGURE 5.6 Signals that induce osteoclast activation. (A) Adhesion signals. The induction of osteoclast function begins with adhesion to the bone matrix via vitronectin receptors (*αVβ3*). Vitronectin receptors recognize the RGD sequence of extracellular matrix proteins in bone. Adhesion signals induce the formation of a signaling complex of SRC, PYK2, and $p130^{CAS}$. This signaling complex induces clear zone formation. Adhesion signals also recruit SLP-76, which functions as an adaptor of VAV3. VAV3 then activates RAC, which participates in αVβ3-mediated cytoskeletal organization in osteoclasts. These adhesion-induced signals are also involved in the induction of the bone-resorbing activity of osteoclasts. **(B) Cytokine signals.** In addition to adhesion signals, cytokine signals need to be transmitted into osteoclasts to induce bone-resorbing activity. M-CSF plays a role in the regulation of bone resorption in collaboration with αVβ3-mediated signals. IL-1 as well as RANKL activates osteoclast function. IL-1 and RANKL use TRAF6 as a signal transducing adaptor. TNFα, which mainly uses TRAF2 as an adaptor, may induce the activation of osteoclasts if each of the endogenous inhibitory molecules is decreased. SIGLEC-15-mediated signals induce the bone-resorbing activity of osteoclasts. WNT5A also promotes the bone-resorbing activity of osteoclasts through the ROR2−RHOA−PKN3−SRC signaling axis. Therefore, adhesion signals and cytokine signals need to be simultaneously transmitted to osteoclasts to induce their bone-resorbing activation. *FMS*, M-CSF receptor; *DAP-12*, DNAX activation protein 12; *IL*, interleukin; *ITAM*, immunoreceptor tyrosine-based activation motif; *M-CSF*, macrophage colony-stimulating factor; *RANKL*, receptor activator of NF-κB ligand; *$p130^{CAS}$*, p130 CRK-associated substrate; *PKN3*, protein kinase N3; *PYK2*, proline-rich tyrosine kinase 2; *ROR2*, receptor tyrosine kinase orphan receptor 2; *SIGLEC-15*, sialic acid-binding immunoglobulin-like lectin 15; *SLP*, SRC homology 2 domain-containing leukocyte protein; *SYK*, spleen tyrosine kinase; *TNF*, tumor necrosis factor; *TRAF*, tumor necrosis factor receptor-associated factor.

phosphorylated in SRC-deficient osteoclasts, indicating that $p130^{CAS}$ is a downstream molecule of SRC. Thus, the three molecules SRC, PYK2, and $p130^{CAS}$ make a complex that plays a role in osteoclast activation (Nakamura et al., 2012).

β3-integrin-null osteoclasts has been shown to be dysfunctional in vivo and in vitro (McHugh et al., 2000; Faccio et al., 2003; Teitelbaum, 2011). VAV3 is a Rho family guanine nucleotide exchange factor. VAV3-deficient osteoclasts showed defective actin cytoskeleton organization and polarization in response to αVβ3 integrin and FMS activation (Faccio et al., 2005). SYK is an upstream regulator of VAV3 in osteoclasts. SYK exerts its effects via intermediaries including SLP adaptor molecules. SLP of 76 kDa (SLP-76) is involved in the SYK-induced activation of VAV3 in osteoclasts (Reeve et al., 2009; Teitelbaum, 2011). Activated VAV3 converts the inactive GDP-bound form of RAC to the active GTP-bound form. RAC then participates in the αVβ3-mediated organization of the osteoclast cytoskeleton. VAV3-deficient mice showed an increased bone mass and were protected from bone loss induced by PTH and RANKL.

Cytokine signals

M-CSF enhances the survival of osteoclasts and also plays a role in the regulation of bone resorption in collaboration with αVβ3-mediated signals (Feng and Teitelbaum, 2013) (Fig. 5.6). The IL-1 receptor (IL-1R) as well as RANK uses TRAF6 as a signal transducing adaptor. IL-1 does not induce osteoclast differentiation, but strongly activates osteoclast function (Thomson et al., 1986; Jimi et al., 1999). Therefore, we considered TRAF6-mediated signals to induce the activation of osteoclasts. However, RANKL stimulation was found to induce the pit-forming activity of TRAF6-deficient osteoclasts when cultured on bone slices (Yao et al., 2017). This finding suggests that a TRAF(s) other than TRAF6 induces the bone-resorbing activity of osteoclasts treated with RANKL. As described previously, TNFα induces the resorptive activity of RANK-deficient osteoclasts in the absence of inhibitory molecules such as NF-κB p100, TRAF3, and RBP-J (Boyce et al., 2015; Zhao et al., 2012). TNFRI and TNFRII mainly use TRAF2 as a signal transducing adaptor. These findings suggest that the TRAF2-mediated signal induces osteoclast activation in the absence of endogenous inhibitory molecules. SIGLEC-15-mediated signals and ROR2-mediated signals in osteoclasts also induce the bone-resorbing activity of osteoclasts. Thus, osteoclast activation is induced through several ligand−receptor systems. These signals appear to cross talk with each other. Importantly, adhesion signals and cytokine signals must be simultaneously transmitted into osteoclasts to induce their resorptive activity (Fig. 5.6).

Characteristics of osteoclast precursors in vivo

RANKL has been considered to influence the site of osteoclast formation because it is expressed by osteoblastic cells. However, when sRANKL is administered to RANKL-deficient mice, osteoclasts are accurately induced in bone (Yamamoto et al., 2006; Takahashi et al., 2010). This is also the case for the administration of M-CSF to *op/op* mice: when M-CSF is administered to M-CSF-deficient *op/op* mice, osteoclasts appear only in bone (Nakamichi et al., 2012). We analyzed the mechanism by which osteoclasts are formed in bone only. Our findings revealed that the lineage-committed precursors that are determined to differentiate into osteoclasts exist in hematopoietic tissues such as bone marrow and the spleen (Mizoguchi et al., 2009; Arai et al., 2012). Lineage-committed precursors are nondividing cells: therefore, we named them "cell cycle-arrested quiescent osteoclast precursors," or qOPs (Muto et al., 2011). As described earlier, qOPs moved from the spleen to bone in *op/op* mice in response to an M-CSF injection. Some qOPs circulate in the bloodstream and settle in bone. qOPs present in bone strongly express RANK. We showed that M-CSF and WNT5A produced by osteoblastic cells induced RANK expression in osteoclast precursors. We named these osteoclast precursors located in bone tissue as "responding osteoclast precursors" (rOPs). rOPs quickly differentiate into osteoclasts without cell cycle progression in response to RANKL. Our hypothesis on osteoclast precursors in vivo is shown in Fig. 5.7.

When TNFα was injected into mice deficient in both RANK and NF-κB p100, osteoclasts formed only in bone. Similarly, a TNFα injection effectively induced osteoclast formation in bone in RBP-J-deficient mice. These findings suggest that if endogenous inhibitory molecules are removed, rOPs differentiate into osteoclasts in response to TNFα. The essential task of RANKL appears to be to effectively eliminate inhibitory molecules in rOPs. We assume that osteoblastic cells play a role in the conversion of qOPs to rOPs. We consider the distribution of rOPs to influence the accurate site of osteoclast formation in vivo.

Conclusion and perspective

Osteoclasts are special cells that secrete hydrochloric acid and proteolytic enzymes from ruffled borders into resorption lacunae and also take up degradation products from ruffled borders into transcytotic vesicles. Degradation products are exocytosed from the FSD. The ruffled border is formed by the fusion of acidified lysosomes to the side of the plasma membrane facing bone. The differentiation of osteoclasts is regulated by M-CSF and RANKL. RANKL expressed by osteoblasts, osteocytes, and hypertrophic chondrocytes, but not by T cells, may support physiological osteoclast formation. In addition to FMS and RANK-mediated signals, ITAM-mediated costimulatory signals are essentially involved in the induction of NFATc1, a master transcription factor for osteoclastogenesis. Canonical and noncanonical WNT signals are important players in the regulation of osteoclast differentiation and function. To induce the resorptive activity of osteoclasts, adhesion signals and cytokine signals must both be simultaneously transmitted into osteoclasts. When RANKL is injected into RANKL-deficient mice, osteoclasts are induced in bone, but not in other tissues. We demonstrate that certain cells such as rOPs are exclusively present in bone. Findings obtained over the past decade have deepened our understanding of osteoclasts. Still, important questions concerning osteoclasts remain as future studies. How do osteoclasts cease bone resorption? Is there a new signaling pathway that controls osteoclast differentiation and function? Is it possible to

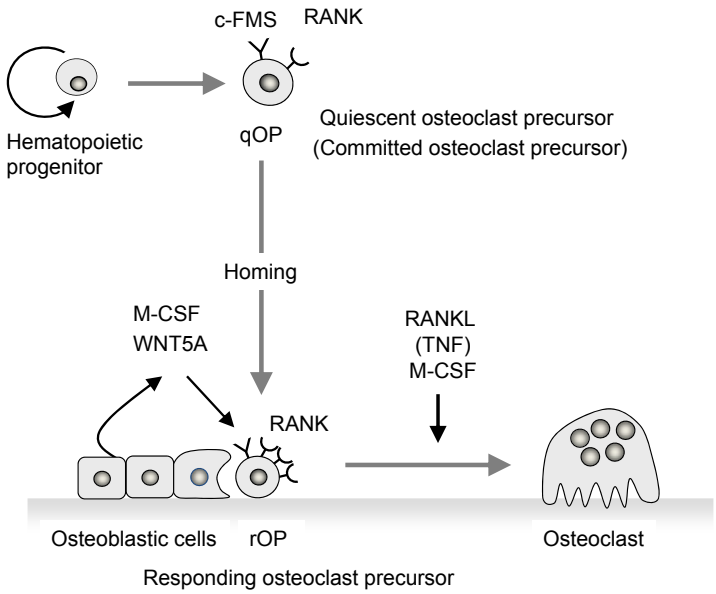

FIGURE 5.7 A hypothetical model of osteoclast differentiation. Osteoclasts are formed from cell cycle−arrested precursors in vivo. These precursor cells are named quiescent osteoclast precursors (*qOPs*). qOPs are the osteoclast lineage−committed precursors derived from hematopoietic tissues. Some qOPs circulate in the bloodstream and settle in bone. qOPs then differentiate into responding osteoclast precursors (*rOPs*). Macrophage colony-stimulating factor (*M-CSF*) and WNT5A produced by osteoblastic cells induce receptor activator of NF-κB (*RANK*) expression in qOPs, suggesting that osteoblastic cells play a role in the appearance of rOPs in bone. rOPs quickly differentiate into osteoclasts in response to receptor activator of NF-κB ligand (*RANKL*). When endogenous inhibitory molecules are removed, rOPs differentiate into osteoclasts in response to tumor necrosis factor α (*TNFα*). When the soluble form of RANKL is administered to RANKL-deficient mice, osteoclasts are induced in bone, but not in other tissues. By assuming rOPs, we may explain why osteoclasts form only in bone. *c-FMS*, M-CSF receptor.

prevent bone loss by adjusting the ITAM and WNT signals? What are the mechanisms integrating adhesion signals and cytokine signals to induce osteoclast activation? How do osteoblastic cells prepare rOPs in bone? These issues are expected to be clarified by future studies.

Chapter outline

Introduction

The osteocyte is the most abundant cell type in bone. There are approximately 10 times as many osteocytes as osteoblasts in adult human bone (Parfitt, 1977), and the number of osteoclasts is only a fraction of the number of osteoblasts. Our current knowledge of osteocytes lags behind what we know of the properties and functions of both osteoblasts and osteoclasts. However, the striking structural design of bone predicts an important role for osteocytes, and novel techniques have allowed this gap in knowledge to shrink rapidly in the past years.

Considering that osteocytes are located inside the bone, not on the bone surface, and spaced regularly throughout the mineralized matrix, and considering their typical morphology of stellate cells, which are connected to one another via long, slender cell processes, a parallel with the nervous system springs to one's mind. Are the osteocytes the "nerve cells" of the mineralized bone matrix, and if so, what are the stimuli that "excite" these cells? Both theoretical considerations and experimental results have strengthened the notion that osteocytes are the pivotal cells in the biomechanical regulation of bone mass and structure (Cowin et al., 1991; Mullender and Huiskes, 1994, 1995; Klein-Nulend et al., 1995b; Tatsumi et al., 2007; Klein-Nulend et al., 2013 [review]). This idea poses many questions that have to be answered. The development of osteocyte isolation techniques, the use of highly sensitive (immuno)cytochemical and in situ hybridization procedures, and the usefulness of molecular biological methods even when only small numbers of cells are available have rapidly increased our knowledge about this least understood cell type of bone, and will certainly continue to do so in the future. The use of transgenic mouse models to perform targeted deletion of genes has provided considerable information on the function and importance of this bone cell type.

The osteocytic phenotype

The osteocyte network

Mature osteocytes are stellate-shaped or dendritic cells enclosed within the lacunocanalicular network of bone. The lacunae contain the cell bodies. From these cell bodies, long, slender cytoplasmic processes, dendrites, radiate in all directions, but with the highest density perpendicular to the bone surface (Fig. 6.1). They pass through the bone matrix via small canals, the canaliculi. Processes and their canaliculi may be branched. The more mature osteocytes are connected by these cell processes to neighboring osteocytes, the most recently incorporated osteocytes to neighboring osteocytes and to the cells lining the bone surface. Some of the processes oriented to the bone surface, however, appear not to connect with the lining cells, but pass through this cell layer, thereby establishing a direct contact between the osteocyte network and the extraosseus space. This intriguing observation by Kamioka et al. (2001) suggests the existence of a signaling system between the osteocyte and the bone marrow compartment without intervention of the osteoblasts/lining cells. Osteocytes also appear to be able to retract and extend their dendritic processes, not only between cells in the bone matrix, but also into marrow spaces as shown by dynamic imaging (Veno et al., 2006). This has implications with regard to osteocytes making and breaking communication between cells.

Dramatic changes occur in the distribution of actin-binding proteins during terminal differentiation of osteoblasts to osteocytes (Kamioka et al., 2004). The typical morphology of the osteocyte was originally thought to be enforced on differentiating osteoblasts during their incorporation into the bone matrix. Osteocytes have to remain in contact with other cells and ultimately with the bone surface to ensure the access of oxygen and nutrients. Culture experiments with isolated osteocytes have shown, however, that although the cells lose their stellate shape in suspension, they reexpress this morphology as soon as they settle on a support (Van der Plas and Nijweide, 1992) (Fig. 6.2). Apparently, the typical stellate morphology and the need to establish a cellular network are intrinsic characteristics of terminal osteocyte differentiation.

In bone, gap junctions are present between the tips of the cell processes of connecting osteocytes (Doty, 1981). Within each osteon or hemiosteon (on bone surfaces), therefore, osteocytes form a network of gap junction−coupled cells. As the lacunae are connected via the canaliculi, the osteocyte network represents two network systems: an intracellular one and an extracellular one. Gap junctions are transmembrane channels connecting the cytoplasm of two adjacent cells that regulate the passage of molecules of less than 1 kDa (Goodenough et al., 1966; Bennett and Goodenough, 1978). Gap junction channels are formed by members of a family of proteins known as connexins. One of these members, connexin 43 (Cx43), appears to play an important role in bone cells, as Cx43-null mice have delayed ossification, craniofacial abnormalities, and osteoblast dysfunction (Lecanda et al., 2000). It has been proposed that gap junctions function through the propagation of intracellular signals contributing to mechanotransduction in bone, thereby regulating bone cell differentiation (Donahue, 2000). Fluid-flow-induced shear stress stimulates gap junction−mediated intercellular communication and increases Cx43 expression (Cheng et al., 2001), while oscillating fluid flow has been shown to upregulate gap junction communication by

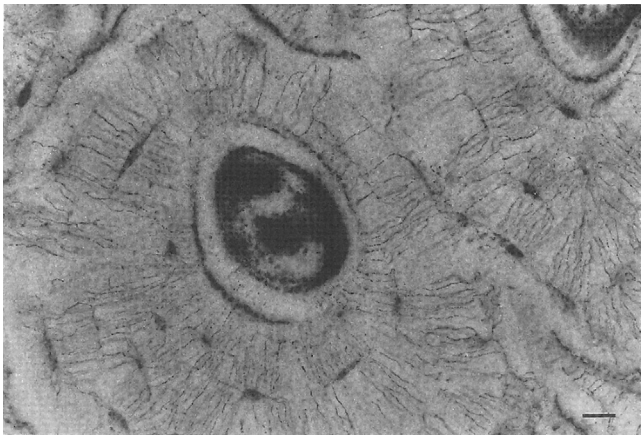

FIGURE 6.1 Osteon in mature human bone. Osteocytes are arranged in concentric circles around the central haversian channel. Note the many cell processes, radiating from the osteocyte cell bodies, in particular in the perpendicular directions. Schmorl staining. (Original magnification, ×390; bar, 25 μm.)

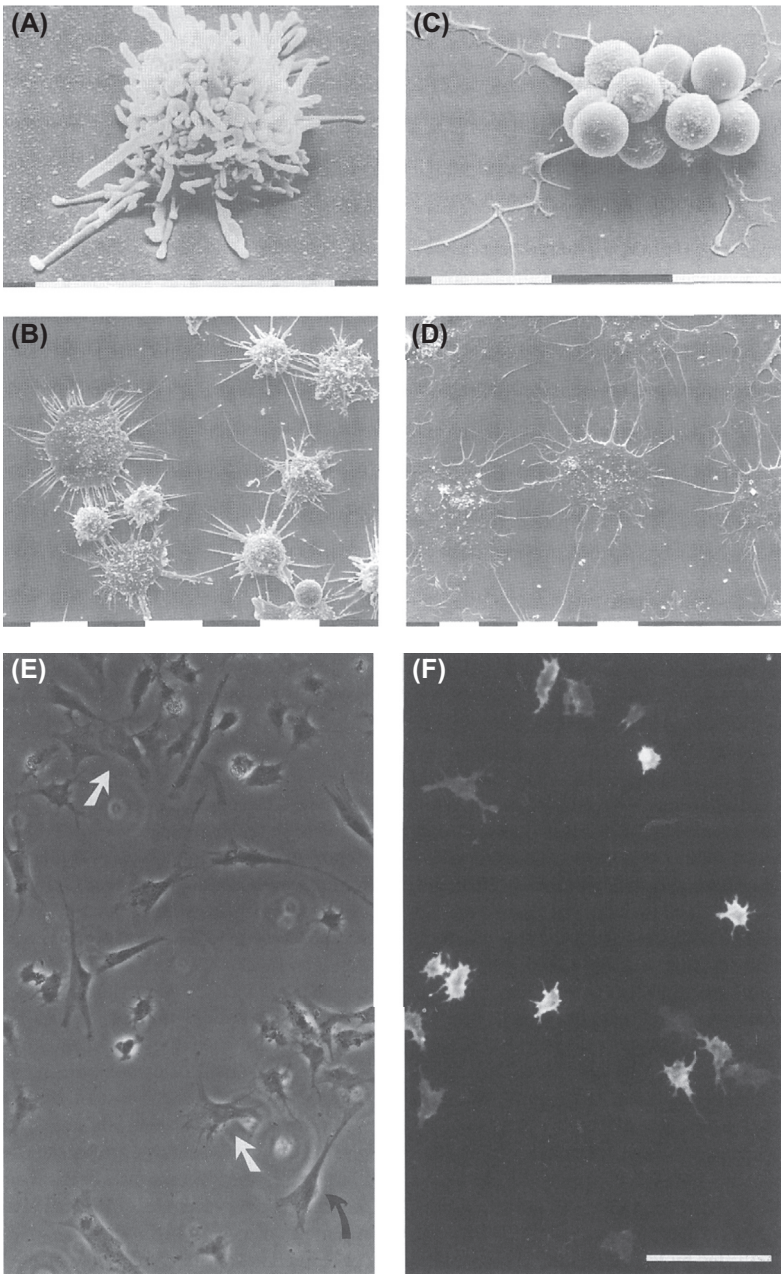

FIGURE 6.2 Isolated osteocytes in culture. Osteocytes were isolated by an immunodissection method using MAb OB7.3-coated magnetic beads. After isolation the cells were seeded on a glass support, cultured for (A) 5 min, (B) 30 min, or (C and D) 24 h and studied with a scanning electron microscope. Immediately after attachment, osteocytes form cytoplasmic extrusions in all directions (A). During subsequent culture the cell processes perpendicular on the support disappear, while the processes in the plane of the support elongate (B) and ultimately form smooth connections between neighboring cells (D). In (A), (B), and (D) the immunobeads were removed from the cells before seeding; in (C) the beads were left on the cells. (Original magnifications, (A) ×7200, (B) ×1400, (C) ×2900, and (D) ×940; bar, 10 μm.) (E and F) Cells were also isolated from periosteum-free 18-day-old chicken calvariae by collagenase digestion, seeded, and cultured for 24 h. Subsequently the osteocytes in the mixed population were specifically stained with MAb OB7.3 in combination with biotinylated horse anti-mouse IgG and streptavidin-Cy3. (E) Phase contrast. (F) Immunofluorescence. *Black arrow*, fibroblast-like cells; *white arrows*, osteoblast-like cells. (Original magnification, ×300; bar, 100 μm.)

an extracellular signal-regulated kinase (ERK) 1/2 mitogen-activated protein kinase-dependent mechanism (Alford et al., 2003) in MLO-Y4 osteocyte-like cells.

Hemichannels, unapposed halves of gap junction channels (Goodenough and Paul, 2003), have been identified in osteocytes localizing at the cell surface, independent of physical contact with adjacent cells. Primary osteocytes and MLO-

Y4 osteocyte-like cells (Kato et al., 1997) express very large amounts of Cx43 compared with other cell types such as osteoblasts, yet these cells are in contact only through the tips of their dendritic processes, raising a question regarding the function of Cx43 on the rest of the cell membrane. The opening of hemichannels results in ATP and NAD^+ release, which in turn raises intracellular Ca^{2+} levels and wave propagation of Ca^{2+}. It has been shown that oscillating fluid flow activates hemichannels in MLO-Y4 osteocyte-like cells, but not in MC3T3-E1 osteoblast-like cells. This activation involved protein kinase C, and resulted in ATP and prostaglandin E_2 (PGE_2) release (Genetos et al., 2007). Hemichannels expressed in bone cells such as MLO-Y4 cells appear to function as essential transducers of the antiapoptotic effects of bisphosphonates (Plotkin et al., 2002) and serve as a portal for the exit of elevated intracellular PGE_2 in osteocytes induced by fluid flow shear stress (Cherian et al., 2005). Integrin $\alpha5\beta1$ interacts with Cx43 to mediate the opening of hemichannels to release prostaglandin in MLO-Y4 cells in response to mechanical stimulation independent of the integrin association with fibronectin and its interaction with the extracellular matrix (Batra et al., 2012). Therefore, gap junctions at the tips of dendrites mediate intracellular communication, while hemichannels along the dendrite and the cell body mediate extracellular communication within the osteocyte network.

In vivo studies have provided additional, sometimes conflicting, information on the functions of Cx43 gap junctions and hemichannels in osteoblasts and osteocytes. Deletion of Cx43 in osteoblasts results in animals with increased osteocyte apoptosis (Bivi et al., 2012). However, mice lacking Cx43 in osteoblasts and/or osteocytes show an increased anabolic response to loading, and decreased catabolic response to unloading (Plotkin et al., 2015). Xu and colleagues generated mice expressing a mutated Cx43 with impaired gap junctions and mice expressing a Cx43 mutant able to form functional hemichannels but unable to form gap junction channels. Mice without both functional gap junctions and functional hemichannels exhibit increased bone mass, whereas mice expressing only hemichannels were not different from wild-type littermate controls (Xu et al., 2015). This study suggests that it is the Cx43 hemichannel and not the gap junction that is responsible for the bone phenotype. It was proposed that hemichannels play a dominant role in osteocyte survival.

Osteocyte formation and death

Osteogenic cells arise from multipotential mesenchymal stem cells (see Chapter 2). These stem cells have the capacity to also differentiate into other lineages, including those of chondroblasts, fibroblasts, adipocytes, and myoblasts (Aubin et al., 1995, Chapter 2). By analogy with hemopoietic differentiation, each of these differentiation lineages is thought to originate from a different committed progenitor, which for the osteogenic lineage is called the osteoprogenitor. Osteodifferentiation progresses via a number of progenitor and precursor stages to the mature osteoblast. Osteoblasts have one of three fates: embedding in their own osteoid, differentiating into an osteocyte; quiescing into a lining cell, or undergoing apoptosis (for review see Manolagas, 2000). The mechanism by which osteoblasts differentiate into osteocytes is, however, still unknown. Imai et al. (1998) found evidence that osteocytes may stimulate osteoblast recruitment and differentiation by expressing osteoblast stimulating factor-1 (OSF-1) (Tezuka et al., 1990). The osteoblasts further differentiate into osteocytes, being surrounded by the osteoid matrix that they produce, and they then may become a new source of OSF-1 for the next round of osteoblast recruitment. The expression of OSF-1 in osteocytes may be activated by local damage to bone or local mechanical stress (Imai et al., 1998). Marotti (1996) has postulated that a newly formed osteocyte starts to produce an osteoblast inhibitory signal when its cytoplasmic processes connecting the cell with the osteoblast layer have reached their maximal length. The osteoid production of the most adjacent, most intimately connected osteoblast will be relatively more inhibited by that signal than that of its neighbors. The inactivated osteoblast then spreads over a larger bone surface area, thereby reducing its linear appositional rate of matrix production even further. A second consequence of the widening and flattening of the cell is that it may intercept more osteocytic processes carrying the inhibitory signal. This positive feedback mechanism results in the embedding of the cell in matrix produced by the neighboring osteoblasts. Ultimately, the cell will acquire the typical osteocyte morphology and the surrounding matrix will become calcified. The theory of Marotti (1996) is based entirely on morphological observations. There is no biochemical evidence on the nature or even the existence of the proposed inhibitory factor. Martin (2000) has, however, used the concept successfully in explaining mathematically the changing rates of matrix formation during bone remodeling.

Osteoid-osteocytes were described by Palumbo (1986) to be cells actively making matrix and calcifying this matrix while the cell body reduces in size in parallel with the formation of cytoplasmic processes. Bordier et al. (1976) and Nijweide et al. (1981) proposed that osteoid-osteocytes play an important role in the initiation and control of mineralization of the bone matrix. During the time in which an osteoblast has become an osteocyte, the cell has manufactured three times its own volume in matrix (Owen, 1995). Franz-Odendaal et al. (2006) propose that once a cell is surrounded by osteoid, the differentiation process has not ended, but continues.

An enzyme that is produced in high amounts by embedding osteoid-osteocytes and not by osteoblasts, casein kinase II, appears to be responsible for the phosphorylation of matrix proteins essential for mineralization (Mikuni-Takagaki et al., 1995). Phosphoproteins appear to be essential for bone mineralization as evidenced in vitro by crystal nucleation assays (Boskey, 1996) and in vivo by osteomalacia in animal models with deletion of (osteocyte-specific) genes such as dentin matrix protein 1 (DMP1) and PHEX (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) (Strom et al., 1997). The roles of these proteins in mineral homeostasis will be discussed later in this chapter. An osteocyte-selective promoter, the 8-kb DMP1, driving green fluorescent protein (GFP) identifies embedding and embedded osteocytes (Kalajzic et al., 2004). With the identification of other markers selective for osteocytes, such as E11/gp38 for early osteocytes (Zhang et al., 2006) and sclerostin for late osteocytes (Poole et al., 2005), new tools have been generated for the study of osteocyte formation.

The life span of osteocytes is probably largely determined by bone turnover, when osteoclasts resorb bone and either "liberate" or destroy osteocytes. Osteocytes may have half-lives of decades if the particular bone they reside in has a slow turnover rate (Parfitt, 1977). The fate of living osteocytes that are liberated by osteoclast action is unknown as of this writing. Some of them, only half released by osteoclastic activity, may be reembedded during new bone formation that follows the resorption process (Suzuki et al., 2000). These osteocytes are then the cells that cross the cement lines between individual osteons, sometimes seen in cross sections of osteonal bone. It has been shown by Kalajzic et al. that isolated osteocytes can partially dedifferentiate into osteoblasts (Torregiani et al., 2013). Most of the osteocytes, however, will probably die by apoptosis and become phagocytosed. Phagocytosis of osteocytes by osteoclasts as part of the bone resorption process has been documented in several reports (Bronckers et al., 1996; Elmardi et al., 1990).

Apoptosis of osteocytes in their lacunae is attracting growing attention because of its expected consequence of decreased bone mechanoregulation, which may lead to osteoclastic bone resorption (Tan et al., 2007, 2008). Osteocyte apoptosis can occur with immobilization, microdamage, estrogen deprivation, elevated cytokines, glucocorticoid treatment, osteoporosis, osteoarthritis, and aging. The resulting fragility is considered to be due to loss of the ability of osteocytes to signal other bone cells for repair due to loss of the capacity to sense microdamage (Manolagas, 2000; Noble et al., 2003). Apoptotic regions around microcracks were found to be surrounded by surviving osteocytes expressing Bcl-2, whereas dying osteocytes appeared to be the target of resorbing osteoclasts (Verborgt et al., 2000, 2002). Apoptotic changes in osteocytes were shown to be associated with high bone turnover (Noble et al., 1997). However, fatigue-related microdamage in bone may cause decreased osteocyte accessibility for nutrients and oxygen, inducing osteocyte apoptosis and subsequent bone remodeling (Burger and Klein-Nulend, 1999; Verborgt et al., 2000). Lack of oxygen elevates hypoxia-inducible factor-1α, a transcription activator, by inactivation of prolyl hydroxylase leading to apoptosis and induction of the osteoclastogenic factor tumor necrosis factor α (TNFα) (Gross et al., 2001), vascular endothelial growth factor, and osteopontin, a mediator of environmental stress and a potential chemoattractant for osteoclasts (Gross et al., 2005).

In contrast to overloading, which induces microdamage, physiological mechanical loads might prevent osteocyte apoptosis in vivo. Mechanical stimulation of osteocytes in vitro, by means of a pulsating fluid flow (PFF), affects TNFα-induced apoptosis. One-hour PFF (0.70 ± 0.30 Pa, 5 Hz) inhibited (25%) TNFα-induced apoptosis in osteocytes, but not in osteoblasts or periosteal fibroblasts (Tan et al., 2006). Although the exact mechanism is not clear, loading-induced nitric oxide production by the osteocytes might be involved in the antiapoptotic effects of mechanical loading. Prostaglandin produced by osteocytes in response to fluid flow shear stress also blocks MLO-Y4 apoptosis (Kitase et al., 2006).

Also, loss of estrogen (Tomkinson et al., 1998) and chronic glucocorticoid treatment (Weinstein et al., 1998) were demonstrated to induce osteocyte apoptosis, which may, at least in part, explain the bone-deleterious effects of these conditions. Several agents, such as bisphosphonates and calcitonin (Plotkin et al., 1999), CD40 ligand (Ahuja et al., 2003), calbindin-D28k (Liu et al., 2004), and estrogen and selective estrogen receptor modulators (Kousteni et al., 2001), have been found to reduce or inhibit osteoblast and osteocyte apoptosis. Bisphosphonates inhibit apoptosis through interaction with Cx43 hemichannels and the ERK pathway (Plotkin and Bellido, 2001). Interestingly, the two antiapoptotic agents parathyroid hormone (PTH) and monocyte chemotactic protein-3 (MCP-3) have been shown to be selective for apoptosis induced by one particular agent, glucocorticoids. Unlike the agents listed earlier, both PTH (Jilka et al., 1999) and MCP-3 will inhibit only glucocorticoid-induced apoptosis, and not TNFα-induced apoptosis, of MLO-Y4 osteocyte-like cells (Kitase et al., 2006).

Osteocyte viability is crucial for the normal functioning of the skeleton and the normal function of other organs such as kidney through fibroblast growth factor 23 (FGF23) production by osteocytes, but also muscle. Osteocyte factors such as PGE_2 and Wnt3a promote myogenesis and enhance muscle function (Mo et al., 2012; Huang et al., 2017). Mice with targeted deletion of Cx43 in osteocytes have a reduced muscle phenotype (Shen et al., 2015). Conversely, secreted muscle factors prevent glucocorticoid-induced osteocyte apoptosis (Jahn et al., 2012), and β-aminoisobutyric acid produced by

contracted muscle with exercise will prevent reactive oxygen−induced osteocyte apoptosis (Kitase et al., 2018). These investigators also found that this muscle metabolite will prevent bone and muscle loss with unloading.

Both mechanical loading and intracellular autophagy play important roles in bone homeostasis. Autophagy is a catabolic process that is regulated by multiple factors and is associated with skeletal diseases. It has been shown that fluid shear stress induces protective autophagy in osteocytes and that mechanically induced autophagy is associated with ATP metabolism and osteocyte survival (Zhang et al., 2018). Moreover, microRNA-199a-3p is involved in the estrogen regulatory networks that mediate MLO-Y4 osteocyte autophagy, potentially by targeting insulin-like growth factor 1 (IGF-1) and mammalian target of rapamycin (Fu et al., 2018).

In summary, osteocyte viability may play a significant role in the maintenance of bone homeostasis and integrity and other organs (Dallas et al., 2013), yet agents that block apoptosis may exacerbate conditions that require repair.

Osteocyte isolation

Analysis of osteocyte properties and functions has long been hampered by the fact that osteocytes are embedded in a mineralized matrix. Although sensitive methods are now available, such as immunocytochemistry and in situ hybridization, by which osteocytes can be studied in the tissue in some detail, osteocyte isolation and culture offer a major step forward. This approach became possible by the development of osteocyte-specific antibodies (Fig. 6.3) directed to antigenic sites on the outside of the cytoplasmic membrane (Bruder and Caplan, 1990; Nijweide and Mulder, 1986). Using an immunodissection method, Van der Plas and Nijweide (1992) subsequently succeeded in the isolation and purification of chicken osteocytes from mixed bone cell populations isolated from fetal bones by enzymatic digestion. A detailed description of the isolation procedure has been published (Semeins et al., 2012). Isolated osteocytes appeared to behave in vitro like they do in vivo in that they reacquired their stellate morphology and, when seeded sparsely, formed a network of cells coupled to one another by long, slender, often branched cell processes (Fig. 6.2). The cells retained this morphology in culture throughout the time studied (5−7 days) and even reexpressed it when passaged for a second time (Van der Plas and Nijweide, 1992).

Mikuni-Takagaki et al. (1995) isolated seven cell fractions from rat calvariae by sequential digestion. They claimed that the last fraction consisted of osteocytic cells. The cells displayed dendritic cell processes, were negative for alkaline phosphatase, had high extracellular activities of casein kinase II and ecto-5′-nucleotidase, and produced large amounts of osteocalcin. After a few days of little change in cell number, the cells of fraction VII, the osteocytic cells, proliferated, but

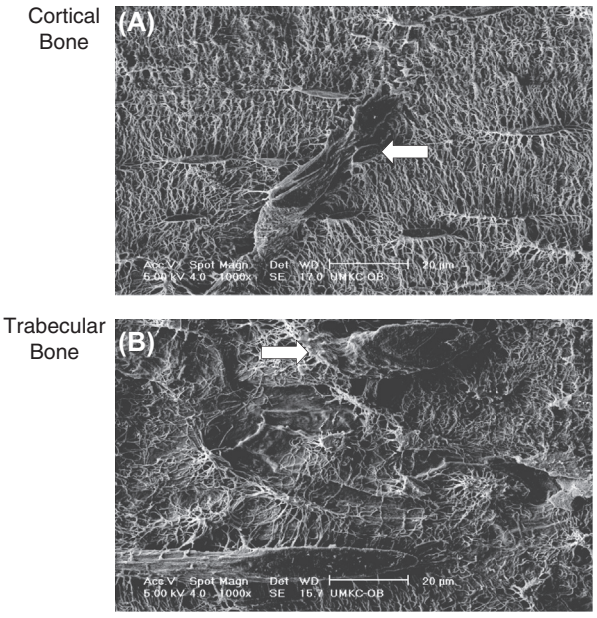

FIGURE 6.3 Images of acid-etched resin-embedded murine (A) cortical and (B) trabecular bone visualized by scanning electron microscopy showing the complexity of the osteocyte lacunocanalicular system and the intimate relationship between the lacunocanalicular system and blood vessels. In the cortical bone, note the linear alignment of the lacunae and the complexity of the canaliculi. In the trabecular bone, the lacunae are not as organized as in the cortical bone. In both sections, note the close relationship of some osteocyte lacunae with blood vessels (*arrows*).

equally fast as those of fraction III, the osteoblastic cells, in culture. With the identification of new osteocyte-selective markers such as Sost, E11/gp38, Dmp1, Phex, and Mepe, it is becoming easier to identify isolated osteocytes (see later).

A methods paper written by Stern and Bonewald (2015) provides a review of the different approaches used to isolate osteocytes from bone. Consistent approaches include collagenase digestions and calcium chelation. In this review, the authors also described isolation of osteocytes from aged bone through the use of bone particle culture. The yield of primary osteocytes decreases with the age of the animal. The isolation is easiest when the bone is hypomineralized as in young animals but becomes more difficult in hypermineralized bone as occurs in aged animals. In summary, whereas primary osteocytes can be isolated from bone, the process is still long compared with soft tissue or bone surface cells.

As of this writing, culture of human osteocytes in vitro remains a challenge. Culture of denuded human bone chips with osteocytes embedded in their native matrix has been shown to overcome this challenge, and provides a three-dimensional model that can be used to study osteocyte function and signaling (Pathak et al., 2016). Pathak and colleagues showed that these osteocytes highly express mRNA of osteocyte-specific signaling molecules (Pathak et al., 2016). The isolation of osteocytes from human trabecular bone samples acquired during surgery has been described (Prideaux et al., 2016). A protocol was used whereby the cells were digested from the bone matrix by sequential collagenase and ethylenediaminetetraacetic acid (EDTA) digestions, and the cells from later digests displayed characteristic dendritic osteocyte morphology when cultured ex vivo. These cells represent an important tool in enhancing current knowledge in human osteocyte biology.

Osteocyte markers

In bone, osteocytes are fully defined by their location within the bone matrix and their stellate morphology. One marker for isolated osteocytes is therefore their typical morphology, which they reacquire in culture (Mikuni-Takagaki et al., 1995; Van der Plas and Nijweide, 1992). Related to this stellate morphology, osteocytes have a typical cytoskeletal organization, which is important for the osteocyte's response to loading (McGarry et al., 2005a,b). It has been shown that the dendrite is the primary mechanosensing part of the osteocyte compared with the cell body (Burra et al., 2010). The prominent actin bundles in the osteocytic processes, together with the abundant presence of the actin-bundling protein fimbrin, are exemplary for osteocytes and are retained after isolation (Tanaka-Kamioka et al., 1998). In addition, osteocytes are generally found to express osteocalcin, osteonectin, and osteopontin, but show little alkaline phosphatase activity, particularly the more mature cells (Aarden et al., 1996b). As stated previously, these metabolic markers have, however, little discriminating value in mixtures of isolated cells. Franz-Odendaal et al. (2006) provide a list of molecular markers for the preosteoblast to the osteocyte.

Initially mainly morphology was used to describe osteocytes until osteocyte-specific antibodies became available. Early examples are the monoclonal antibodies MAb OB7.3 (Nijweide and Mulder, 1986) (Fig. 6.2), MAb OB37.11 (Nijweide et al., 1988), and MAb SB5 (Bruder and Caplan, 1990). All three are specific for avian osteocytes and do not cross-react with mammalian cells. The identities of two of the three antigens involved have not been reported, but that of OB7.3 has been elucidated and found to be the avian homolog of mammalian *Phex* (Westbroek et al., 2002). Using an antibody to Phex allowed purification of avian osteocytes from enzymatically isolated bone cells.

Osteoblast/osteocyte factor 45 (OF45), also known as MEPE (matrix extracellular phosphoglycoprotein), is also highly expressed in osteocytes compared with osteoblasts. Messenger RNA expression of OF45/MEPE begins at embryonic day 20 in more differentiated osteoblasts that have become encapsulated by bone matrix (Igarashi et al., 2002). *Mepe* was isolated and cloned from a TIO tumor cDNA library (Rowe et al., 2000). Cathepsin D or B can cleave MEPE, releasing the highly phosphorylated C-terminal ASARM region that is a potent inhibitor of mineralization in vitro (Bresler et al., 2004; Rowe et al., 2005). OF45/MEPE-null mice have increased bone formation, bone mass, and resistance to age-associated trabecular bone loss (Gowen et al., 2003). The authors speculate that osteocytes act directly on osteoblasts through OF45/MEPE to inhibit their bone-forming activity.

Both Toyosawa et al. (2001) and Feng et al. (2006) found Dmp1 to be highly expressed in osteocytes with very low expression in osteoblasts. DMP1 is specifically expressed along and in the canaliculi of osteocytes within the bone matrix (Feng et al., 2006). Deletion of this gene in mice results in a phenotype similar if not identical to the hyp phenotype, suggesting that Dmp1 and Phex are interactive and essential for phosphate metabolism. Potential roles for DMP1 in osteocytes may be related to the posttranslational processing and modification resulting in a highly phosphorylated protein and regulator of hydroxyapatite formation. Interestingly, Dmp1 and OF45/MEPE belong to the SIBLING (small, integrin-binding ligand, N-linked glycoprotein) family, which also includes bone sialoprotein, osteopontin, and sialophosphoprotein (Fisher and Fedarko, 2003). This family of proteins may function differently in osteocytes compared with other cell

types, especially upon phosphorylation with casein kinase II, a marker of the osteoblast-to-osteocyte transition (Mikuni-Takagaki et al., 1995).

Schulze et al. (1999) and Zhang et al. (2006) have described the expression of E11/gp38 exclusively in osteocytes and not in osteoblasts in vivo. A punctate antibody reaction is observed at the interface between osteoblasts and uncalcified osteoid at the tips and along dendritic processes with less reactivity in osteocytes deeper in the bone matrix. E11/gp38 appears to be responsible for the formation of dendritic processes, as a reduction in protein expression using a short interfering RNA approach led to a decrease in dendrite extension in MLO-Y4 osteocyte-like cells in response to shear stress (Zhang et al., 2006). E11/gp38 colocalizes with ezrin, radixin, and moesin (Scholl et al., 1999), which are concentrated in cell-surface projections where they link the actin cytoskeleton to plasma membrane proteins and are involved in cell motility (Mangeat et al., 1999). CD44 is highly expressed in osteocytes compared with osteoblasts (Hughes et al., 1994), and as E11 is physically associated with CD44 in tumor vascular endothelial cells (Ohizumi et al., 2000), this association most likely occurs in osteocytes to regulate the formation of dendritic processes.

Sclerostin appears to be highly expressed in the mature and not the early osteocyte (Poole et al., 2005). Transgenic mice lacking sclerostin have increased bone mass, and the human condition sclerostosis is due to a premature termination of the SOST gene (Balemans et al., 2001). Sclerostin clearly functions as a Wnt antagonist by binding Lrp5 (Van Bezooijen et al., 2004), a receptor shown to be an important positive regulator of bone mass (Li et al., 2005). Sclerostin protein may be transported through canaliculi to the bone surface to inhibit bone-forming osteoblasts. Sclerostin is downregulated by mechanical loading (Robling et al., 2006). It has also been proposed that the anabolic effects of PTH are through inhibition of SOST expression (Bellido et al., 2005). Neutralizing antibody to sclerostin is being developed as a therapeutic to treat osteoporosis. The antibody blocks or reduces bone loss and supports bone formation, promotes fracture healing, and is a potential therapeutic for a number of conditions of low bone mass, such as osteogenesis imperfecta (Clarke, 2014). In clinical trials, despite very potent effects in increasing bone mass, the FDA rejected approval of the anti-sclerostin antibody romosozumab for osteoporosis treatment due to a higher rate of serious adverse cardiovascular events compared with alendronate (Medscape, 2017). This was a devastating event after following such a potent inducer of bone mass for over a decade. However, as of this writing, the late-phase data from this clinical study are being refiled to show the drug has a positive risk−benefit profile, while other anti-sclerostin monoclonal antibodies are being developed (MacNabb et al., 2016).

FGF23 is a major phosphate-regulating hormone responsible for autosomal dominant hypophosphatemic rickets, for phosphate wasting in tumor-induced osteomalacia, and for X-linked hypophosphatemia. FGF23 is not normally expressed at high levels in osteocytes in the healthy state but is dramatically upregulated in both DMP1- and PHEX-associated hypophosphatemic rickets (Liu et al., 2007). Clinkenbeard and White (2016) performed FGF23 deletion using Col2.3-Cre for osteoblasts and DMP1-Cre for early osteocytes and showed that both osteoblasts and osteocytes are the physiological source of FGF23. More information on the function and regulation of FGF23 is provided later.

It has been shown that receptor activator of NF-κB ligand (RANKL) is a functional marker of osteocytes. Primary osteocytes express RANKL (Kramer et al., 2010), and osteocytes express greater amounts of RANKL than osteoblasts and are better supporters of osteoclast formation (Nakashima et al., 2011; Xiong et al., 2011, 2015). Deletion of RANKL using the 10-kb Dmp1-Cre or Sost-Cre results in mice with increased bone mass. Like sclerostin, RANKL is increased with unloading (Xiong et al., 2011).

In summary, it is becoming easier to define cells as osteocytic. Even though the E11/gp38 molecule is expressed in other tissues (known as podoplanin in kidney and also known as PA2.26, T1a, etc.), it is expressed only in osteocytes, not osteoblasts, in bone (Zhang et al., 2006). While E11/gp38, Phex, and Dmp1 appear to be markers for the early osteocyte, MEPE and Sost/sclerostin are specific markers for the late osteocyte (Poole et al., 2005). Dmp1 and Phex, while expressed in low levels in osteoblasts and other tissues, are highly elevated in early osteocytes. Combining these markers with other properties such as dendricity and low or no alkaline phosphatase can be useful to define not only isolated primary cells, but also cell lines.

Osteocytic cell lines

Since the number of primary osteocytes that can be isolated from chickens each time (Van der Plas and Nijweide, 1992) is limited, several groups have tried to establish osteocytic cell lines. Basically, an osteocytic cell line is a contradiction in terms. Osteocytes are postmitotic. However, a cell line of proliferating precursor cells that would differentiate into osteocytes under specific circumstances could prove to be very valuable in the study of osteocyte properties and functions. HOB-01-C1 (Bodine et al., 1996) is a temperature-sensitive cell line, prepared from immortalized, cloned human adult bone cells. It proliferates at 34°C but stops dividing at 39°C. HOB-01-C1 cells display putative osteocytic markers, such as cellular processes, low alkaline phosphatase activity, high osteocalcin production, and the expression of CD44.

MLO-Y4 (Kato et al., 1997) is an osteocyte-like cell line that expresses high amounts of E11/gp38 (Zhang et al., 2006), CD44, osteocalcin, and osteopontin and has low alkaline phosphatase activity. Numerous investigators have used these cells to examine gap junctions, hemichannels, apoptosis, and other potential functions of osteocytes (Genetos et al., 2007; Plotkin et al., 2005; Vatsa et al., 2006, 2007; Xiao et al., 2006; Zaman et al., 2006; Zhang et al., 2006; Cherian et al., 2005; Liu et al., 2004; Alford et al., 2003; Ahuja et al., 2003; Zhao et al., 2002; Heino et al., 2002, 2004; Cheng et al., 2001; Yellowley et al., 2000) and, as of the updating of this chapter, there are over 250 references using these cells to investigate osteocyte function. Estrogen will reduce support of osteoclast formation by MLO-Y4 cells through an increase in transforming growth factor β3 (Heino et al., 2002) and induce MLO-Y4 cells to support osteoblast mesenchymal stem cell differentiation (Heino et al., 2004), supporting the hypothesis that osteocytes are orchestrators of both bone resorption and bone formation. Observations using these cells have been validated in vivo. For example, MLO-Y4 cells support osteoclast formation through RANKL expression (Zhao et al., 2002) and apoptotic bodies released from MLO-Y4 cells express RANKL (Kogianni et al., 2008). The outcomes using this cell line have been validated using transgenic mouse models generated by two different laboratories showing that RANKL is mainly functional in osteocytes (Nakashima et al., 2011; Xiong et al., 2011).

MLO-A5 cells, a postosteoblast/preosteocyte-like cell line established from the long bones of 14-day-old mice expressing the large T antigen driven by the osteocalcin promoter, differentiate into osteoid-osteocyte-like cells (Kato et al., 2001). MLO-A5 cells express all of the markers of the late osteoblast, such as high alkaline phosphatase, bone sialoprotein, PTH type 1 receptor, and osteocalcin, but begin to express markers of osteocytes such as E11/gp38 as they generate cell processes. MLO-A5 cells generate nanospherites that bud from and mineralize on their developing cellular processes. As the cellular process narrows in diameter, these mineralized structures become associated with and initiate collagen-mediated mineralization (Barragan-Adjemian et al., 2006). PTH has been shown to reduce Sost/sclerostin expression in these cells (Bellido et al., 2005). This is an excellent cell line to study collagen production, regulation, and mineralization, as they are prodigious producers of collagen (Yang et al., 2015; Lu et al., 2018).

Compared with primary osteoblasts and clonal cells, the MLO-Y4 cells show relatively high expression of osteocalcin and Cx43 with low expression of collagen type I and periostin, as well as low alkaline phosphatase activity. However, both MLO-A5 and MLO-Y4 cells have their limitations, such as the lack of sclerostin expression and low DMP1 expression by MLO-Y4 cells. This makes MLO-Y4 cells less suitable for studying signaling molecule production by mature osteocytes. Alternative cell lines that have been used to study sclerostin expression include the SaOS2 osteosarcoma cell line and the osteoblast-like UMR-106 cells. IDG-SW3 (Woo et al., 2011) and Ocy454 (Spatz et al., 2015) are osteocyte cell lines that express relatively high levels of SOST/sclerostin as well as FGF23, both key regulators of bone homeostasis, and could therefore be used to study osteocyte signaling toward other cell types.

The IDG-SW3 osteocyte cell line undergoes a temporally dependent process that replicates the osteoblast-to-osteocyte transition (Woo et al., 2011). This cell line was made from long bones of mice carrying a Dmp1 promoter driving GFP crossed with the Immortomouse. These cells can be expanded at 33°C in the presence of interferon γ (IFN-γ) and then allowed to resume their original phenotype at 37°C in the absence of IFN-γ. Another cell line has been made from the same mice, called Ocy454 (Spatz et al., 2015). Comparisons between the two cell lines suggest that sclerostin expression occurs earlier and is higher in the Ocy454 cells compared with IDG-SW3.

Cementocytes, like osteocytes, are mechanosensory cells, and when the cementocyte cell line IDG-CM6 was compared with IDG-SW3 in their response to shear stress, IDG-CM6 cells significantly increased RANKL, with no change in IDG-SW3 cells, and significantly reduced osteoprotegerin (OPG) in contrast to increased expression by IDG-SW3 cells. The higher OPG/RANKL ratio in IDG-CM6 cementocytes under fluid flow shear stress suggests a potential mechanism for the lack of cementum resorption observed during physiological use and in orthodontic tooth movement (Zhao et al., 2016). Cementocytes in vivo and in vitro express key markers known to be important in osteocyte differentiation, including *Dmp1*/DMP1, *E11/gp38*, and *Sost*/sclerostin. Loss-of-function studies in mice produced cellular cementum phenotypes resembling those in bone, showing that these factors operate in similar fashions in both tissues.

Matrix synthesis

The subcellular morphology of osteocytes and the fact that they are encased in mineralized matrix do not suggest that osteocytes partake to a large extent in matrix production. Osteocytes, especially the more mature cells, have relatively few organelles necessary for matrix production and secretion. Nevertheless, a limited secretion of specific matrix proteins may be essential for osteocyte function and survival. Several arguments are in favor of such limited matrix production. First, as the mineralization front lags behind the osteoid formation front in areas of new bone formation, osteocytes may be involved in the maturation and mineralization of the osteoid matrix by secreting specific matrix molecules. It is, however,

also possible that osteocytes enable the osteoid matrix to be mineralized by phosphorylating certain matrix constituents, as was suggested by Mikuni-Takagaki et al. (1995). Mikuni-Takagaki et al. proposed that casein kinase II, produced in high amounts by embedding osteoid-osteocytes and not by osteoblasts, is responsible for phosphorylation of matrix proteins essential for mineralization. Therefore, the embedding osteoid cell and the osteocyte probably play roles in the mineralization process and potentially in phosphate metabolism (see later). Osteocytes have to inhibit mineralization of the matrix directly surrounding them to ensure the diffusion of oxygen, nutrients, and waste products through the lacunocanalicular system. Osteocalcin, which is expressed to a relatively high extent by osteocytes, may play an important role here (Aarden et al., 1996b; Ducy et al., 1996; Mikuni-Takagaki et al., 1995), as do OF45/MEPE and Sost. Osteocytes have been found positive for osteocalcin and osteonectin (Aarden et al., 1996b), molecules that are probably involved in the regulation of calcification. Osteopontin, fibronectin, and collagen type I (Aarden et al., 1996b) have also been demonstrated in and immediately around (isolated) osteocytes. These proteins may be involved in osteocyte attachment to the bone matrix (see later). Osteocytes also express Notch, which plays a critical role in mineralization (Shao et al., 2018a, 2018b). Finally, if osteocytes are the mechanosensor cells of bone (see later), the attachment of osteocytes to matrix molecules is likely to be of major importance for the transduction of stress signals into cellular signals. Production and secretion of specific matrix molecules offer a possibility for the cells to regulate their own adhesion and, thereby, sensitivity for stress signals.

In addition to collagenous and noncollagenous proteins, the bone matrix contains proteoglycans. These macromolecules consist of a core protein to which one or more glycosaminoglycan side chains are covalently bound. Early electron microscopical studies (Jande, 1971) showed that the osteocyte body, as well as its cell processes, is surrounded by a thin layer of unmineralized matrix containing collagen fibrils and proteoglycans. The proteoglycans were shown to consist of chondroitin 4-sulfate, dermatan sulfate, and keratan sulfate with immunocytochemical methods (Maeno et al., 1992; Smith et al., 1997; Takagi et al., 1997). These observations are supported by the findings of Sauren et al. (1992), who demonstrated an increased presence of proteoglycans in the pericellular matrix by staining with the cationic dye cuprolinic blue. Of special interest is the reported presence of hyaluronan in osteocyte lacunae (Noonan et al., 1996). CD44, which is highly expressed on the osteocyte membrane, is a hyaluronan-binding protein and also binds to collagen, fibronectin, and osteopontin (Nakamura and Ozawa, 1996; Yamazaki et al., 1999). The essential pericellular matrix component perlecan/HSPG2, a large monomeric heparan sulfate proteoglycan, acts as a strong but elastic tether that connects the osteocyte cell body to the bone matrix (Wijeratne et al., 2016). Solute transport in the lacunar–canalicular system plays an important role in osteocyte metabolism and cell–cell signaling. The pericellular matrix-filled lacunar–canalicular system is bone's chromatographic column, where fluid/solute transport to and from the osteocytes is regulated. A better definition of the chemical composition, deposition rate, and turnover rate of the osteocyte pericellular matrix will improve our understanding of osteocyte physiology and bone metabolism (reviewed by Wang, 2018).

The osteocyte cytoskeleton and cell–matrix adhesion

As mentioned earlier, the cell–matrix adhesion of osteocytes is of importance for the translation of biomechanical signals produced by loading of bone into chemical signals. Study of the adhesion of osteocytes to extracellular matrix molecules became feasible with the development of osteocyte isolation and culture methods (Van der Plas and Nijweide, 1992). These studies found little difference between the adhesive properties of osteocytes and osteoblasts, although the patterns of adhesion plaques (osteocytes, many small focal contacts; osteoblasts, larger adhesion plaques) were quite different (Aarden et al., 1996a). Both cell types adhered equally well to collagen type I, osteopontin, vitronectin, fibronectin, and thrombospondin. Integrin receptors are involved, as is shown by the inhibiting effects of small peptides containing an RGD sequence on the adhesion to some of these proteins. Adhesion to all aforementioned matrix molecules was blocked by an antibody reacting with the β_1-integrin subunit (Aarden et al., 1996a). The identity of the α units involved is unknown as of this writing.

Deformation of the bone matrix upon loading may cause a physical "twisting" of integrins at sites where osteocytes adhere to the matrix. Integrins are coupled to the cytoskeleton via molecules such as vinculin, talin, and α-actinin. In osteocytes, especially in the osteocytic cell processes, the actin-bundling protein fimbrin appears to play a prominent role (Tanaka-Kamioka et al., 1998). Mechanical twisting of the cell membrane via integrin-bound beads has been demonstrated to induce cytoskeletal rearrangements in cultured endothelial cells (Wang and Ingber, 1994). The integrin–cytoskeleton complex may therefore play a role as an intracellular signal transducer for stress signals (Litzenberger et al., 2010; Santos et al., 2010). Spectrin, another structural cytoskeletal protein required for the differentiation of osteoblasts to osteocytes (Bonewald, 2011), has been identified as a mechanosensitive element within the osteocyte (Wu et al., 2017). Disruption of the spectrin network promotes Ca^{2+} influx and nitric oxide (NO) secretion as a result of reduced stiffness. In addition to the integrins, the nonintegrin adhesion receptor CD44 may contribute to the attachment of osteocytes to the surrounding

matrix. CD44 is present abundantly on the osteocyte surface (Hughes et al., 1994; Nakamura et al., 1995) and is also linked to the cytoskeleton.

Evidence is accumulating highlighting the crucial role of the cytoskeleton in a multitude of cellular processes. The cytoskeleton, just like our bony skeleton, provides structure and support for the cell, is actively adapted, and is highly responsive to external physical and chemical stimuli. The cytoskeleton is strongly involved in processes such as migration, differentiation, mechanosensing, and even cell death, and largely determines the material properties of the cell (i.e., stiffness).

For bone cells it was shown that the production of signaling molecules in response to an in vitro fluid shear stress (at 5 and 9 Hz) and vibration stress (5−100 Hz) correlated with the applied stress rate (Bacabac et al., 2004, 2006; Bacabac et al., 2006a,b; Mullender et al., 2006). The faster the stress was applied, the stronger the observed response of the cells. Interestingly, high-rate stimuli were found to condition bone cells to be more sensitive to high-frequency, low-amplitude loads (Bacabac et al., 2005). From the field of physics, it is known that the effects of stresses applied at different rates on an object are largely determined by the material properties of that object. This implies that bone cellular metabolic activity (e.g., the production of signaling molecules) and mechanical properties of the cell are related. Bacabac et al. (2006b) developed a novel application of two-particle microrheology, for which he devised a three-dimensional in vitro system using optical traps to quantify the forces induced by cells on attached fibronectin-coated probes (4 μm). The frequency at which the cells generate forces on the beads is related to the metabolic activity of the cell. This system can also be used to apply controlled forces on the cell using the beads, and enables the study of cells under a controlled three-dimensional morphological configuration, with possibilities for a variety of probe coatings for simulating cell−extracellular matrix attachment. Using this setup the generation of forces by different cells was probed to understand the relation between cellular metabolic activities and material properties of the cell. It was shown that at 37°C, CCL-224 fibroblasts exhibited higher force fluctuation magnitude compared with MLO-Y4 osteocytes (Bacabac et al., 2006b). The force fluctuations on the attached probes reflect intracellular movement, which might include actin (and microtubule) polymerization, as well as motor and cross-linker dynamics. Since cell migration involves these dynamic processes, the lower magnitude of force fluctuation might reflect a lower capacity of osteocytes for motility compared with fibroblasts.

Using the optical trap device, the material properties of round suspended MLO-Y4 osteocytes and flat adherent MLO-Y4 osteocytes were characterized. In addition, the cells were loaded with an NO-sensitive fluorescent dye (Vatsa et al., 2006) and the NO response of the cells to forces applied on the cell using the attached probes was studied. Osteocytes under round suspended morphology required lower force stimulation to show an NO response, even though they were an order of magnitude more elastic compared with flat adherent cells (Bacabac et al., 2006b). Apparently, elastic osteocytes require less mechanical force to respond than stiffer cells. On the other hand, flat adherent MLO-Y4 cells, primary chicken osteocytes, MC3T3-E1 osteoblasts, and primary chicken osteoblasts all showed similar elastic moduli of less than 1 kPa (Bacabac et al., 2006b), even though osteocytes are known to be more responsive to mechanical stress than osteoblasts (Klein-Nulend et al., 1995a). This indicates that differences in mechanosensitivity between cells might not be directly related to the elasticity of the cell, but might be more related to other cell-specific properties (i.e., the presence of receptors or ion channels in the membrane). Alternatively, the mechanosensitivity of a cell might be related to how cells change their material properties in relation to deformation.

Simultaneous with the increased NO release in response to mechanical stimulation, MLO-Y4 osteocytes showed increased force traction on the attached beads. In other words, the cells started to "pull harder" on the beads and generated a force up to nearly 30 pN, which interestingly is within the order of forces necessary for activating integrins. Whether there is a causal link between loading-induced NO production by the cells and force generation is under investigation at the time of writing. Since force generation and cell elasticity are (indirectly) related, these results might indicate that osteocytes adapt their elasticity in response to a mechanical stimulus. Indeed, experiments with an atomic force microscope and optical tweezers have shown that osteocytes become "stiffer" after mechanical loading (Bacabac et al., 2006b, and unpublished observations). This stiffening response was related to actual changes in material properties of the cell, suggesting that the cells actively change their cytoskeleton in response to a mechanical load.

Considering the role of the osteocytes as the professional mechanosensors of bone, and the importance of the cytoskeleton for the response of osteocytes to mechanical loading, much is to be expected from research focusing on the cytoskeletal components of the osteocyte (reviewed by Klein-Nulend et al., 2012).

Hormone receptors in osteocytes

PTH receptors have been demonstrated on rat osteocytes in situ (Fermor and Skerry, 1995) and on isolated chicken osteocytes (Van der Plas et al., 1994). Administered in vitro, PTH was reported to increase cAMP levels in isolated chicken

osteocytes (Van der Plas et al., 1994; Miyauchi et al., 2000) and, administered in vivo, to increase fos protein (Takeda et al., 1999) and the mRNAs of c-fos, c-jun, and I1-6 in rat osteocytes (Liang et al., 1999). Matrix metalloproteinase 14 (MMP14) has been shown to be a novel target of PTH signaling in osteocytes that controls resorption by regulating soluble RANKL production (Delgado-Calle et al., 2018). As it is now generally accepted that osteocytes are involved in the transduction of mechanical signals into chemical signals regulating bone (re)modeling, PTH might modulate the osteocytic response to mechanical strain. Injection of PTH into rats was shown to augment the osteogenic response of bone to mechanical stimulation in vivo, whereas thyroparathyroidectomy abrogated the mechanical responsiveness of bone (Chow et al., 1998). However, such an approach cannot separate an effect at the level of osteocyte mechanosensing from one at the level of osteoprogenitor recruitment. One mechanism by which PTH may act on osteocytes was suggested by the reports of Schiller et al. (1992) and Donahue et al. (1995). These authors found that PTH increased Cx43 gene expression and gap-junctional communication in osteoblastic cells. In osteocytes, where cell-to-cell communication is so important, a similar effect might lead to more efficient communication within the osteocyte network. Osteocytes also express the receptor for the carboxy-terminal region of PTH that may play a role in osteocyte viability (Divieti et al., 2001). Activation of receptors for 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$), which were also shown to be present in osteocytes by immunocytochemistry (Boivin et al., 1987) and by in situ hybridization (Davideau et al., 1996), may have similar effects.

Parfitt concluded in the 1970s that osteocytes control the rapid release of calcium (within minutes) in response to PTH (Parfitt, 1976). More recent in vivo studies have supported Parfitt's hypothesis that osteocytes are the target of PTH. There are profound skeletal effects in transgenic mice with the activation of the PTH receptor in osteocytes (O'Brien et al., 2008; Rhee et al., 2011). Mice lacking the PTH receptor in osteocytes lose less bone with lactation, and an increase in osteocyte lacunar size is absent (Qing et al., 2012). This "perilacunar remodeling" related to "osteocytic osteolysis" (Bélanger, 1969) is achieved by the expression of so-called "osteoclast-specific genes" such as carbonic anhydrases, ATPases, MMP13, cathepsin K, and TRAP (tartrate-resistant acid phosphatase) by the osteocyte. In 2017 it was shown that osteocytes reduce the pH within their lacunocanalicular network during lactation, a process necessary for the release of calcium (Jähn et al., 2017).

Another important hormone involved in bone metabolism is estrogen. Numerous studies have demonstrated that a decrease in blood estrogen levels is accompanied by a loss of bone mass. One explanation for this phenomenon is that estrogen regulates the set point for the mechanical responsiveness of bone (Frost, 1992), i.e., that lowering the ambient estrogen level increases the level of strain in bone necessary for the bone to respond with increased bone formation. If osteocytes are the main mechanosensors of bone, it is reasonable to suppose that osteocytes are the site of set-point regulation by estrogen. Estrogen receptors (ERα) were demonstrated in osteocytes with immunocytochemistry and in situ hybridization (Braidman et al., 1995; Hoyland et al., 1999) in tissue sections. In addition, Westbroek et al. (2000b) found higher levels of ERα in isolated osteocytes than in osteoblasts or osteoblast precursors. It has been shown that the anabolic response of bone to mechanical loading requires ERα (Lee et al., 2003). Studies suggest that osteocytes indeed use ERα to respond to strain, although the ERα content is regulated by estrogen (Zaman et al., 2006). In vivo studies performing targeted deletion of ERα in osteocytes using the Dmp1-Cre model have generally found a reduction in trabecular bone either in females (Kondoh et al., 2014) or in males (Windahl et al., 2013). It is not clear why these studies observed differences in the two sexes.

Receptors for PTH, $1,25(OH)_2D_3$, and estrogen, as well as the androgen receptor (Abu et al., 1997), the glucocorticoid receptor α (Abu et al., 2000; Silvestrini et al., 1999), and various prostaglandin receptors (Lean et al., 1995; Sabbieti et al., 1999), have been described in osteocytes. The prostaglandin receptors, in addition to viability, may be important for communication within the osteocyte network during mechanotransduction (see later). As outlined earlier, glucocorticoids clearly induce osteocyte apoptosis, but may have additional effects. Glucocorticoid treatment causes mature osteocytes to enlarge their lacunae and remove mineral from their microenvironment (Lane et al., 2006). Therefore, osteocytes appear to be able to modify their microenvironment in response to certain factors such as PTH/PTH-related protein and glucocorticoids.

Osteocyte function

Blood–calcium/phosphate homeostasis

The organization of osteocytes as a network of gap junction–coupled cells in each osteon represents such a unique structure that one expects it to have an important function in the metabolism and maintenance of bone. The network offers two advantages that may be exploited by the tissue:

1. a tremendous cell−bone surface contact area, about 2 orders of magnitude larger than the contact area the osteoblasts and lining cells have (Johnson, 1966),
2. an extensive intracellular and an extracellular communication system between sites within the bone and the bone surface.

The first consideration led Bélanger (1969) and others to propose the hypothesis that osteocytes are capable of local bone remodeling or osteocytic osteolysis. According to this hypothesis, osteocytes are coresponsible for blood−calcium homeostasis. Later studies (Boyde, 1980; Marotti et al., 1990) supplied alternative explanations for the observations that appeared to support the osteocytic osteolysis theory. The possibility remains, however, that osteocytes are involved in the facilitation of calcium diffusion in and out of the bone (Bonucci, 1990). Although the bulk of calcium transport in and out of the bone is apparently taken care of by osteoblasts and osteoclasts (Boyde, 1980; Marotti et al., 1990), osteocytes may have a function in the fine regulation of blood−calcium homeostasis. The major emphasis of present-day thinking is, however, on the role of the osteocyte network as a three-dimensional sensor and communication system in bone.

Osteocytes may also play a major role in phosphate homeostasis. PHEX is a metalloendoproteinase found on the plasma membrane of osteoblasts and osteocytes (Ruchon et al., 2000) whose substrate is not known. The precise function of PHEX is unclear but it clearly plays a role in phosphate homeostasis and bone mineralization. *Pex* deletion or loss of function results in X-linked hypophosphatemic rickets (The HYP Consortium, 1995). Nijweide and coworkers (Westbroek et al., 2002) were one of the first groups to propose that the osteocyte network could be considered a gland that regulates bone phosphate metabolism through expression of PHEX.

Other proteins known to regulate mineralization and mineral homeostasis are also highly expressed in osteocytes, such as DMP1, Mepe, and sclerostin. Deletion or mutation of DMP1, a gene that is highly expressed in embedding osteocytes and mature osteocytes, results in hypophosphatemic rickets (Feng et al., 2006), similar to the deletion of Phex. DMP1 is expressed along the canalicular wall, while Phex is expressed on the membrane surface of dendrites and the cell body. Other players in mineral metabolism include MEPE and FGF23, which are also highly expressed in osteocytes (Liu et al., 2006). FGF23 is highly elevated in osteocytes in DMP1-null mice, which results in hypophosphatemia in these animals. The osteocyte network might be viewed as an endocrine gland regulating mineral metabolism. Another fascinating hypothesis is that mineral metabolism is regulated by mechanical loading. DMP1 and Pex gene expression are increased in response to load (Gluhak-Heinrich et al., 2003), Sost expression is inhibited (Robling et al., 2006), while a biphasic response is observed for Mepe expression (Gluhak-Heinrich et al., 2005). Whether FGF23 expression is also regulated by loading is unknown as of this writing. Therefore proteins known to regulate mineralization and mineral homeostasis are also regulated by mechanical loading in osteocytes. These osteocyte regulators of mineral homeostasis can also be responsible for disease. For a review of the physiological and pathological functions of these molecules see Bonewald (2017).

Functional adaptation, Wolff's law

Functional adaptation is the term used to describe the ability of organisms to increase their capacity to accomplish a specific function with increased demand and to decrease this capacity with lesser demand. In the 19th century, the anatomist Julius Wolff proposed that mechanical stress is responsible for determining the architecture of bone and that bone tissue is able to adapt its mass and three-dimensional structure to the prevailing mechanical usage to obtain a higher efficiency of load bearing (Wolff, 1892). For the past century, Wolff's law has become widely accepted. Adaptation will improve an individual animal's survival chance because bone is not only hard but also heavy. Too much of it is probably as bad as too little, leading either to uneconomic energy consumption during movement (for too high a bone mass) or to an enhanced fracture risk (for too low a bone mass). This readily explains the usefulness of mechanical adaptation as an evolutionary driver, even if we do not understand how it is performed.

Osteocytes as mechanosensory cells

In principle, all cells of bone may be involved in mechanosensing, as eukaryotic cells in general are sensitive to mechanical stress (Oster, 1989). However, several features argue in favor of osteocytes as the mechanosensory cells *par excellence* of bone as discussed earlier in this chapter. From a cell biological viewpoint, therefore, bone tissue is a three-dimensional network of cells, most of which are surrounded by a very narrow sheath of unmineralized matrix, followed by a much wider layer of mineralized matrix. The sheath of unmineralized matrix is penetrated easily by macromolecules such as albumin and peroxidase (McKee et al., 1993; Tanaka and Sakano, 1985). However, others have shown that although small

tracers (<6 nm) readily pass through the lacunar–canalicular porosity in the absence of mechanical loading, there appears to be an upper limit of size between 6 and 10 nm for molecular movement from bone capillaries to osteocytic lacunae in rat long bone. It was suggested that this range of pore size represents the fiber spacing that has been proposed for the annular space based on the presence of a proteoglycan fiber matrix surrounding the osteocytes (Wang et al., 2004). Therefore, there is an intracellular as well as an extracellular route for the rapid passage of ions and signal molecules. This allows for several types of cellular signaling from osteocytes lying deep within the bone tissue to surface-lining cells and vice versa (Cowin et al., 1995).

Experimental studies indicate that osteocytes are indeed sensitive to stress applied to intact bone tissue. In vivo experiments using the functionally isolated turkey ulna have shown that immediately following a 6-min period of intermittent (1 Hz) loading, the number of osteocytes expressing glucose-6-phosphate dehydrogenase activity was increased in relation to local strain magnitude (Skerry et al., 1989). The tissue strain magnitude varied between 0.05% and 0.2% (500–2000 microstrain), in line with in vivo peak strains in bone during vigorous exercise. Other models, including strained cores of adult dog cancellous bone, embryonic chicken tibiotarsi, mouse ulnae, rat caudal vertebrae, and rat tibiae, as well as experimental tooth movement in rats, have demonstrated that osteocytes in intact bone change their enzyme activity and RNA synthesis rapidly after mechanical loading (El-Haj et al., 1990; Dallas et al., 1993; Lane et al., 2006; Lean et al., 1995; Forwood et al., 1998; Terai et al., 1999). These studies show that intermittent loading produces rapid changes of metabolic activity in osteocytes and suggest that osteocytes may indeed function as mechanosensors in bone. The mechanical environment of the stress-sensitive osteocyte varies with the geometry of the osteocyte lacuna (McCreadie et al., 2004). Computer simulation studies of bone remodeling, assuming this to be a self-organizational control process, predict a role for osteocytes, rather than lining cells and osteoblasts, as stress sensors of bone (Mullender and Huiskes, 1995, 1997; Huiskes et al., 2000; Ruimerman et al., 2005). A regulating role of strain-sensitive osteocytes in basic multicellular unit (BMU) coupling has been postulated by Smit and Burger (2000). Using finite-element analysis, the subsequent activation of osteoclasts and osteoblasts during coupled bone remodeling was shown to relate to opposite strain distributions in the surrounding bone tissue. In front of the cutting cone of a forming secondary osteon, an area of *decreased* bone strain was demonstrated, whereas a layer of *increased* strain occurs around the closing cone (Smit and Burger, 2000). Osteoclasts therefore attack an area of bone where the osteocytes are underloaded, whereas osteoblasts are recruited in a bone area where the osteocytes are overloaded. Hemiosteonic remodeling of trabecular bone showed a similar strain pattern (Smit and Burger, 2000). Thus, bone remodeling regulated by load-sensitive osteocytes can explain the maintenance of osteonic and trabecular architecture as an optimal mechanical structure, as well as adaptation to alternative external loads (Huiskes et al., 2000; Smit and Burger, 2000; Van Oers et al., 2014 [review]).

Osteocytes are thought to be the major regulator of bone mechanosensation events, but little is known about how osteocytes in vivo acutely respond to tissue-level mechanical loading. A technique has been reported for the direct in vivo observation of osteocyte calcium signaling events with simultaneous whole-bone loading (Lewis et al., 2017). Osteocyte populations were found to integrate mechanical signals by altering the number of responding cells and this effect was dependent on loading frequency (Lewis et al., 2017). Ca^{2+} signaling in the osteocyte network in chick calvariae has been studied using three-dimensional time-lapse imaging (Tanaka et al., 2017). In response to flow, intracellular Ca^{2+} significantly increased in developmentally mature osteocytes in comparison with young osteocytes in the bone matrix, indicating that developmentally mature osteocytes are more responsive to mechanical stress than young osteocytes and have important functions in bone formation and remodeling (Tanaka et al., 2017).

If osteocytes are the mechanosensors of bone, how do they sense mechanical loading? This key question is, unfortunately, still open because it has not yet been established unequivocally how the loading of intact bone is transduced into a signal for the osteocytes. The application of force to bone during movement results in several potential cell stimuli. These include changes in hydrostatic pressure, direct cell strain, fluid flow, and electric fields resulting from electrokinetic effects accompanying fluid flow (Pienkowski and Pollack, 1983). Evidence has been increasing steadily for the flow of canalicular interstitial fluid as the likely stress-derived factor that informs the osteocytes about the level of bone loading (Cowin et al., 1991, 1995; Cowin, 1999; Weinbaum et al., 1994; Klein-Nulend et al., 1995b; Knothe-Tate et al., 2000; Burger and Klein-Nulend, 1999; You et al., 2000; Bakker et al., 2009). Moreover, a realistic high-resolution image-based three-dimensional model has been used to analyze the microscale fluid flow in a human osteocyte canaliculus (Kamioka et al., 2012). In this view, canaliculi are the bone porosity of interest, and the osteocytes the mechanosensor cells.

Canalicular fluid flow and osteocyte mechanosensing

In healthy, adequately adapted bone, strains as a result of physiological loads (e.g., resulting from normal locomotion) are quite small. Quantitative studies of the strain in bones of performing animals (e.g., galloping horses, fast-flying birds, even

a running human volunteer) found a maximal strain not higher than 0.2%−0.3% (Rubin, 1984; Burr et al., 1996). This poses a problem in interpreting the results of in vitro studies of strained bone cells, where much higher deformations, on the order of 1%−10%, were needed to obtain a cellular response (for a review, see Burger and Veldhuijzen, 1993). In these studies, isolated bone cells were usually grown on a flexible substratum, which was then strained by stretching or bending. For instance, unidirectional cell stretching of 0.7% was required to activate PGE_2 production in primary bone cell cultures (Murray and Rushton, 1990). However, in intact bone, a 0.15% bending strain was already sufficient to activate prostaglandin-dependent adaptive bone formation in vivo (Turner et al., 1994; Forwood, 1996). If we assume that bone organ strain is somehow involved in bone cell mechanosensing, then bone tissue seems to possess a lever system whereby small matrix strains are transduced into a larger signal that is detected easily by osteocytes. The canalicular flow hypothesis proposes such a lever system. Indeed, in vitro experiments that relate the effects of fluid flow and substrate straining have shown that fluid-flow-induced shear stress induces higher release of signaling molecules (McGarry et al., 2005a,b). A numerical study showed that the deformation of cells on a two-dimensional substrate caused by fluid flow is fundamentally different from that induced by substrate straining (McGarry et al., 2005a,b). Fluid shear stress had a larger overturning effect on the bone cells, while substrate strain predominantly affected cell−substrate attachments. Whether these observations can be extrapolated toward osteocytes that are embedded in a three-dimensional matrix is a matter of debate, but they clearly indicate that substrate deformation and a flow of interstitial fluid could have differential effects on cells.

The flow of extracellular tissue fluid through the lacunocanalicular network as a result of bone tissue strains was made plausible by the theoretical study of Piekarski and Munro (1977) and has been shown experimentally by Knothe-Tate et al. (1998, 2000). This strain-derived extracellular fluid flow may help keep osteocytes healthy, particularly the deeper ones, by facilitating the exchange of nutrients and waste products between the haversian channel and the osteocyte network of an osteon (Kufahl and Saha, 1990). However, a second function of this strain-derived interstitial fluid flow could be the transmission of "mechanical information" (Fig. 6.4). The magnitude of interstitial fluid flow through the lacunocanalicular network is directly related to the amount of strain of the bone organ (Cowin et al., 1991). Because of the narrow diameter of the canaliculi, bulk bone strains of about 0.1% will produce a fluid shear stress in the canaliculi of roughly 1 Pa (Weinbaum et al., 1994), enough to produce a rapid response in endothelial cells (Frangos et al., 1985; Kamiya and Ando, 1996).

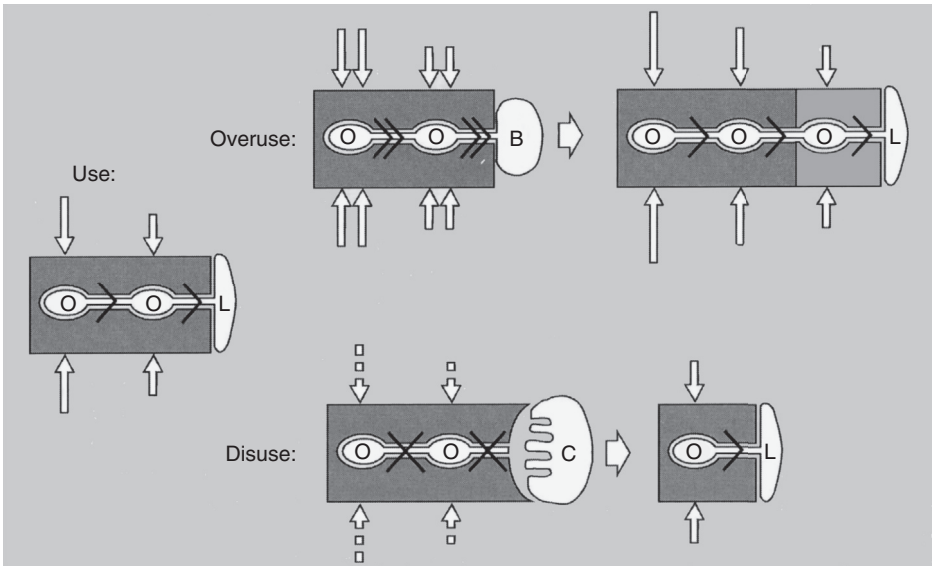

FIGURE 6.4 Schematic representation of how the osteocyte network may regulate bone modeling. In the steady state (*Use*), normal mechanical use ensures a basal level of fluid flow through the lacunocanalicular porosity, indicated by an *arrowhead* through the canaliculi. This basal flow keeps the osteocytes viable and also ensures basal osteocyte activation and signaling, thereby suppressing osteoblastic activity as well as osteoclastic attack. During (local) overuse (*Overuse*), osteocytes are overactivated by enhanced fluid flow (indicated by *double arrowheads*), leading to the release of osteoblast-recruiting signals. Subsequent osteoblastic bone formation reduces the overuse until normal mechanical use is reestablished, thereby reestablishing the steady state of basal fluid flow. During (local) disuse (*Disuse*), osteocytes are inactivated by lack of fluid flow (indicated by *crosses* through canaliculi). Inactivation leads to a release of osteoclast-recruiting signals, to a lack of osteoclast-suppressing signals, or both. Subsequent osteoclastic bone resorption reestablishes normal mechanical use (or loading) and basal fluid flow. *O*, osteocyte; *L*, lining cell; *B*, osteoblast; *C*, osteoclast; *dark gray area*, mineralized bone matrix; *light gray* area, newly formed bone matrix; *white arrows* represent direction and magnitude of loading. *Adapted from Burger, E.H., Klein-Nulend, J., 1999. Mechanotransduction in bone: role of the lacuno-canalicular network. FASEB J. 13, S101−S112.*

Experimental studies in vitro have demonstrated that osteocytes are indeed quite sensitive to the fluid shear stress of such a magnitude compared with osteoblasts and osteoprogenitor cells (Klein-Nulend et al., 1995a,b; Ajubi et al., 1996; Westbroek et al., 2000a,b; Westbroek et al., 2001). These results suggest that the combination of the cellular three-dimensional network of osteocytes and the accompanying porous network of lacunae and canaliculi acts as the mechanosensory organ of bone. Different loading-induced canalicular flow patterns around cutting cone and reversal zone during remodeling could, for instance, explain the typical alignment of haversian canals (Burger et al., 2003). Volumetric strain in the bone around a BMU cutting cone has been related to canalicular fluid flow (Smit et al., 2002), and the predicted area of low canalicular flow around the tip of the cutting cone was proposed to induce local osteocyte apoptosis. Unloading-induced osteocyte apoptosis has been shown in rat bone and was highly associated with osteoclastic bone resorption (Basso and Heersche, 2006). Osteocyte apoptosis at the tip of the cutting cone would attract osteoclasts, leading to further excavation of bone in the direction of loading. Importantly, mechanical loading by fluid shear stress has been shown to promote osteocyte survival (Bakker et al., 2004). The model by Smit et al. (2002) further predicts that at the base of the cutting cone and farther down the reversal zone, osteocytes receive enhanced fluid shear stress during loading. This could prevent osteocyte apoptosis, but may also promote the retraction and detachment of osteoclasts from the bone surface. These two mechanisms, attraction of osteoclasts to the cutting cone tip and induction of osteoclast detachment from the cutting cone base, together explain the mechanically meaningful behavior of osteoclasts during remodeling.

The flow of interstitial fluid through the bone canaliculi will have two effects: a mechanical one derived from the fluid shear stress and an electrokinetic one derived from streaming potentials (Pollack et al., 1984; Salzstein and Pollack, 1987). Either of the two, or both in combination, might activate the osteocyte. For instance, streaming potentials might modulate the movement of ions such as calcium across the cell membrane (Hung et al., 1995, 1996), whereas shear stress will pull at the macromolecular attachments between the cell and its surrounding matrix (Wang and Ingber, 1994). Both ion fluxes and cellular attachment are powerful modulators of cell behavior and therefore good conveyors of physical information (Sachs, 1989; Ingber, 1991). In vitro experiments using bone cells subjected to a flow of fluid of increasing viscosity suggest that fluid shear stress is the major activator of the bone cell response to loading (Bakker et al., 2001). However, care should be taken when extrapolating results obtained with cells seeded on a two-dimensional surface to the three-dimensional in vivo situation.

Mechanosensation and the resulting mechanotransduction of biochemical signals may be a complex event (Bonewald, 2006). Perturbation of dendrites, the cell body, and even primary cilia could be involved in combination or sequentially in this response. The osteocytes' response to different kinds of mechanical loading has predominantly been studied in cell cultures or entire bone, while knowledge of mechanosensing in osteocytes at the single-cell level is essential for understanding the complex process of bone adaptation. For instance, the mechanosensitive part of the osteocytes, the cell body or the cell processes, has not been determined yet. More information is needed on the single osteocyte's response to a localized mechanical stimulation. It has been postulated that the osteocyte processes are an order of magnitude more sensitive to mechanical loading than their cell bodies (Cabahug-Zuckermann et al., 2018). The underlying mechanisms are not clear but may be related to the infrequent $\alpha V\beta 3$ integrin sites where the osteocyte cell processes attach to canalicular walls (Cabahug-Zuckermann et al., 2018). These sites develop dramatically elevated strains during load-induced fluid flow in the lacunar canalicular system and might be primary sites for osteocyte mechanotransduction.

It has been suggested that fluid flow over dendrites in the lacunar–canalicular porosity can induce strains in the actin filament bundles of the cytoskeleton that are more than an order of magnitude larger than tissue level strains. Using the latest ultrastructural data for the cell process cytoskeleton and the tethering elements that attach the process to the canalicular wall, a realistic three-dimensional model was created for the osteocyte process. Using this model, the deformed shape of the tethering elements and the hoop strain on the central actin bundle as a result of loading-induced fluid flow were predicted. It was found that tissue-level strains of >1000 microstrain at 1 Hz resulted in a hoop strain of $>0.5\%$. The tethering elements of the osteocyte process can thus act as a strain amplifier (Han et al., 2004).

It has been published that osteocytes express a single primary cilium (Xiao et al., 2006). These authors also showed that polycystin 1 (PKD1/PC1), a known mechanosensory protein in the kidney, does play a role in normal bone structure. Primary cilia in other cells clearly function as sensors of odors, light, and movement (Singla and Reiter, 2005). It remains to be determined whether the bone defect in animals with defective PKD1 function is due to defective function of PKD1 in cilia, or whether PKD1 has a function in another location in the cell. Early data suggest that loss of cilia results in decreased sensitivity to fluid flow shear stress (Malone et al., 2006). Determining the function of PKD1 and/or cilia should lend insight into mechanotransduction in osteocytes.

The osteocyte has been viewed as either a quiescent cell acting as a "placeholder" in bone or as a mechanosensory cell as outlined in this chapter. Most observations using static two-dimensional imaging suggest that the dendritic processes are somewhat permanently anchored to the lacunar wall. Dallas et al. have shown cell body movement and the extension and retraction of dendritic processes over time using dynamic imaging of living osteocytes within their lacunae (Veno et al., 2006). Calvarial explants from transgenic mice with GFP expression targeted to osteocytes revealed that, far from being a static cell, the osteocyte is highly dynamic. Therefore, dendrites, rather than being permanent connections between osteocytes and with bone surface cells, may have the capacity to connect and disconnect and reconnect. With this new information, theories regarding shear stress within lacunae and osteocyte signaling will require modification.

Osteocyte shape and mechanosensing

The ability of osteocytes to sense and respond to mechanical stimuli depends on many factors, such as the shape of the osteocyte cell bodies, number and length of the cell processes, structure of the cytoskeleton, and presence of primary cilia (Willems et al., 2017). One intriguing factor is osteocyte lacunar shape, which has been hypothesized to affect the transduction of strain on the whole bone to the direct osteocyte microenvironment (Nicolella et al., 2006). It has been shown that considerable variations in the shape of osteocytes and their lacunae exist and that these variations may depend on anatomical location and the age of the bone (Van Hove et al., 2009; Vatsa et al., 2008a,b; Bacabac et al., 2008). Considering that a proper response of osteocytes to mechanical stimuli is highly important to maintain bone strength, the question arises whether changes in lacunar morphology could underlie the alterations in the bone adaptive response seen with aging (reviewed by Hemmatian et al., 2017).

Modifications in the morphology and orientation of osteocytes and their lacunae could result from hormonal changes, as well as from changes in mechanical loading. The alignment and shape of the osteocytes and their lacunae are related to the direction of the mechanical loading (Vatsa et al., 2008a,b; Sugawara et al., 2013). More flattened and elongated osteocytes and lacunae are observed in fibula loaded unidirectionally than in calvarial bone, which is loaded in different directions (Vatsa et al., 2008a,b). Irregularly shaped osteocytes distributed in different directions are found in the femurs of embryonic mice in the absence of mechanical loading, whereas the osteocytes in the femurs of 6-week-old mice subjected to mechanical loading are more flat and spindle shaped, and oriented parallel to the longitudinal axis of the bone (Sugawara et al., 2013). Furthermore, in neurectomized mice under little or no mechanical loading during growth, the osteocytes are round without any preferred orientation (Sugawara et al., 2013). The actin filaments in the osteocyte cytoskeleton distribute in the same direction as the mechanical loading (Vatsa et al., 2008a,b). In addition, the osteocyte morphology might vary in bone pathologies, i.e., the shape of osteocytes and their lacunae are significantly different in the tibia of individuals with osteopetrosis, osteoporosis, and osteoarthritis (Van Hove et al., 2009). Osteocyte lacunae in bone from osteoporotic persons are large and round, lacunae from osteopetrotic persons are small and discoid shaped, whereas lacunae from osteoarthritic persons are large and elongated (Van Hove et al., 2009). Furthermore, in the osteopetrotic bone, the osteocyte lacunae are less oriented to the loading direction in comparison with the orientation of osteocyte lacunae in the osteoarthritic and osteopenic bone (Van Hove et al., 2009). The variations in the shape and alignment of osteocytes and their lacunae in different bone pathologies could reflect an adaptation to the different micromechanical environments with different matrix strain associated with differences in bone mineral density.

Mechanoresponsive osteocytes regulate bone mass, which is important for, among others, dental implant success. Significant differences in osteocyte surface area and orientation seem to exist locally in maxillary bone, which may be related to the tensile strain magnitude and orientation. This might reflect local differences in the osteocyte mechanosensitivity and bone quality, suggesting differences in dental implant success based on the location in the maxilla (Wu et al., 2018).

Response of osteocytes to fluid flow in vitro

The technique of immunodissection, as discussed earlier in this chapter, made it possible to test the canalicular flow hypothesis by comparing the responsiveness of osteocytes, osteoblasts, and osteoprogenitor cells to fluid flow. The strength of the immunodissection technique is that three separate cell populations with a high (90%) degree of homogeneity are prepared, representing (1) osteocytes, with the typical "spider-like" osteocyte morphology and little matrix synthesis, (2) osteoblasts, with a high synthetic activity of bone matrix-specific proteins, and (3) (from the periosteum) osteoprogenitor cells, with a fibroblast-like morphology and very high proliferative capacity (Nijweide and Mulder, 1986). Because the cells are used within 2 days after isolation from the bone tissue, they may well represent the three differentiation steps of osteoprogenitor cell, osteoblast, and osteocyte. In contrast, mixed cell cultures derived from bone that are generally used to

represent "osteoblastic" cells are likely to contain cells in various stages of differentiation. Therefore, changes in mechanosensitivity related to progressive cell differentiation cannot be studied in such cultures. The development of differentiation-stage-specific bone cell lines has facilitated the comparison of cell-type-specific responses to mechanical loading. Ponik et al. (2007) have described significant differences in the response to fluid shear between MC3T3-E1 osteoblasts and MLO-Y4 osteocytes. Stress fibers were formed and aligned within osteoblasts after 1 h of unidirectional fluid flow, but this response was not observed until greater than 5 h of oscillatory fluid flow (Ponik et al., 2007). However, due to their clonal selection, cell lines do not necessarily express the whole range of bone-specific genes characteristic of primary bone cells. Therefore, the use of primary bone cells can be preferred to the use of cell lines when comparing osteoblasts' and osteocytes' behavior.

Using immunoseparated primary cell populations, osteocytes were found to respond far more strongly to fluid flow than osteoblasts, and these stronger than osteoprogenitor cells (Klein-Nulend et al., 1995a,b; Ajubi et al., 1996; Westbroek et al., 2000a). Osteocytes also appeared to be more responsive to fluid flow than osteoblasts or osteoprogenitor cells with respect to the production of soluble signaling molecules affecting osteoblast proliferation and differentiation (Vezeridis et al., 2005). The release of these soluble factors was at least partially dependent on the activation of an NO pathway in osteocytes in response to fluid flow. PFF with a mean shear stress of 0.5 Pa (5 dyn/cm^2) with a cyclic variation of $\pm$0.2 Pa at 5 Hz stimulated the release of NO and PGE_2 and PGI_2 rapidly from osteocytes within minutes (Klein-Nulend et al., 1995a; Ajubi et al., 1996). Osteoblasts showed less response, and osteoprogenitor cells (periosteal fibroblasts) still less. Intermittent hydrostatic compression of 13,000 Pa peak pressure at 0.3 Hz (1 s compression followed by 2 s relaxation) needed more than 1 h application before prostaglandin production was increased, again more in osteocytes than in osteoblasts, suggesting that mechanical stimulation via fluid flow is more effective than hydrostatic compression (Klein-Nulend et al., 1995b). A 1-h treatment with PFF also induced a sustained release of PGE_2 from the osteocytes in the hour following PFF treatment (Klein-Nulend et al., 1995b). This sustained PGE_2 release, continuing after PFF treatment had been stopped, could be ascribed to the induction of prostaglandin G/H synthase-2 (or cyclooxygenase 2, COX-2) expression (Westbroek et al., 2000a). Again, osteocytes were much more responsive than osteoblasts and osteoprogenitor cells, as only a 15-min treatment with PFF increased COX-2 mRNA expression by threefold in osteocytes but not in the other two cell populations (Westbroek et al., 2000a,b). Upregulation of COX-2 but not COX-1 by PFF had been shown earlier in a mixed population of mouse calvarial cells (Klein-Nulend et al., 1997) and was also demonstrated in primary bone cells from elderly women (Joldersma et al., 2000), whereas the expression of COX-1 and COX-2 in osteocytes and osteoblasts in intact rat bone has been documented (Forwood et al., 1998). These in vitro experiments on immunoseparated cells suggest that as bone cells mature, they increase their capacity to produce prostaglandins in response to fluid flow (Burger and Klein-Nulend, 1999). First, their immediate production of PGE_2, PGI_2, and probably $PGF_{2\alpha}$ (Klein-Nulend et al., 1997) in response to flow increases as they develop from osteoprogenitor cell, via the osteoblastic stage, into osteocytes. Second, their capacity to increase expression of COX-2 in response to flow, and thereby to continue to produce PGE_2 even after the shear stress has stopped (Westbroek et al., 2000a), increases as they reach terminal differentiation. Since induction of COX-2 is a crucial step in the induction of bone formation by mechanical loading in vivo (Forwood, 1996), these results provide direct experimental support for the concept that osteocytes, the long-living terminal differentiation stage of osteoblasts, function as the "professional" mechanosensors in bone tissue.

PFF also rapidly induced the release of NO in osteocytes but not osteoprogenitor cells (Klein-Nulend et al., 1995a). Rapid release of NO was also found when whole rat bone rudiments were mechanically strained in organ culture (Pitsillides et al., 1995) and in human bone cells submitted to fluid flow (Sterck et al., 1998). In line with these in vitro observations, inhibition of NO production inhibited mechanically induced bone formation in animal studies (Turner et al., 1996; Fox et al., 1996). NO is a ubiquitous messenger molecule for intercellular communication, involved in many tissue reactions in which cells must collaborate and communicate with one another (Koprowski and Maeda, 1995). The intracellular upregulation of NO after mechanical stimulation has been shown in single bone cells using DAR-4M AM chromophore (Vatsa et al., 2007). It was shown that a single osteocyte can disseminate a mechanical stimulus to its surrounding osteocytes via extracellular soluble signaling factors, which reinforces the putative mechanosensory role of osteocytes and demonstrates a possible mechanism by which a single mechanically stimulated osteocyte can communicate with other cells in a bone multicellular unit, which might help us to better understand the intricacies of intercellular interactions in BMUs and thus bone remodeling (Vatsa et al., 2007). Another interesting example of the involvement of NO in tissue reactions in which cells must collaborate and communicate with one another is the adaptation of blood vessels to changes in blood flow. In blood vessels, enhanced blood flow, e.g., during exercise, leads to widening of the vessel to ensure a constant blood pressure. This response depends on the endothelial cells, which sense the increased blood flow and produce intercellular messengers such as NO and prostaglandins. In response to these messengers, the smooth muscle cells around the vessel relax to allow the vessel to increase in diameter (Kamiya and Ando, 1996). The capacity of endothelial

cells to produce NO in response to fluid flow is related to a specific enzyme, endothelial NO synthase or ecNOS. Interestingly, this enzyme was found in rat bone-lining cells and osteocytes (Helfrich et al., 1997; Zaman et al., 1999) and in cultured bone cells derived from human bone (Klein-Nulend et al., 1998). Both endothelial and neuronal NOS isoforms are present in osteocytes (Caballero-Alias et al., 2004). The rapid release by mechanically stressed bone cells makes NO an interesting candidate for intercellular communication within the three-dimensional network of bone cells. Treatment with pulsatile fluid flow increased the level of ecNOS RNA transcripts in the bone cell cultures (Klein-Nulend et al., 1998), a response also described in endothelial cells (Busse and Fleming, 1998; Uematsu et al., 1995). Enhanced production of prostaglandins is also a well-described response of endothelial cells to fluid flow (Busse and Fleming, 1998; Kamiya and Ando, 1996). It seems, therefore, that endothelial cells and osteocytes possess a similar sensor system for fluid flow and that both cell types are "professional" sensors of fluid flow.

Mechanotransduction starts by the conversion of physical-loading-derived stimuli into cellular signals. Several studies suggest that the attachment complex between intracellular actin cytoskeleton and extracellular matrix macromolecules, via integrins and CD44 receptors in the cell membrane, provides the site of mechanotransduction (Wang et al., 1993; Watson, 1991; Ajubi et al., 1996, 1999; Pavalko et al., 1998). An important early response is the influx of calcium ions through mechanosensitive ion channels in the plasma membrane and the release of calcium from internal stores (Hung et al., 1995, 1996; Ajubi et al., 1999; Chen et al., 2000; You et al., 2000). The rise in intracellular calcium concentration activates many downstream signaling cascades such as protein kinase C and phospholipase A_2 and is necessary for activation of calcium/calmodulin-dependent proteins such as NOS. The activation of phospholipase A_2 results, among others, in the activation of arachidonic acid production and PGE_2 release (Ajubi et al., 1999). Other genes whose expression in osteocytes is modified by mechanical loading include c-fos, MEPE, and IGF-1 (Lean et al., 1995, 1996). MEPE has been shown to be involved in the inhibition of osteoclastogenesis by mechanically loaded osteocytes (Kulkarni et al., 2010).

Many steps in the mechanosignaling cascade are still unknown in osteocytes as well as other mechanosensory cells. One of the most important signaling pathways in response to mechanical loading in the osteocyte is the Wnt/β-catenin pathway. While important for osteoblast differentiation, proliferation, and matrix production, it was hypothesized and then shown that this pathway plays a role in transmitting signals of mechanical loading from osteocytes to cells on the bone surface (Bonewald and Johnson, 2008; Bonewald, 2011). Deletion of various components of the Wnt/β-catenin pathway has effects on bone responses to loading and unloading. For example, deletion of Lrp5 results in impaired osteogenic responses to anabolic loading. It has been shown that the Wnt family of proteins strongly modulates the anabolic response of bone to mechanical loading (Robinson et al., 2006). Mechanical loading by PFF modulates gene expression of proteins involved in Wnt signaling pathways in osteocytes (Santos et al., 2009). Whereas targeted deletion of β-catenin using the Dmp1-Cre driver results in dramatic bone loss (Kramer et al., 2010), deletion of only one allele results in mice with a normal skeleton but a completely abrogated response to anabolic loading (Javaheri et al., 2014). Mechanical loading decreases sclerostin in bone, whereas hindlimb unloading increases expression. Taking all these studies together, it appears that β-catenin signaling plays an important in bone responses to loading. More research will need to be conducted to elucidate the physiological role of Wnts in bone cell mechanotransduction. Undoubtedly, in the meantime, new players in the field of bone cell mechanotransduction will be identified.

Mechanosensitive osteocytes regulate bone mass in adults, while interleukin 6 (IL-6), such as is present during orthodontic tooth movement, also strongly regulates bone mass. Interestingly, IL-6 is produced by shear-loaded osteocytes, suggesting that IL-6 may affect bone mass by modulating osteocyte communication toward osteoblasts (Bakker et al., 2014). Multiple factors contribute to bone loss in inflammatory diseases, but circulating inflammatory factors and immobilization play a crucial role. Systemic inflammation affects human osteocyte-specific protein and cytokine expression (Pathak et al., 2016). Mechanical loading prevents bone loss in the general population, but the effects of mechanical loading in patients with inflammatory disease are less clear. Pathak et al. (2015) found that serum from patients with inflammatory disease upregulated osteocyte-to-osteoclast communication, while mechanical loading nullified this upregulation, suggesting that mechanical stimuli contribute to the prevention of osteoporosis in inflammatory disease. In addition, it has been shown that mechanical loading prevents the stimulating effect of IL-1β, of which plasma and synovial fluid levels are higher in inflammatory diseases, on osteocyte-modulated osteoclastogenesis, suggesting that mechanical loading may abolish IL-1β-induced osteoclastogenesis (Kulkarni et al., 2012).

Summary and conclusion

Tremendous progress has been made in discerning the function of osteocytes since this chapter was first written over 7−8 years ago. One only has to search the term "osteocytes" on PubMed to see the dramatic increase in references to and studies of this elusive bone cell. Markers for osteocytes have been expanded to delineate early to late stages of osteocyte

differentiation and the critical role of mineralization in this process. Genomic profiling of osteocytes is a storehouse of information regarding the potential functions of these cells and their response to strain.

Molecular mechanisms and pathways involved in osteocyte mechanosensation have been identified and expanded significantly. Although some investigators hold to the concept of a single mechanoreceptor initiating a linear cascade of events, new theories suggesting simultaneous triggering events in response to load are being investigated. It remains to be determined what makes these cells more responsive to shear stress than osteoblasts and what role the cell body, dendrites, and even cilia may play in this response.

These cells make up 90%–95% of all bone cells in the adult skeleton. Collectively, any minor modulation of the entire population could have significant local and systemic effects, not only on bone, but also on other organs. Although postulated several decades ago that osteocytes could potentially play a role in calcium metabolism, it appears that this cell may have a more important role in phosphate metabolism. It remains to be determined how factors produced by osteocytes can enter the circulation, suggesting an intimate connection between the lacunocanalicular system and the blood supply.

One reason for the dramatic expansion in knowledge in the field of osteocyte biology is the generation of new tools and advancement of technology. No longer is this cell safe within its mineralized cave from "prying eyes." Transgenic technology has targeted the osteocyte with fluorescent markers and generated conditional deletions. Cell lines and osteocyte-selective and -specific antibodies and probes have been generated. Advanced instrumentation such as Raman spectroscopy and atomic force microscopy can probe and characterize the osteocyte microenvironment. Dynamic imaging has revealed osteocyte movement within their lacuna and canaliculi.

Even with these advances we may still be seeing only "the tip of the iceberg" with regard to osteocyte function. It has been proposed that the osteocyte could be the orchestrator of bone remodeling in the adult skeleton directing both osteoblast and osteoclast function. The future looks exciting and full of new discoveries with regard to the biology of the osteocyte and its role in mechanosensation.

Acknowledgments

The authors would like to acknowledge the pioneering leadership in the field of osteocyte biology of Drs. Els Burger and Peter Nijweide, original authors of this chapter. These two individuals laid the foundation upon which the present authors have founded their research. The authors wish to thank Dr. Astrid Bakker for critically reading the manuscript.

The authors would also like to acknowledge funding support from the National Institutes of Health, NIH NIA PO1AG039355 (L.F.B.) and The Netherlands Foundation for Fundamental Research on Matter (ALW/FOM/NWO project 01FB28/2) (J.K.N.) and The Netherlands Institute for Space Research (SRON grant MG-055) (J.K.N.).

Chapter 7

Transcriptional control of osteoblast differentiation and function

Gérard Karsenty
Département of Genetics and Development, Columbia University Medical Center, New York, NY, United States

Chapter outline

As is the case for every cell differentiation process, differentiation of a mesenchymal pluripotent cell into any cell type is governed in large part by transcription factors that trigger the entire program of cell differentiation. Our knowledge about the transcriptional control of osteoblast differentiation made its main strides at the end of the 20th century and has been significantly refined since then, with the emergence of novel mechanisms regulating gene expression in addition to transcription factors. Briefly and ideally, a transcription factor that is a differentiation factor for a given cell type should (1) be expressed in progenitors of this cell type, (2) regulate the expression of all cell-specific genes in this cell type, (3) induce expression of the aforementioned genes when ectopically expressed in other cell types (sufficiency criterion), and (4) be necessary for the differentiation of this cell type in vivo, in mice, and at best in humans. As presented in this chapter, the transcription factor currently viewed as the master gene of osteoblast differentiation is one of the very few differentiation factors to fulfill all these criteria.

Runx2, a master control gene of osteoblast differentiation in bony vertebrates

The power of a combined effort between molecular biologists and human geneticists in identifying key genes regulating cell differentiation, which has been so beneficial for our understanding of skeletal biology, is best illustrated by the realization at the end of the 1990s that Runt-related transcription factor 2 (Runx2) is a master gene of osteoblast differentiation. Runx2, previously termed Pebp2a1, AmI3, or Cbfa1, was originally cloned in 1993 as one of three mammalian homologs of the *Drosophila* transcription factor Runt (Kagoshima et al., 1993; Ogawa et al., 1993). Based on the premise that it might be expressed in thymus and T cell lines, but not in B cell lines, Runx2 was thought to be involved in T cell differentiation and was deleted to study T cell differentiation (Ogawa et al., 1993; Satake et al., 1995). However, 4 years after the cloning of Runx2, its crucial role as a transcriptional determinant of osteoblast differentiation was demonstrated by several investigators working independent of one another and using different yet complementary experimental approaches (Ducy et al., 1997; Komori et al., 1997; Lee et al., 1997; Mundlos et al., 1997; Otto et al., 1997).

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00007-5

One approach, purely molecular, was aimed at the identification of osteoblast-specific transcription factors through the systematic analysis of the promoter of what was then the only osteoblast-specific gene, *Osteocalcin*. The analysis of a proximal promoter fragment of one of the two mouse *Osteocalcin* genes led to the identification of the only two known osteoblast-specific *cis*-acting elements, termed OSE1 and OSE2 (Ducy and Karsenty, 1995). Remarkably, as of this writing, those two *cis*-acting elements remain the only known strictly osteoblast-specific *cis*-acting elements. Sequence inspection of OSE2 revealed homology for the DNA-binding site of Runt family transcription factors, and subsequent analysis demonstrated that the factor binding to OSE2 is related immunologically to transcription factors of the Runt family (Geoffroy et al., 1995; Merriman et al., 1995). Eventually, screening of a mouse osteoblast cDNA library revealed that only one of the three mammalian *Runx* genes, namely *Runx2*, is expressed predominantly in cells of the osteoblast lineage (Ducy et al., 1997). Indeed, in situ hybridization further revealed that during mouse development, *Runx2* expression is first detected in the lateral plate mesoderm at 10.5 days postcoitus (dpc), and later is confined in cells of the mesenchymal condensations. Until 12.5 dpc these cells, which prefigure the future skeleton, represent common precursors of osteoblasts and chondrocytes. At 14.5 dpc osteoblasts first appear and maintain the expression of *Runx2*, whereas in chondrocytes *Runx2* expression decreases significantly and becomes restricted to prehypertrophic and hypertrophic chondrocytes. After birth, *Runx2* expression is strictly restricted to osteoblasts and cells of the perichondrium. This spatial and temporal expression pattern suggested Runx2 might play a critical role as a regulator of osteoblast differentiation (Ducy et al., 1997).

The demonstration that Runx2 was indeed an osteoblast differentiation factor came from several synergistic lines of molecular and genetic evidence. First, in addition to the *Osteocalcin* promoter, functional OSE2-like elements were identified in the promoter regions of most other genes that are expressed at relatively high levels in osteoblasts, such as *α1(II)-collagen*, *Osteopontin*, and *Bone sialoprotein*, and eventually many more (Ducy et al., 1997). Second, and more decisively, forced expression of *Runx2* in nonosteoblastic cell lines or primary skin fibroblasts induced osteoblast-specific gene expression in these cells, demonstrating that Runx2 acts as a transcriptional activator of osteoblast differentiation in vitro (Ducy et al., 1997). This was subsequently verified in vivo, where it was shown that the constitutive expression of Runx2 at low levels in nonhypertrophic chondrocytes triggered the entire cascade of endochondral bone formation, which normally does not occur in the cartilaginous ribs. Remarkably, however, ectopic expression of Runx in chondrocytes cannot cause transdifferentiation of chondrocytes into osteoblasts (Takeda et al., 2001). This suggests that if trans-differentiation of chondrocytes into osteoblasts can exist it remains a rather rare event. Third, the ultimate demonstration that Runx2 is an indispensable transcriptional activator of osteoblast differentiation came from genetic studies in mice and humans. At the same time, two groups deleted the *Runx2* gene from the mouse genome, both expecting an immunological phenotype based on the assumption that *Runx2* was involved in T cell differentiation (Komori et al., 1997; Otto et al., 1997). Instead, all *Runx2*-deficient mice had no skull, because intramembranous bone formation did not occur. In the rest of their skeleton, there are no osteoblasts in *Runx2*-deficient mice, an observation confirmed by the lack of expression of osteoblast marker genes.

The critical importance of Runx2 for osteoblast differentiation was further emphasized by the finding that mice lacking only one allele of *Runx2* display hypoplastic clavicles and delayed closure of the fontanelles, i.e., defects of intra-membranous ossification (Otto et al., 1997). This phenotype is identical to what is seen in a human disease termed cleidocranial dysplasia (CCD), and subsequent genetic analysis of CCD patients revealed disease-causing heterozygous mutations of the *RUNX2* gene, thereby demonstrating the relevance of Runx2 for osteoblast differentiation also in humans (Lee et al., 1997; Mundlos et al., 1997). Taken together, this overwhelming molecular and genetic evidence has led to the generally accepted view that Runx2 is a master control gene of osteoblast differentiation, providing a molecular switch inducing osteoblast-specific gene expression in mesenchymal progenitor cells (Lian and Stein, 2003). Remarkably, many, although not all, of the subsequent advances that have been made in the field are centered around the biology of Runx2.

In addition to its prominent role in osteoblast differentiation and skeletogenesis, Runx2 is also involved in the regulation of bone formation beyond development. This has been demonstrated in several ways. First, transgenic mice expressing a dominant-negative variant of Runx2 specifically in fully differentiated osteoblasts are viable, but develop severe osteopenia caused by a decreased rate of bone formation, in the face of normal osteoblast numbers (Ducy et al., 1999). This phenotype is readily explained by the finding that several Runx2 target genes encoding bone extracellular matrix proteins are expressed at much lower levels. Second, mice lacking *StatI*, a transcription factor attenuating the nuclear translocation of Runx2, as discussed later, display a high-bone-mass phenotype that is explained not only by increased osteoblast differentiation, but also by increased bone matrix deposition (Kim et al., 2003). Third, a similar, but even more severe, phenotype is observed in mice lacking the nuclear adapter protein Shn3. Because Shn3, as discussed later, is involved in the ubiquitination and proteasomal degradation of Runx2, the increased bone formation of the Shn3-deficient mice is readily explained by increased Runx2 levels in osteoblasts that in turn lead to enhanced bone matrix deposition (Jones et al., 2006). Given these results, it came as a surprise that another transgenic mouse model,

overexpressing intact *RU/u2* under the control of an osteoblast-specific 0.1 *(I)-collagen* promoter fragment, did not display the expected high-bone-mass phenotype, but a severe osteopenia accompanied by an increased fracture risk (Liu et al., 2001). Although these mice had increased numbers of osteoblasts, their bone formation rate was strikingly reduced, which likely illustrates the fact that the dosage of Runx2 needs to be tightly regulated to orchestrate proper bone formation in vivo.

Runx2 functions during skeletogenesis beyond osteoblast differentiation

Although most of these results demonstrating a key role for Runx2 in osteoblasts were already discussed in the last edition of this book, there is accumulating novel evidence that the role of Runx2 in skeletogenesis is much more complex than previously anticipated. The starting point for these findings was the observation that Runx2-deficient mice also display defects of chondrocyte hypertrophy in some skeletal elements (Inada et al., 1999; Kim et al., 1999). Moreover, because *Runx2* is transiently expressed in prehypertrophic chondrocytes of mouse embryos, there was a possibility of a function of Runx2 in chondrocyte differentiation. One way to address this possibility was the generation of a transgenic mouse model expressing *Runx2* in nonhypertrophic chondrocytes, using an *α1(II)-collagen* promoter/enhancer construct (Takeda et al., 2001).

In line with the suspected role of Runx2 as a positive regulator of chondrocyte hypertrophy, these transgenic mice displayed accelerated chondrocyte maturation in the growth plates, but also evidence of ectopic cartilage formation in the rib cage or in the trachea, among other locations. Moreover, the presence of this transgene in a Runx2-deficient genetic background prevented the absence of skeletal mineralization that is normally associated with *Runx2* deficiency. However, the skeleton of these mice contained only hypertrophic cartilage, and no bone matrix, thereby demonstrating that Runx2 induces chondrocyte hypertrophy, but not a transdifferentiation into osteoblasts (Takeda et al., 2001).

Because *Runx2* expression in prehypertrophic chondrocytes is transient, the main function of Runx2 here is probably to establish the growth plate. However, through another site of expression, namely in perichondrial cells, Runx2 has an additional function in the regulation of chondrogenesis. In these cells Runx2 positively regulates the expression of Fgfl8, a diffusible molecule that inhibits chondrocyte maturation and osteoblast differentiation (Hinoi et al., 2006; Liu et al., 2002; Ohbayashi et al., 2002). Taken together, these results establish that Runx2 is more than the master gene of osteoblast differentiation; it is, in fact, along with Sox9, the major transcriptional regulator of cell differentiation during skeletogenesis, acting positively and negatively on osteoblast and chondrocyte differentiation.

Regulation of Runx2 accumulation and function

In essence, the accumulation and demonstration that Runx2 exhibits, in vivo in mice and humans, all the characteristics of an osteoblast differentiation factor raised the usual questions: (1) What is upstream of Runx2? (2) How is Runx2 function regulated? (3) What is downstream of Runx2?

The search for mechanisms regulating *Runx2* expression is still ongoing. However, progress in this area of research came when a peculiarity of osteoblast differentiation was confronted in other progress in bone biology. This peculiarity of osteoblast biology is that the synthesis of type I collagen, the overwhelmingly most abundant protein of the bone extracellular matrix, precedes the expression of Runx2 (Wei et al., 2015). The fact that osteoblasts regulate glucose metabolism through the hormone osteocalcin prompted, of course, the study of the regulation of glucose metabolism in osteoblasts (Lee et al., 2007). This 2007 study showed that glucose is the main nutrient of osteoblasts and that, in vivo, glucose is transported in osteoblasts through Glut1, whose expression in cells of the osteoblasts lineage precedes that of Runx2. Glucose uptake favors osteoblast differentiation by preventing the proteasomal degradation of Runx2. Accordingly, Runx2 cannot induce osteoblast differentiation when glucose uptake is compromised, and raising blood glucose levels is sufficient to initiate bone formation in Runx2-deficient embryos. That Runx2 favors Glut1 expression determines the onset of osteoblast differentiation during development (Wei et al., 2015).

In addition to this strong metabolic regulation of osteoblast differentiation, other transcription factors have been shown to act upstream of Runx2. There are several lines of evidence showing that, for instance, certain homeodomain-containing transcription factors are involved in the regulation of *Runx2* expression. One of these proteins is Msx2, whose role in skeletal development was demonstrated through the identification of gain- and loss-of-function mutations in human patients suffering from Boston-type craniosynostosis or enlarged parietal foramina, respectively (Jabs et al., 1993; Wilke et al., 2000). Likewise, *Msx2*-deficient mice display defective ossification of the skull and of bones developing by endochondral ossification (Satokata et al., 2000). Moreover, because the expression of *Osteocalcin* and *Runx2* is strongly reduced in *Msx2*-deficient mice, it appears that Msx2 acts upstream of Runx2 in a transcriptional cascade regulating

osteoblast differentiation. A similar observation has been described for mice lacking the homeodomain-containing transcription factor *Bpx* (Tribioli and Lufkin, 1999). These mice die at birth owing to a severe dysplasia of the axial skeleton, whereas the appendicular skeleton is virtually unaffected. *Runx2* expression in *Bpx*-deficient mice is strongly reduced in osteo-chondrogenic precursor cells of the prospective vertebral column, thereby indicating that *Bpx* is required for *Runx2* expression specifically in these skeletal elements.

There are also negative regulators of *Runx2* expression. One of them is another homeodomain-containing transcription factor, Hoxa2. *Hoxa2*-deficient mice display ectopic bone formation in the second branchial arch, which is readily explained by an induction of *Runx2* expression exactly in this region (Kanzler et al., 1998). Consistent with these observations, transgenic mice expressing *Hoxa2* in craniofacial bones under the control of an *Msx2* promoter fragment lack several bones in the craniofacial area. Beyond development there is at least one factor required to limit *Runx2* expression in osteoblast precursor cells, namely, the high-mobility group−containing transcription factor Sox8. Sox8-deficient mice display an osteopenia that is caused by accelerated osteoblast differentiation accompanied by enhanced expression of *Runx2* (Schmidt et al., 2005). Likewise, transgenic mice expressing *Sox8* under the control of an osteoblast-specific *α1(I)-collagen* promoter fragment virtually lack differentiated osteoblasts because of a decreased expression of *Runx2*. In addition to the existence of transcriptional regulators of *Runx2* expression, there are also factors interacting with the Runx2 protein, thereby activating or repressing its activity. One identified positive regulator of Runx2 action is the nuclear matrix protein Satb2. The importance of this protein in skeletogenesis was first discovered in human patients with cleft palate that carry a heterozygous chromosomal translocation inactivating the *SATB2* gene (Fitzpatrick et al., 2003). The generation of a *Satb2*-deficient mouse model confirmed the importance of this gene in craniofacial development, skeletal patterning, and osteoblast differentiation (Dobreva et al., 2006). The last function was in part attributed to an increased expression of *Hoxa2*, a negative regulator of bone formation discussed earlier, whose expression is repressed by the binding of Satb2 to an enhancer element of the *Hoxa2* gene.

In addition to this type of action, there is also a Hoxa2-independent influence of Satb2 on the transcription of *Bone sialoprotein* and *Osteocalcin*. Whereas in the case of *Bone sialoprotein*, Satb2 directly binds to an osteoblast-specific element in the promoter of this gene, the activation of *Osteocalcin* expression by Satb2 requires a physical interaction with Runx2. This was demonstrated by cotransfection assays using a *Luciferase* reporter gene under the control of an osteoblast-specific *Osteocalcin* promoter fragment, but also by coimmunoprecipitation experiments. Moreover; the synergistic action of Satb2 and Runx2 in osteoblasts was genetically confirmed through the generation and analysis of compound heterozygous mice lacking one allele of each gene (Dobreva et al., 2006). Taken together, these results identified Satb2 as an important regulator of osteoblast differentiation in mice and humans. Moreover, the finding that Satb2 also interacts with Activating transcription factor 4 (ATF4), another transcription factor involved in osteoblast differentiation and function that will be discussed later, illustrates that the transcriptional network regulating bone formation is much more complex than previously anticipated.

This is further highlighted by the discovery of several other proteins that physically interact with Runx2, thereby attenuating its activity. One of these proteins is Stat1, a transcription factor regulated by extracellular signaling molecules, such as interferons. Stat1-deficient mice, as already mentioned, are viable, but develop a high-bone-mass phenotype explained by enhanced bone formation (Kim et al., 2003). The increase in osteoblast differentiation and function in these mice is molecularly explained by the lack of a Stat1-mediated inhibition of the transcriptional activity of Runx2. Interestingly, the physical interaction of both proteins is independent of Stat1 activation by phosphorylation, and it inhibits the translocation of Runx2 into the nucleus. Thus, overexpression of Stat1 in osteoblasts leads to a cytosolic retention of Runx2, and the nuclear translocation of Runx2 is much more prominent in Stat1-deficient osteoblasts (Kim et al., 2003).

Another protein interacting with Runx2, thereby decreasing its availability in the nucleus, is Shn3. Shn3 is a zinc finger adapter protein originally thought to be involved in VDJ recombination of immunoglobulin genes (Wu et al., 1993). Unexpectedly, however, the generation of an Shn3-deficient mouse model revealed that it plays a major function in bone formation. In fact, the *Shn3*-deficient mice display a severe adult-onset osteosclerotic phenotype owing to a cell-autonomous increase in bone matrix deposition (Jones et al., 2006). Interestingly, although several Runx2 target genes are expressed at higher rates in Shn3-deficient osteoblasts, *Runx2* expression itself is not affected by the absence of Shn3. Importantly, however, the Runx2 protein level is strikingly increased in *Shn3*-deficient osteoblasts. This finding is molecularly explained by the function of Shn3 as an adapter molecule linking Runx2 to the E3 ubiquitin ligase WWP1. The Shn3-mediated recruitment of WWP1 in turn leads to an enhanced proteasomal degradation of Runx2, which is best highlighted by the finding that RNA interference−mediated downregulation of WWP1 in osteoblasts leads to increased Runx2 protein levels and enhanced extracellular matrix mineralization, thus virtually mimicking the defects observed in the absence of Shn3 (Jones et al., 2006). Taken together, these data identify Shn3 as a key negative regulator of Runx2 actions in vivo. Accordingly, and as anticipated, *Glut1* expression and glucose uptake are significantly increased in

shn3$^{-/-}$ osteoblasts, as is *Runx2* expression (Wei et al., 2015). Moreover, given the postnatal onset of the bone phenotype of the *Shn3*-deficient mice, it has been speculated that compounds blocking the interaction of Runx2, Shn3, and WWP1 may serve as specific therapeutic agents for the treatment of bone loss diseases, such as osteoporosis. This does not exclude the possibility that *Shn3* may regulate osteoblast differentiation through additional mechanisms (Shim et al., 2013).

While Stat1 and Shn3 exemplify the importance of a negative regulation of Runx2 in postnatal bone remodeling, there is also a need for a negative regulation of Runx2 activity before bone development starts and when *Runx2* is already expressed. This is highlighted by the finding that *Runx2* expression in the lateral plate mesoderm is already detectable as early as embryonic day (E) 10 of mouse development, whereas the expression of molecular markers of differentiated osteoblasts cannot be detected before E13.5 at the earliest (Ducy, 2000). One molecular explanation for this delay between *Runx2* expression and osteoblast differentiation came from the functional analysis of Twist proteins that are transiently coexpressed with *Runx2* early during development and inhibit osteoblast differentiation by interacting with Runx2. In essence, the initiation of osteoblast differentiation occurs only when *Twist* gene expression fades away.

In brief, the fact that Runx2 expression precedes osteoblast differentiation by more than 4 days led to the assumption that Runx2 function must be regulated negatively in Runx2-expressing cells. The identification of such a factor relied on human genetic evidence. Haploinsufficiency at the *RUNX2* locus causes a lack of bone in the skull, whereas haploinsufficiency at the *TWIST1* locus causes essentially too much bone in the skull, a condition called craniosynostosis (EI Ghouzzi et al., 1997; Howard et al., 1997). Because the same phenotypes are observed in the corresponding mouse models lacking one allele of either gene, it was possible to demonstrate a genetic interaction of *Runx2* and *Twist1* through the generation of compound heterozygous mice. In fact, these mice did not display any detectable defects of skull development and suture fusion (Bialek et al., 2004). In contrast, the defects of clavicle development caused by haploinsufficiency of *Runx2* were not rescued by heterozygosity of *Twist1*, but by the deletion of *Twist2*. Thus, both Twist proteins have similar functions but in different skeletal elements. This is totally consistent with their expression pattern in mouse embryos (Bialek et al., 2004).

Both Twist proteins are presumably basic helix−loop−helix (bHLH) transcription factors, yet this function of Twist is not determined by the bHLH domain, but rather by the C-terminal 20 amino acids, the so-called Twist box, whose sequence is fully conserved in both Twist proteins, in mice and humans. Through the Twist box, Twist proteins interact with the Runx2 DNA-binding domain and prevent its DNA binding. The importance of this sequence motif for Twist function in vivo was confirmed by the existence of a Twist-box mutation within the human *TWISTI* gene that causes a severe form of craniosynostosis (Gripp et al., 2000). Moreover, an ethylnitrosourea-mutagenesis approach in mice led to the identification of an amino acid substitution within the Twist box of Twist1 that causes premature osteoblast differentiation in vivo (Bialek et al., 2004).

Unexpectedly, this mouse model, termed Charlie Chaplin, also displayed decreased chondrocyte maturation, thereby suggesting an additional physiological role of Twist1, independent of its antiosteogenic function (Hinoi et al., 2006). Because *Twist1* is not expressed in chondrocytes, but in mesenchymal cells of the perichondrium, it appears that it is required to inhibit the induction of *Fgf18* expression in these cells by the action of Runx2, which was described earlier. Indeed, whereas transgenic mice overexpressing *Twist1* under the control of an osteoblast-specific 0.1 *(I)-collagen* promoter fragment displayed enhanced chondrocyte maturation, the decreased chondrocyte maturation in the *CC/CC* mice was normalized by haploinsufficiency of *Runx2* (Hinoi et al., 2006). Taken together, these data demonstrate that Twist1, through inhibition of Runx2 DNA binding, not only limits osteoblast differentiation and bone formation, but also enhances chondrocyte maturation during skeletal development. Other negative regulators of Runx2 function in vivo have been described based on their abilities to influence the CCD phenotype of *Runx2*$^{+/-}$ mice. One of them, another zinc finger−containing protein termed zinc finger protein 521 (2fp521), antagonizes Runx2 function in a histone deacetylase 3 (HDAC3)-dependent manner.

Osterix, a Runx2-dependent osteoblast-specific transcription factor required for bone formation

In addition to Runx2, there is at least one more transcription factor, termed Osterix (Osx), whose activity is absolutely required in mice for osteoblast differentiation. Osx is a zinc finger−containing transcription factor that is specifically expressed in osteoblasts of all skeletal elements. Inactivation of Osx in mice results in perinatal lethality owing to a complete absence of bone formation (Nakashima et al., 2002). Unlike the *Runx2*-deficient mice whose skeleton is completely unmineralized, the *Osx*-deficient mice lacked a mineralized matrix only in bones formed by intramembranous ossification. In contrast, the bones formed by endochondral ossification contained mineralized matrix, but this resembled

calcified cartilage, not mineralized bone matrix. This finding suggested that Osx, unlike Runx2, is not required for chondrocyte hypertrophy, thereby demonstrating that it specifically induces osteoblast differentiation and bone formation in vivo. The comparative expression analysis by in situ hybridization further revealed that *Osx* is not expressed in *Runx2*-deficient embryos, and that *Runx2* is normally expressed in *Osx*-deficient embryos (Nakashima et al., 2002). These results demonstrated that Osx acts downstream of Runx2 in a transcriptional cascade of osteoblast differentiation, and its expression is apparently directly regulated by the binding of Runx2 to a responsive element in the promoter of the Osx gene (Nishio et al., 2006).

In contrast to the steadily increasing knowledge about the function of Runx2 and its regulation by other molecules, the molecular mechanisms underlying the action of Osx in osteoblasts are less well understood. Moreover, unlike for *RUNX2*, no human mutations of the *OSX* gene have yet been identified that would be associated with decreased bone formation. Nevertheless, one 2005 publication indicates that Osx contributes to the negative effects of nuclear factor of activated T cells (NFAT) inhibitors on bone mass (Koga et al., 2005). NFAT inhibitors, such as *FKS06* or cyclosporin A, are commonly used as immune suppressants, e.g., after organ transplantation. However, this treatment is often accompanied by the development of osteopenia in the patient (Rodino and Shane, 1998). Likewise, treatment of mice with *FKS06* leads to decreased bone mass owing to impaired bone formation, and the same phenotype was observed in mice lacking the transcription factor Nfatc1. The deduced role of Nfatc1 as a physiological activator of osteoblast differentiation and function can be molecularly explained by an interaction with *Osx*. In fact, both proteins synergistically activate transcription of a *Luciferase* reporter gene driven by an osteoblast-specific *α1(I)-collagen* promoter fragment, which is based on the formation of a DNA-binding complex of Nfatc1 and Osx (Koga et al., 2005). It has been shown that Osx might act as a cofactor for Dlx5 for osteoblast specification (Hojo et al., 2016).

ATF4, a transcriptional regulator of osteoblast functions and a mediator of the neural regulation of bone mass

The role of ATF4 in skeletal biology also arose from a combination of molecular biology and human and mouse genetic data. *RSK2*, which encodes a kinase, is the gene mutated in Coffin–Lowry syndrome, an X-linked mental retardation condition associated with skeletal abnormalities (Trivier et al., 1996). Like Rsk2-deficient mice, $Atf4^{-/-}$ mice display a lower bone mass owing to impaired bone formation (Yang et al., 2004). In vitro kinase assays demonstrated that ATF4 is strongly phosphorylated by Rsk2, and that this phosphorylation is undetectable in osteoblasts derived from *Rsk2*-deficient mice. The subsequent analysis of an *Atf4*-deficient mouse model revealed that this transcription factor plays a crucial role in bone formation. In fact, *Atf4*-deficient mice display a delayed skeletal development and thereafter develop a severe low-bone-mass phenotype caused by a decrease in bone formation (Yang et al., 2004).

Molecularly, ATF4 was identified as the factor binding to the osteoblast-specific element OSE1 in the *Osteocalcin* promoter, thereby directly activating the transcription of this gene. Moreover, ATF4 is required for proper synthesis of type I collagen, although this function is not mediated by a transcriptional regulation of *type I collagen* expression. In fact, because type I collagen synthesis in the absence of nonessential amino acids is specifically reduced in primary osteoblast cultures lacking ATF4, it appears that ATF4 is required for efficient amino acid import in osteoblasts, as has been described for other cell types (Harding et al., 2003). Because a reduced type I collagen synthesis was subsequently also observed in mice lacking Rsk2, these data provided evidence that the diminished ATF4 phosphorylation in the absence of Rsk2 may contribute to the skeletal defects associated with Coffin–Lowry syndrome (Yang et al., 2004).

In addition to its role in bone formation, ATF4, through its expression in osteoblasts, regulates bone resorption (Elefteriou et al., 2005). This function is molecularly explained by the fact that ATF4 binds to the promoter of the *Rankl* (receptor activator of NF-κB ligand) gene to promote osteoclast differentiation (Teitelbaum and Ross, 2003). As a result, ATF4-deficient mice have a decreased number of osteoclasts because of their reduced *Rankl* expression. Most importantly, this function of ATF4 is involved in the control of bone resorption by the sympathetic nervous system. In fact, treatment of normal osteoblasts with isoproterenol, a surrogate of sympathetic signaling, enhanced osteoclastogenesis of cocultured bone marrow macrophages through an induction of osteoblastic *Rankl* expression (Elefteriou et al., 2005). As expected, this effect was blunted when the osteoblasts were derived from mice lacking the β2-adrenergic receptor Adrb2. However, the effect of isoproterenol was also blunted by an inhibitor of protein kinase A, or by using osteoblasts derived from ATF4-deficient mice (Elefteriou et al., 2005). Taken together, these results demonstrated that ATF4 is an important mediator of extracellular signals, such as β-adrenergic stimulation, in osteoblasts.

Thus, it is not surprising that the function of ATF4 is mostly regulated posttranslationally. For example, as already mentioned, ATF4 also interacts with other proteins, such as the nuclear matrix protein Satb2 (Dobreva et al., 2006). Also as

described earlier, the proximal *Osteocalcin* promoter contains two osteoblast-specific elements, termed OSE1 and OSE2, that serve as binding sites for ATF4 and Runx2, respectively (Ducy and Karsenty, 1995; Ducy et al., 1997; Schinke and Karsenty, 1999; Yang et al., 2004). Because of the proximity of both elements, there is indeed a physical interaction of the two proteins, which is stabilized by Satb2, which acts as a scaffold enhancing the synergistic activity of Runx2 and ATF4, which is required for optimum *Osteocalcin* expression (Xiao et al., 2005; Dobreva et al., 2006).

Other aspects of ATF4 biology are also regulated posttranslationally. In fact, even the osteoblast specificity of ATF4 function is not determined by osteoblast-specific *ATF4* expression, but by a selective accumulation of the ATF4 protein in osteoblasts, which itself is explained by the lack of proteasomal degradation (Yang and Karsenty, 2004). This is best demonstrated by the finding that the treatment of nonosteoblastic cell types with the proteasome inhibitor MG 115 leads to accumulation of the ATF4 protein, thereby resulting in ectopic *Osteocalcin* expression. Taken together, these data provided the first evidence for the achievement of a cell-specific function of a transcriptional activator by a posttranslational mechanism. They are therefore of general importance for our understanding of the transcriptional networks controlling cellular differentiation and function.

Remarkably, ATF4 biology further illustrates how the molecular understanding of a disease-causing gene can translate into therapeutic interventions. Indeed, an increased Rsk2-dependent phosphorylation of ATF4 may also be involved in the development of the skeletal abnormalities in human patients suffering from neurofibromatosis (Ruggieri et al., 1999; Stevenson et al., 1999). This disease, which is primarily known for tumor development within the nervous system, is caused by inactivating mutations of the *NF1* gene, which encodes a Ras-GTPase-activating protein (Klose et al., 1998). The generation of a mouse model lacking *Nf1* specifically in osteoblasts ($Nf1^{-/-}_{ob}$) led to the demonstration that this gene plays a major physiological role in bone remodeling. In fact, the $Nf1^{-/-}_{ob}$ mice displayed a high-bone-mass phenotype that is caused by increased bone turnover and is accompanied by enrichment of unmineralized osteoid (Elefteriou et al., 2006). The analysis of this phenotype revealed an increased production of type I collagen in the absence of *Nf1*, which is molecularly explained by an Rsk2-dependent activation of ATF4. Likewise, transgenic mice overexpressing *ATF4* in osteoblasts display a phenotype similar to that of the $Nf1^{-/-}_{ob}$ mice, and the increased type I collagen production and osteoid thickness in the latter are significantly reduced by haploinsufficiency of ATF4 (Elefteriou et al., 2006).

These molecular findings may also have therapeutic implications. Given the previously discussed function of ATF4 in amino acid import, it appeared reasonable to analyze whether the skeletal defects of the $Nf1^{-/-}_{ob}$ mice can be affected by dietary manipulation. Indeed, the increased bone formation and osteoid thickness of $Nf1^{-/-}_{ob}$ mice can be normalized by a low-protein diet, and the same was the case in the transgenic mice overexpressing *ATF4* in osteoblasts (Elefteriou et al., 2006). Likewise, the defects of osteoblast differentiation and bone formation observed in both the *ATF4*- and the Rsk2-deficient mice were corrected by feeding a high-protein diet. Taken together, these data not only emphasize the importance of ATF4 in osteoblast biology, but also demonstrate how knowledge about its specific functions in osteoblasts can be useful for the treatment of skeletal diseases.

Additional transcriptional regulators of osteoblast differentiation and function

Activator protein 1 (AP-1) is a heterodimeric transcription factor composed of members of the Jun and Fos families of basic leucine zipper proteins (Karin et al., 1997). These include the Jun proteins c-Jun, JunB, and JunD, as well as the Fos proteins c-Fos, Fra1, Fra2, and Fosb, respectively. Although AP-1 transcription factors have been demonstrated to fulfill various functions in different cell types, it is striking that some of the family members play specific roles in bone remodeling, as demonstrated by several loss- or gain-of-function studies in mice (Wagner and Eferl, 2005). For instance, the deletion of *c-Fos* from the mouse genome results in severe osteopetrosis owing to an arrest of osteoclast differentiation, whereas the transgenic overexpression of *c-Fos* results in osteosarcoma development (Grigoriadis et al., 1993, 1994). Moreover, transgenic mice overexpressing either *Fml* or *i1fosB*, a splice variant of *FosB*, display a severe osteosclerotic phenotype caused by increased osteoblast differentiation and function (Jochum et al., 2000; Sabatakos et al., 2000). Likewise, mice lacking Fra1 in extraplacental tissues display an osteopenia associated with reduced bone formation, indicating a physiological role of Fra1 in osteoblasts (Eferl et al., 2004). When the same approach was used to inactivate JunB in extraplacental tissues, thereby circumventing the embryonic lethality caused by a complete genomic deletion of *JunB*, the resulting mice developed a state of low bone turnover, owing to cell-autonomous defects in osteoblasts, but also in osteoclast differentiation (Kenner et al., 2004).

Taken together, these data provide evidence for a crucial role of AP-1 transcription factors in the regulation of bone formation, although their connection to the other transcriptional regulators described earlier still needs to be further investigated. For instance, it is known from other cell types that Jun proteins can also interact with ATF family members, thus raising the possibility that heterodimerization with ATF4 may be one mechanism by which these proteins can regulate

osteoblast-specific gene expression (Chinenov and Kerppola, 2001). Interestingly, it has been demonstrated that the osteosarcoma development of *c-Fos* transgenic mice is dramatically decreased in an Rsk2-deficient genetic background (David et al., 2005). This observation is molecularly explained by the lack of c-Fos phosphorylation by Rsk2, thereby leading to increased proteasomal degradation. Thus, Rsk2 apparently not only is involved in the physiological regulation of bone formation via phosphorylation of ATF4, but may also have an influence on the development of osteosarcomas via phosphorylation of c-Fos.

Another potential mechanism by which AP-1 family members might be involved in the regulation of bone formation came- from the analysis of mouse models with impaired circadian regulation. These mice, which lack components of the molecular clock, namely the *Per* or *Cry* genes, display a high-bone-mass phenotype caused by increased bone formation (Fu et al., 2005). Moreover, they respond to intracerebroventricular infusion of leptin with a further increase in bone mass, suggesting that the components of the molecular clock are involved in the regulation of bone formation via the sympathetic nervous system. Interestingly, virtually all genes encoding members of the AP-1 transcription factor family were expressed at higher levels in osteoblasts derived from mice lacking either the *Per* genes or the β2-adrenergic receptor Adrb2 (Fu et al., 2005). This increase was especially pronounced in the case of the *c-Fos* gene, whose expression can also be induced by the addition of isoproterenol in wild-type osteoblasts. In turn, c-Fos leads to a direct activation of *c-Myc* transcription, thereby indirectly increasing the intracellular levels of cyclin D1 and promoting osteoblast proliferation. Taken together, these data demonstrated that the expression of AP-1 components is activated via sympathetic signaling, and that this induction is counteracted by the activity of clock gene products.

Finally, another transcription factor that, like AP-1, is not cell specific but plays a great role in osteoblast biology, is the cAMP-responsive element binding protein (CREB), a transcription factor mediating changes in gene expression caused by signaling through various G-protein-coupled receptors. The demonstration that gut-derived serotonin is an inhibitor of bone formation in mice, rats, and humans, the regulation of the synthesis of which is under the control of Lrp5 signaling in the gut, raised the question of how serotonin signals in osteoblasts (Yadav et al., 2008; Frost et al., 2011). Expression analysis and cell-specific gene deletion experiments in the mouse showed that Htr1B is the receptor of serotonin, mediating its function in osteoblasts, namely, an inhibition of proliferation, and that the transcription factor mediating this effect is CREB (Yadav et al., 2008).

Transcription factors acting downstream of Wnt signaling in osteoblasts: what do they actually do in differentiated osteoblasts?

The discovery of the *LRP5* gene as a major determinant of bone mass in humans because of its homology to a Wnt coreceptor in *Drosophila* has generated an enormous interest and hope in what the canonical Wnt signaling could do in cells of the osteoblast lineage and especially in differentiated osteoblasts. An obligatory implication of this belief, an implication that cannot be ignored or dismissed, is that ablating canonical Wnt signaling in differentiated osteoblasts should lead to an osteopetrotic phenotype. Unfortunately, when taken at face value as they should, the experiments performed to test this hypothesis not only did not provide any evidence that it is the case, but in fact clearly showed that it is not the case.

Indeed, the osteoblast-specific inactivation of β-catenin, the molecular node of the canonical Wnt signaling pathway, resulted in the expected low-bone-mass phenotype; however, this was caused by an isolated and massive increase in bone resorption (Glass et al., 2005). The molecular explanation for the regulation of osteoclast differentiation by β-catenin expression in osteoblasts came from the expression analysis of *Osteoprotegerin* (*Opg*), a well-known inhibitor of bone resorption, blocking the activity of Rankl (Simonet et al., 1997; Yasuda et al., 1998). Surprisingly, although *Opg* expression was markedly increased in osteoblasts from mice expressing the stabilized form of β-catenin, its expression was decreased in mice harboring an osteoblast-specific deletion of β-catenin (Glass et al., 2005). That similar results were observed when β-catenin was deleted from osteocytes established that it is a general rule of bone biology. Of note, these results need to be considered together with the experimental evidence gathered by two different laboratories, using for that purpose mutant mouse strains also generated in two different laboratories, that mice lacking Lrp5 signaling in osteoblasts only do not have any bone phenotype to speak of (Yadav et al., 2008; Kode et al., 2014).

One of the transcription factors activated by β-catenin in osteoblasts has already been identified as Tcfl, whose importance for the regulation of gene expression in osteoblasts is highlighted by several lines of evidence. First, in situ hybridization revealed that *Tcfl* is expressed in osteoblasts during bone development and after birth. Second, *Tcfl*-deficient mice display a low-bone-mass phenotype caused by an increase in bone resorption. Third, the compound heterozygosity of *Tcfl* and *β-catenin* in osteoblasts also results in low bone mass, which is not observed when one allele of each gene is

inactivated alone. Fourth, *Opg* expression is decreased in osteoblasts of *Tcfl*-deficient mice, and the molecular analysis of the *Opg* promoter revealed the existence of a Tcf1-binding site, whose functional activity was subsequently proven by chromatin immunoprecipitation and DNA cotransfection assays (Glass et al., 2005). The implication of these results cannot be underestimated, without taking great and yet predictable risks, when proposing to harness the canonical Wnt signaling pathway for therapeutic purposes in the context of osteoporosis.

Regulation of osteoblast differentiation by means other than transcription factors

Chromatin structure, which influences by posttranslational modifications of histone proteins around which the DNA is wrapped, is a major determinant of gene expression (Allis et al., 2007). Histone acetylation promotes gene transcription by relaxing the chromatin structure, whereas deacetylation of histones by HDACs induces chromatin condensation and transcriptional repression (Berger, 2002; Verdin et al., 2003; Allis et al., 2007). Class II HDACs contain a poorly active catalytic domain and a long N-terminal extension to which transcription factors can bind. The existence of this domain has suggested that class II HDACs can link extracellular cues to the genome of a given cell (Verdin et al., 2003; Haberland et al., 2009). Several class I HDACs (Hdac1 and Hdac3) are expressed in osteoblasts, and conditional deletion of Hdac3 within osteo-chondroprogenitor cells decreases osteoblast number, and, as mentioned earlier, one mechanism whereby Zpf521 inhibits Runx2 functions during osteoblast differentiation is by interacting with HDAC3. On the other hand, one class II HDAC, HDAC4, acts as a central integrator of two extracellular cues acting on osteoblasts. One is parathyroid hormone, which targets HDAC4 for degradation and thereby releases MeF2c that can now transactivate *Rankl*, and thus favors osteoclast differentiation. The other is sympathetic tone, which instead favors HDAC4 accumulation in the nucleus, its association with ATF4, and again Rankl expression and osteoclast differentiation (Obri et al., 2014).

Another mode of regulation of osteoblast differentiation that has received much attention since the last edition of this book is the one fulfilled by small noncoding RNAs. MicroRNAs (miRNAs) are small noncoding RNAs that down-regulate expression of their target genes by either mRNA degradation or translational inhibition (Valencia-Sanchez et al., 2006; Bartel, 2009; Djuranovic et al., 2011; Huntzinger and Izaurralde, 2011). Although most miRNAs are broadly expressed, some have a more restricted pattern of expression and influence cell differentiation (Poy et al., 2004). The importance of this mode of gene regulation during skeletogenesis is inferred from the observation that inactivation of

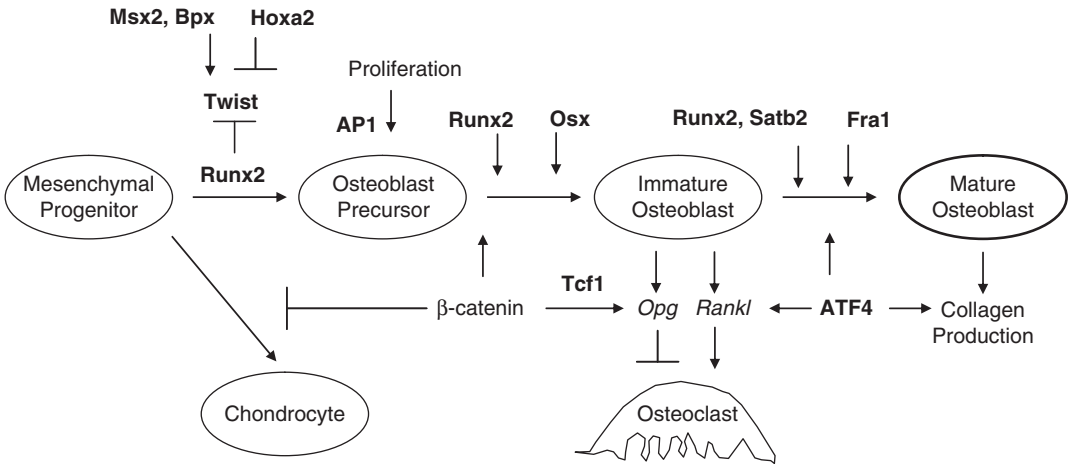

FIGURE 7.2 *Schematic representation of the transcriptional control of osteoblast differentiation and functions.*

DICER, a protein necessary for processing of miRNAs, affects osteoblast differentiation (Gaur et al., 2010). Accordingly, it has been suggested that miRNAs may be involved in osteoblast proliferation and/or differentiation (Hassan et al., 2010). However, these observations were derived from gain-of-function experiments performed in cell culture. Few miRNAs had been shown, through cell-specific loss-of-function experiments performed in the mouse, to regulate osteoblast proliferation and/or differentiation in vivo. A first example of these was miRNA-2561, whose silencing in the mouse reduces Runx2 accumulation without, however, causing a characteristic CCD phenotype (Li et al., 2009). Two other miRNAs, miR-34b and miR-34c, were shown through cell-specific gene deletion to inhibit osteoblast proliferation by suppressing cyclin D1, CDK4, and CDK6 accumulation (Wei et al., 2012). They also hampered osteoblast differentiation by inhibiting the function of SATB2, a protein interacting with Runx2 and ATF4 (Wei et al., 2012). Another miRNA, miR-124, inhibits bone formation by targeting another transcription factor implicated in osteoblast differentiation, ATF4, whereas miR-188 was shown to favor bone formation in an HDAC9-dependent manner (Li et al., 2015) (Fig. 7.1 and 7.2).

Chapter outline

Introduction

The first two decades of the 21st century have witnessed a literal explosion in our understanding of fundamental biological processes, catalyzed in large part by the human genome project and the vast repertoire of technologies that are now available to identify genes and study gene function. The field of bone biology has certainly benefited from these advances as illustrated by many of the chapters in this book. Not surprisingly perhaps, the genetic dissection of single-gene human disorders that present with skeletal abnormalities has led to advances in our understanding of bone biology, oftentimes in directions that could not have been anticipated by the current state of knowledge.

The Wnt/β-catenin pathway and its sister pathways (planar cell polarity, or PCP, and Wnt/Ca^{2+}) are one of five key signaling pathway families critical for normal development. They control a spectrum of cellular functions from differentiation to proliferation and growth and are involved in many aspects of patterning during development. As such it is not surprising that we now recognize that a wide spectrum of diseases have been attributed to mutations in members of the pathway or aberrant regulation of one of the Wnt pathways (Goggolidou and Wilson, 2016; Libro et al., 2016; Wang et al., 2016; Abou Ziki and Mani, 2017; Butler and Wallingford, 2017; Lodish, 2017; Nusse and Clevers, 2017). The field of bone biology was introduced to the Wnt/β-catenin signaling pathway in 2001−2 as a result of the discovery of mutations in the low-density lipoprotein receptor (LDLR)-related protein 5 (*LRP5*) gene that give rise to conditions of decreased (Gong et al., 2001) or increased bone mass (Boyden et al., 2002; Little et al., 2002). This was followed shortly after by the identification of *SOST* gene mutations as causal for sclerosteosis (Balemans et al., 2001; Brunkow et al., 2001) and, in the next year, for Van Buchem disease (Balemans et al., 2002; Staehling-Hampton et al., 2002). However, the recognition that sclerostin, the product of the *SOST* gene, was a key negative regulator of Wnt/β-catenin signaling was not made until 2005 (Li et al., 2005). Targeting sclerostin with humanized anti-sclerostin antibodies has become the focus of major clinical trials for the treatment of osteoporosis and has several other potential applications (see later). Since those initial descriptions of altered bone mass, several key components of the Wnt signaling pathway (see Fig. 8.1) have been shown to underlie a large number of monogenic bone diseases (see for review Maupin et al., 2013; Malhotra and Yang, 2014; Lara-Castillo and Johnson, 2015; Wang et al., 2016; Reppe et al., 2017). In many cases normal polymorphisms in these genes are associated

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00008-7

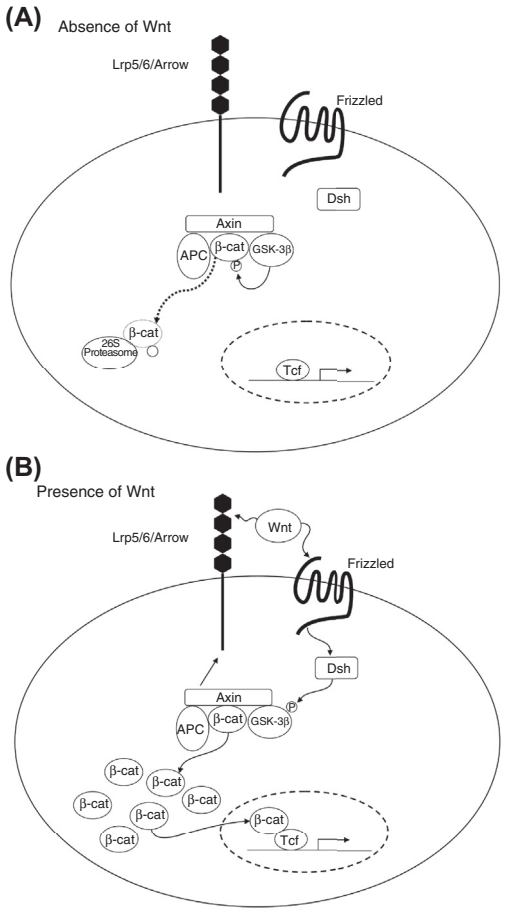

FIGURE 8.1 The Wnt/β-catenin signaling pathway. The Wnt/β-catenin signaling pathway is controlled by two cell surface coreceptors, Frizzled and one of the low-density lipoprotein receptor–related proteins (Lrp5 or Lrp6) in vertebrates or Arrow in *Drosophila*, that cooperatively bind the Wnt protein ligand. (A) In the absence of Wnt, the degradation complex consisting of the scaffolding protein Axin, adenomatous polyposis coli (*APC*), and glycogen synthase kinase-3β (*GSK-3β*), along with several other proteins (not shown), coordinates the phosphorylation (*P*) of β-catenin (*β-cat*), which is then ubiquitinated and degraded by the 26S proteasome complex. This serves to keep the intracellular levels of free β-catenin at a low level. (B) When Wnt ligand is bound by the Lrp5/6/Arrow and Frizzled coreceptors the protein Dishevelled (*Dsh*) is activated, which results in the phosphorylation of GSK-3β, thereby inhibiting its activity. The degradation complex is also induced to bind to the cytoplasmic tail of Lrp5/6/Arrow and the combination of events leads to the intracellular accumulation of high levels of free β-catenin. β-Catenin can then translocate into the nucleus, and upon binding to the T cell factor/lymphoid enhancer-binding factor (*Tcf*/LEF) family of transcription factors, regulate the expression of a number of target genes.

with or contribute to some degree of variance in complex bone traits such as bone density (see for review Urano and Inoue, 2014; Lara-Castillo and Johnson, 2015; Rocha-Braz and Ferraz-de-Souza, 2016; Reppe et al., 2017).

Prior to these human genetic studies the role of Wnt/β-catenin signaling in bone was limited mainly to skeletal development, but because of the explosion of research that occurred as a result of those seminal publications we now appreciate the role of this pathway in bone cell differentiation, proliferation, and apoptosis; bone mass regulation; and the ability of bone to respond to changes in mechanical load. While Wnts can signal through multiple pathways, in this chapter the focus will be on what is known about the Wnt/β-catenin signaling pathway and its regulation as pertains to bone.

Wnt genes and proteins

As of this writing, there are 19 known *Wnt* genes in humans. Wnt proteins are secreted, highly posttranslationally modified proteins that play key roles in development and homeostasis through their involvement in cell differentiation, proliferation, and apoptosis. Nusse and Varmus first described Wnt as the mouse protooncogene integration site/locus (*int-1*) of the murine mammary tumor virus that resulted in breast tumors (Nusse and Varmus, 1982). Because of the challenges in purifying Wnt in a biologically active form, Nusse turned to a genetic system to help characterize the downstream components of the pathway when it was found that the *Drosophila* segment polarity gene *Wingless* (*Wg*) was homologous

to the *int-1* gene (Rijsewijk et al., 1987). In 1991, several of the founding researchers in this field who came from the fields of *Drosophila* genetics, mammary viral oncogenesis, and early embryonic development in *Xenopus* came together to standardize the nomenclature for the growing number of Int-1- and Wg-related genes that were being identified and coined the term "Wnt" as a combination of Wingless and Int-1 (Nusse et al., 1991).

The Wnt proteins are difficult to study because of posttranslational modifications (mainly palmitoylation) that make them extremely hydrophobic and difficult to purify in a biologically active form. In fact, it took 21 years after the initial discovery of Wnt to work out the conditions to purify recombinant Wnt protein in a manner that retained its signaling activity (Willert et al., 2003). Thus, historically, much of what we know about Wnt proteins was based on their DNA sequence analysis and genetic screens in *Drosophila* and, later, *Caenorhabditis elegans* (Sawa and Korswagen, 2013). The various Wnt genes share general homology in the range of 35%, although within subgroups the homology can be as high as 83%. The molecular weight of the various Wnt proteins ranges from 39 to 46 kDa. All Wnts contain 23 or 24 conserved cysteine residues that are spaced similarly between proteins, suggesting an important conservation of function, possibly proper folding of the protein, which is required for Wnt activity.

Nusse and colleagues successfully purified Wnt3a from mouse L cells (Willert et al., 2003). Subsequently Schulte et al. (Schulte et al., 2005) used a similar strategy to purify Wnt5a. Both groups originally thought that the addition of a palmitate to the first, most amino-terminally conserved of the cysteine residues was absolutely required for Wnt3a and Wnt5a activity. In fact, the identification of this cysteine residue as the site of palmitoylation turned out to be incorrect, as subsequent studies showed that, in fact, a serine residue was the target of palmitoylation in Wnt proteins (Takada et al., 2006; Janda et al., 2012). The implications for this are discussed in the following.

In *Drosophila* the gene *porcupine* and in *C. elegans* the gene *mom-1* encode acyltransferase enzymes that are the proteins responsible for the palmitoylation of Wnts (Kadowaki et al., 1996; Nusse, 2003). Interestingly, these proteins are membrane bound and found in the endoplasmic reticulum, indicating that the palmitoylation occurs intracellularly. While palmitoylation of secreted proteins is somewhat unusual (Dunphy and Linder, 1998), the hedgehog family of proteins is also palmitoylated and secreted in this manner (Nusse, 2003). Subsequent work revealed two functional aspects related to palmitoylation of this serine. First, it is essential for transport of Wnt ligands from the endoplasmic reticulum to the cell surface for secretion. Upon palmitoylation, a multipass transmembrane protein, Wntless, binds to the palmitoylated Wnt and acts as a chaperone protein to facilitate its transport through the Golgi to the cell surface (Banziger et al., 2006; Bartscherer et al., 2006). Loss of either Porcupine or Wntless renders a cell functionally null for the ability to secrete any Wnt ligands.

The second functional role of the palmitoylated serine residue is its requirement for facilitating the binding of Wnt to Frizzled on the cell surface. This role was identified as a result of the first successful crystal structure of the Wnt−Frizzled interaction (Janda et al., 2012). This structure revealed that the palmitoleic group attached to the serine fits into a deep, hydrophobic group in the cysteine-rich domain (CRD) of Frizzleds.

Components of the Wnt/β-catenin signaling pathway

A detailed description of the various components of the Wnt/β-catenin signaling pathway can be found at the Wnt homepage website maintained by Dr. Roel Nusse (http://web.stanford.edu/group/nusselab/cgi-bin/wnt/). The major players in the Wnt/β-catenin signaling pathway in bone are (1) the cell surface coreceptors Lrp5/6 and Frizzled; (2) the intracellular proteins Dishevelled (Dsh), glycogen synthase kinase-3β (GSK-3β), Axin, and β-catenin; and (3) the T cell factor/lymphoid enhancer-binding factor (TCF/LEF) nuclear transcription factors that bind β-catenin and regulate gene expression. In addition, there are a number of other extracellular and intracellular proteins involved in regulation of this pathway that serve to modify the functionality of one of these key proteins. Particularly important are a number of proteins that bind Lrp5/6 to modulate its binding of Wnt ligand.

The details of the Wnt/β-catenin pathway are illustrated in Fig. 8.1. Ultimately the Wnt/β-catenin signaling pathway controls the intracellular levels of free β-catenin. In the absence of Wnt ligand the intracellular levels of β-catenin are extremely low due to the activity of a degradation complex comprising Axin, GSK-3β, the adenomatous polyposis coli (APC) protein, and several other proteins. This complex, specifically GSK-3β or -3α, is responsible for the phosphorylation of β-catenin, which leads to its ubiquitination and degradation by the 26S proteasome complex (Fig. 8.1A). Wnt binding to the Lrp5/6-Frizzled coreceptors results in Dsh activation and Axin binding to the cytoplasmic tail of Lrp5/6. Dsh activation leads to GSK-3β phosphorylation and inhibition of its activity. β-Catenin is no longer phosphorylated and this, coupled with the binding of Axin to the cytoplasmic tail of Lrp5/6, releases β-catenin. β-Catenin accumulates in the cytoplasm and then translocates into the nucleus where it binds to the TCF/LEF family of transcription proteins and regulates the expression of specific target genes (Fig. 8.1B).

Lrp5, Lrp6, and frizzled

Lrp5 and Lrp6 (Arrow in *Drosophila*) are highly homologous proteins that until their role in bone biology was described were considered orphan members of the LDLR family, which includes at least 13 members (Strickland et al., 2002). One of the hallmark structural characteristics of this family is the presence of YWTD (tyrosine−tryptophan−threonine−aspartic acid) repeat motifs framed by epidermal growth factor repeats in the extracellular domain of the proteins. These repeat clusters form β-propeller structures that are important for ligand binding. Based on the amino acid sequence of Lrp5 and Lrp6 derived from cDNA cloning (Brown et al., 1998; Dong et al., 1998; Hey et al., 1998; Kim et al., 1998), Lrp5/6 each contain four of these repeat clusters. However, the YWTD motif is degenerate and one of the six repeat sequences comprising each motif in Lrp5 is substituted by LFAN (leucine−phenylalanine−alanine−asparagine) or FFTN sequences (Johnson and Summerfield, 2005). Many of these LDLR family members have a consensus sequence of NPxY (asparagine−proline−x−tyrosine) in their cytoplasmic tail that is required for endocytosis of the receptor (Chen et al., 1990). Lrp5 and Lrp6 lack an NPxY sequence. Also the orientation of their extracellular domain is reversed relative to other members of the LDLR family in that LDL-A type repeats (complement-like repeats) are adjacent to the transmembrane spanning region rather than at the amino-terminal end (or clustered throughout the extracellular domain). There are also only three of these LDL-A type repeats in Lrp5 and Lrp6.

Originally human *LRP5* was proposed as a candidate gene for susceptibility to type 1 diabetes in the insulin-dependent diabetes mellitus 4 locus that was mapped to chromosome 11q13 (Figueroa et al., 2000; Twells et al., 2001). However, subsequent genetic association studies failed to confirm this functional role (Twells et al., 2003). At the same time, Arrow (Wehrli et al., 2000) and Lrp6 (Tamai et al., 2000) were shown to mediate Wnt/β-catenin signaling and $Lrp6^{-/-}$ mutant mouse embryos displayed skeletal abnormalities similar to those found in mice carrying mutations in various Wnt genes (Pinson et al., 2000). Subsequently mutations in human *LRP5* were shown to cause osteoporosis pseudoglioma syndrome (OPPG) (Gong et al., 2001), which is characterized by low bone mass and progressive blindness, and the high bone mass (HBM) mutation G171V was reported in two separate kindreds (Boyden et al., 2002; Little et al., 2002). A large number of additional mutations that give rise to conditions of increased or decreased bone mass have been reported in the literature (Balemans and Van Hul, 2007). Also, allelic variants of *LRP5* have been shown to contribute to variation in bone mass in several studies, although the relative degree varies and sex differences are noted in many of the studies (Karasik et al., 2016).

The role of LRP6 in human bone density variation has been studied to a limited degree. One report indicates that the *LRP6* Ile1062Val allele contributes to a higher risk for fragility and vertebral fracture in men and that this allelic variant in combination with the *LRP5* A1330V allele accounted for 10% of the fractures in males (van Meurs et al., 2006). It has also been shown that $Lrp6^{+/-}$:$Lrp5^{-/-}$ mice have lower adult bone mineral density compared with $Lrp6^{+/+}$:$Lrp5^{-/-}$ mice, suggesting a role for Lrp6 in bone mass accrual (Holmen et al., 2004). A mutation in *LRP6* ($LRP6^{R611C}$) was linked to early-onset coronary artery disease in a family, and the five mutation carriers that were studied also had low bone density, confirming a role for LRP6 in bone mass accrual as suggested by the studies in mice (Mani et al., 2007). Also, a hypomorphic *Lrp6* mutation in the mouse (called *ringelschwanz*) has been identified, and studies in that model confirm a role for Lrp6 in somitogenesis and osteogenesis (Kokubu et al., 2004).

Given that both appear to be coexpressed in most cells/tissues that have been examined, it was of interest to determine whether Lrp5 and Lrp6 served totally redundant roles in skeletal development and homeostasis. Using the Dermo1-Cre strain to drive conditional gene deletion in mesenchymal progenitors, it was demonstrated that Lrp5 and Lrp6 played redundant roles at this stage (Joeng et al., 2011). Interestingly, deletion of the genes in mature osteoblasts (using OCN-Cre) revealed that Lrp6 and Lrp5 played overlapping, but not redundant, roles at that stage (Riddle et al., 2013). The role of Lrp5 and the Wnt/β-catenin signaling pathway in the response of bone to mechanical loading has been firmly established. Based upon analysis of the phenotype of affected members of the HBM trait kindred we had speculated that the *LRP5* G171V mutation gene might somehow have altered the sensitivity of the skeleton to mechanical loading (Johnson et al., 2002). Several lines of evidence now support a central role for Lrp5 and the Wnt/β-catenin signaling pathway in the response of bone/bone cells to mechanical loading. Sawakami et al. (Sawakami et al., 2006) have shown that the bone formation response after loading is reduced by 88% in male and 99% in female $Lrp5^{-/-}$ mice compared with wild-type loaded mice. Mice carrying the LRP5 cDNA containing the G171V mutation have increased sensitivity to mechanical loading (Cullen et al., 2004). Osteocyte β-catenin haploinsufficiency protects against bone loss in male mice subjected to hindlimb unloading (Maurel et al., 2016). Changes in the expression of Wnt/β-catenin signaling pathway target genes have been shown to occur both in vivo in bone (Robinson et al., 2006) and in vitro in bone cells (Lau et al., 2006; Robinson et al., 2006) in response to mechanical loading. Given that Lrp5 is required for the response of bone to mechanical loading, the question that next needs to be answered is, where does Lrp5/Wnt/β-catenin signaling fit into the cellular cascade events

that occur in response to mechanical loading? A partial answer to this question will be discussed further later in this chapter. Another unanswered question is, does Lrp6 play a role in the response to loading? At this writing we have no definitive answer, but given the results of the ulna loading studies performed with the $Lrp5^{-/-}$ mice and that these mice have normal alleles of Lrp6, it would seem that Lrp6 plays little or no role in mechanoresponsiveness in bone.

As of this writing there are 10 known members of the Frizzled family of proteins in humans and a homologous protein called Smoothened that functions in Hedgehog signaling. The Frizzled proteins contain a CRD at the amino terminus and seven transmembrane-spanning domains. The CRD is responsible for binding of Wnt ligands (Bhanot et al., 1996). The Frizzled proteins are generally thought to be coupled to trimeric G proteins (Sheldahl et al., 1999; Katanaev et al., 2005). It also seems evident that different Frizzleds regulate different intracellular signaling cascades. However, the specific combinations are not completely understood. Specific Frizzleds functioning in combination with Lrp5 or Lrp6 in the binding of specific Wnt proteins lead to activation of β-catenin signaling; however, some Frizzleds acting alone appear to be involved in the activation of at least three other Wnt signaling pathways. These other Wnt pathways are the PCP (Mlodzik, 2002), the Wnt/Ca^{2+} involving protein kinase C (Kuhl et al., 2000), and a protein kinase A (PKA) pathway involved in muscle myogenesis (Chen et al., 2005). Dsh also appears to be involved in the first two of these Frizzled-regulated pathways. It is still not clear which of the 10 different Frizzleds are involved in the activation of each of the four Wnt pathways. However, it is known that some of the Wnt proteins preferentially activate the β-catenin signaling pathway (e.g., Wnt1 and Wnt3A), whereas other Wnts activate only one of the other pathways (e.g., Wnt5A activates the Wnt/Ca^{2+} signaling pathway) (Miller, 2001).

Recent work has begun to link specific Frizzled genes to skeletal development and homeostasis. Mouse strains carrying global deletions in most of the 10 Frizzled genes have been created (Wang et al., 2016). However, only two have been evaluated in detail for skeletal phenotypes. $Fzd8^{-/-}$ mice have osteopenia with normal bone formation and increased osteoclast activity (Albers et al., 2013), while $Fzd9^{-/-}$ mice have low bone mass associated with reduced chemokine expression but normal Wnt/β-catenin signaling (Albers et al., 2011; Heilmann et al., 2013). Based on work in human patients, Fzd2 probably plays a central role in early limb development. Specifically, deleterious heterozygous mutations in Fzd2 were associated with autosomal dominant omodysplasia or variations of Robinow syndrome, syndromes in which skeletal dysplasia is characterized by facial dysmorphism and shortening of the limbs (Saal et al., 2015; Turkmen et al., 2017). It is not clear whether the alteration of Fzd2 produces a protein that acts in a dominant negative fashion or if phenotypes are a result of haploinsufficiency for Fzd2. One report showed that an Fzd2 allele associated with autosomal dominant omodysplasia produced a protein truncated shortly after the seventh transmembrane domain of Fzd2 that was unable to activate β-catenin signaling. However, this work did not distinguish whether the underlying mechanistic effect was due to haploinsufficiency or a dominant negative effect of the truncated protein (Saal et al., 2015). Identification of the genetic alterations underlying the development of Robinow syndrome has revealed that mutations causing similar human phenotypes can be found in the following genes: WNT5A, FZD2, ROR2, DVL1, DVL3, and RAC3 (White et al., 2018). One interpretation of this is that a pathway initiated by WNT5A binding to the FZD2 and ROR2 receptors activates DVL proteins, resulting in the activation of RAC3 and its downstream targets.

The discovery that Lrp5/6/Arrow was also required for the activation of the Wnt/β-catenin signaling pathway suggested a model in which Lrp5/6/Arrow and Frizzled function as coreceptors (Tamai et al., 2000; Wehrli et al., 2000). The role of Wnt was proposed to perhaps facilitate the association/interaction of the coreceptors and this was the key event leading to pathway activation. Several lines of evidence obtained from the construction of various fusion proteins suggest that this is most likely the case (Holmen et al. 2002, 2005; Tolwinski et al., 2003). Wnt binding and the formation of this ternary complex leads to a Frizzled-dependent activation of Dsh. However, the exact molecular mechanism mediating Dsh activation is not clear. Dsh phosphorylation appears to be one common feature in all of the signaling pathways through which it is known to act. The kinases casein kinase 1 (CK1) (Peters et al., 1999) and CK2 (Willert et al., 1997) and PAR-1 (Sun et al., 2001) are the leading candidates for carrying out the phosphorylation of Dsh, which can occur through both Lrp5/6-dependent (leading to the β-catenin signaling pathway) and independent mechanisms (Wnt binding to Frizzled in the absence of Lrp5/6) (Gonzalez-Sancho et al., 2004). Three different models of how Frizzled and Dsh may interact have been proposed (He et al., 2004), but it is not clear which one functions in conjunction with Wnt and Lrp5/6/Arrow.

Dishevelled, glycogen synthase kinase-3β, Axin, and β-catenin

Dsh serves an important intermediary function between Frizzled and GSK-3β in the Wnt/β-catenin signaling pathway. Dsh also serves as an intermediary in the Wnt/Ca^{2+} signaling pathway (Kuhl et al., 2000) and the PCP pathway (Mlodzik, 2002). The PCP pathway is responsible for the proper orientation of wing hairs and thoracic bristles in *Drosophila.* Mutants with hairs/bristles that were improperly oriented led to the identification of the *Frizzled* and *Dishevelled* genes

(see for review Adler, 2002). Evidence suggests that Frizzled signals through the $G\alpha_o$ subunit in both the Wnt/β-catenin pathway and the PCP pathway (Katanaev et al., 2005). While it is not fully understood how Dsh becomes activated upon Wnt binding and how it can discriminate between which pathway(s) to activate, a model has been proposed that suggests that differential intracellular localization of Dsh may be involved in determining some aspects of its function. Dsh associated with cytoplasmic vesicles has been proposed to be linked to signaling through the Wnt/β-catenin pathway, while Dsh associated with actin and the plasma membrane is proposed to signal via the PCP pathway (Capelluto et al., 2002; Povelones and Nusse, 2002). It may also be that Frizzled localization and the specific Frizzled present in the cell, along with the distribution of downstream components and the specific Wnt ligand participating in the initial binding events, are critical as well (Bejsovec, 2005; Katoh, 2005).

The mechanism responsible for the activation of Dsh is not fully understood nor is the mechanism whereby Dsh acts known. There are three domains in Dsh that appear to be critical for its function. There is a DIX domain, which is also found in Axin; a PDZ domain; a conserved stretch of basic amino acids; and a DEP domain that is found in other vertebrate proteins that interact with trimeric G proteins (Cadigan and Nusse, 1997; He et al., 2004). Activation of Dsh occurs through phosphorylation and this appears to occur in the other Wnt signaling pathways that involve Dsh. The kinases CK1 (Peters et al., 1999) and CK2 (Willert et al., 1997) and PAR-1 (Sun et al., 2001) are the leading candidates to carry out the phosphorylation of Dsh. Gonzalez-Sancho et al. (Gonzalez-Sancho et al., 2004) have suggested that Frizzled−Dsh−Axin and Lrp5/6/Arrow−Axin associations occur in parallel and both are required for stabilization of β-catenin. However, much remains to be understood about the role of Dsh in Wnt/β-catenin signaling and with regard to its role in the other Wnt signaling pathways.

GSK-3 has two isoforms, α and β. While most of the current evidence implicates GSK-3β in the control of intracellular levels of β-catenin, GSK-3α may also play a role (McManus et al., 2005; Asuni et al., 2006). GSK-3β was first identified as playing a key role in the regulation of glycogen synthesis by phosphorylating (and thereby inhibiting) glycogen synthase (see for review Hermida et al., 2017). GSK-3α and -3β are themselves both inhibited by phosphorylation at an amino-terminal serine residue, serine 21 (α) (Sutherland and Cohen, 1994) or serine-9 (β) (Sutherland et al., 1993; Stambolic and Woodgett, 1994). This phosphorylation is known to be catalyzed by a number of kinases, including mitogen-activated protein (MAP) kinase (Sutherland and Cohen, 1994), protein kinase B (PKB)/Akt (Haq et al., 2000), protein kinase C (Cook et al., 1996), and PKA (Fang et al., 2000). However, this inhibitory phosphorylation may not be linked to GSK-3-mediated regulation of β-catenin signaling (Papadopoulou et al., 2004; McManus et al., 2005). To explain this paradox, Forde and Dale (Forde and Dale, 2007) have suggested that GSK-3β phosphorylation is a redundant form of regulation with respect to β-catenin signaling. Integrin-linked kinase also regulates GSK-3β, but apparently not through phosphorylation at serine 9 (Delcommenne et al., 1998). While there are many other regulators of GSK-3β (Hardt and Sadoshima, 2002), the aforementioned kinases all have described roles in bone and, as will be discussed later, this intersection with the Wnt/β-catenin signaling pathway suggests possible cross talk between pathways.

The kinase activity of GSK-3β appears to be enhanced by a priming phosphorylation at nearby sites. In proteins such as Lrp5/6, where multiple GSK-3β phosphorylation sites are present in the cytoplasmic tail, GSK-3β can self-prime. The initial priming phosphorylation of β-catenin needed for the subsequent GSK-3β phosphorylation is carried out by CK1 (Liu et al., 2002). GSK-3β has also been shown to phosphorylate two sites within Axin (T609 and S614), which is prerequisite for the binding of β-catenin (Jho et al., 1999). It has been proposed that Wnt signaling leads to a dephosphorylation of these sites and this is part of the mechanism leading to the release of β-catenin from the degradation complex. In addition, protein phosphatase 2A (PP2A), which binds to Axin, APC, and Dsh (Hsu et al., 1999; Seeling et al., 1999; Yamamoto et al., 2001), plays an important counterbalancing role opposing GSK-3β. When CK1 phosphorylates its substrates within the degradation complex, PP2A dissociates, which favors further net phosphorylation and the release of β-catenin (Gao et al., 2002). Phosphorylated β-catenin is then ubiquitinated and degraded by the 26S proteasome complex (Aberle et al., 1997).

Axin acts as a scaffolding protein that directly interacts with/binds Dsh, GSK-3β, APC, PP2A, and β-catenin (Behrens et al., 1998; Hart et al., 1998; Ikeda et al., 1998; Itoh et al., 1998; Nakamura et al., 1998; Sakanaka et al., 1998; Yamamoto et al., 1998; Fagotto et al., 1999; Farr et al., 2000). Axin was first identified as the product of the mouse fused locus (Zeng et al., 1997). In vertebrates there are two forms of Axin: Axin 1, which is constitutively expressed and is the main form of the degradation complex, and Axin 2 (also known as Conductin). Axin 2 expression is induced by Wnt signaling and it functions as a negative feedback inhibitor of β-catenin signaling (Jho et al., 2002). Axin has several functional domains required for its interactions with the various other proteins of the degradation complex. It appears that amino acids 581−616 are responsible for binding β-catenin, while the RGS domain interacts with APC, and GSK-3β appears to bind to amino acids 444−543 (Nakamura et al., 1998), although GSK-3β was observed only when β-catenin was present. The Armadillo repeats in β-catenin mediate the interaction with Axin, while a Dix domain similar to the one found in Dsh

probably mediates the interactions between Axin and Dsh. Mutations in the human AXIN2 gene have been linked to familial tooth agenesis and are predisposing for colon cancer (Lammi et al., 2004).

The collapse of the degradation complex and the release of β-catenin is a complex cascade of poorly understood events. Wnt binding to the coreceptors induces Axin to bind to the cytoplasmic tail of Lrp5/6/Arrow (after the coreceptor is phosphorylated and FRAT-1 binds). When Wnt is not present, β-catenin is bound to APC and APC to Axin as a consequence of specific phosphorylations mediated by GSK-3β (and other kinases). In the presence of Wnt and the activation of Dsh, these phosphorylation events are inhibited, and binding of Axin to the cytoplasmic tail of Lrp5/6/Arrow leads to the collapse of the complex and release of β-catenin into the cytoplasm.

β-Catenin is highly homologous to the *Drosophila* segment polarity gene *armadillo* (McCrea et al., 1991). The human β-catenin gene (*CTNNB*) is located on chromosome 3p21 and encodes a protein of 781 amino acids (~85 kDa). Two pools of β-catenin exist within the cell: one associated with E-cadherin and the other in the cytoplasm (Nelson and Nusse, 2004). β-Catenin contains a cassette of 12 Armadillo repeats in the middle of the protein that are the interaction sites with E-cadherin, APC, and the nuclear transcription factors (Cadigan and Nusse, 1997; Willert and Nusse, 1998). A number of mutations in β-catenin have been identified that give rise to human cancers. The amino-terminal end of the protein (mainly between amino acids 29–49) contains key residues whose phosphorylation by GSK-3β plays a critical role in the subsequent degradation of the protein, and when one or more of these residues are mutated the protein is more stable and the increased signaling results in tumor formation/growth (Yost et al., 1996; Polakis, 2000). Exactly how β-catenin is translocated from the cytoplasm into the nucleus is not fully understood, although there is evidence that this may require participation with estrogen receptor α (ERα) (Armstrong et al., 2007).

Transcriptional regulation by β-catenin

Once inside the nucleus, β-catenin binds to the TCF/LEF family of transcription factors and regulates the expression of a large (and ever-increasing) list of target genes. It has been shown that β-catenin can also interact with the FOXO family of transcriptional regulators and that this association is particularly important during oxidative stress (Essers et al., 2005), which may play a role in age-associated bone loss (Almeida et al., 2006). A consensus TCF/LEF core sequence has been identified that is required for binding of the TCF/LEF proteins (CCTTTGATC) (Korinek et al., 1997). The TCF/LEF proteins have DNA-binding ability but require the transactivating domain of β-catenin (at the C-terminal end) to regulate transcription.

A large number of proteins (see http://www.stanford.edu/~rnusse/ for a detailed listing) participate in the transcriptional regulation mediated by β-catenin. As of this writing, the model for how β-catenin regulates target gene transcription involves the formation of a larger complex of proteins that induces a change in chromatin structure (Barker et al., 2001). In *Drosophila*, when Wnt is not present, TCF acts as a repressor of Wnt/Wg target genes by forming a complex with Groucho (Cavallo et al., 1998), whose repressing ability is regulated by the histone deacetylase enzyme, Rpd3 (Chen et al., 1999). Studies in *Xenopus* have shown that β-catenin interacts with the acetyltransferases p300 and CBP to activate the *siamois* gene promoter (Hecht et al., 2000). Other proteins that control β-catenin signaling include the antagonist Chibby, which binds to the C-terminal end (Takemura et al., 2003), and the protein ICAT (Tago et al., 2000), which negatively regulates the interaction between β-catenin and TCF-4. TCF/LEF can also be phosphorylated by the MAP kinase–related protein NLK/Nemo (Ishitani et al., 2003), which reduces the affinity for β-catenin. Considerably less is known about the interaction of β-catenin with the FOXO family of transcription factors, but presumably it also involves cooperative and repressive interactions with a number of proteins. Also, it is not understood how choices are made as to which interactions are favored under any given set of cellular circumstances.

There are a large number of known Wnt/β-catenin target genes. Interestingly, many of these targets are components of the Wnt signaling pathway (see http://www.stanford.edu/~rnusse/ for a more complete listing), which creates a complicated set of feedback loops that can potentially serve to further amplify or inhibit signaling through the pathway. Some of these target genes will be discussed further in the following sections as they play important roles in bone.

Wnt signaling and bone cell function

Osteoblast differentiation and function

Many aspects of osteoblast differentiation have been covered in other chapters in this book (see Chapters 4 and 7). Wnt/β-catenin signaling plays important roles at several levels. A search of the PubMed database using the terms "Wnt and osteoblast and differentiation" yielded over 1000 published articles since 2002. Obviously a comprehensive, detailed

review of what we now understand regarding the role of Wnt/β-catenin signaling in osteoblast differentiation is not possible, but several excellent reviews have been published that cover key aspects (Hartmann, 2006; Baron and Kneissel, 2013; Zhong et al., 2014; Lerner and Ohlsson, 2015; Ahmadzadeh et al., 2016; Kobayashi et al., 2016).

Skeletal stem cells (Robey, 2017) are capable of differentiating into adipocytes, chondrocytes, and osteoblastic lineage cells. In part, the commitment to these different cell lineages is controlled by Wnt ligands that activate either the Wnt/β-catenin or the noncanonical Wnt signaling pathway. MacDougal and colleagues (Ross et al., 2000; Bennett et al., 2005) demonstrated that Wnt10b stimulates osteoblastogenesis and inhibits adipogenesis. Subsequently, Zhou et al. (Zhou et al., 2008) suggested a model involving glucocorticoid-induced *Wnt* gene expression in osteoblasts, and the expressed Wnt proteins then induce Runx2 expression and inhibit peroxisome proliferator-activated receptor γ expression in progenitor cells, thereby leading to increased osteoblastogenesis versus adipogenesis. Control of chondrogenesis is complex, with both canonical Wnt/β-catenin and noncanonical signaling having been demonstrated in the regulation of chondrogenesis at various levels in the differentiation pathway. Wnt1 and Wnt7a have been shown to play inhibitory roles in the early prechondrogenic mesenchyme. Hartmann and Tabin (Hartmann and Tabin, 2000) demonstrated specific patterns of expression of Wnt5a, Wnt5b, and Wnt4 in the chicken limb chondrogenic regions, with Wnt5a and Wnt4 having opposing effects. Wnt5a inhibits chondrogenesis and bone collar formation, while Wnt4 accelerates these processes. Church et al. (Church et al., 2002) have shown that Wnt5a is expressed in the joints and perichondrium, with Wnt5b and Wnt11 localized to the region of prehypertrophic chondrocytes. Akiyama et al. (Akiyama et al., 2004) have shown that Sox9, a transcription factor required for chondrogenesis, directly binds to β-catenin and thereby competes for Tcf/Lef-mediated transcription by β-catenin. Reciprocally, Wnt3a has been shown to inhibit chondrocyte differentiation by upregulating the expression of *c-Jun* leading to activation of activator protein 1, which suppresses Sox-9 (Hwang et al., 2005). Hill et al. (Hill et al., 2005) proposed a model in which β-catenin is necessary, but not sufficient, for suppressing chondrogenic commitment of progenitor cells. Thus, the role of Wnt signaling in the fate decisions for differentiation between adipogenesis, chondrogenesis, and osteogenesis within the skeletal stem population is complex and fine-tuned by various Wnt ligands and is tightly controlled both spatially and temporally.

The commitment toward osteoblastogenesis is driven by the Runt domain−containing transcription factor, Runx2 (Ducy et al., 1997; Komori et al., 1997; Lee et al., 1997; Otto et al., 1997) (AML3/PEB2α/CBFA1), and the transcription factor Osterix (Osx) (Nakashima et al., 2002), which acts downstream of Runx2. The original descriptions of human LRP5 mutations in low- and high-bone-mass traits suggested an important role for Wnt signaling in osteoblast proliferation and differentiation (Gong et al., 2001; Boyden et al., 2002; Little et al., 2002). Subsequent studies with a transgenic mouse expressing the HBM $LRP5^{G171V}$ mutation provided further support for Wnt/β-catenin signaling in the regulation of osteoblast differentiation and function (Babij et al., 2003). There is a complicated relationship between activation of Wnt/β-catenin signaling and Runx2. Gaur et al. (Gaur et al., 2005) demonstrated that β-catenin induced Runx2 expression and Haxaire et al. have shown that Runx2 is a negative regulator of Wnt/β-catenin signaling (Haxaire et al., 2016). Runx2 and Osx activate the expression of SOST (Perez-Campo et al., 2016), a negative regulator of the pathway, which may partially explain the decrease in Wnt/β-catenin signaling.

Studies have also shown an important role for microRNAs (miRNAs) in the regulation of osteoblastogenesis, in part through their regulation of Wnt/β-catenin signaling. DICER, which is a key component of miRNA processing, has been shown to be significantly upregulated by Runx2 (Zheng et al., 2017). The miRNAs miR-335-5p and miR-17-92 decrease Dickkopf-1 (Dkk-1) levels (Zhang et al., 2017; Zheng et al., 2017). miR-142-3p inhibits APC, leading to increased β-catenin nuclear translocation and signaling (Hu et al., 2013). During osteoblast differentiation miR-218 is induced, which leads to activation of Wnt/β-catenin signaling by downregulating the expression of SOST, DKK-2, and sFRP2, but in a feed-forward loop the activation of the pathway subsequently further increases expression of miR-218 (Hassan et al., 2012). Similarly, miR-29 expression has also been shown to be induced by activation of Wnt/β-catenin signaling, and miR-29a and -29c repress the expression of several pathway inhibitors in a positive feedback loop (Kapinas et al. 2009, 2010).

In addition to its role in osteoblast differentiation, Wnt/β-catenin signaling also plays important roles in the proliferation, apoptosis, metabolism, and mineralization of the skeleton driven by osteoblasts. The role of Wnt signaling in regulating these functions is complex and includes both direct effects on the osteoblast itself and indirect effects through the expression of other osteoblast-derived factors that affect other bone cells and involves both canonical and noncanonical Wnt signaling pathways. For example, Wnt3a has been shown to induce matrix extracellular phosphoglycoprotein (Mepe) by stimulating expression of the *Mepe* gene. Wnt3a has also been shown to stimulate bone morphogenetic protein 2 (BMP-2) gene expression (Cho et al., 2012; Zhang et al., 2013), which also regulates *Mepe* gene expression (Cho et al., 2012). Studies have demonstrated differentiation-stage-specific effects of Wnt signaling in osteoblasts (Eijken et al., 2008; Bao et al., 2017).

Kato et al. (Kato et al., 2002) demonstrated in the $Lrp5^{-/-}$ mouse that the low-bone-mass phenotype was due to decreased osteoblast proliferation and reduced matrix deposition. Gong et al. (Gong et al., 2001) demonstrated that Wnt3a, but not Wnt5a, increased alkaline phosphatase activity in C3H10T1/2 and ST2 cell lines. Based on their data, they suggested that LRP5 and the Wnt/β-catenin signaling pathway play important roles in osteoblast differentiation and proliferation. Boyden et al. (Boyden et al., 2002) observed elevated serum osteocalcin levels, a marker of bone formation, but normal collagen type I urinary N-telopeptide levels, a marker of bone resorption. This suggested that the $LRP5^{G171V}$ mutation leads to exuberant osteoblast activity resulting in increased bone density. Babij et al. (Babij et al., 2003) developed a transgenic mouse (over)expressing the human $LRP5^{G171V}$ cDNA and also observed normal osteoclast activity with increased mineralizing surface and enhanced alkaline phosphatase staining in osteoblasts. However, Glass et al. (Glass et al., 2005), using mouse models with targeted deletion or overexpression of β-catenin in osteoblasts, identified another important role in the regulation of osteoclast activity through the production of osteoprotegerin (OPG). Why mutations in the Wnt receptor lead to increased osteoblast activity and alterations in β-catenin levels resulting in altered osteoclast activity is not entirely clear.

Another area of osteoblast function that has garnered attention is the role of Wnt signaling in the regulation of cellular energy metabolism in osteoblasts (Frey et al., 2017; Yao et al., 2017). The Wnt effects appear to be mediated by β-catenin in the case of fatty acid catabolism (Frey et al., 2017), mTORC2 in the case of aerobic glycolysis (Esen et al., 2013), and mTORC1 involving glutamine metabolism (Karner et al., 2015). Interestingly, both of the mTORC1/2-mediated effects appear to involve LRP5/Lrp6/Frizzled binding of a Wnt ligand (Karner and Long, 2017).

Studies have clearly shown an important role for the Wnt/β-catenin signaling pathway in the prevention of both osteoblast and osteocyte apoptosis. Kato et al. (Kato et al., 2002) demonstrated in the $Lrp5^{-/-}$ mouse that the hyaloid vessels failed to undergo apoptosis, resulting in the persistence of this vasculature network into the adult, which could explain the blindness associated with human OPPG patients carrying LRP5-null mutations. Babij et al. (Babij et al., 2003), using the HBM transgenic mouse, showed decreased osteoblast and osteocyte apoptosis attributable to the $LRP5^{G171V}$ mutation. Secreted Frizzled-related protein-1 (sFRP-1) is a Wnt/β-catenin signaling pathway inhibitor (Bodine et al., 2004), and blocking sFRP with a small-molecule inhibitor caused a significant reduction in osteoblast apoptosis in cell culture (Bodine et al., 2009).

Osteoclast function

Osteoclasts are derived from hematopoietic (myeloid lineage) progenitors. Macrophage colony-stimulating factor (M-CSF) (Yoshida et al., 1990) and receptor activator of NF-κB ligand (RANKL) (Kong et al., 1999) are critical for osteoclast replication and differentiation, respectively. The early studies of osteoblast-targeted deletion or constitutive activation of β-catenin in mice surprisingly demonstrated a critical role for the pathway in the regulation of osteoclastogenesis, which was attributed to altered expressed of the RANKL ligand decoy receptor OPG (Glass et al., 2005; Holmen et al., 2005). Studies in MC3T3-E1 cells also demonstrated that activation of Wnt/β-catenin signaling downregulates the expression of RANKL (Spencer et al., 2006). Thus, by regulating the OPG/RANKL ratio, the Wnt/β-catenin signaling pathway in osteoblasts can control osteoclastogenesis. It is now recognized that the osteocyte is an important source of RANKL, and its role in osteoclastogenesis will be discussed further in a subsequent section.

Wnt signaling within osteoclasts is also an important role. The Wnt pathway inhibitor sFRP-1 has been shown to bind to RANKL and inhibit osteoclast formation (Hausler et al., 2001). Wei et al. (Wei et al., 2011) demonstrated that β-catenin-mediated Wnt signaling was induced during the M-CSF quiescence-to-replication/proliferation phase, but downregulated during the RANKL proliferation-to-differentiation phase of osteoclastogenesis. Mechanistically, Wnt/β-catenin signaling promoted proliferation of osteoclast precursors by increasing expression of GATA2 and Evi1 and blocked differentiation by inhibiting c-Jun phosphorylation. Extending this work further, Weivoda et al (Weivoda et al., 2016) have demonstrated that Lrp5/6/Frizzled binding of Wnt3a affects osteoclastogenesis through β-catenin and the noncanonical cAMP/PKA pathway. The latter pathway functions to block early osteoclast progenitors from differentiating by phosphorylation of nuclear factor of activated T cells 1.

Human genome-wide association studies have revealed that Wnt16 contributes to variation in bone density (Medina-Gomez et al., 2012; Zheng et al., 2012). Wnt16 through Wnt/β-catenin signaling has been shown to be involved in intramembranous ossification and to suppress osteoblast differentiation and mineralization (Jiang et al., 2014). Osteoblast-derived Wnt16 has been shown to stimulate OPG production by osteoblasts, which indirectly affects osteoclastogenesis, and to directly inhibit RANKL-mediated action in preosteoclasts through a c-Jun-mediated mechanism, rather than by canonical Wnt/β-catenin signaling (Weivoda et al., 2016). Additional Wnt ligands that have been implicated in osteoclast differentiation include Wnt4 and Wnt5a (Kobayashi et al. 2015a, 2015b).

Osteocyte function

In recent years, the role of the osteocyte in orchestrating the activity of osteoblasts and osteoclasts has been clearly established. Several excellent reviews have been published that detail the myriad of mechanisms through which osteocytes exert their regulation of bone formation and resorption (Bonewald and Johnson, 2008; Baron and Kneissel, 2013; Burgers and Williams, 2013; O'Brien et al., 2013; Schaffler et al., 2014; Johnson and Recker, 2017) (see also Chapter 6).

Based upon the skeletal phenotype of the HBM kindred, Johnson et al. (Johnson et al., 2002) first proposed that one of the main roles of the Wnt/β-catenin signaling pathway in bone was as a key component of the response to mechanical loading. In support of this hypothesis it was subsequently demonstrated that the $LPR5^{G171V}$ mutation resulted in increased bone formation (Bex et al., 2003; Cullen et al., 2004) and that loss of Lrp5 resulted in a lack of bone formation in response to load (Sawakami et al., 2006). Activation of Wnt/β-catenin signaling occurs following in vivo loading (Kamel et al., 2006; Lau et al., 2006; Robinson et al., 2006; Sawakami et al., 2006; Javaheri et al., 2014; Lara-Castillo et al., 2015), and targeted deletion of osteocyte β-catenin results in severe bone loss and compromised load responsiveness (Kramer et al., 2010; Javaheri et al., 2014; Kang et al., 2016). While the exact mechanism by which osteocytes (bone cells) perceive mechanical load is unresolved, a number of downstream events are now known to occur that are central to the biochemical response by the cell. Bonewald and Johnson (Bonewald and Johnson, 2008) suggested a model describing how the Wnt/β-catenin signaling pathway activates in response to mechanical load. In support of this model, Kamel et al. (Kamel et al., 2010) demonstrated that prostaglandin E_2 (PGE_2) was able to stimulate β-catenin nuclear translocation through a phosphatidylinositol 3-kinase (PI3K)/Akt-mediated mechanism. Lara-Castillo et al. (Lara-Castillo et al., 2015) subsequently demonstrated in vivo that loading rapidly activated β-catenin signaling in osteocytes and, in agreement with prior work by Sawakami et al. (Sawakami et al., 2006), found a concordant reduction in sclerostin and Dkk-1 levels in osteocytes. Pretreatment with Carpofen, a cyclooxygenase 2 inhibitor, blocked activation of Wnt/β-catenin signaling (Lara-Castillo et al., 2015), in agreement with their in vitro studies (Kamel et al., 2010).

Several other functions of the osteocyte involve aspects of Wnt/β-catenin pathway regulation, either directly or through the expression of its downstream targets. It is now recognized that the osteocyte is a key regulator of osteoblast and osteoclast function via its production of sclerostin (Poole et al., 2005; van Bezooijen et al., 2005) and RANKL (Nakashima et al., 2011; Xiong et al., 2011) and that sclerostin plays a role in osteocyte RANKL production (Wijenayaka et al., 2011). Glucocorticoids are known to induce osteocyte autophagy or apoptosis depending upon the dose (Jia et al., 2011). Protection against glucocorticoid-induced apoptosis is mitigated, in part, by the induction of PGE_2 upon mechanical loading and subsequent activation of Wnt/β-catenin signaling (Kitase et al., 2010). Parathyroid hormone (PTH) has been implicated in the regulation of sclerostin expression (Bellido et al., 2005; Keller and Kneissel, 2005) through regulation of the *Sost* gene enhancer involving MEF2 family transcription factors (Leupin et al., 2007). However, the bone anabolic effects of PTH cannot be fully explained by its regulation of sclerostin and/or interaction with Wnt/β-catenin signaling (Powell et al., 2011; Kedlaya et al., 2016; Delgado-Calle et al., 2017).

The fact that mutations in another member of the LDLR-related family, LRP4, were linked to phenotypes similar to those seen in human patients carrying loss-of-function mutations in the sclerostin gene was the catalyst for studies that eventually showed that LRP4 serves as a receptor for sclerostin, facilitating its presentation to Lrp5 or Lrp6 at the membrane and allowing it to inhibit Wnt/β-catenin signaling (Leupin et al., 2011). The importance of this interaction and its inhibition of both Lrp5 and Lrp6 signaling have been demonstrated by genetically engineered mouse models and inhibitory antibody studies (Chang et al., 2014).

Interactions between Wnt/β-catenin signaling and other pathways important in bone mass regulation

The Wnt/β-catenin signaling pathway is not the only pathway that is known to be important in the regulation of bone cell activities, and considerable effort is now being focused on understanding how all of these various pathways interact to regulate bone mass. As already discussed, GSK-3β is the critical intracellular enzyme controlling β-catenin levels. Therefore any pathway that can regulate GSK-3β activity has the potential to interact with the Wnt/β-catenin signaling pathway independent of the Lrp5/6/Frizzled coreceptors and any modulators that function at that level.

One set of well-known pathways that have the potential to cross talk with the Wnt/β-catenin signaling pathway comprises those pathways that signal through Akt/PKB. Akt/PKB is activated by PI3K, whose activity is opposed by the phosphatase and tensin homolog deleted on chromosome 10 (PTEN) tumor suppressor (Datta et al., 1999; Kandel and Hay, 1999). Akt/PKB has been shown to be stimulated by Wnt and, in association with Dsh, to phosphorylate GSK-3β (Fukumoto et al., 2001). This raises the potential for several growth factors to potentially cross talk with the Wnt/β-catenin

signaling pathway. It has been shown that the growth of colon cancer cells induced by PGE_2 is partially the result of activation of the Wnt/β-catenin pathway through a dual mechanism involving Akt-mediated phosphorylation of GSK-3β and the $G\alpha_s$ subunit trimeric G proteins associated with the PGE_2 EP2 receptor binding to Axin and thereby promoting dissociation of the degradation complex (Castellone et al., 2005). PGE_2 release/production in bone cells is a well-known early response to mechanical loading. Fluid-flow shear stress has been shown to increase the phosphorylation of both Akt and GSK-3β in osteoblasts (Norvell et al., 2004). Fluid-flow shear stress results in an initial activation of the β-catenin signaling that is Lrp5 independent and probably mediated through cross talk with PGE_2 signaling (Kamel et al. 2006, 2010). As of this writing, we are testing a model in which this initial activation results in a feedback amplification loop that functions at the level of Lrp5 and leads to new bone formation. When Lrp5 is not present, the amplification loop does not occur and no new bone formation can occur, as was observed in the loading studies on the $Lrp5^{-/-}$ mouse (Sawakami et al., 2006). It has also been shown that integrin-linked kinase can regulate Akt/PKB and GSK-3β (Delcommenne et al., 1998), which potentially connects the important role of integrins in the response of bone cells to mechanical loading (Pavalko et al., 1998; Wozniak et al., 2000) with the Wnt/β-catenin signaling pathway through a cross talk mechanism.

In addition, signaling pathways that regulate the expression of activators or inhibitors (discussed previously) of the Wnt/β-catenin pathway thereby interact at this level. For example, results of studies with PTH suggest that PTH acts in part through a complementary pathway and not entirely through the Lrp5 Wnt/β-catenin signaling pathway. Continuous PTH treatment of rats in vivo or UMR 106 cells in culture results in a downregulation of *Lrp5* and *Dkk1* and an upregulation of *Lrp6* and *Fzd1* (Kulkarni et al., 2005) and, based on these studies, it was suggested that the effects of PTH are in part mediated by a cAMP/PKA pathway. In studies with the sFRP-1-knockout mouse, it was concluded that PTH and Wnt signaling may share some common components, but PTH action appears to extend beyond the Wnt pathway (Bodine et al., 2004). However, studies with the $Lrp5^{-/-}$ mouse have shown that Lrp5 is not required for the anabolic effects of PTH on bone (Iwaniec et al., 2004; Sawakami et al., 2006). Evidence has been presented that PTH infusion in mice decreases *Sost* mRNA expression and sclerostin levels in osteocytes (Bellido et al., 2005). This finding implies a negative feedback control mechanism in which sclerostin production by osteocytes opposes the actions of Wnts and/or BMPs on osteoblast precursors, and PTH, by decreasing sclerostin levels, indirectly therefore stimulates osteoblast differentiation and bone formation. Thus the picture of PTH that emerges is complex.

Likewise, several groups have examined potential cross talk between the BMP signaling pathway and Wnt/β-catenin signaling (Rawadi et al., 2003; He et al., 2004; van den Brink, 2004; Nakashima et al., 2005; Tian et al., 2005; Gaur et al., 2006; Liu et al., 2006). One model that has been proposed (Liu et al., 2006) for cross talk between these two pathways in bone marrow stromal cells involves a Dsh−Smad1 interaction in the unstimulated state that becomes disrupted when Wnt is present. When both Wnt and BMP-2 are present the phosphorylation of Smad1 stabilizes the interaction and thereby inhibits Wnt/β-catenin signaling (Liu et al., 2006). In intestinal crypt stem cell self-renewal, BMP inhibitory effects have been proposed to be mediated through the suppression of Wnt/β-catenin signaling through a mechanism involving PTEN, PI3K, and Akt (He et al., 2004). In bone, it has been proposed that BMP-2 increases the expression of Wnt proteins that then activate the Wnt/β-catenin signaling pathway in an autocrine/paracrine feedback loop (Rawadi et al., 2003). It has also been proposed that Wnts induce the expression of BMPs and this induction is necessary for expression of alkaline phosphatase (Winkler et al., 2005). This model also implicated sclerostin as imposing a level of control preferentially at the level of BMP signaling versus Wnt signaling. However, there is now clear evidence for sclerostin being a negative regulator of the Wnt/β-catenin signaling through binding to Lrp5 (Ellies et al., 2006; Semenov and He, 2006). Thus, while it is clear that these two pathways are somehow intertwined, the exact nature of their interaction(s) is complex (Marcellini et al., 2012).

As mentioned previously, there is now compelling evidence for the involvement of Lrp5 and the Wnt/β-catenin signaling pathway in the formation of new bone induced by mechanical loading of bone. Evidence also indicates that the $LRP5^{G171V}$ mutation may also protect against bone loss related to disuse, but that bone loss due to estrogen withdrawal is not affected by this mutation (Bex et al., 2003). However, it has been shown that ERα and β-catenin can/do form a functional interaction and potentially regulate gene expression (Kousmenko et al., 2004). It has also been suggested that in bone there is a convergence of the ER, kinases, BMP, and Wnt signaling pathways that regulates the differentiation of osteoblasts (Kousteni et al., 2007).

What other pathways might also interact with the Wnt/β-catenin signaling pathway? An emerging concept in the Wnt field is that there are numerous β-catenin-independent pathways that are altered upon inhibition of GSK-3. The term "Wnt-dependent stabilization of proteins," or Wnt-STOP, has been proposed for this aspect of Wnt signaling (Acebron et al., 2014; Huang et al., 2015; Koch et al., 2015; Acebron and Niehrs, 2016). One such example of this type of regulation is the GSK-3-dependent (but β-catenin-independent) regulation of the mammalian target of rapamycin (mTOR) pathway (Inoki et al., 2006; Karner and Long, 2017). This example may be particularly relevant for understanding the role of Wnt

signaling in bone biology (Esen et al., 2013; Chen et al., 2014; Karner et al., 2015; Sun et al., 2016). It is likely that more Wnt-dependent pathways will be identified and that only by understanding the complex interplay of these various pathways will the control of the differentiation, proliferation, and function of bone cells be fully appreciated.

The Wnt signaling pathway as a target for anabolic therapy in bone

The $LRP5^{G171V}$ mutation results in an HBM phenotype and a skeleton that is resistant to fracture (Johnson et al., 1997). The affected members of this kindred seem to have no other health consequences related to the presence of this mutation, although in a second kindred with the $LRP5^{G171V}$ mutation affected members all had torus lesions in the oral cavity to varying degrees (Boyden et al., 2002). It has also been reported that some mutations in *LRP5* (Gong et al., 2001; Whyte et al., 2004) may have associated pathology. The finding that Lrp5 and Wnt/β-catenin signaling are critical components of bone responsiveness to mechanical loading (Bonewald and Johnson, 2008; Javaheri et al., 2014; Lara-Castillo et al., 2015) suggests a potentially novel pharmaceutical approach. Perhaps one strategy would be to use a pharmaceutical agent that can alter regulation of the pathway (mimicking the effect of the LRP^{G171V} mutation) in combination with an exercise regimen to produce an optimal bone anabolic effect. It might even be possible to use such a combination therapy approach with a drug dose that by itself has little consequence on bone mass and thus perhaps avoid undesirable side effects.

Given the major role of Wnt/β-catenin signaling in skeletal development and adult bone mass regulation, it is not surprising that soon after the description of the LRP5 mutations that regulate bone mass, considerable attention was focused on using key components of the pathway as targets for new drug development (Janssens et al., 2006; Baron and Rawadi, 2007; Baron and Kneissel, 2013). Caution was raised in these early discussions that misregulation of the pathway could lead to undesirable side effects such as cancer (Polakis, 2000; Moon et al., 2002; Prunier et al., 2004; Nusse, 2005; Johnson and Rajamannan, 2006). The discovery that sclerostin, the product of the *SOST* gene and a key negative regulator of the Wnt/β-catenin signaling pathway, was expressed mainly by osteocytes provided a potential solution to this paradox (Bellido et al., 2005; Li et al., 2005; Poole et al., 2005; van Bezooijen et al., 2005).

Two major pharmaceutical clinical trials using humanized monoclonal antibodies to sclerostin (romosozumab and blosozumab) have been reported in the literature (McClung, 2017). Clinical trials with romosozumab (Cosman et al., 2016; Ishibashi et al., 2017; Langdahl et al., 2017; Saag et al., 2017) consistently showed significant gains in areal bone mineral density at the lumbar spine, total hip, and femoral neck and reduced fracture risk. Studies in rats suggested that there was no significant carcinogenic risk in humans (Chouinard et al., 2016), which had been a concern identified as a result of rat studies on the use PTH(1−34) (Vahle et al., 2002). However, in a 2017 study (Saag et al., 2017) there was a slight, but significant, increase in adverse cardiovascular events that was not observed in previous studies. The basis for this cardiovascular issue is not clear. However, it is known that Wnt/β-catenin signaling plays a role in vascular calcification (Johnson and Rajamannan, 2006; Towler et al., 2006; Bostrom et al., 2011), and the question that needs to be more fully explored is whether these cardiovascular adverse events occurred in individuals with underlying vascular disease that was not excluded in the enrollment of subjects for these studies. Interestingly, the other reports did not report any observable differences in adverse events between treatment groups. Phase II clinical trials with blosozumab have also yielded similar positive gains in bone density (McColm et al., 2014; Recker et al., 2015; Recknor et al., 2015), with no significant differences in adverse events being detected in these initial studies between groups. Blosozumab has been removed from consideration for FDA approval as of this writing, and the impact of the adverse cardiovascular risk observed in the romosozumab phase III trials on FDA approval is unclear.

Are there other possibilities for exploiting this pathway pharmaceutically to treat diseases of low bone mass (Baron and Kneissel, 2013)? The majority of pharmaceutical agents on the market target either receptors or specific enzymes. In the Wnt/β-catenin pathway the obvious targets in this regard are the coreceptors Lrp5 and Frizzled and GSK-3β, which is the key enzyme controlling intracellular β-catenin levels.

Regulation of GSK-3β activity has already been reported to produce a bone anabolic effect. LiCl treatment, which inhibits GSK-3β, restores bone mass in the $Lrp5^{-/-}$ mouse (Clement-Lacroix et al., 2005), and in humans the use of lithium appears to have an associated decreased fracture risk and a trend for decreased risk of osteoporotic fractures of the spine and wrist (Colles fracture) (Vestergaard et al., 2005). GSK-3β inhibitors have also been shown to produce a bone anabolic effect in vivo and to increase expression of bone formation markers and induce osteoblast cell differentiation in vitro (Kulkarni et al., 2006; Robinson et al., 2006). In one of these studies, changes in gene expression profile that were obtained from treatment with these agents were virtually identical to changes observed in HBMtg mouse bones, in bone cells after mechanical loading, and in primary bone cells from affected members of HBM (Robinson et al., 2006). What these studies suggest is that, as we learn more about how the Wnt/β-catenin signaling pathway functions in bone, it will be possible to design better and more specific pharmaceutical agents and approaches.

Given the cross talk between other signaling pathways and the Wnt/β-catenin signaling pathway it may be that as we understand more about the nature of these complex interactions and regulation of the pathway, these studies will reveal targets/approaches for treatment (Johnson and Recker, 2017). PTH has been proposed to decrease levels of sclerostin produced by osteocytes and thus release the inhibition on osteoblast differentiation (Bellido et al., 2005). Could it be possible to regulate *Sost* gene expression through other means and thereby affect a bone anabolic effect? BMPs appear to induce the expression of Wnts (and perhaps vice versa), and so understanding what regulates Wnt gene expression in bone may provide a key to new pharmaceutical approaches. The result of β-catenin nuclear translocation is a change in expression of a number of genes, many of which function in a feedback loop as inhibitors or activators of the pathway. As we understand more about the nature of these genes/proteins and their regulation, it may be possible to design drugs that can alter the activity of these proteins and thereby tip the balance between bone formation and bone resorption in favor of formation and either increase bone mass or prevent bone loss. DKK-1 is another inhibitor of the pathway, and early animal studies have shown promise for this approach, which is similar to the anti-sclerostin antibodies therapies discussed earlier (Glantschnig et al., 2010; Li et al., 2011; Florio et al., 2016). DKK-1 antibodies have also gained considerable interest as a therapy to treat and manage myeloma bone disease (Terpos et al., 2017).

Interestingly, the importance of the Wnt pathway in bone homeostasis has also been emphasized by work in human clinical trials for cancer treatment. Several therapeutic strategies for blocking Wnt signaling to treat cancer are being tested in phase I trials (Rey and Ellies, 2010; Krishnamurthy and Kurzrock, 2018). In some instances, these trials had to be at least temporarily halted because patients displayed evidence of fracture or significant bone loss (Jimeno et al., 2017). This is consistent with several mouse models in which mice that have been genetically engineered to lack the ability to secrete Wnt ligands from osteoblasts have extremely low bone mass (Zhong et al., 2012; Wan et al., 2013; Tan et al., 2014). Strategies designed to mitigate these effects are undoubtedly being evaluated in animal models, and a greater knowledge of the specific Wnt receptors that are necessary for adult bone homeostasis may facilitate more targeted treatments.

While many of these ideas about creating new therapies targeting this pathway in bone may be considered fanciful speculation at this point, if we have learned anything since the discovery in the early years of the 21st century of the mutations in *LRP5* that give rise to low and high bone mass, it may simply be that the discoveries of the next five years may be even more enlightening in terms of our understanding of the role of Wnt/β-catenin signaling in bone.

Chapter outline

Introduction

Bone is a highly vascularized and innervated organ. During development, all the long bones of the skeleton form via an avascular and noninnervated cartilage template. The conversion of the cartilaginous model into bone is dependent on its primary invasion by blood vessels, a process that is associated with the development of a bone marrow cavity and its infiltration by various cell types populating the bone, including bone-forming osteolineage cells, bone-resorbing osteoclasts, and hematopoietic cells. The presence of an adequate vascular supply is absolutely required for further bone formation and remodeling, to supply the necessary oxygen, nutrients, and hormones and to remove waste products (Maes, 2013). Furthermore, the close physical relationship and molecular crosstalk between the endothelial cells of the blood vessels and the osteoprogenitors residing in the perivascular space are thought to contribute to angiogenic−osteogenic coupling (Maes, 2013; Dirckx et al., 2013). This term refers to the close spatial−temporal association of angiogenesis and osteogenesis, as observed during fetal skeletal development, during the juvenile growth spurt, in remodeling bone throughout adulthood, and in fracture healing (Schipani et al., 2009; Maes, 2013; Wang et al., 2007). For some time, compromised vascularity and reduced blood flow in bone have been associated with age-related declines in bone mass and osteoporosis as well as poor bone repair, emphasizing the potential therapeutic value of understanding the vasculature of bone and how to modulate it (Maes, 2013; Ramasamy et al., 2016; Tomlinson et al., 2013; Tomlinson and Silva, 2013; Mekraldi et al., 2003; Burkhardt et al., 1987; Saran et al., 2014; Carano and Filvaroff, 2003; Street et al., 2002). Interestingly, nerves accompany the blood vessels that supply bone tissue; in fact, innervation and vascularization of developing bone are tightly coordinated and possibly interdependent processes. The presence of nerves in bone has been appreciated since work of the early microscopists, who utilized routine histological methods such as toluidine blue or silver staining to reveal nerve axons in calcified tissue (Miller and Kasahara, 1963; Milgram and Robinson, 1965; Linder, 1978; Thurston, 1982). These studies helped validate the numerous clinical observations regarding skeletal pain emanating from bone tissue itself, particularly following surgery necessitated by neoplastic bone disease. Immunohistochemical studies, beginning in the mid-1980s (Hohmann et al., 1986), began to dissect the various types and subtypes of neuronal axons in bone. This work gradually revealed that the skeleton is richly innervated by sensory, sympathetic, and parasympathetic axons of the

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00009-9

peripheral nervous system, with axons found in the periosteum and marrow space as well as calcified tissue (Bjurholm et al., 1988; Wojtys et al., 1990; Hill and Elde, 1991; Hukkanen et al., 1992; Mach et al., 2002; Castañeda-Corral et al., 2011). Furthermore, each of these nerve types appears to serve unique functions within the bone microenvironment, many of which are under active investigation. In this chapter, we will review the current understanding of the origin, location, and function of the blood vessels and different nerve types in bone.

The vasculature of bone

Vascularization of developing bone

The development of the long bones of the skeleton by endochondral ossification is characterized by the initial formation of a cartilage template that prefigures the future bone. Cartilage is inherently avascular, in line with the typical production of angiogenic inhibitors by chondrocytes during their immature and differentiating states. When chondrocytes reach their final maturation stage and become hypertrophic chondrocytes, the balance shifts toward the predominant expression of angiogenic stimulators. At this stage, hypertrophic chondrocytes begin expressing vascular endothelial growth factor (VEGF). As a consequence, hypertrophic cartilage becomes invaded by blood vessels, which triggers the formation of the primary ossification center and the nascent bone marrow cavity. Osteoprogenitors coinvade the middiaphyseal bone region along with blood vessels originating from the perichondrium, and instigate bone formation inside the shaft (Maes et al., 2010a). The excavation of the original cartilaginous template is probably steered by both angiogenesis-related tissue remodeling and osteoclastic resorption of the calcified cartilage matrix. While the fate of the hypertrophic chondrocytes proper was classically considered to be apoptotic cell death, studies using genetic lineage tracing strategies in mice have revived the long-standing hypothesis of transdifferentiation of terminally differentiated growth plate chondrocytes into osteoblasts (Zhou et al., 2014; Yang et al., 2014; Park et al., 2015). Whether the incoming vasculature may have an instructive role in defining the fate of the hypertrophic chondrocyte, which seems highly plausible, needs to be defined.

The concept that hypertrophic chondrocytes direct the cartilage-to-bone transition through VEGF release during endochondral bone growth was established through the use of a variety of mouse models. First, administration of a soluble VEGF receptor chimeric protein (sFlt-1) that acts to inhibit VEGF was shown to impair vascular invasion of the growth plate in juvenile mice, which was associated with reduced longitudinal bone growth and trabecular bone formation (Gerber et al., 1999). Concomitantly, the mice showed a pronounced extension of the layer containing hypertrophic chondrocytes in their growth plates (Gerber et al., 1999), a feature that had also been transiently observed in knockout mice lacking the matrix metalloproteinase 9 (MMP-9) (Vu et al., 1998). In joining these findings, the theory was proposed that capillary invasion of the growth cartilage brings osteoclasts—cells of hematopoietic origin sharing a precursor with macrophages—to the chondro-osseous junction. MMP-9 production and matrix resorption by osteoclasts or postulated related cells called "chondroclasts" would progressively release matrix-bound VEGF from the degrading cartilage matrix, creating a positive-feedback system steering capillary growth, hypertrophic cartilage matrix decay and resorption, and trabecular bone formation (Karsenty and Wagner, 2002). Although the fine details of the cellular sources and situated actions of MMP-9 are as yet to be resolved, the important role of VEGF as coordinator of the progressive turnover of cartilage into bone and driver of longitudinal bone growth has been further substantiated and refined through the use of conditional knockout mice and knock-in models (reviewed in greater detail in Maes, 2013, 2017; Dirckx et al., 2013; Dirckx and Maes, 2016). These studies furthermore annotated specific functions to the major VEGF splice isoforms (VEGF120, VEGF164, and VEGF188 in the mouse), primarily based on their differential solubility versus matrix-binding characteristics. The shorter, soluble VEGF isoforms (VEGF120 and to some extent VEGF164) can diffuse and attract distant blood vessels toward the source of VEGF secretion, thus stimulating angiogenic growth of the capillary bed. The longer isoforms (VEGF164 and especially VEGF188) have strong affinity to bind heparin-containing matrix components, become sequestered in the cartilage matrix, and are released upon proteolytic degradation of the matrix, thereby serving a coordinating role in linking cartilage-to-bone turnover to the progressive vascularization of the growing bone (Maes, 2017; Maes et al., 2002, 2004; Zelzer et al., 2002) (Fig. 9.1).

VEGF plays essential roles in the initial osteo-angiogenic invasion of fetal bones during primary ossification center (POC) formation, as well as in triggering the vascularization processes that mediate the formation of the secondary ossification centers in the epiphyses later in skeletal development (Maes et al., 2004, 2012a; Duan et al., 2015). Mice engineered to express only the VEGF120 isoform or only the VEGF188 isoform showed a delay in the initial vascular invasion and development of the long bones, indicating the importance of the VEGF164 isoform or a combination of soluble and matrix-bound VEGF (Maes et al., 2002, 2004; Zelzer et al., 2002). The levels of VEGF need to be tightly

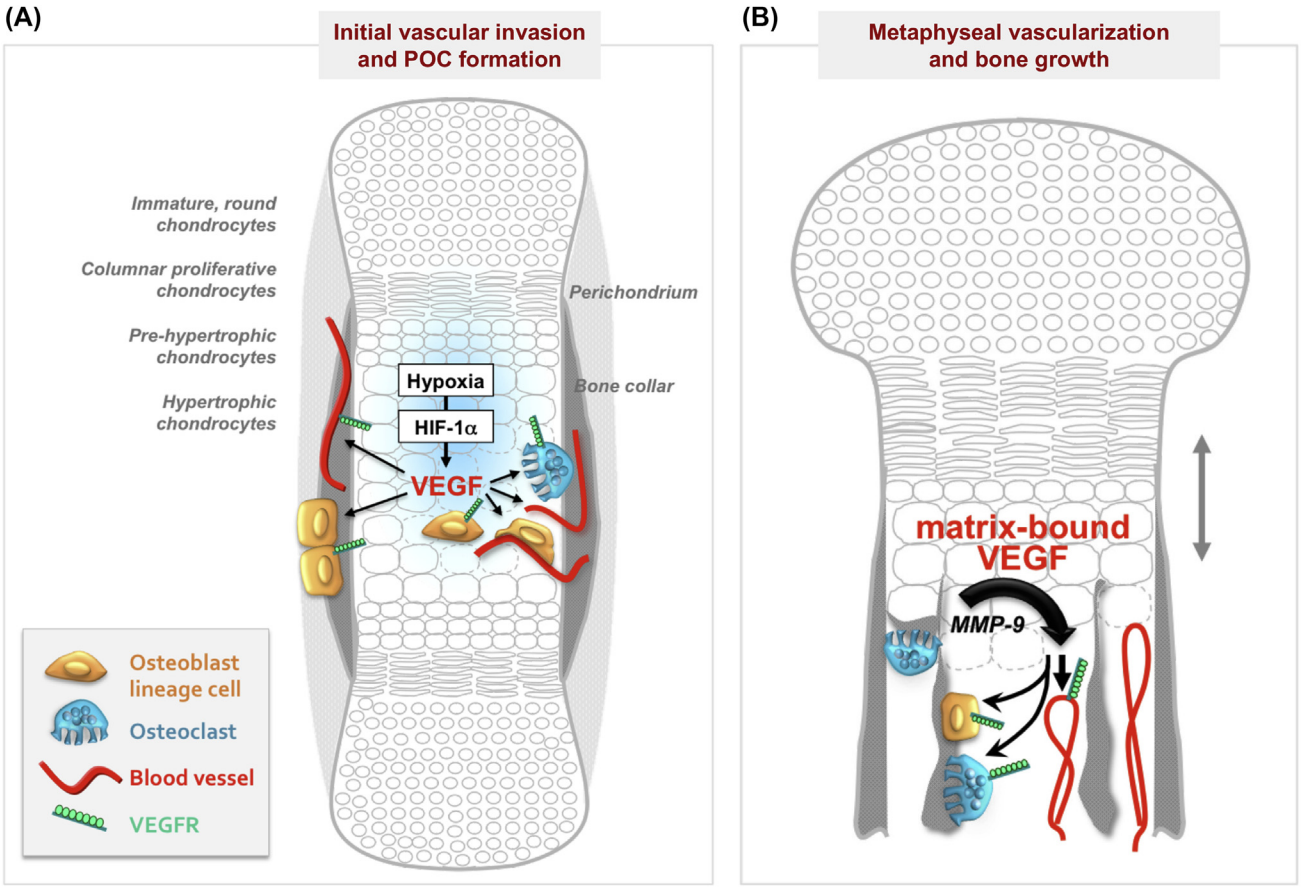

FIGURE 9.1 The roles of hypoxia-inducible factor (HIF) and vascular endothelial growth factor (VEGF) in the neovascularization of cartilage and its conversion to bone. (A) VEGF controls the initial osteo-angiogenic invasion of the endochondral bone template. During long bone development, hypertrophic chondrocytes in the middle diaphyseal region of the avascular cartilage template become hypoxic and express high levels of VEGF. Both HIF-1α and VEGF are required for the timely invasion of the template by blood vessels from the perichondrium. Along with the endothelium, osteoprogenitors move into the tissue, start to deposit bone, and establish the primary ossification center (POC). Osteoclasts, cells of hematopoietic origin, also appear, coinciding with vascular accumulation in the perichondrium, and coinvade the cartilage. All the cell types involved express VEGF receptors (*VEGFR*) and can respond directly to VEGF signaling by enhanced migration, recruitment, proliferation, and/or differentiation. **(B) VEGF actions at the chondro-osseous junction and the metaphysis of growing long bones.** The matrix-binding isoforms of VEGF, VEGF164 and VEGF188, are stored in the cartilage matrix after their secretion by hypertrophic chondrocytes. Upon cartilage resorption, mediated by osteoclasts and matrix metalloproteinase-9 (*MMP-9*), the released VEGF attracts blood vessels toward the growth plate and stimulates angiogenesis. Indirectly (via the vascular growth) and directly (via VEGFR signaling), VEGF stimulates bone formation by osteoblasts and cartilage resorption and bone remodeling by osteoclasts, thereby coordinating the conversion of cartilage into bone at the chondro-osseous junctions and stimulating the growth of the long bones. *Figure reproduced from Maes, C., 2017. Signaling pathways effecting crosstalk between cartilage and adjacent tissues: seminars in cell and developmental biology: the biology and pathology of cartilage. Semin. Cell Dev. Biol. 62, 16–33.*

controlled though, as either partial loss or local increase of VEGF is detrimental to bone development (Maes et al., 2010b; Haigh et al., 2000). In fact, Col2-Cre-driven conditional overexpression of VEGF164 in the fetal skeleton led to premature osteo-angiogenic invasion of developing bones, hypervascularization of the primary ossification center, aberrant bone deposition, and severely misshapen limbs (Maes et al., 2010b). The physiological induction of high levels of VEGF expression in hypertrophic chondrocytes appears to be fundamentally coupled to the differentiation progression of the cells and involves several transcriptional regulators, including Runx2, Osterix (Osx), and hypoxia-inducible factors (HIFs), particularly HIF-1α, the prime driver of the cellular responses to low-oxygen conditions (Chen et al., 2012; Zelzer et al., 2001; Tang et al., 2012; Cramer et al., 2004; Lin et al., 2004). HIF-1α signaling and other hypoxia-driven control mechanisms also contribute to the fine regulation of the more moderate VEGF levels in the hypoxic center of the developing growth plate and the preinvasion cartilaginous template; these signals are important for stimulating perichondrial angiogenesis as well as ensuring survival of the hypoxic chondrocytes (Maes et al., 2004, 2012a; Duan et al., 2015; Schipani et al., 2001; Provot et al., 2007; Amarilio et al., 2007; Eshkar-Oren et al., 2009).

Vascularization of the mature skeleton

Also beyond development, the skeletal vascular system remains an essential player in the regulation of bone formation and remodeling, as characterized most comprehensively in the long bones. These bones are supplied by a dense network of blood vessels comprising epiphyseal, metaphyseal, and periosteal blood vessels. The nutrient arteries provide the main entry of the blood into the bone shaft. Within the shaft, the vessels are organized in a highly branched and organized network of sinusoidal capillaries, arteries, and arterioles in the bone marrow environment, with endosteal vessels near the cortical bone and metaphyseal capillaries arranged in longitudinal orientation among the trabecular bone spicules toward the chondro-osseous junction of the growth plate (Brookes and Revell, 1998; Roche et al., 2012). Recent work has termed the endosteal and metaphyseal capillaries "H-type" blood vessels, because of their strong reactivity to antibodies recognizing the endothelial cell markers CD31/PECAM-1 and endomucin (EMCN) ($CD31^{high}$;$EMCN^{high}$). The sinusoidal blood vessel network in the diaphyseal bone shaft is by these molecular criteria designated as the "L-type" endothelium in bone ($CD31^{low}$;$EMCN^{low}$) (Kusumbe et al., 2014). Processes of adult bone remodeling and bone mass homeostasis, fracture repair, and bone tissue regeneration, as well as proper hematopoiesis, all rely on optimal bone and bone marrow vascularization. Yet, different types of skeletal blood vessels may provide differential support and contributions to these various processes. For instance, particularly H-type capillaries in growing and mature bones are heavily associated with perivascular osteoprogenitor cells, including Runx2-, Osx-, and platelet-derived growth factor (PDGF) receptor β-expressing cells, which are thought to be important for bone formation. The vascular system may thus help deliver these osteoprogenitor populations to bone formation sites, in addition to providing the necessary oxygen, nutrients, and growth factors for their controlled differentiation and activity (Dirckx et al., 2013; Maes et al., 2010a). Loss of these populations is observed with aging in mice and may be related to the well-documented age-related and osteoporosis-linked declines in both vascular density and bone mass (Maes, 2013; Ramasamy et al., 2016; Mekraldi et al., 2003; Burkhardt et al., 1987; Kusumbe et al., 2014). On the other hand, bone marrow arterioles and sinusoidal L-type vessels are surrounded by specific subsets of hematopoietic stem cells (HSCs) and provide critical components of the niche microenvironments that control their quiescence and differentiation balances (Ramasamy et al., 2016; Kusumbe et al., 2016; Itkin et al., 2016). Impaired revascularization has been long known to be detrimental to bone repair, but the specifics of the angiogenic processes and blood vessel types in fracture healing are only starting to be determined (Wang et al., 2017). Clearly, angiogenesis in bone and its coupling with osteogenesis provide promising therapeutic angles for low bone mass—associated diseases and for bone repair and regeneration, highlighting the importance of understanding the underlying crosstalk and regulatory mechanisms operating in osteolineage cells and in endothelial cells, as outlined next in this section (Fig. 9.2).

Bone cells' control of skeletal vascularization and oxygenation

Signaling from hypertrophic chondrocytes, osteoblast lineage cells, and osteoclasts has been found instructive toward the development, growth, and maintenance of the skeletal vascular system (Maes, 2013; Maes et al., 2012b). As the prime angiogenic factor, VEGF produced by these cell types plays a major role in adult bone. Moreover, the hypoxia-induced and HIF-mediated signaling pathways represent major regulators of the tight coupling between angiogenesis and osteogenesis in postnatal bone formation and bone remodeling, at least in part by functioning as key upstream inducers of VEGF expression (Maes et al., 2012b; Schipani et al., 2009). Some of the mouse models that exposed these roles include Cre-loxP-mediated conditional knockouts employing Osx-Cre, type I collagen-Cre, and osteocalcin (OC)-Cre driver strains to target osteoprogenitors, maturing osteoblasts, and differentiated osteoblasts, respectively. The first evidence for the importance of the HIF pathway components in the adult murine skeleton was provided by genetic targeting of HIF-1α and the upstream negative regulator of HIF activity, Von Hippel—Lindau (VHL), in OC-expressing osteoblasts (Wang et al., 2007). Mice lacking HIF-1α in osteoblasts exhibited narrower bones and reduced trabecular bone volume, associated with reduced vascular density and decreased bone formation (Wang et al., 2007; Shomento et al., 2010). Conversely, VHL inactivation, which is associated with constitutive HIF stabilization and boosted hypoxia signaling pathway activity, was associated with increased trabecular bone volume and increased VEGF levels and vascular density in bone (Wang et al., 2007). This study implicated osteoblastic HIF signaling in the regulation of angiogenesis in the bone microenvironment in response to hypoxia and postulated the principle of angiogenic—osteogenic coupling by hypoxia-sensing mechanisms, involving the indirect stimulation of osteogenesis as a consequence of skeletal vascular expansion (Wang et al., 2007). The critical oxygen-sensing prolyl hydroxylase enzymes (PHDs), which regulate HIF degradation in normoxia and control hypoxic HIF activity, have correspondingly been found to play important roles in the control of skeletal vascularization, bone formation, and bone remodeling (Wu et al., 2015). Combined inactivation of PHD1, PHD2, and PHD3 in osteoprogenitors resulted in extreme HIF signaling and excessive bone accumulation associated with overstimulation of angiogenic—osteogenic coupling (Wu et al., 2015).

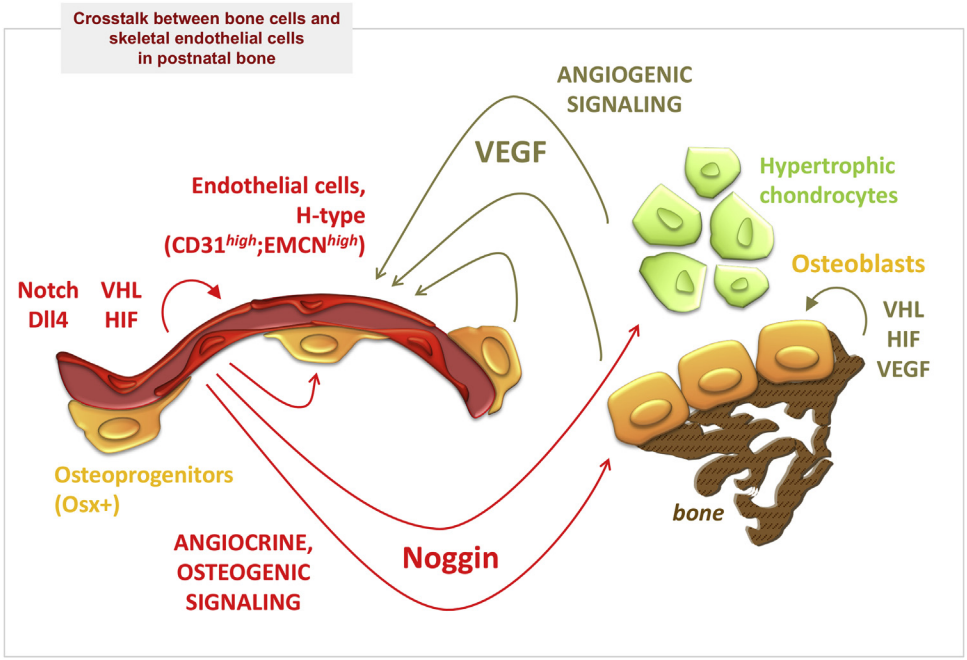

FIGURE 9.2 Bidirectional crosstalk between chondro-osteoblast lineage cells and skeletal endothelial cells, mediating angiogenic–osteogenic coupling in postnatal bone. Schematic view of the dynamic and reciprocal interplay between the different cell types in the bone environment that couples angiogenesis and osteogenesis. (Right and upper part) In the osteogenic compartment of the long bones, the signaling pathway governed by Von Hippel–Lindau (VHL), hypoxia-inducible factor (HIF), and vascular endothelial growth factor (VEGF) has been identified as a key driver of angiogenic–osteogenic coupling, by exerting both (1) cell-autonomous roles in chondrocytes, osteoprogenitors, and osteoblasts and (2) VEGF-mediated paracrine effects on the blood vessels in the bone environment, stimulating angiogenesis. (Left and lower part) In the vasculature of the bone and bone marrow environment, a specialized subtype of endothelial cells (ECs) expressing high levels of the endothelial markers CD31 and endomucin (EMCN) constitute the "type H" vessels in the metaphysis and endosteum. These ECs mediate the growth of the blood vessels in bone, through a tissue-selective mechanism of angiogenesis involving positive regulation by the VHL/HIF and Notch/Dll4 signaling pathways. Coupling of angiogenesis back to osteogenesis is mediated by osteoregulatory signals produced by ECs (i.e., angiocrine, osteogenic signals), such as Noggin. Osx, Osterix. *Figure adapted from Maes, C., Clemens, T.L., 2014. Angiogenic-osteogenic coupling: the endothelial perspective. Bonekey Rep. 3, 578.*

Work has also revealed additional roles of the hypoxia signaling pathways in the complex bone environment, as shown by using the Osx-Cre mouse to inactivate VHL in osteoprogenitors, either constitutively from fetal life onward or induced only later in the postnatal skeleton (by applying doxycycline/reverse tetracycline-controlled transactivator–mediated suppression of the activity of the Osx-Cre driver), and through other related mouse models. These studies revealed that the combined actions of the HIFs (both HIF-1 and HIF-2) increase angiogenesis and osteogenesis, alter hematopoiesis (mainly erythropoiesis), and enhance glycolytic cell metabolism in osteolineage cells (Shomento et al., 2010; Dirckx et al., 2018; Rankin et al., 2012; Regan et al., 2014). The last aspect appeared to be also associated with effects beyond bone on global energy metabolism, as hyperactivated hypoxia signaling through VHL deletion caused excessive glucose uptake and glycolysis in osteoblasts and an overall increased skeletal glucose consumption, along with impaired systemic control of glucose homeostasis (Dirckx et al., 2018). Altogether, the combined functions of the hypoxia pathway in bone are mediated by a large number of proteins encoded by direct HIF target genes (Semenza, 2012), with key roles ascribed to VEGF, erythropoietin, and genes involved in anaerobic cell metabolism, such as glucose transporters (e.g., Glut1) and key glycolytic enzymes including pyruvate dehydrogenase kinase 1, phosphoglycerate kinase 1, and lactate dehydrogenase A. As such, a growing number of effector proteins are being implicated in the responses to low oxygen in osteoblasts and other bone cell types, ensuring both cellular adaptation as well as remediation of the low oxygenation state within the tissue.

For VEGF specifically, the advantageous effects on osteogenesis are mediated partly indirectly by its paracrine proangiogenic actions—thereby stimulating the delivery of oxygen, nutrients, hormones, and angiocrine signaling factors (also see later) to the bone-forming osteoblasts—and partly directly. Indeed, most bone cell types express VEGF receptors, and ample in vitro studies have evidenced that VEGF signaling in osteolineage cells can induce their migration, differentiation, and bone-forming activity (reviewed in Maes, 2013). In vivo, a study overexpressing VEGF in the bone environment of adult mice suggested that cell-autonomous effects mediated by β-catenin signaling in osteoblast lineage

cells contributed to the phenotype, which was overall characterized by high bone mass, expansion of the osteoprogenitor pool, bone marrow fibrosis, and hematopoietic defects (Maes et al., 2010b). Conversely, conditional inactivation of *VEGF* in osteoprogenitors (driven by the Osx-Cre mouse strain) was shown to result in increased bone marrow adipogenesis at the expense of osteogenesis, and implicated intracrine-acting VEGF in cell fate decisions of stromal progenitors in the bone environment (Liu et al., 2012). Proper angiogenic–osteogenic coupling thus requires tight regulation and dynamic fine-tuning of the hypoxia signaling events and VEGF levels within the bone environment.

These hypoxia-related mechanisms have also been implicated in widespread bone pathologies, and pharmacological PHD inhibitors could be of great therapeutic value, for instance, in age-related osteoporosis and compromised fracture healing. Genetic inactivation of VHL or PHDs in mice or treatment with PHD-inhibiting compounds was effective in protecting mice against age- or ovariectomy-induced bone loss (Kusumbe et al., 2014; Wu et al., 2015; Zhao et al., 2012; Weng et al., 2014; Liu et al., 2014). Furthermore, activation of HIFs can be a successful strategy to improve fracture repair and bone regeneration, as supported by experimental animal models (Wan et al., 2008; Shen et al., 2009).

Endothelial and angiocrine signaling in bone

The aforementioned studies amply showed that osteolineage cells are equipped with the molecular tools to sense oxygen tension and direct adjustments in vascularization by signaling to endothelial cells. In addition, the regulation of skeletal vascularization and angiogenic–osteogenic coupling also involves endothelial cell-intrinsic mechanisms and angiocrine signals secreted by the endothelium, including the HIF signaling pathway, Notch, and bone morphogenetic protein (BMP) family signaling. Indeed, the oxygen-regulated program mediated by HIFs is also key in the endothelial cells of the skeletal blood vessels, in line with the hypoxic status of the postnatal bone and bone marrow environment. This has been shown by endothelium-specific, inducible inactivation of VHL in mice (using the vascular endothelial–cadherin [or Cdh5] promotor to drive the expression of CreERt2), which led to a striking increase in H-type blood vessels in the bones of juvenile mice (Kusumbe et al., 2014). Concomitantly, the pool of $Runx2^{+}$ or Osx^{+} cells associated with these vessels was expanded and the bone volume increased. The converse phenotype was seen upon endothelial cell-targeted inactivation of HIF-1α, as this mutation led to severe vascular defects and reduced numbers of osteoprogenitors (Kusumbe et al., 2014). It is thought that endothelial cells of H-type blood vessels secrete pro-osteogenic factors such as fibroblast growth factors, PDGFs, and BMPs, and as such contribute to the coupling of angiogenesis and osteogenesis (Ramasamy et al., 2016; Kusumbe et al., 2014). One signaling system that was found to be very important in the local production of angiocrine signals by vascular endothelial cells in the bone microenvironment is the Notch pathway (Ramasamy et al., 2014). Loss- and gain-of-function mouse models established that Notch/Dll4 signaling in H-type capillary endothelial cells regulated angiogenesis but also osteogenesis, by influencing the endothelial production and secretion of the BMP antagonist Noggin, which surprisingly was found to positively influence osteolineage cells and bone formation in vivo (Ramasamy et al., 2014).

These studies and further work are increasingly revealing that the endothelial cells of the skeletal blood vessels exert important signaling functions contributing to the control of bone development, growth, homeostasis, and regeneration, as well as to hematopoiesis. Indeed, within the skeletal system, blood vessels also constitute critical components of the niche microenvironments for HSCs in the bone marrow; the specific localization, nature, and molecular determinants of the vascular niches for HSCs are topics of intensive ongoing investigations at the interface between bone biology and hematology, with broad therapeutic application (Kusumbe et al., 2016; Itkin et al., 2016).

The nerve system of bone

Innervation of developing bone

The development of the nervous system is a complex process of axonal growth, synapse formation, and cellular signaling, during which the spinal cord forms from the neural tube during neurulation (Ciani and Salinas, 2005). Sensory axons enter the spinal cord through the dorsal roots and then ascend through the emerging white matter to the brain, whereas sympathetic neurons migrate ventrally to coalesce in prevertebral sympathetic ganglia (Glebova and Ginty, 2005). Both sensory and sympathetic axons are guided to their appropriate peripheral target tissues, including bone, by neurotrophic factors (Pezet and McMahon, 2006). In fact, developing tissues dictate the amount and type of innervation they require by secreting the specific neurotrophin that promotes neuronal survival of its corresponding axon type (Reichardt, 2006). At least one such neurotrophin is known to be active in developing long bone: nerve growth factor (NGF). In a 2016 study, this prototypical neurotrophic factor was found to be expressed by osteoprogenitor cells during both primary and secondary ossification (Tomlinson et al., 2016). Moreover, sensory neurons located in the dorsal root ganglion project axons

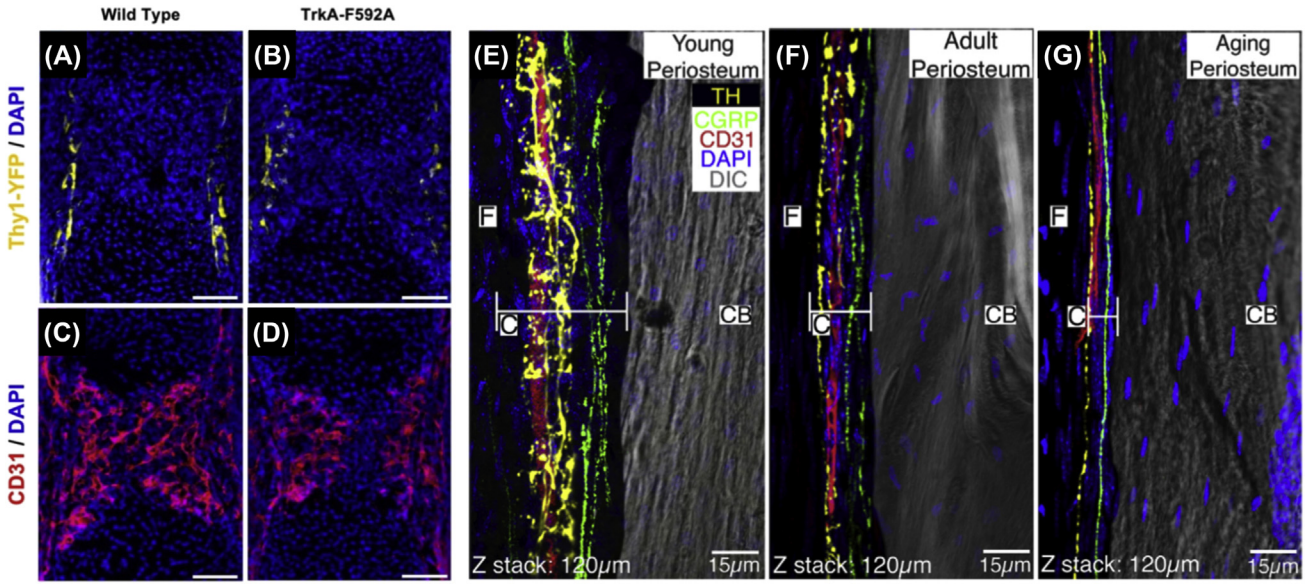

FIGURE 9.3 Skeletal nerves in the periosteum from beginning to end. (A) Thy1-YFP reporter mice were used to visualize nerve axons in the perichondrial region at embryonic day 15.5, just after primary ossification centers have formed. (B) Inhibition of nerve growth factor (NGF)−tyrosine kinase receptor 1 (TrkA) signaling in TrkA-F592A mice diminished nerve axons in the perichondrial region. (C, D) Similarly, inhibition of NGF−TrkA signaling impaired vascular invasion of the ossification center, as visualized by staining against CD31. Scale bars, 100 μm. (E) The periosteum of a young mouse is teeming with $CD31^+$ blood vessels (*red*), calcitonin gene-related peptide $(CGRP)^+$ sensory nerve axons (*green*), and tyrosine hydroxylase (TH)+ sympathetic nerve axons (*yellow*). (F, G) As the mouse ages to adulthood and beyond, the cambium layer shrinks but sensory and sympathetic nerve fibers along with blood vessels remain intact in the periosteum. Cambium (*C*) and fibrous (*F*) layers of the periosteum and cortical bone (*CB*) are labeled. *(C, D) Adapted from Tomlinson R.E., Li, Z., Zhang, Q., Goh B.C., Li, Z., Thorek D.L.J., Rajbhandari, L., Brushart T.M., Minichiello, L., Zhou, F., Venkatesan, A., Clemens T.L., 2016. NGF-TrkA signaling by sensory nerves coordinates the vascularization and ossification of developing endochondral bone. Cell Rep. 16 (10), 2723−2735. (F, G) Adapted from Chartier, S.R., Mitchell, S.A.T., Majuta, L.A., Mantyh, P.W., 2018. The changing sensory and sympathetic innervation of the young, adult and aging mouse femur. Neuroscience 387, 178−190.*

expressing neurotrophic tyrosine kinase receptor 1 (TrkA), the high-affinity receptor for NGF, which reach perichondrial bone surfaces adjacent to primary ossification centers at a time coincident with the initiation of NGF expression in osteochondral progenitor cells. Inactivation of TrkA signaling in mice impaired skeletal innervation, delayed vascular invasion, and decreased the number of osteoprogenitor cells, resulting in decreased femoral bone length and volume. These results were consistent with previous studies on the skeletal action of semaphorin 3A (Sema3A), a well-characterized inhibitor of neuronal outgrowth. Mice lacking Sema3a were observed to have gross defects in nerve, heart, and skeletal patterning (Behar et al., 1996). Subsequent work found that selective loss of Sema3a in neurons, but not osteoblasts, decreased skeletal sensory innervation and postnatal bone mass (Fukuda et al., 2013). To date, no studies have conclusively examined the timing and location of the arrival of sympathetic or parasympathetic nerves in bone. Given that sympathetic innervation of the mesenteric arteries in mouse takes place postnatally, it is unlikely that autonomic nerve fibers play a major role in primary or secondary ossification (Brunet et al., 2014) (Fig. 9.3).

Innervation of the mature skeleton

Somatic nervous system

Sensory nerves of the somatic nervous system are distributed throughout the body, including the skin, bones, joints, tendons, and muscles, and transduce signals involved in spatial orientation (proprioception), pain and noxious stimuli (nociception), temperature changes, and the perception of nonpainful tactile stimuli (Julius and Basbaum, 2001; McKemy et al., 2002; Proske and Gandevia, 2012; Jones and Smith, 2014). To accomplish these functions, nerve endings generally express a wide variety of receptors and channels that will initiate the appropriate signaling cascades in response to perturbations (Pongratz and Straub, 2013). These include Toll-like receptors, cytokine and prostaglandin receptors, transient receptor potential ion channels, and growth factor receptors, among many others (Pongratz and Straub, 2013). Surprisingly, the vast majority (>80%) of nerves in mature bone are thinly myelinated or unmyelinated sensory nerves that express

TrkA, a consequence of the expression of NGF during development (Castañeda-Corral et al., 2011; Tomlinson et al., 2016; Jimenez-Andrade et al., 2010). Furthermore, the density of sensory nerves in the adult mouse femur is highest in the periosteum and marrow space, relatively low in the mineralized bone, and essentially zero in healthy cartilage (Mach et al., 2002; Castañeda-Corral et al., 2011).

In general, the most familiar and best understood function of sensory nerves is pain sensation, which is profoundly apparent following traumatic bone fracture or in patients with bone malignancies. The central mediator of osseous pain sensation is NGF, which transmits nociceptive signals either by directly activating the abundant TrkA+ sensory nerves in bone or through indirect mechanisms that enhance the response of other nociceptive pathways (Mantyh, 2014). This upstream position of the NGF−TrkA signaling pathway in pain sensation has made it an attractive target for developing pharmaceuticals for treating pain associated with cancer and osteoarthritis as well as an active area of research. Several studies have documented upregulated expression of NGF in progenitor cells, osteoblasts, and chondrocytes during fracture repair in rodents (Asaumi et al., 2000; Grills and Schuijers, 1998). Correspondingly, blockade of NGF function has been observed to significantly decrease behavior associated with pain following fracture in mice (Jimenez-Andrade et al., 2007; Koewler et al., 2007), and additional studies demonstrated that this analgesia can be provided without affecting standard fracture healing outcomes (Rapp et al., 2015). However, others have shown that topical application of NGF to rib fractures in rats and the distraction callus in rabbit mandibles significantly decreases healing time and improves subsequent repair strength (Grills et al., 1997; Wang et al., 2006). This effect is thought to be mediated through NGF-induced release of neuropeptides such as calcitonin gene-related peptide (CGRP) and substance P (Malcangio et al., 1997; Quarcoo et al., 2004), which are both known to positively influence bone formation (Baldock et al., 2007; Goto et al., 2001, 2007; Li et al., 2010; Long et al., 2010; Lundberg et al., 2007; Sample et al., 2011). As a result, more work must be done to fully understand the role of NGF−TrkA signaling in bone fracture repair. Nonetheless, widespread therapeutic use of the highly effective anti-NGF antibodies for pain relief may be imminent (Lane et al., 2010; Jayabalan and Schnitzer, 2017; Birbara et al., 2018). Although phase III clinical trials were halted in 2010 due to an increased incidence of adverse events (Hochberg, 2015), the humanized monoclonal anti-NGF antibody tanezumab (Pfizer and Lilly) received FDA fast-track approval in 2017 as the first in a new class of nonopioid pain relievers.

In addition to pain sensation, sensory nerves in bone have also been found to play an important role in responding to mechanical loads placed on the skeleton. This line of inquiry was initiated based on the observation that primary afferent sensory nerves are present in a dense meshlike network on the periosteal and endosteal surfaces (Martin et al., 2007), which are the preferential sites for the perception of skeletal deformation. Mature, OC-expressing osteoblasts on the periosteal and endosteal surfaces of bone were observed to robustly express NGF in response to mechanical loading in mice (Tomlinson et al., 2017). Furthermore, the researchers found that inactivation of NGF−TrkA signaling significantly attenuated bone formation in response to load, via a decrease in osteocytic Wnt/β-catenin signaling. Since sensory nerves remain essentially intact in the periosteum throughout life, even as bone undergoes marked changes associated with aging (Chartier et al., 2018), targeting NGF−TrkA signaling for bone accrual may be a viable strategy in cases in which bone cell−targeted therapies may fail. Importantly, more research is necessary to determine if anti-NGF therapeutic agents for pain will substantially affect strain-adaptive bone remodeling in humans.

Autonomic nervous system

The autonomic nervous system (ANS), part of the peripheral nervous system, is divided into two antagonistic branches: the sympathetic nervous system and the parasympathetic nervous system. Whereas sympathetic nerves primarily signal through the release of norepinephrine to activate α- and β-adrenergic receptors, parasympathetic nerves release acetylcholine that activates muscarinic acetylcholine receptors (mAChRs) and nicotinic acetylcholine receptors (nAChRs). In general, these two nerve types serve to coordinate bodily functions not consciously directed, such as breathing or the regulation of blood pressure. Both nerve types are present in bone tissue, and have been primarily visualized in close contact with the main arteries that provide the blood supply to long bones (Bjurholm et al., 1988; Hill and Elde, 1991; Tabarowski et al., 1996). In particular, nerves expressing tyrosine hydroxylase (TH) (the rate-limiting enzyme in the synthesis of catecholamines) are routinely observed wrapping around blood vessels in bone with a spiral-type morphology (Mach et al., 2002; Castañeda-Corral et al., 2011). Similarly, parasympathetic nerves with immunoreactivity against vesicular acetylcholine transporter and choline acetyltransferase can be observed readily, particularly in the marrow space (Artico et al., 2002; Bajayo et al., 2012). However, the specific locations, densities, and distributions throughout the bone and marrow space are not well described.

Generally, it is held that the ANS exerts its effect on the skeleton via close contact with bone cells. However, given the limited direct interaction of ANS nerve fibers with skeletal cells (Dénes et al., 2005), others have proposed that a diffusion mechanism may have a role (Elefteriou, 2018). Nonetheless, osteoblasts and osteoclasts have both been observed to express a wide variety of adrenergic receptors, most notably the β2-adrenergic receptor (Kajimura et al., 2011), which can respond to the norepinephrine released by sympathetic nerve terminals (Togari, 2002). Work has shown that neither osteoblasts nor osteoclasts express detectable levels of mAChRs, but nAChRs are readily observable, particularly the α2 and β2 subunits, which may respond to the release of acetylcholine from parasympathetic nerve terminals (Bajayo et al., 2012).

Bone remodeling activity is at least partially restrained by signals emanating from the ANS via regulation of bone resorption (Elefteriou et al., 2005). Several studies have shown that sympathetic nervous outflow stimulates bone resorption that, in turn, negatively affects bone formation (Elefteriou et al., 2005; Katayama et al., 2006), whereas parasympathetic signaling appears to favor bone accrual by inhibiting bone resorption (Bajayo et al., 2012). This paradigm is consistent with the circadian rhythm of the ANS. Generally, sympathetic nervous activity is dominant during the day, during peak bone resorption; conversely, parasympathetic nervous activity is dominant during the night, during peak bone formation (Dudek and Meng, 2014; Komoto et al., 2012; Shao et al., 2003). Furthermore, mice lacking β2-adrenergic receptor in the osteoblast lineage have significantly increased bone formation coupled with decreased bone resorption, leading to an eventual increase in total bone mass in adulthood (Kajimura et al., 2011). However, pharmacological studies do not recapitulate this encouraging result: treatment with either a β-adrenergic receptor agonist (salbutamol) or an antagonist (isoprenaline) was associated with bone loss in mice, mainly through increased bone resorption (Bonnet et al., 2007; Kondo and Togari, 2011). Nonetheless, the known safety profile of "β blockers," which block activation of β-adrenergic receptors and have achieved widespread use for the treatment of cardiovascular disease, has resulted in significant interest in modulating ANS signaling to increase bone mass in humans. Encouragingly, a recent meta-analysis of seven cohort and nine case−control studies found that the use of β blockers was associated with a 15% decrease in overall fracture risk, with β1-specific blockers most strongly associated with the risk reduction (Toulis et al., 2014). Nonetheless, a 2015 randomized clinical trial was unable to establish an effect of β2-adrenergic agonists or antagonists on human bone turnover (Veldhuis-Vlug et al., 2015). Furthermore, preclinical studies have concluded that the contribution of sympathetic signaling to load-induced bone formation in bone is minimal (de Souza et al., 2005); no studies have investigated the role of parasympathetic signaling in this process. In total, much work remains to determine the direct and specific effects of the ANS on bone metabolism.

Conclusion

The pre-eminent role of vascularization in bone was originally reported in the 1960s (Trueta and Buhr, 1963; Trueta and Caladias, 1964) and is now well established. Moreover, much has been learned about the regulation of vascular growth in bone and the roles of VEGF and the hypoxia signaling pathways, both in physiology and in bone defect repair. Altogether, studies performed in this field are progressively uncovering the molecular underpinnings of osteo-angiogenic coupling, which obviously involves a vigorous bidirectional crosstalk between endothelial cells and osteolineage cells that is only beginning to be uncovered. Especially little is known, as of this writing, about the nature of angiocrine signaling factors emanating from the endothelium and their roles in developing, growing, remodeling, and healing bones. Many other aspects of the organization, integrity, and functioning of the vasculature in the skeletal system remain to be investigated in further depth, including the molecular specifics of the specialized vascular environments for skeletal stem/progenitor cell harboring and bone formation, and of the niches controlling the maintenance of HSCs and the support of hematopoiesis in the bone marrow environment. Increasing insights into these areas will direct future studies exploring how the bone vasculature can ultimately be modulated to achieve anabolic treatments of osteoporosis and other bone disorders, to support compromised fracture repair and tissue engineering therapies, and to improve treatments of hematological pathologies and stem cell transplantation protocols.

Similarly, the skeleton is densely innervated by a wide variety of somatic and autonomic nerve axons that carry out their unique functions in a complex microenvironment. Despite tremendous advances, much remains to be uncovered regarding the nerves in bone. These lingering questions include the timeline of sympathetic innervation in bone, the role of NGF−TrkA signaling in bone repair, the identification of nerve-derived osteogenic cues, the specific action of the ANS on bone remodeling, and the alterations in nerve signaling that occur with aging.

Finally, the mechanisms by which bone vascular and nerve systems interact during development, homeostatic bone remodeling, and fracture repair still need to be uncovered. Answers to these fundamental questions will inevitably lead to novel approaches for improving overall skeletal health.

Chapter outline

Introduction:—bone modeling and bone remodeling

Skeletal structure and function are regulated by hormones, cytokines, and the central and sympathetic nervous systems in response to a range of factors, including changes in mechanical loading and stimuli emanating from the immune and reproductive systems. Not only does the skeleton provide mechanical strength to the body, protection of internal organs, and sites of muscle attachment for locomotion, but bone is also a very significant endocrine organ with major influences on calcium, phosphate, and glucose metabolism.

Skeletal structure is determined by two processes: modeling and remodeling. The key difference between these two processes is the relationship between bone-forming osteoblasts and bone-resorbing osteoclasts. In modeling, actions of osteoblasts and osteoclasts occur in separation (i.e., on different surfaces), while in remodeling, the actions of osteoblasts and osteoclasts occur in sequence on the same bone surface.

Modeling modifies the shape of the skeleton. This includes both the construction of bone, which takes place from the beginning of skeletogenesis during fetal life until the end of the second decade, when the longitudinal growth of the skeleton is completed (Frost, 1964), and changes in bone shape associated with aging (Parfitt et al., 1983; Robling and Turner, 2009) or in response to mechanical load. In modeling bone formation occurs independently (i.e., without prior bone resorption), as does bone resorption (without subsequent bone formation). In this way bone is formed at sites of greatest mechanical load and removed where it is not required. For example, bone formed and deposited on the outer surface of the bone widens a growing bone; at the same time, bone is resorbed at a different location to enlarge the medullary cavity containing the bone marrow.

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00010-5

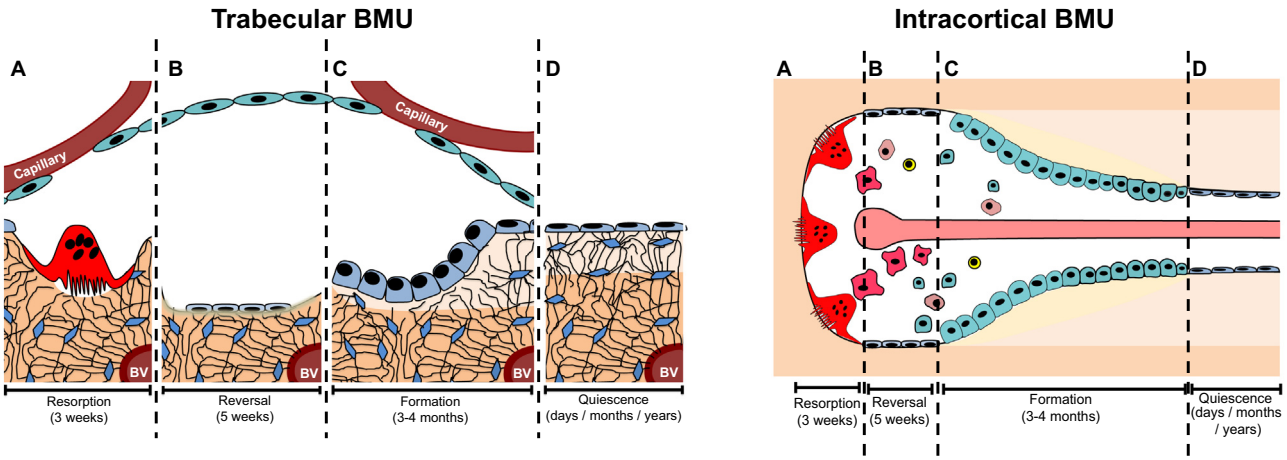

FIGURE 10.1 The basic structure of trabecular (left) and intracortical (right) basic multicellular units (*BMUs*), showing how the cell populations present on the surface change over time. (A) Initiation of remodeling, with lifting of the canopy, and osteoclast-mediated resorption on the bone surface. Osteoclast progenitors may be supplied by the capillaries adjacent to the canopy. (B) After bone resorption, the surface is covered by osteoblast lineage reversal cells. (C) Following the reversal period, osteoblasts fill the pit resorbed by osteoclasts by generating new osteoid, which is gradually mineralized over time; again, osteoblasts may be supplied by the nearby vasculature. (D) The process is complete, the pit filled, the surface is covered with bone-lining cells, and the canopy can no longer be detected. Mineralization of the osteoid continues until it reaches maximal levels, or until the next remodeling cycle occurs. *BV*, blood vessel.

Remodeling was initially described as two linked processes: (1) a destructive process, wrought by bone-resorbing osteoclasts, followed by (2) a productive process ascribed to bone-forming osteoblasts; this was based on Harold Frost's examination of multiple sections through trabecular bone from normal adult skeletons (Hattner et al., 1965). The sequence of resorption followed by formation was likened to the healing of a soft-tissue wound, and analogous progressions were noted to take place in the formation of several epithelia (e.g., Ford and Young, 1963). The tissue wound analogy is apt, since the principal functions of bone remodeling are to provide a means of adapting the skeleton to changes in loading and to remove and replace damaged or old bone. Remodeling occurs asynchronously throughout the skeleton at many anatomically distinct sites termed basic multicellular units (BMUs) (Frost, 1964; Hattner et al., 1965). In BMUs, tiny packets of bone are removed by osteoclasts and subsequently replaced by new bone matrix (osteoid) produced by osteoblasts; that matrix is mineralized to form new bone substance. In trabecular bone the BMU is located on the bone surface. In Haversian cortical bone the BMU comprises cutting zones led by osteoclasts that proceed through bone, followed by differentiating osteoblasts (Fig. 10.1) (Parfitt, 1982; Eriksen, 1986; Eriksen et al., 1993; Hauge et al., 2001). The roles of remodeling and modeling will be discussed in detail elsewhere in this book (Seeman, Chapter 11).

Development of the concept of coupling

When Frost introduced the BMU, he also introduced the concept of "coupling" as the process by which resorption of a certain amount of bone is followed by formation of the amount sufficient to replace it (Hattner et al., 1965). This was a remarkable insight given that little was known of the cells of bone at that time; their origins were not at all understood, and it was more than another decade before they could be studied directly. The events within the BMU progress from quiescence to activation, resorption, and formation, and finally return to quiescence when filling of the resorbed space is complete (Fig. 10.1).

The bone resorption activity in a BMU in adult human bone takes approximately 3 weeks (Eriksen et al., 1984b), the formation response 3−4 months (Eriksen et al., 1984a), and between the two activities there is a "reversal phase" (Tran Van et al., 1982), which takes several weeks (Eriksen et al., 1984b). The process occurs with sufficient frequency, and at sufficient sites, to replace 5%−10% of the skeleton per year, with the entire adult human skeleton replaced in around 10 years (Parfitt, 1980). In rodents the duration of this sequence is compressed, but a time delay between resorption and formation still exists: in rat alveolar bone the reversal phase lasts for approximately 3.5 days (Vignery and Baron, 1980). These numbers vary also with site, skeletal health, and treatment (Jensen et al., 2014), and in some conditions, including osteoporosis, there is an increased duration, or even arrest, of the reversal phase (Parfitt, 1982; Andersen et al., 2013).

Coupled remodeling is asynchronous throughout the skeleton

When we consider the time course over which remodeling occurs it must be noted that BMUs throughout the skeleton are active at different stages of the remodeling cycle. Indeed, it is an essential feature of bone remodeling that it does not occur uniformly throughout the skeleton, but takes place where it is needed to repair damaged or replace old bone. The events are initiated asynchronously, at sites geographically and chronologically separated from one another. Therefore, at any one time, bone is being resorbed in BMUs at some locations, while at others, a BMU is in its formation or reversal phase. Systemically administered drugs that influence bone remodeling will therefore act upon BMUs at all sites and in differing phases of their remodeling cycle. This presents a special challenge to pharmacological interventions aimed at preventing and reversing the structural decay associated with menopause and advancing age. It also needs to be borne in mind when considering ways in which circulating hormones might influence bone remodeling.

The development of a BMU in bone begins with resorption by osteoclasts, leaving scalloped contours in Howship's lacunae, followed by generation of the cement line, upon which bone formation by osteoblasts would take place (Fig. 10.1). Scalloped cement lines are used in histology to indicate that formation has taken place on previously resorbed surfaces, whereas smooth cement lines signify bone being formed on surfaces without previous resorption, i.e., modeling; while these are observed in larger mammals, they are rarely observed in murine bone, because the pits formed by mouse osteoclasts are more shallow. In adult trabecular bone, about 96% of bone formation takes place on resorbed surfaces (i.e., remodeling surfaces), the remainder on intact surfaces (modeling), with some of the latter reflecting overfilling of the resorbed lacunae (Hattner et al., 1965). The remodeling sequence proposed by Frost, of activation, resorption, and formation (ARF) (Frost, 1964), was extended by Baron, who proposed the existence of a reversal phase between resorption and formation, a stage characterized by the presence of mononuclear cells and the formation of a cement line separating new from old bone (Baron, 1977). Although the reversal phase, lasting as long as 5 weeks in human bone remodeling, has been poorly understood, it is now being investigated in some detail and will be discussed later. Frost's view of bone remodeling was readily adopted by others (Frost, 1964; Harris and Heaney, 1969; Parfitt, 1982).

Coupling is unidirectional and sequential: bone formation following bone resorption

The term "coupling" is illustrative, because it calls to mind the coupling of a train carriage to a locomotive: the osteoclast is analogous to the engine commencing the process of remodeling, with osteoblasts being the carriage coupled to it and following behind.

The first essential step in the remodeling cycle was proposed to be the generation of active osteoclasts. This suggestion was made even before it was recognized that osteoclasts develop from hemopoietic precursors. Osteoclasts are probably derived from early and late precursors available in marrow adjacent to activation sites (reviewed by Takahashi et al., Chapter 5); they may be drawn to the site by chemoattractants derived from osteocytes or from the bone matrix itself (Sims and Gooi, 2008). They may also be recruited from blood available at the bone interface through a sinus structure of bone remodeling compartments (Hauge et al., 2001; Kristensen et al., 2013). At each BMU, the resorption of a volume of bone is followed by new bone formation sufficient to fill the space. The BMU resorbs and replaces old bone at the same location so there is no change in bone size or shape. If the volumes of bone removed and replaced are equal, there will be no permanent loss of bone or compromise in bone mass.

Coupling does not include the major mechanism of intercellular communication in bone that was proposed some years later, of osteoblastic lineage cells controlling osteoclast formation (Chambers, 1980; Rodan and Martin, 1981) by their production of receptor activator of NF-κB ligand (RANKL) and osteoprotegerin (OPG) (Lacey et al., 1998; Yasuda et al., 1998; Suda et al., 1999). The Frost coupling concept preceded this by decades. The control of osteoclast formation and function by osteoblasts (or cells in that lineage) is not coupling, although this mistake is commonly made in the literature. Coupling refers strictly to *the process by which products of bone resorption and of osteoclasts and other cells within the BMU influence recruitment and differentiation of the osteoblast lineage to mature osteoblasts that synthesize bone and mineralize it*. Frost provided a great service in identifying the coupling mechanism as one that was likely to be important physiologically and important in devising therapeutic approaches; this simple concept has come to be recognized as a complex process with many participants, as will be discussed.

Coupling as a multicellular process

The balance between bone formation and resorption requires participation of a number of cell types beyond differentiated osteoclasts and osteoblasts. Coupling is therefore not simply an event taking place between osteoclasts and osteoblasts, but

an extensive process of information transfer involving diverse cells and interactions aimed ultimately at regulating osteoblast differentiation/bone formation (Sims and Martin, 2015). Since the several stages of the process are prolonged in duration, any cellular communication mechanisms have to provide for the separation of these events in time.

Coupling occurs locally within a basic multicellular unit

In discussing the mechanisms of coupling, including osteoclast formation, activity, and maintenance, we are considering only local factors. They seem better equipped than circulating hormones to activate asynchronous events throughout the skeleton.

Although very little was known about osteoclasts at the time of Frost's proposal, the key initial event was agreed to be the initiation of resorption by osteoclasts. When the steps in osteoclast formation and activation were eventually revealed as being derived from precursors in the bone marrow, the question of how osteoclasts commenced BMU formation at a site of need was asked.

Much interest has developed in the data showing the development of a canopy extending over the active BMU during its initiation. This was proposed first by Rasmussen and Bordier (Rasmussen and Bordier, 1974) and suggests a mechanism to isolate the BMU and allow local communication between differing cell types. Direct evidence came from Hauge et al. (Hauge et al., 2001), who suggested that lining cells lift from the underlying bone at the start of remodeling activity and form a canopy over the site to be resorbed, whether on the surface in trabecular bone or within the substance of cortical bone undergoing haversian remodeling. The capillary blood supply closely associated with the canopy (Kristensen et al., 2013) was proposed as a source of hematopoietic precursors for osteoclast formation (Fig. 10.1). Osteoclast formation can take place rapidly in vivo; this may be made possible by partially differentiated niches of cells available for the BMU. Such partially differentiated osteoclast precursors, designated as "quiescent osteoclast precursors," have been characterized in mouse and rat (Mizoguchi et al., 2009), having arrived there in the circulation (Muto et al., 2011), but have not yet been identified in human subjects. They are reported in Takahashi et al. (Chapter 5).

Capillaries associated with the canopy also provide a mechanism for ingress of other cells, including mesenchymal precursors (Eghbali-Fatourechi et al., 2007) and immune and endothelial cells. Consistent with such supply from blood was the demonstration that red blood cells could be seen within the active cortical BMU (Andersen et al., 2009). The canopy has also been demonstrated in rabbit bone (Jensen et al., 2014), which undergoes Haversian remodeling in the cortex, although the canopy has not been convincingly shown yet in intracortical "cutting cones." Although a similar canopy has been predicted in the mouse, it has been observed only above bone-forming surfaces (Narimatsu et al., 2010). Tissue-specific macrophages ("osteomacs") have been found to form a canopy over bone-forming sites in the mouse (Chang et al., 2008), but the relationship between the two canopies remains unclear.

Osteocytes are recognized as important in mechanosensing and regulation of bone remodeling (Bonewald and Johnson, 2008). They are the most abundant cell of bone and are situated to communicate both throughout the skeleton and with bone-lining cells on the surface. Recognition of the need to remove or repair a region of bone could be achieved by osteocytes. Indeed, apoptosis of osteocytes as a result of microdamage coincides with bone resorption by osteoclasts (Verborgt et al., 2000; Noble et al., 2003; Heino et al., 2009; Kennedy et al., 2012), implicating this as a mechanism to target the initiation of remodeling for bone repair. A signal emitted by osteocytes to lining cells could lead them to lift and begin to form the canopy overlying and containing the BMU (Eghbali-Fatourechi et al., 2007; Eriksen et al., 2007). The nature of the signal to attract osteoclast precursors to the bone surface is unknown, but a number of chemoattractants have been suggested (Sims and Gooi, 2008). RANKL and macrophage colony-stimulating factor (M-CSF) production by local mesenchymal-derived cells may also play a role in the initial formation of the BMU. Since the canopy mesenchymal cells themselves have been suggested to be a source of osteoblast precursors (Delaisse, 2014), they may, in addition to lining cells, mesenchymal precursors within the BMU, and osteocytes, also be sources of RANKL and M-CSF as the necessary stimuli for osteoclast generation at the site.

Coupling and balance: what is the difference?

The amount and quality of bone is retained in the skeleton during balanced bone remodeling because the processes within BMUs are matched: the amount of bone synthesized replaces the amount removed. The two processes are "balanced" through mechanisms of intercellular communication (see later). This is the key to integrity of the remodeling process and the success of the BMU system in ensuring maintenance of normal bone during young adult life, when bone mass is maintained at a constant level. It is what led Frost to propose the coupling of bone formation and resorption processes within the remodeling BMU. At other times in life, the balance is negative (bone mass is lost) or positive (bone mass is

gained), but this does not mean there a loss of coupling (although the term "uncoupling" is frequently used): formation still follows resorption, but there is an imbalance in the activities between the bone cells. This caution is especially pertinent in studies claiming (for example) that pharmacological agents or genetic alterations uncouple bone formation from resorption on the basis of serum biochemical markers; these markers represent the sum of all formation and resorption activities in the skeleton, including both modeling and remodeling.

Some forms of uncoupling or dissociation may occur at the BMU level, for example, when osteoclasts are nonfunctional or not present (and therefore are unable to initiate remodeling and provide signals to osteoblasts) (Henriksen et al., 2011) or in instances of reversal phase "arrest," when the canopy over the BMU is disrupted as in myeloma bone disease (Andersen et al., 2010) and some cases of osteoporosis (Andersen et al., 2014). This will be discussed later.

The resorption phase of remodeling and its cessation in the basic multicellular unit

Once a BMU site is activated, resorption must be limited in some way. An important unanswered question about osteoclast behavior and the control of resorption in the remodeling cycle is: how does each osteoclast know when to stop resorbing? The process is likely to finish with osteoclast death, which has been studied in vitro to some extent, but its regulation in vivo remains obscure. There are several possible mechanisms. Osteoclasts phagocytose osteocytes, which might provide a mechanism to remove the signal for resorption (Elmardi et al., 1990). The very high (millimolar) concentrations of calcium generated during mineral dissolution, capable of inhibiting osteoclasts (Zaidi et al., 1989), might come into play particularly in the localized and focused conditions of the BMU. Transforming growth factor β (TGFβ) is available either when it is resorbed from the matrix and activated by acid pH or when it is secreted by the osteoblast lineage and can promote osteoclast apoptosis (Hughes and Boyce, 1997). A direct effect of estrogen to enhance osteoclast apoptosis has been identified in mouse genetic experiments (Nakamura et al., 2007). Some insights into the control of apoptosis arise from genetic and pharmacological studies showing that inhibition of acidification of the resorption space by blockade of either chloride channel-7 (ClC-7) or the V-type H^+ ATPase of the osteoclast results in prolonged osteoclast survival (Henriksen et al., 2004; Karsdal et al. 2005, 2007). This might suggest a role for acidification in determining osteoclast life span, perhaps even through TGFβ activation. In determining how resorption ends in the BMU, there is much to be learned of mechanisms regulating osteoclast apoptosis. There might be several events limiting resorption to only a certain amount of bone at each BMU, including the possibility that accumulation of osteoblast progenitors provides a signal, but no dominant governing control has yet been identified.

Coupling mechanisms originate from several cellular sources

The development of the coupling concept led to an extensive search for possible "coupling factors"— messengers from the active osteoclast controlling the differentiation and activity of subsequent osteoblasts on the same surface. Many candidate factors have now been identified and are listed in Table 10.1. We propose, however, that rather than a single coupling factor, or even a team of coupling factors, there are a range of "coupling mechanisms" promoting and limiting bone formation in the BMU (Fig. 10.2). Some coupling mechanisms derive from osteoclasts and their activities: (1) matrix-derived signals released by osteoclasts during bone resorption and (2) factors synthesized by the mature osteoclast (which may include secreted factors, membrane-bound factors, or factors released in cell-derived vesicles). But there are also coupling mechanisms emanating from other cell types within the BMU: (3) topographical changes effected by the osteoclast on the bone surface and sensed by osteoblasts; (4) secreted and membrane-bound products of osteoblast lineage cells, including osteoblast precursors, lining cells, and osteocytes; (5) secreted products of immune and endothelial cells; and (6) neurogenic stimuli arising from the extensive innervation circuitry in bone. The last will not be considered in this chapter since they are speculative and have not been subject to direct experiment. The others will each be discussed in turn.

It is also important to note the many different contexts in which osteoclasts communicate to osteoblasts: not every signal from an osteoclast that changes osteoblast differentiation or function should be considered a coupling factor. There are three pertinent examples of this. First, during endochondral ossification, the process by which the cartilage surrounding hypertrophic chondrocytes is resorbed by osteoclast-like cells and replaced by osteoblasts is analogous to remodeling of bone; it is sequential, and both resorption of matrix and formation of new bone occur on the same surface (Baron and Sims, 2000). However, the control mechanisms existing in that anatomical location are likely to be different, because of contributions from the hypertrophic chondrocytes and adjacent invading blood vessels (Poulton et al., 2012). Second, osteoclasts appear to produce "osteotransmitter" signals transmitted through the cortical osteocyte network (either by lacunocanalicular transport or by a signal relay) to influence the function of osteoblasts on the periosteal surface (Johnson et al., 2015). Third, in murine calvariae, in which there is no remodeling and hence no coupling, osteoblasts and

TABLE 10.1 A summary of osteoclast-derived coupling factors and their other sources and influences near or in the basic multicellular unit. Influences listed are from *in vitro* studies, unless otherwise indicated. RANKL, receptor activator of NF-kappa B ligand.

Factor	Production by osteoclasts	Other potentially relevant sources	Influences on osteoblast differentiation and bone formation	Other potential influences in remodeling
Transforming growth factor β	Released from matrix (Oreffo et al., 1989)	Osteoblasts (Robey et al., 1987) T lymphocytes (Chen et al., 1998) Macrophages (Fadok et al., 1998)	Stimulates progenitor expansion (Robey et al., 1987; Hock et al., 1990) Stimulates progenitor migration and differentiation (Tang et al., 2009) Stimulates bone formation in organ culture (Hock et al., 1990)	Stimulates osteoclastogenesis by direct action on osteoclast precursors (Sells Galvin et al., 1999) Stimulates sclerostin expression (Loots et al., 2012)
Bone morphogenetic protein (BMP) 2	Released from matrix (Oreffo et al., 1989) Secreted (Garimella et al., 2008)	Osteoblasts (Robubi et al., 2014) Macrophages (Champagne et al., 2002)	Stimulates progenitor expansion and migration (Fiedler et al., 2002) Stimulates osteoblast differentiation (Rickard et al., 1994)	Stimulates osteoclast activity (Hanamura et al., 1980; Kanatani et al., 1995)
Insulin-like growth factors	Released from matrix (Centrella and Canalis, 1985a)	Osteoblasts (Canalis and Gabbitas, 1994) Macrophages (Fournier et al., 1995)	Stimulates progenitor expansion (Xian et al., 2012)	Stimulates osteoclastogenesis (Wang et al., 2006)
Platelet-derived growth factor BB	Released from matrix (Centrella and Canalis, 1985a) Secreted (Kreja et al., 2010)	Osteoblasts (Zhang et al., 1991) Endothelial cells (Daniel and Fen, 1988) Osteoclasts (Lees et al., 2001)	Promotes progenitor replication (Hock and Canalis, 1994) Promotes progenitor migration (Sanchez-Fernandez et al., 2008; Kreja et al., 2010) Stimulates bone formation in vivo (Mitlak et al., 1996) Inhibits osteoblast differentiation (Hock and Canalis, 1994; Kubota et al., 2002)	Stimulates osteoclast precursor recruitment (Hock and Canalis, 1994)
Cardiotrophin-1	Secreted (Walker et al., 2008)		Stimulates bone formation in vivo (Walker et al., 2008) Stimulates osteoblast commitment (Walker et al., 2008) Suppresses sclerostin expression (Walker et al., 2008) Bone formation is low in null mice (Walker et al., 2008)	Stimulates osteoclastogenesis (Richards et al., 2000) Bone resorption is low in null mice (Walker et al., 2008)
BMP-6	Secreted (Garimella et al., 2008)	Mesenchymal and hematopoietic stem cells (Martinovic et al., 2004; Friedman et al., 2006)	Stimulates osteoblast differentiation (Friedman et al., 2006)	Stimulates osteoclastogenesis from human marrow cells (Wutzl et al., 2006)

Wnt10b	Secreted (Pederson et al., 2008)	T cells (Terauchi et al., 2009)	Stimulates osteoblast differentiation in vivo (Bennett et al., 2007)	Stimulates osteoclast activity in vivo (Bennett et al., 2007)
Sphingosine-1-phosphate (S1P)	S1P production catalyzed by secreted sphingosine-1-kinase (Pederson et al., 2008)	Vasculature (Scariano et al., 2008) Red blood cells (Pappu et al., 2007)	Induces osteoblast precursor recruitment (Pederson et al., 2008) Promotes osteoblast survival (Ryu et al., 2006; Pederson et al., 2008) Promotes osteoblast migration (Ryu et al., 2006)	Stimulates osteoclast recruitment (Scariano et al., 2008). Stimulates RANKL expression by osteoblasts and T cells (Ryu et al., 2006) Stimulates osteoclast precursor chemotaxis (Ishii et al., 2010) Intracellular S1P inhibits osteoclast differentiation (Ryu et al., 2006)
collagen triple-helix repeat –containing 1	Secreted (Takeshita et al., 2013)	Mesenchymal cells, osteoblasts (Kimura et al., 2008), and osteocytes (Y-R Jin Bone, 2017, p153)	Stimulates osteoblast differentiation (Kimura et al., 2008) Stimulates bone formation in vivo (Kimura et al., 2008; Takeshita et al., 2013) Osteoclast-specific null mice show reduced bone formation (Takeshita et al., 2013) Osteoblast-specific overexpression causes increased bone formation (Kimura et al., 2008)	Inhibits osteoclast formation and activity (Y-R Jin Bone, 2017, p153)
Complement 3a	Secreted (Matsuoka et al., 2014)	Circulating (50 ng/mL in human serum) (Wlazlo et al., 2013)	Stimulates alkaline phosphatase activity and mineralization in calvarial osteoblasts (Matsuoka et al., 2014).	Increases cytokine output from macrophages and T cells (Carroll, 2004) Osteoclast recruitment (Sato et al., 1993)
Oncostatin M	Secreted (Fernandes et al., 2013)	Macrophages (Zarling et al., 1986) Osteoblasts (Walker et al., 2010) Osteocytes (Walker et al., 2010) T lymphocytes (Clegg et al., 1996)	Promotes osteoblast commitment (Walker et al., 2010) Stimulates bone formation in vivo (Walker et al., 2010)	Synergizes with BMP-2 (Fernandes et al., 2013) Stimulates osteoclast formation (Tamura et al., 1993)
Semaphorin 4D	Membrane bound (Negishi-Koga et al., 2011)	T lymphocytes (including soluble forms) (Wang et al., 2001)	Inhibits bone formation (Negishi-Koga et al., 2011) Gene deletion leads to enhanced bone formation (Negishi-Koga et al., 2011)	Stimulates osteoclastogenesis (Dacquin et al., 2011).
EphrinB2	Membrane bound (Zhao et al., 2006)	Osteoblasts (Zhao et al., 2006) Osteocytes (Allan et al., 2008)	Promotes osteoblast differentiation through EphB4 (Zhao et al., 2006) Suppresses osteoblast apoptosis (Tonna et al., 2014) Promotes late-stage osteoblast differentiation in vivo (Takyar et al., 2013)	Inhibits osteoclast differentiation (Zhao et al., 2006) Inhibits RANKL production by osteoblasts (Tonna et al., 2014)

Factor	Production by osteoclasts	Other potentially relevant sources	Influences on osteoblast differentiation and bone formation	Other potential influences in remodeling
Cxcl16	Secreted (Ota et al., 2013)	Vascular smooth muscle cells (Wagsater et al., 2004) Macrophages (Barlic et al., 2009)	May stimulate osteoblast precursor migration (Ota et al., 2013)	
Leukemia inhibitory factor	Secreted (Ota et al., 2013)	Mesenchymal stem cells (Sims and Johnson, 2012)	Stimulates bone formation in vivo (Cornish et al., 1993) Stimulates osteoblast precursor expansion (Cornish et al., 1997) Promotes osteoblast differentiation (Poulton et al., 2012) Suppresses sclerostin expression (Walker et al., 2010) Gene deletion leads to low bone formation in remodeling (Poulton et al., 2012)	Stimulates osteoclastogenesis (Reid et al., 1990) Inhibits marrow adipogenesis (Poulton et al., 2012)
miR-214-3p	Exocytosed (Li et al., 2016)	Monocytes	Circulating miR-214-3p associated with less bone formation in vivo (Li et al., 2016) Suppresses osteoblast differentiation (Li et al., 2016)	
RANKL reverse signal	Membrane bound (Furuya et al., 2018)	Osteoblast precursors, osteocytes (Kartsogiannis et al., 1999; Lacey et al., 1998; Matsuzaki et al., 1998)	Promotes bone formation (Ikebuchi et al., 2018)	

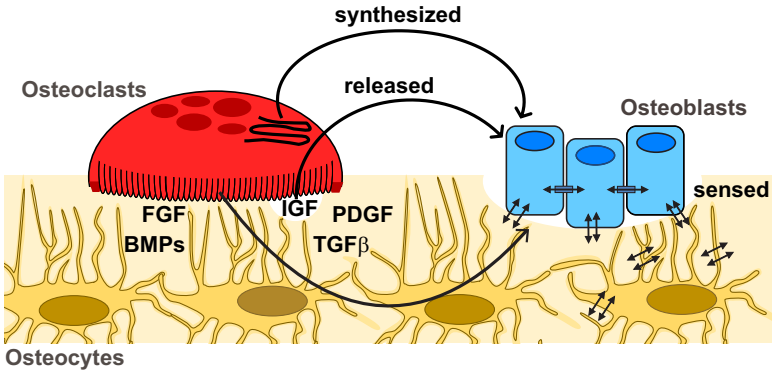

FIGURE 10.2 How do osteoblasts know how much bone to make? Signals, including proteins, are synthesized and secreted by osteoclasts and act directly on cells of the osteoblast lineage (including precursors and osteocytes). Osteoclasts also release matrix-bound growth factors such as insulin-like growth factor (*IGF*), bone morphogenetic proteins (*BMPs*), transforming growth factor β (*TGFβ*), platelet-derived growth factor (*PDGF*), and fibroblast growth factor (*FGF*) during the process of resorption; these also modify the function of osteoblast lineage cells. Osteoblasts also themselves sense the size of the pit left by the osteoclast, and signal to one another either via gap junctions or through secreted and membrane-bound proteins. Osteocytes also sense the changing mechanical strain both during the process of resorption and during bone formation, which changes the nature of the signals they release to influence bone-forming activity.

nonresorbing osteoclasts come into direct contact with each other (Furuya et al., 2018). This implies that osteoblasts may therefore inhibit osteoclast function by a direct contact mechanism in this context; this example of direct contact between the cells may also mediate communication from the osteoclast to the osteoblast, but mechanisms have not yet been identified. The range of coupling factors already identified may have also functions extending beyond coupling to these other examples of communication between these two lineages.

Matrix-derived resorption products as coupling factors

The first suggestion of a molecular mechanism for coupling came from Howard et al. (Howard et al., 1981). The bone matrix had long been known to contain a store of latent growth factors, including TGFβ, bone morphogenetic protein 2 (BMP-2), platelet-derived growth factor (PDGF), and the insulin-like growth factors (IGFs) (Hanamura et al., 1980; Centrella and Canalis, 1985a,b; Oreffo et al., 1989; Hock et al., 1990; Pfeilschifter et al., 1995). All are deposited by osteoblasts during matrix production and then released from the bone surface and activated by acidification during osteoclastic resorption, at which point they become available as agents influencing cells within the BMU, including osteoblasts and their precursors. The amount of bone resorbed by the osteoclast would determine the concentration of factors released, thereby modifying bone formation in a manner proportional to resorption.

Availability of these matrix-derived growth factors does not depend exclusively on resorption. Each is also synthesized by the osteoblasts themselves in latent forms activated by plasmin generated by plasminogen activators (Campbell et al., 1992; Yee et al., 1993) or matrix metalloproteinases (Dallas et al., 2002). In the case of PDGF-BB, its local involvement might be predominantly from a cell source, since it is produced by both osteoblasts and osteoclasts (Canalis and Ornitz, 2000), and its secretion by osteoclast precursors induces vessel formation and bone formation during both modeling and remodeling (Xie et al., 2014).

The hypothesis that coupling could be exerted by resorption-derived growth factors brought the issue before the field. It needed to take into account, though, that growth factor concentrations in matrix are high but variable in locations throughout the skeleton. The quantity and identity of growth factors contained within the matrix are determined by their production and release by osteoblasts and their incorporation into the matrix during bone formation in the previous remodeling cycle(s). Since precise replacement of bone at each site is a key requirement in coupling within the BMU, the active growth factor activities would need to be made available precisely in the quantities needed and in a spatially and temporally controlled manner. That could be difficult to achieve. Furthermore, if resorbed matrix is the main source of the growth factors, their primary availability would be at the earliest stage of the remodeling cycle (during resorption), which is temporally separate from the commencement of bone formation in the BMU (see Fig. 10.1). It seems unlikely that these growth factors would remain within the bone microenvironment for some weeks during the reversal phase until they could influence mature osteoblasts upon their arrival at the bone surface.

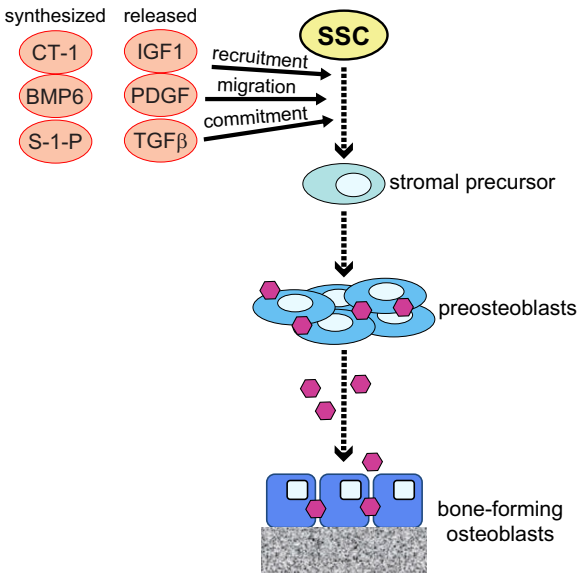

FIGURE 10.3 How do growth factors released by osteoclasts influence bone formation? Factors are synthesized by osteoclasts (such as cardiotrophin-1 [*CT-1*], bone morphogenetic protein 6 [*BMP6*], or sphingosine-1-phosphate [*S-1-P*]; see Table 10.1 for other examples) or released by osteoclast-mediated bone resorption of the matrix (such as insulin-like growth factor 1 [*IGF1*], platelet-derived growth factor [*PDGF*], and transforming growth factor β [*TGFβ*]; see Table 10.1 for other examples). These are likely to act on stromal stem cells (*SSCs*) to stimulate progenitor recruitment, to promote their migration to the bone surface, and to stimulate their early commitment to differentiate into mature, bone-forming osteoblasts. Preosteoblasts and mature osteoblasts throughout their differentiation communicate to each other through the release of factors such as TGFβ and parathyroid hormone–related protein and through the action of membrane-bound molecules such as EphrinB2 (represented by hexagons).

This conceptual difficulty with the growth factor/coupling concept has been helped by the outcome of mouse genetic experiments showing that active TGFβ release during bone resorption acts as a chemoattractant to induce migration of osteoblast precursors to prior sites of resorption (Tang et al., 2009) (Fig. 10.3). This provides osteoblast precursor cells within the BMU where they are available for stimulation by other signals promoting their differentiation and matrix production. The ability of osteoblast- and matrix-derived IGF-1 to promote osteoblast differentiation by favoring recruitment of mesenchymal stem cells (MSCs) (Xian et al., 2012) also links early release of growth factors to later differentiation of osteoblasts. These proposals for the mechanisms of growth factor action make it easier to understand how growth factors released by resorption, or from cell sources, could enhance subsequent bone formation in the BMU. Rather, their main influences would be to stimulate osteoblast progenitors, including their recruitment (Xian et al., 2012), migration (Fiedler et al., 2002; Sanchez-Fernandez et al., 2008; Tang et al., 2009; Kreja et al., 2010), and differentiation (Mitlak et al., 1996). The necessary precise quantitation could be achieved during the next stage through influences on the number and progression of stem cells after they enter the remodeling site.

Coupling factors synthesized and secreted by osteoclasts

Osteoclasts themselves might also be the source of coupling activity. This first arose during consideration of the anabolic action of intermittently injected parathyroid hormone (PTH), which was known to be achieved through activation of new and existing BMUs (Martin and Sims, 2005). This raised the question, what mechanisms determine replacement of the precise amount of bone resorbed in a BMU to preserve bone balance (Fig. 10.2)? Attention began to focus on identifying contributing osteoclast-derived factors, acting either independently or cooperatively with matrix-derived factors.

There were clues from human and mouse genetics. The failure of bone resorption results in the clinical syndrome of osteopetrosis: this may occur due to osteoclast deficiency or impaired activity. In forms of osteopetrosis with failed osteoclast formation—"osteoclast-poor" osteopetrosis—such as in the rare example of individual human subjects with lost RANKL/RANK signaling (Sobacchi et al., 2007), the bone is devoid of osteoclasts. This can be mimicked in a murine model by genetic ablation of *c-fos*, a transcription factor essential for osteoclast formation, and such mice have osteopetrosis noted by their failure to generate osteoclasts, and theirgreatly reduced bone formation (Grigoriadis et al., 1994).

The other form of osteopetrosis is "osteoclast-rich." Individuals with osteopetrosis due to defective osteoclast function, caused by mutations in either ClC-7 or the corresponding osteoclastic V-ATPase subunit A3 (also called TCIRG1), had

high numbers of inactive osteoclasts (Henriksen et al., 2004; Karsdal et al., 2005). Unlike osteoclast-poor osteopetrosis, bone formation was normal or even increased, rather than diminished, as might be expected because of the greatly impaired resorption (Alatalo et al., 2004; Del Fattore et al., 2006). The level of bone formation has been linked directly to the presence of increased numbers of nonresorbing osteoclasts by direct correlation between the number of osteoclasts and the number of bone-forming osteoblasts (Del Fattore et al., 2006). Furthermore, when osteoclasts generated from the peripheral blood of a patient with osteopetrosis due to a mutation in the V-ATPase subunit A3 were cultured in vitro, conditioned medium from those osteoclasts was able to stimulate mineralized nodule formation in vitro despite their inability to resorb bone (Henriksen et al., 2012). This correlated well with earlier work in osteoclasts cultured on plastic (and therefore not resorbing bone), which were found to secrete factors promoting nodule formation (Karsdal et al., 2008; Pederson et al., 2008).

The findings from human genetics were supported by several studies in mice, whether deficient in *c-src* (Marzia et al., 2000), cathepsin K (Pennypacker et al., 2009), or *Pyk2* (Gil-Henn et al., 2007); in each case bone resorption is inhibited without inhibition of formation. In each of these knockout mice, while resorption is greatly reduced, osteoclast numbers are not. This is strikingly different from the case of *c-fos*-deficient mice that lack osteoclasts and have impaired bone formation (Grigoriadis et al., 1994). In support of the idea that the mutant osteoclasts might have impaired resorptive capacity but retain their ability to promote bone formation, transplantation of hematopoietic precursor cells deficient in the osteoclastic V-ATPase subunit a3 required for resorptive function into normal adult mice led to a significant reduction in resorption with increased osteoclast numbers but no reduction in bone formation (Lee et al., 2006). This was observed for up to 18 weeks following induction of osteopetrosis and was associated with improved bone volume and strength (Henriksen et al., 2011). A further instructive study (Thudium et al., 2014) compared osteopetrosis induced by transplanting irradiated normal mice with osteoclast precursors from oc/oc mice (osteoclast-rich osteopetrosis) or with RANK-deficient (osteoclast-poor) cells. The increase in bone volume was larger with the oc/oc cell transplantation, despite a similar reduction in bone resorption, indicating that the nonfunctional osteoclasts retained their ability to support bone formation also in vivo.

Other genetic evidence in mice indicated an intrinsic anabolic activity emanating from osteoclasts. An example is an early in vivo study showing that a signal from the active osteoclast is required for bone formation in mice lacking the osteoclast inhibitor OPG (Nakamura et al., 2003). These mice exhibit very high levels of osteoclastogenesis and resorption, resulting in severe osteopenia. They also show a high level of bone formation. Risedronate treatment reduced osteoclast activity, while osteoclast numbers remained high. The reduction in osteoclast activity was associated with a low level of bone formation, even in the presence of a BMP-2 implant, indicating that active osteoclasts produce bone formation-simulating activity. In a later study these authors (Koide et al., 2017) found that conditioned medium from osteoclasts of OPG-deficient mice included leukemia inhibitory factor as a potential osteoclast-derived coupling factor, as had been suggested by others (Pederson et al., 2008; Poulton et al., 2012). It should be emphasized, though, that it is difficult to prove whether it is a coupling factor in the context of bone remodeling or simply a factor produced by osteoclasts that can also stimulate bone formation.

Based on experiments in mice with inactivating mutations of each of the two alternative signaling pathways of gp130 it was concluded that resorption alone was insufficient to promote coupled bone formation, but that active osteoclasts are the likely source, and that the coupling pathway is interleukin-6 dependent (Sims et al., 2004; Martin and Sims, 2005). Another proposed pathway of gp130 involvement was through the gp130-signaling cytokine cardiotrophin-1 (CT-1). In mice with global deletion of CT-1, although osteoclast numbers are high, their activity is low, and so too is the activity of their osteoblasts, indicating a lack of coupling factor production (Walker et al., 2008). CT-1 was detected in resorbing osteoclasts by immunohistochemistry (IHC) and shown to stimulate osteoblast differentiation in vitro and bone formation in vivo (Walker et al., 2008).

When osteoclast conditioned medium stimulated MSC migration and osteoblastic differentiation, Pedersen et al. (Pederson et al., 2008) undertook a microarray study identifying sphingosine-1-phosphate (S1P), Wnt10b, and BMP-6 as osteoclast products, suggesting they might be coupling factors. Each of these skeletal anabolic agents was known to be secreted by osteoclasts to a greater extent than by macrophages (Baron and Rawadi, 2007; Vukicevic and Grgurevic, 2009). Whether important as an osteoclast product or not, Wnt10b has been invoked as a T cell product mediating the anabolic effect of PTH (Terauchi et al., 2009; Bedi et al., 2012). The roles of S1P in bone are also likely to be quite complex. It can have inhibitory or stimulatory effects on osteoblasts depending on the stage of cell differentiation and on the source of precursors, such as human MSCs, immortalized MSCs, and mouse calvarial osteoblasts (Ryu et al., 2006; Pederson et al., 2008; Quint et al., 2013). S1P is also expressed by cells in the vasculature and acts on its receptor, expressed in osteoclast precursors, to stimulate osteoclastic recruitment in vitro (Ishii et al., 2009). Furthermore, in vivo and in vitro studies indicated that S1P can limit bone resorption by regulating the chemotaxis and migration of osteoclast precursors, essentially resulting in increased recirculation from bone to blood (Ishii et al., 2010). In that same work,

knockout of the S1P receptor S1PR1 yielded mice with excessive bone loss and enhanced osteoclast attachment to bone surfaces, and treatment with FTY720, a drug agonist of four of the five S1P receptors, including S1PR1, was effective in preventing bone loss in ovariectomized mice. Data more likely suggesting a role for osteoclast-derived S1P in the coupling mechanism came from a study in which *cathepsin K* was rendered null in osteoclasts, resulting in impaired resorption, while osteoclast numbers and bone formation were maintained (Lotinun et al., 2013). Ex vivo cultures showed that the mutated osteoclasts had a greater capability to promote aspects of osteoblast differentiation in coculture, an effect inhibited by an S1P receptor antagonist. Suggestive though this is of a role for S1P in the coupling process in the BMU, it needs to be explored further and put into the context of other actions of S1P, which has been invoked as a signaling mechanism in the actions of a number of cytokines, growth factors, and hormones (reviewed in Alvarez et al., 2007).

Other candidate osteoclast-secreted coupling factors have emerged from in vitro and ex vivo studies (listed in Table 10.1). These include afamin, a member of the albumin/vitamin D-binding protein family (Lichenstein et al., 1994); it is produced by osteoclasts and caused the recruitment of a mouse preosteoblastic cell line in vitro, in a manner that was lost by in vitro knockdown of afamin production (Kim et al., 2012). Another is PDGF-BB, produced by nonresorbing osteoclasts, which induces migration of bone marrow−derived human MSCs (Kreja et al., 2010) and mouse preosteoblasts (Sanchez-Fernandez et al., 2008), although an earlier study indicated that PDGF-BB inhibited osteoblastogenesis (Kubota et al., 2002). Perhaps more convincing evidence for a role for PDGF-BB in remodeling is from the mouse genetic studies that show its promotion of angiogenesis when mobilized by resorption and acting early in remodeling (Xie et al., 2014). Two candidate coupling activities, collagen triple-helix repeat−containing 1 and complement factor 3A (C3A), were put forward by one group (Takeshita et al., 2013; Matsuoka et al., 2014), but in each case they were produced by cells other than osteoclasts, and the high circulating level of C3A tended to exclude it from a role as a local regulator of coupling within the BMU. A more recent suggestion has been that microRNAs are released as coupling factors contained within exosomes that reach the circulation (Li et al., 2016). While it is appealing that osteoclast-derived membranous vesicles could provide a way of regulating osteoblast function, it is difficult to see how this could be controlled, either within the confines of the BMU or at the level of the whole individual.

Membrane-bound coupling factors synthesized by osteoclasts

Some of the osteoclast-derived coupling factors proposed are membrane-bound molecules, expressed on the cell surface of osteoclasts. Such molecules therefore require direct cell−cell contact with osteoblast lineage cells to produce effects that might favor osteoblast differentiation. These membrane-bound proteins have been discovered through a combination of genetic and pharmacological approaches. Factors proposed to act in this cell-contact-dependent manner include EphrinB2 (Zhao et al., 2006) and semaphorin D (Negishi-Koga et al., 2011). While plausible in vitro, and observed in the highly active murine calvarial suture that lacks BMUs (Furuya et al., 2018), such cell-contact-dependent mechanisms are problematic in the BMU because osteoclasts and osteoblasts are present on the bone surface at different times during remodeling, and therefore are rarely, if ever, in contact. If such mechanisms occur, they may exist between osteoclasts and osteoblast precursors very early in remodeling, or between osteoclasts and osteoblast lineage cells in the remodeling canopy. The latter possibility will be discussed in light of anatomic structural studies of the reversal phase, later.

The Eph family constitutes the largest family of receptor tyrosine kinases, notable because both receptors (Eph proteins) and ligands (Ephrin proteins) are membrane bound and both forward (through receptor) and reverse (through ligand) signaling takes place upon their interaction. EphrinB2 is expressed at all stages of osteoblast differentiation, as well as in osteoclasts and their precursors (Zhao et al., 2006; Allan et al., 2008). The first study of ephrin/Eph interaction in bone seemed to present an exciting prospect of EphrinB2 from the osteoclast acting as a coupling factor through a cell-contact-dependent mechanism with osteoblasts (Zhao et al., 2006). In vitro data indicated that contact between osteoclasts and osteoblasts initiated signaling in both cells such that EphrinB2 signaling in the osteoclast lineage limited their differentiation, while simultaneous EphB4 signaling in the osteoblast stimulated bone formation. However, osteoclast lineage−specific deletion of EphrinB2 presented no detectable in vivo bone phenotype (Zhao et al., 2006), nor did osteoclast precursors from an osteoclast-specific knockout of EphrinB2 show any alteration in osteoclast differentiation (Tonna et al., 2014). Further, EphrinB2/EphB4 interaction within the osteoblast lineage in vivo played a crucial role in maintaining osteoblast differentiation and attaining normal bone strength (Takyar et al., 2013). Specific blockade of EphrinB2/EphB4 signaling both in vitro and in vivo impaired osteoblast function and the anabolic response to PTH in vivo (Tonna et al., 2014). The latter was dependent on the availability of EphrinB2 for reverse signaling. Indeed, the earlier published evidence (Zhao et al., 2006) for a mild anabolic effect of transgenic EphB4 overexpression in vivo, and treatment of osteoblasts with clustered EphB4-Fc in vitro, might be explained by such an action through EphrinB2 signaling within osteoblasts. Given the extensive contact among osteoblasts that is required for bone formation (Ecarot-Charrier et al., 1983;

Abe et al., 1993; Gerber and ap Gwynn, 2001), it seems logical that such membrane-bound proteins are more likely to regulate bone formation through communication between osteoblast lineage cells than in osteoclast−osteoblast coupling activity that links two cell types without physical contact.

Semaphorins include both secreted and membrane-associated molecules that use plexins and neuropilins as their primary receptors. Plexins are the usual receptors for membrane−associated semaphorins, and neuropilins are obligate coreceptors in the case of most soluble class III receptors (Winberg et al., 1998; Takahashi et al., 1999; Tamagnone et al., 1999). Transcriptional arrays carried out on osteoclasts revealed substantial expression of semaphorin 4D (Sema4D), with none detectable in osteoblasts (Negishi-Koga et al., 2011). Targeted genetic ablation of Sema4D in osteoclasts resulted in increased trabecular bone mass, due to increased number and activity of osteoblasts, whereas osteoclast numbers were normal. Marrow transfer to wild-type mice from Sema4D-null mice resulted in increased bone formation and trabecular bone mass, and treatment of osteoblasts in vitro with recombinant soluble Sema4D-Fc decreased formation of mineralized nodules. The data point to Sema4D as an osteoclast-derived inhibitor of osteoblast differentiation and bone formation; these properties would equip it to be a fine-tuning mediator of remodeling in the BMU, acting as an inhibitor of the process. Just as OPG counters RANKL action by providing a powerful negative influence on osteoclast formation and function, it comes as no surprise that there should exist inhibitors of coupling; this raises the possibility that more such activities might exist.

A further membrane-bound coupling activity that has gained support is “outside-in” or “reverse” signaling within osteoblasts by RANK, the receptor for RANKL that signals action to generate osteoclasts (Suda et al., 1999). In addition to its actions to inhibit osteoclastogenesis, a RANKL-binding agent was found to also increase bone formation in vivo and promote osteoblast differentiation in vitro (Furuya et al., 2013). This was confirmed in an animal model of inflammatory arthritis (Kato et al., 2015), and was discussed in an editorial published in the same issue (Sims and Romas, 2015). These pharmacological studies have been supported by identification of an endogenous and potentially physiological action of RANK. RANK secreted in vesicles from maturing osteoclasts was found to increase bone formation by promoting RANKL reverse signaling to activate *runx2* (Ikebuchi et al., 2018). This is an interesting possibility that would require controlled delivery from osteoclasts early in the life of a BMU to appropriate targets in the osteoblast lineage, just as is the case with TGFβ (Tang et al., 2009) and IGF-1 (Xian et al., 2012) (*vide supra*, discussion under “Matrix-derived resorption products as coupling factors”).

Perspective on candidate osteoclast-derived coupling factors identified to date

Research activity focused on the search for local osteoclast-derived coupling factors (whether by active secretion or resorption of bone matrix) has yielded many candidate molecules, summarized in Table 10.1, indicating the nature of the experiment used and the cells capable of producing those molecules. Since many of these have been identified only since 2009, most require validation by independent groups of researchers working in multiple systems. This is particularly true of those factors identified in conditioned media. These can point to factors that may be important, but they each require validation of their specificity and their in vivo relevance.

A striking feature of these published data is that none of these candidate osteoclast-derived coupling factors can be said confidently to be exclusively derived from the osteoclast. Many are also products of cells in close proximity with, and even within, the BMU, such as macrophages and other immune cells, and many circulate in concentrations high enough to exclude a primary function as local regulators at multiple sites throughout the skeleton. The frequency of contradictory reports, variability of experimental systems that have been used, and limited nature of in vitro studies have made some of these reports difficult to interpret. Observations arising out of activities discovered in conditioned medium of osteoclast cultures need to be interpreted in light of substantial macrophage contamination in such cultures that is variable between donors and laboratories, and cannot be avoided with existing methods. Furthermore, none of the in vitro studies have set out to determine whether osteoclast products influence different stages of osteoblast differentiation, which seems a likely mechanism by which they could act, given the temporal delay between bone resorption and formation at the BMU. It would seem likely that the coupling process within the BMU would require actions at different stages, as osteoblasts progress through differentiation during remodeling (Fig. 10.3).

How other cells contribute to coupling

In addition to factors released by osteoclasts through resorption, secretion, or membrane budding, other cell types may mediate the signals required to ensure that bone formed during remodeling in the BMU matches the prior level of bone

resorption to maintain bone mass. Some possibilities include signaling by osteoblast lineage cells themselves, macrophages and immune cells, and the cell population resident during the reversal phase.

Osteoblast lineage cells—sensing the surface and signaling to one another

Osteoblast lineage precursors begin their differentiation in the BMU, during which they are in contact with (or at least in close proximity to) other precursors and mature osteoblasts on the bone surface. Bone-forming osteoblasts on the bone surface are also in contact, not only with one another, but also with the highly differentiated osteocytes within the bone matrix. This lends itself to communication within the lineage as part of the overall coupling process.

An example of such intralineage information transfer is the production of latent TGFβ, produced by osteoblasts, activated by proteases, and supplementing the resorption-derived TGFβ that contributes to the initial stages of coupling in the BMU (Yee et al., 1993; Pfeilschifter et al., 1995). We have drawn attention to the role of EphrinB2/EphB4 interaction between osteoblast lineage cells as an important checkpoint that must be passed for the lineage to reach late stages of osteoblast differentiation (Takyar et al., 2013; Tonna et al., 2014). EphrinB2 production remains unchanged throughout osteoblast differentiation, but responds with rapidly increased production when exposed to PTH-related protein (PTHrP) (Allan et al., 2008). Through such interactions within the osteoblast lineage, osteoblast precursors are able to respond to the cues initiated by osteoclast-derived factors to enter the BMU and differentiate to osteoblasts capable of bone matrix production (Fig. 10.3).

The osteocyte, the most abundant cell in bone by far, forms a highly complex cellular communication network through the bone matrix, with a total of ∼3.7 trillion connections throughout the adult skeleton (Buenzli and Sims, 2015). This network has crucial regulatory functions by its production of sclerostin, which limits bone formation though its powerful inhibition of Wnt-stimulated osteoblast differentiation (Bonewald and Johnson, 2008). This action is likely to be important in limiting the amount of bone laid down in modeling, but its production in response to loading (Galea et al., 2011), or to local factors such as prostaglandin E_2 (Genetos et al., 2011) or PTHrP (Ansari et al., 2018), is capable of regulating the bone formation within BMUs. Just as osteoblast precursors are available in the BMU at the time when osteoclasts are present, resorbing bone and releasing or producing coupling factors, so too are osteocytes available to respond to coupling factors. Indeed, a number of osteoclast-derived coupling factors promote bone formation and suppress sclerostin production by osteocytes: these include CT-1 and Leukemia Inhibitory Factor (LIF) (Walker et al., 2008, 2010; Poulton et al., 2012).

Another mechanism to which osteoblasts can respond that would allow them to produce sufficient bone matrix to refill the cavity left by osteoclasts, is their ability to "sense" changes on the bone surface. It was shown in vitro that if rat calvarial cells were provided to bone slices with crevices made by osteoclasts or mechanically excavated grooves, the cells made bone in those defects, filling them exactly to a flat surface (Gray et al., 1996). Osteoblast precursors have been shown to respond to changes in surface topography, whether the change is much larger than the cell itself, as in the aforementioned study, or very much smaller than the cell (Dalby et al., 2006). In response to altered nanotopography, osteoblast lineage cells adhere to the surface and one another and proceed to differentiate. In this way, osteoclasts control osteoblast activity from a distance by establishing the size and shape of the resorptive pit to be filled. It is also possible that the changes brought about on the bone surface by cells in the reversal phase change the topography in a way that determines osteoblast function. Both the proposed growth factor actions and the work of Gray et al. imply that once the formation process is established, the participating cells themselves are able to sense the spatial limits and fill the space through chemical communication, possibly involving gap junctions or cell-contact-dependent communication processes both between bone-forming osteoblasts and between osteoblasts and osteocytes (Tonna and Sims, 2014). Since the in vitro study of Gray used bone that did not contain osteocytes, while they may contribute, osteocytes are not necessary for osteoblasts to respond to topographic clues, at least in vitro.

Osteocytes are the major controlling cells of bone (Bonewald, 2011; Schaffler et al., 2014), producing sclerostin as a powerful inhibitor of bone formation, whether in modeling or remodeling (van Bezooijen et al., 2004). Through their fluid-filled network of communicating channels they sense and respond to mechanical strain; this system might provide an additional coupling mechanism. Osteocytes would sense the increased strain resulting from weakening of the bone as resorption progresses (McNamara et al., 2006), and respond by producing a signal to halt resorption. They would also detect when the strain is relieved as the resorbed pit is refilled by osteoblasts. Such a strain-based model for coupling was proposed some years ago (Rodan, 1991), and as our understanding of osteocyte signaling increases, possible mediators are coming to light. As the mechanical properties of the excavated bone improve, the osteocytes may signal to osteoblasts that enough bone has been made in the BMU, a task that could be filled by sclerostin or by other osteocyte-derived regulators of bone formation such as oncostatin M (OSM) (Walker et al., 2010) or PTHrP (Ansari et al., 2018). Clearly many steps are

required to achieve precision in the coupling process: precursor replication, differentiation, limiting the cell mass to exactly what is required, correct shaping, and level of mineralization.

Macrophages, immune cells, and endothelial cells

As discussed earlier, a key problem of studying osteoclastic effects on osteoblasts is the technical difficulty of obtaining sufficiently purified osteoclasts. Furthermore, the extensive overlap in gene expression between osteoclasts and macrophages suggests that factors produced by osteoclasts can be also produced by macrophages in the vicinity of the BMU.

OSM, a cytokine that signals through gp130, stimulates bone formation in mouse calvariae in vivo and in bone remodeling, as indicated by impaired bone formation in OSM-null mice, and promotes osteoblast commitment by calvarial osteoblasts in vitro (Walker et al., 2010). Although not expressed in osteoclasts, OSM was originally identified in macrophages (Zarling et al., 1986) and was present in media from enriched cultures of human osteoclasts. It was found to be the factor responsible for strongly inducing alkaline phosphatase activity and mineralization by human adipose tissue-derived MSCs (pluripotent osteoblast precursors) (Fernandes et al., 2013), where macrophage populations formed from the same source as the osteoclasts were found to be even more efficient at driving MSC maturation, probably due to higher OSM production. A cautionary finding from some of this work was that differing responses can occur with different types of macrophage activation (Guihard et al., 2012; Nicolaidou et al., 2012). These findings serve to make a broader point: factors identified as osteoclast-derived coupling factors are produced not only by osteoclasts but also by macrophages (to which they have a close ontogenic relationship).

Like the contaminating macrophages in osteoclast cultures, macrophages are present in primary osteoblast cultures from calvariae and promote osteoblast differentiation (Chang et al., 2008). This finding led to the identification of bone-resident tissue macrophages (osteal macrophages defined by F4/80 antigen expression) mingled in large numbers with osteoblasts at the endosteal and periosteal bone surfaces and forming a canopy-like layer above osteoblasts and bone-lining cells at endosteal surfaces (Chang et al., 2008). Despite their emerging importance, defining the resident osteal macrophage population remains problematic since they are primarily defined by location, and as of this writing, cell surface markers do not exist that allow the resident cells to be specifically purified. Such regulatory macrophages would be expected to be sensitive to cues from the immune system. In addition, either a change in their activation state or replacement by recruited inflammatory macrophages and availability within the BMU canopy, by modifying their secretion of factors such as OSM, might alter local bone metabolism, perhaps profoundly (Fig. 10.4).

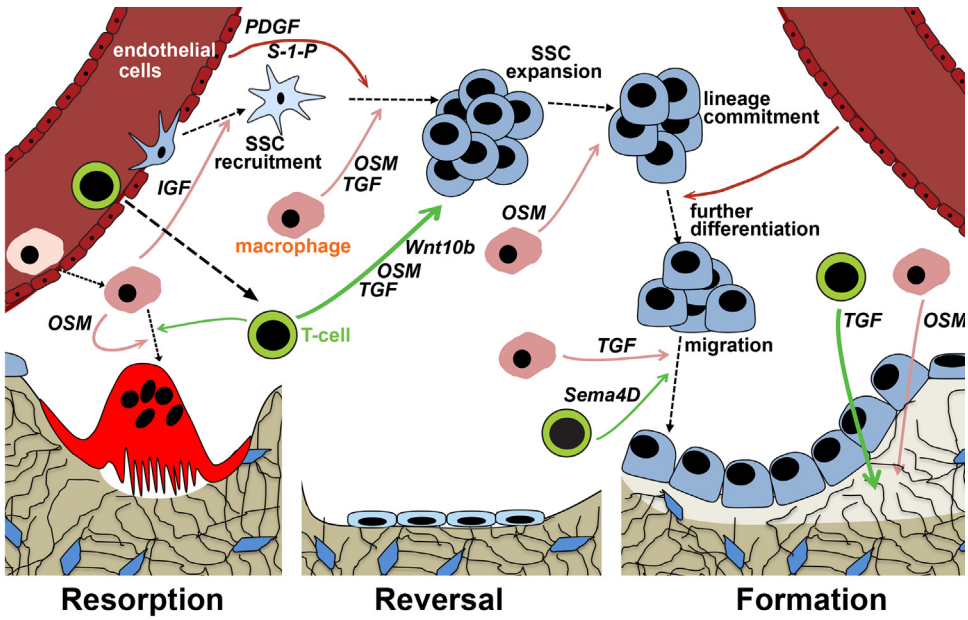

FIGURE 10.4 Signals from "nonresident bone cells" that enter the bone remodeling compartment from the vasculature, such as endothelial cells, T lymphocytes, and macrophages, also contribute to the matching of bone formation to bone resorption during the resorption, reversal, and formation phases of remodeling. Some examples of potential factors from each cell type are illustrated, such as platelet-derived growth factor (*PDGF*), sphingosine-1-phosphate (*S-1-P*), oncostatin M (*OSM*), Wnt10b, and transforming growth factor (*TGF*) are shown. See Table 10.1 for more examples. Factors act on each stage of osteoblast differentiation, including on osteocytes. *IGF*, insulin-like growth factor; *Sema4D*, semaphorin 4D; *SSC*, stromal stem cell.

Immune cells are also able to gain access to remodeling sites through the blood supply at the canopy (Fig. 10.4). Just as OSM may promote bone formation by virtue of its production by macrophages (Zarling et al., 1986), T lymphocytes (Clegg et al., 1996), osteoblasts, and osteocytes (Walker et al., 2010), the same is true of many of the other coupling factors (summarized in Table 10.1). T cells have been invoked as playing a part in normal remodeling by mediating the anabolic effect of intermittent PTH injection in the mouse (Terauchi et al., 2009; Bedi et al., 2012). In that work Wnt10b was reported as the T cell product acting upon the osteoblast lineage to achieve the PTH anabolic effect. The significance of this work might go further, though. Since the PTH anabolic effect is considered to be predominantly through promotion of remodeling, can these findings imply that T cells contribute to normal remodeling events within the BMU? It is relevant to note that Wnt10b was also one of the osteoclast conditioned medium−derived coupling factors identified by Pederson et al. (2008).

The data summarized in Table 10.1 illustrate the redundancy among cell types of secretory products that might promote osteoblast differentiation. They also illustrate the difficulty in identifying any exclusive osteoclast-derived activity. None of these considerations reduces the potential importance of these factors in bone biology. Rather, they illustrate multiple roles for these factors, the likely complexity of the coupling process, the possible involvement of multiple cell types, and the likely cross-regulation of each of these regulatory pathways.

The reversal phase as a coupling mechanism

Publications have suggested a regulatory role for the reversal phase in coupling of osteoblast to osteoclast activity. The existence of a reversal phase between the resorptive and the formative phases of remodeling was proposed originally by Baron, (1977) on the basis of studies in rat bone. Twenty years after Frost's remodeling proposals it was found that toward the end of resorption, mononuclear cells gather at the bottom of resorption pits, where they prepare the pits for the engagement of osteoblasts in bone formation (Villanueva et al., 1986). In this reversal phase of remodeling, macrophages had been long considered responsible for the postresorption digestion of collagen fragments in the BMU. The identification that cells of the osteoblast lineage were able to engulf collagen fragments (Takahashi et al., 1986) was taken further by Everts et al. (Everts et al., 2002), who identified osteoblast lineage bone-lining cells cytologically at sites of resorption, both in calvariae and in long bones, and showed that these cells actually engulf collagen fragments remaining on the bone surface after osteoclasts have resorbed and left it (Everts et al., 2002). This activity appeared to be mediated by membrane matrix metalloproteinases. Thus, although these osteoblast lineage cells are not equipped to lay down an adequate matrix, they nevertheless are able to lay down a thin layer of collagen along Howship's lacuna, closely associated with a cement line. This reversal line (cement line) contains a large abundance of osteopontin (Chen et al., 1994), which is produced by both osteoclasts and osteoblasts. Osteopontin is an RGD-containing extracellular matrix protein that interacts with integrin receptors $\alpha V\beta 3$ in osteoclasts and primarily $\alpha V\beta 5$ in osteoblasts, mediating cell attachment to the bone surface and signaling within the cell. The presence of osteopontin on the reversal line raises the possibility that it may be one of the signals for cessation of osteoclast activity or initiation of osteoblastic bone formation or possibly both.

These findings of Everts et al. were of interest in themselves, in drawing attention to a function of osteoblast lineage cells in remodeling during the period between bone resorption and formation. Further than that, though, the question of whether these lining cells might become "activated" to become matrix-producing osteoblasts after the reversal phase became an active question.

When in situ hybridization (ISH) and IHC were used in human bone biopsy samples, the reversal cells on the surface were confirmed to be of the osteoblastic lineage by virtue of their expression of osteoblast marker genes (Andersen et al., 2013). Furthermore, those next to bone-forming osteoblasts were more mature than those next to osteoclasts (Andersen et al., 2013). This was in contrast to earlier findings in human and other bones, indicating that cells near osteoclasts are tartrate-resistant acid phosphatase (TRAP)-positive mononuclear osteoclasts (Tran Van et al., 1982; Eriksen et al., 1984b; Eriksen, 1986; Bianco et al., 1988). To resolve this, sensitive ISH and IHC methods were used and showed functional and phenotypic changes in the mesenchymal reversal cells as they progressed from near the osteoclasts (TRAP positive by IHC) to near the osteoblasts (TRAP negative) (Abdelgawad et al., 2016). TRAP immunoreactivity was shown to be occurring in cells with no detectable TRAP mRNA, leading to the conclusion that TRAP positivity in the early reversal cells resulted from ingestion from nearby osteoclasts. Runx2 immunoreactivity was uniform throughout the reversal cells, reflecting their osteoblastic lineage.

Removal of the collagen remnants in Howship's lacunae is another potential coupling mechanism, since it is obligatory for bone formation to occur. It is carried out by cells close to osteoclasts, early reversal cells with enhanced collagenolytic activity mediated through production of matrix metalloproteinase-13 (MMP-13) (Abdelgawad et al., 2016) and the

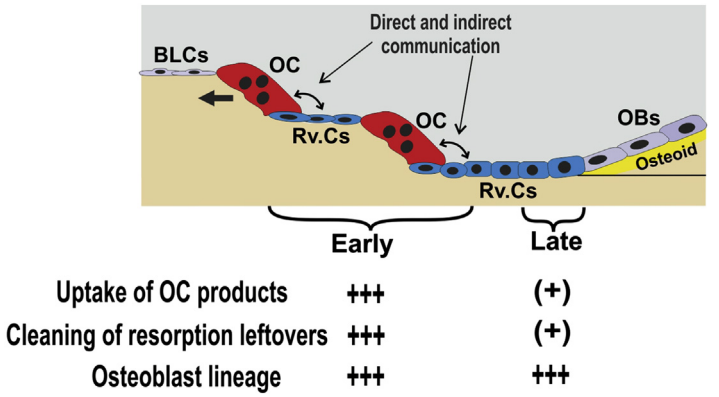

FIGURE 10.5 A new model of the reversal phase of remodeling. During quiescence, bone-lining cells (*BLC*) cover the inactive bone surface. Osteoclasts (*OC*) resorb the bone matrix and are intercalated with osteoblast lineage reversal cells (*Rv.Cs*) in the early reversal phase. In this phase osteoclast products released from the bone matrix or synthesized and secreted by osteoclasts are taken up by reversal cells, and may influence osteoblast progenitors. In the late reversal phase, reversal cells differentiate, on the bone surface, to become bone-forming osteoblasts (*OBs*) capable of synthesizing osteoid. Figure provided by Thomas L Andersen.

endocytic collagen receptor uPARAP/Endo180 (Madsen et al., 2011). With progression to late reversal cells there is much less expression of MMP-13 and uPARAP, constant Runx2, and no TRAP (Abdelgawad et al., 2016).

This evidence indicates a phenotypic change during the reversal phase in the cells on the bone surface. The cells progress from early to late reversal cells, with the latter differentiating directly into osteoid-synthesizing osteoblasts (Delaisse, 2014) (Fig. 10.5). The findings point to potential connections between osteoclasts and early osteoblast lineage cells that could transmit contact-independent or contact-dependent signals. Such contact could influence the function and progress of those osteoblast lineage cells. As an area of cell biology to study it is a fascinating one, if difficult to approach through any other than in vivo experimentation. In contrast to these potential communication points, mature osteoclasts and mature bone-forming osteoblasts are probably almost never in contact in ways that can transfer information.

Evidence consistent with these mechanisms was also obtained from remodeling in cortical bone, which is carried out with different cellular organization. The resorbing osteoclasts generate a cutting cone directed parallel to the diaphysis of long bones, with this resorption followed by the reversal zone and then osteoblasts synthesizing matrix (Eriksen, 1986; Jaworski, 1992) (Fig. 10.1).

Additional work from the same group examined the continuum of the BMU in cutting cones by IHC and ISH to identify osteoblast lineage cells and osteoclasts. In doing so, they described a reversal phase in which osteoblast progenitors differentiate until a critical mass of mature osteoblasts is reached and matrix formation follows (Abdelgawad et al., 2016; Lassen et al., 2017). They also noted the presence of sparsely distributed osteoclasts in the reversal phase in decreasing numbers as time after resorption increased. These osteoclasts are close enough to osteoblast lineage cells to be capable of transmitting signals, and seem to be responsible for a slow "secondary" bone resorption period needed to widen the osteon, as opposed to the longitudinal resorption in the cutting zone (Jaworski and Lok, 1972; Parfitt, 1983). The dynamics of these cells in the reversal phase that are modeled graphically in Fig. 10.5 confer an important role on the reversal phase in the coupling process of bone remodeling. First, it draws attention to the need for the supply of osteoblast precursors at that stage, if they are to progress to form bone. Where do they come from and how? The capillary blood supply identified near the canopy (Kristensen et al., 2013; Delaisse, 2014) is a potential source, as are the very early mesenchymal cells (pericytes) adherent to those nearby capillaries (Bianco et al., 2011). Second, while they are differentiating, these osteoblast lineage cells have osteoclasts distributed among them and are capable of signaling to them with secreted or even membrane-bound coupling activities (Lassen et al., 2017). Where do these "interstitial" osteoclasts come from? Are they newly generated or are they osteoclasts continuing to function from the initial resorption phase? Third, the onset of bone formation, with synthesis of ample osteoid, is an effective signal that dampens osteoclastic resorption, since osteoclasts are not known to attach to osteoid. Fourth, prolongation of the reversal phase for any reason, such as inadequate supply of progenitors with aging, can prolong the process and increase the osteon width, even contributing to porosity (Andreasen et al., 2017). On the other hand, the sooner bone formation starts, the faster secondary/radial bone resorption will stop.

Thus, in considering coupling of bone formation to resorption, the reversal phase is engaged in a remarkable abundance of biological interactions. In attempts to characterize coupling, intercellular communication mechanisms during the

reversal phase might be a more rewarding focus of attention rather than a narrow search for signals from mature osteoclasts to osteoblasts. The many participating signals are likely to have targets and outcomes that are heavily dependent upon the stages of differentiation of cells within the osteoblast lineage.

Conclusion

The coupling of bone formation to bone resorption is the dominant biological feature of bone remodeling. It is useful to consider the relative contributions to its control of circulating hormones and of locally generated factors. The latter might come from osteoclasts, osteoblasts, osteocytes, the matrix, or other cells in the environment, such as immune cells, macrophages, and endothelial cells.

Bone remodeling takes place simultaneously and asynchronously at very many sites throughout the skeleton, with those sites being selected because damaged or old bone needs to be removed and replaced. How those sites are selected we do not know. Once a BMU is initiated, though, it needs to have its activities regulated—its osteoclast formation, activity, and death; its osteoblast differentiation from precursors as primitive as tissue stem cells—and cessation of that process is needed when the filling of the BMU is complete.

All of these are processes and mechanisms that lend themselves readily to local regulation. This makes the process of coupling such an important one to understand. It is less easy to imagine how the progression of the remodeling process could be regulated satisfactorily by circulating hormones. This is especially so when thinking of the initiation of BMUs at specific sites, control of osteoclast activity at those sites, control of the supply of mesenchymal lineage precursors, and then their differentiation.

For these reasons we ask, how could a circulating hormone be a useful contributor to the bone formation process in remodeling? The question arises with PTH, for example, where the available published information tells us that there is a circadian rhythm of circulating PTH levels, but the total change throughout 24 h is on the order of 20% (Jubiz et al., 1972; el-Hajj Fuleihan et al., 1997; Fraser et al., 1998; White et al., 2007; Redmond et al., 2016). Such constancy of circulating PTH seems to equip it poorly for the initiation and/or control of BMUs generated stochastically throughout the skeleton. Locally generated PTHrP, though, could be the way that action through the PTHR1 contributes to remodeling (see Chapter 25).

There might be quite a different view in the case of an inhibitory hormone, such as estrogen. If the function of estrogen is to be available always to maintain a constitutive brake on osteoclast formation and/or activity, complemented by a more effective local inhibitor, e.g., OPG, this could be achieved as a circulating hormone. Lowering of estrogen would be expected to result in escape of control and increased remodeling by initiation of new BMUs, which is indeed what happens. If this line of reasoning is correct, perhaps by analogy we should think of the possibility of there being circulating activity that acts as a constitutive brake on osteoblast differentiation and thence bone formation. Its relationship with the local inhibitor of formation, sclerostin, would be analogous to that between estrogen and OPG.

The process of bone remodeling is a complex one with many participating cells and effectors and many identifiable stages that we are only beginning to understand. What is becoming evident, though, is that it is much easier to inhibit remodeling than it is to stimulate it. That is why therapeutic approaches to inhibit resorption are simple compared with approaches to stimulate formation.

Chapter 11

Modeling and remodeling: the cellular machinery responsible for bone's material and structural strength during growth, aging, and drug therapy

Ego Seeman

Department of Endocrinology and Medicine, Austin Health, University of Melbourne, Melbourne, VIC, Australia; Mary MacKillop Institute for Health Research, Australian Catholic University, Melbourne, VIC, Australia

Chapter Outline

Summary

During growth, the cellular machinery of bone modeling and remodeling assembles bone's size, shape, and microstructure. Bone matrix is synthesized as a composite of organic and inorganic material configured with varying volumes of extracellular fluid—containing void to form its cortical and trabecular compartments. Endocortical resorptive modeling excavates a medullary cavity void volume, which shifts the cortex radially, increasing resistance to bending exponentially while minimizing cortical thickening and so avoiding bulk; larger bone cross sections are assembled with a relatively thinner cortex.

During young adulthood, balanced remodeling renews the mineralized bone matrix volume without permanently compromising bone microstructure. As modeling and remodeling are surface dependent, the large surface area/matrix volume configuration of interconnected thin trabecular plates facilitates accessibility of the matrix to being renewed; this is

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00011-7

an advantage provided that remodeling remains balanced. The lower surface area/matrix volume of compact cortical bone makes it less accessible to being renewed and so liable to damage accumulation.

Around midlife, remodeling becomes unbalanced in both sexes and rapid in postmenopausal women. Unbalanced remodeling transactions deposit less bone than was resorbed, producing permanent cortical thinning, porosity, trabecular thinning, perforation, and loss of connectivity, which compromise bone strength disproportionate to the bone loss producing this deterioration.

Antiresorptive agents do not reverse microstructural deterioration or bone fragility present at the time of initiating treatment. Most antiresorptives only slow remodeling, they do not abolish it, so that total bone matrix volume and microstructure continue to deteriorate, albeit more slowly than without treatment. The slowly declining bone matrix volume is less often remodeled and so becomes more fully mineralized and less ductile, predisposing to damage accumulation. Teriparatide, the only available anabolic agent, produces predominantly remodeling-based bone formation and appears to reduce vertebral and nonvertebral fracture risk more efficaciously than antiresorptive therapy. Encouraging observations have been reported using modeling-based anabolic therapy and combined antiresorptive and anabolic therapy, but reducing the population burden of fractures remains a challenging unmet need.

Bone modeling and remodeling during growth and the attainment of bone's peak material and structural strength

Definition of bone modeling and remodeling

Bone *modeling* or construction is usually thought of as bone formation. Bone modeling is both formative and resorptive. Formative modeling is carried out by osteoblasts, cells that synthesize and deposit a volume of osteoid upon a quiescent bone surface that has not undergone prior bone resorption (Parfitt, 1996). Resorptive modeling is carried out by osteoclasts, cells that resorb a volume of bone without a subsequent phase of bone formation.

Formative and resorptive modeling occur mainly during growth and confer the paradoxical properties of strength for loading, yet lightness for mobility, and resistance to deformation, yet flexibility to allow energy absorption. These properties are conferred by the deposition of bone at locations where it is needed and by removal of bone from locations where it is not needed, thereby changing bone's external and internal size and shape.

Bone *remodeling* or reconstruction maintains the composition and properties of the mineralized bone matrix during young adulthood. Remodeling is carried out by teams of osteoclasts and osteoblasts, basic multicellular units (BMUs), which respectively resorb and replace a volume of damaged or older bone with the same volume of newly synthesized osteoid at the same location (see chapters 4 and 10 for further detail).

The osteoid undergoes rapid primary mineralization within days of deposition to become "bone" and then slower secondary mineralization, a physicochemical process of enlargement of crystals of calcium hydroxyapatite deposited during primary mineralization. The crystals enlarge and displace water without change in the dimensions of the collagen fibrils (Akkus, 2003).

Bone's material and structural strength

Bone is a specialized connective tissue. Type I collagen is tough; it is distensible in tension but lacks resistance to bending, i.e., stiffness. Stiffening is achieved by mineralizing the collagen with platelets of calcium hydroxyapatite. The mineral confers material stiffness but sacrifices the ability to absorb and store energy by deforming. For a given increase in the percentage of mineral ash, stiffness increases fivefold, but the amount of work needed to produce a fracture decreases 14-fold, almost three times more (Currey, 2002) (Fig. 11.1, top).

Nature selects a mineralization density that is suited to the function a bone usually performs. Ossicles of the ear are over 80% mineral, a feature conferring stiffness that is selected for so that they can vibrate like tuning forks and transmit sound with high fidelity. The ability to store energy by deforming is sacrificed, but it is unnecessary (Fig. 11.1, bottom). Cracking is unlikely because ossicles are housed safely in the skull. Deer antlers are less densely mineralized to facilitate deformation, so they can absorb energy like springs during head butting in mating season. Greater energy-absorbing ability of antlers, "toughness" or resilience, is selected for over stiffness, but stiffness is unnecessary because antlers are not load bearing (Currey, 1969).

Although mineral stiffens bone, it is also the most brittle component of bone; an increase in mineral density decreases toughness more than it increases stiffness. So to defend against loss of toughness, the platelets of mineral are protected from being excessively loaded by noncollagenous proteins, glue-like material that releases energy imposed during loading

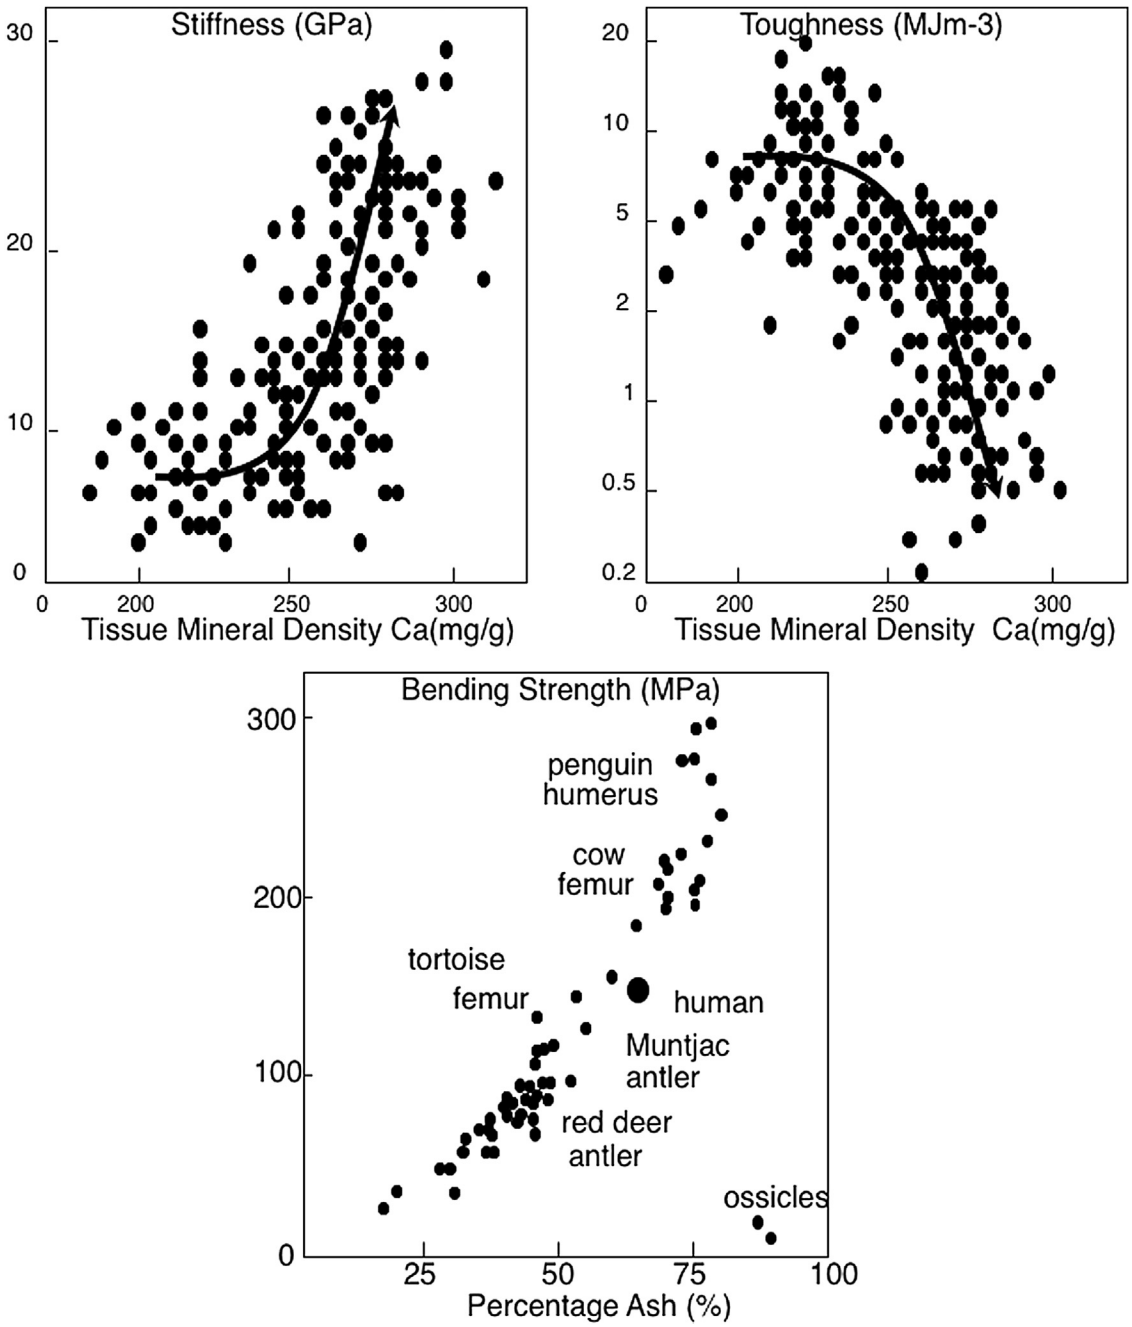

FIGURE 11.1 (Top) As tissue mineral content increases, stiffness increases, but toughness decreases disproportionately. (Bottom) Ossicles of the ear are 90% mineral. They have little resistance to bending. Antlers are about 40% mineral, allowing them to deform without cracking. *(Top) Adapted from Currey, J.D., 2002. Bones. Structure and Mechanics. Princeton UP, New Jersey, pp. 1–380. (Bottom) Adapted from Curry, J.D., 1969. Mechanical consequences of variation in the mineral content of bone. J. Biomechan. 2, 1–11.*

by breaking intrahelical "sacrificial" bonds, which allows uncoiling of the noncollagenous proteins. This provides "hidden" length. Stresses at the tissue, fiber, and mineral levels decrease in proportions of 12:5:2 (Fantner et al., 2005, Gupt et al., 2006) (Fig. 11.2).

Advancing age compromises this mechanism as advanced glycation end products accumulate, reducing the ability of noncollagenous proteins to protect the mineral platelets (Ural and Vashishth, 2014). This predisposes to the development of diffuse damage, which differs from microcracking. Diffuse damage occurs within the osteon. Microcracks occur in the interosteonal (interstitial) matrix. Diffuse damage is reversible and its repair does not involve bone remodeling.

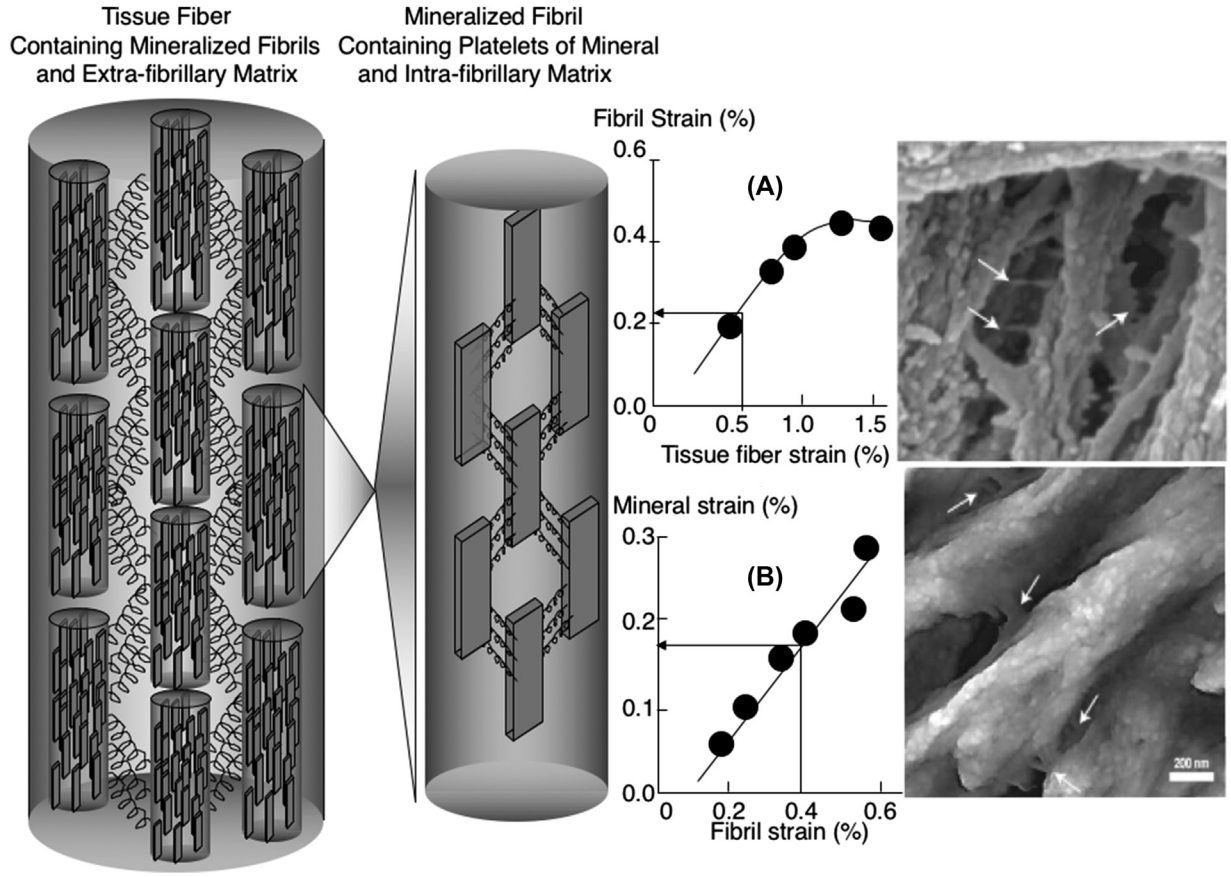

FIGURE 11.2 A collagen tissue fiber contains mineralized fibrils. The fibrils contain mineral platelets bound by noncollagenous proteins, helical structures that can lengthen via the breakage of sacrificial intrahelical bonds to provide "hidden length" and avoid overloading the mineral platelets. (Graph A) Tissue fiber strain distributed to fibrils. (Graph B) Fibrils absorb strain, minimizing mineral strain. *Adapted from Gupta et al. (2005). Images of non-collagenous glue like proteins. From Fantner, G., Hassen kam, T., Kindt, J.H., Weaver, J.C., Birkedal, H., Pechenik, L., Cutroni, J.A., Cidade, G.C., Stucky, G.D., Morse, D.E., Hansma, P.K., 2005. Nat. Mater. 4, 612–616.*

During growth, the mineralized bone matrix volume is fashioned into three-dimensional structures. Although there is variability in the material composition of bone, this composition is similar among land-dwelling mammals (Keaveney et al., 1998). Most of the diversity in bone strength is the result of structural diversity, which is obvious at the macroscopic level from bone to bone and from species to species, but how this diversity in size and shape is achieved is neither obvious nor intuitive.

If bone had only to be strong, this could be achieved by bulk alone—more mass. But mass takes time to grow, is costly to maintain, and limits mobility. Bone also must serve as a lever to facilitate mobility and so it must be light. Longer tubular bones need more mass than shorter bones to construct their length, but in an individual, the diversity in total external and internal cross-sectional areas (CSAs) and varying shapes of a cross section, from cross section to adjacent cross section along the length of a bone is achieved using *similar* amounts of mineralized matrix volume.

In an individual, differences in the total cross section size, shape, and internal architecture of adjacent cross sections of a long bone are achieved by varying the volume of void, not the volume of mineralized bone matrix. For example, at the radius, the large total CSA of the distal metaphysis is assembled using more void volume forming a large medullary canal, not more mineralized matrix volume (Fig. 11.3, left). Most of the mineralized matrix is fashioned as trabecular bone, a porous sponge-like configuration of intersecting thin plates of mineralized matrix. Only a small amount of mineralized matrix is assembled as cortical bone. The cortex is thin and porous with a low matrix mineral density (Ghasem-Zadeh et al., 2017).

More proximally, the *same* mineralized matrix volume is contained within the smaller total CSA of diaphyseal shaft achieved, by assembling it with a smaller medullary void volume, not less material. The constant amount of mineralized bone matrix is fashioned here as a thicker compact cortex with a low porosity and high matrix mineral density. There is little, if any, trabecular bone. This design serves the need for the lever function of a long bone or a cantilever function of a

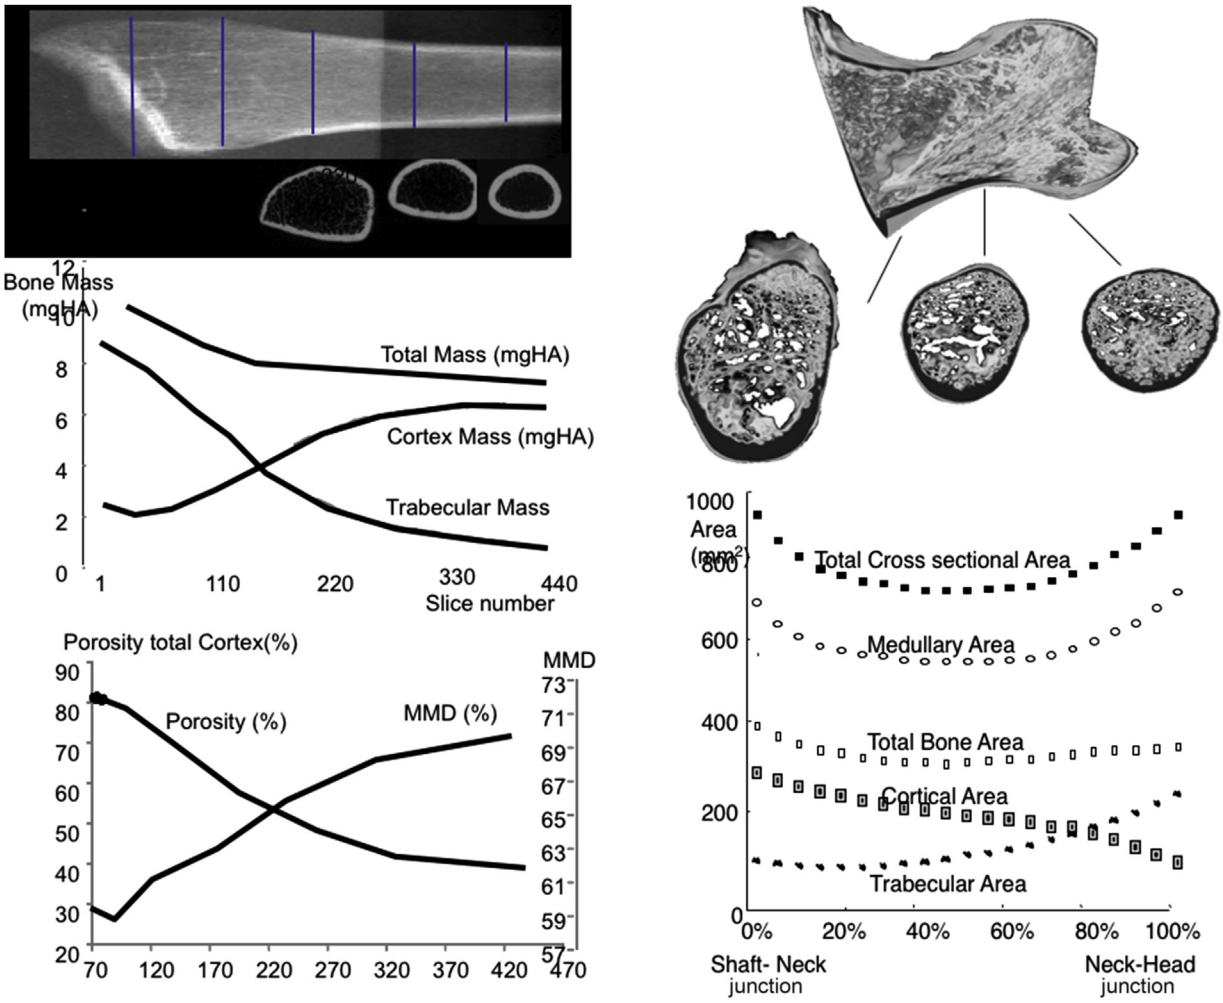

FIGURE 11.3 (Left) Distal radius. The mass is relatively constant along the metaphysis but it is assembled more as trabecular than cortical bone distally, with cortices of higher porosity and lower matrix mineral density. Proximally, the similar amount of material is mainly cortical with low porosity and higher matrix mineral density. (Right) The femoral neck differs in size but each cross section is assembled with a similar amount of material, forming more cortical bone adjacent to the femoral shaft and more trabecular bone nearer the femoral head. *MMD*, Matrix mineral density. *Adapted from Zebaze, R.M., Jones, A., Knackstedt, M., Maalouf, G., Seeman, E., 2007. Construction of the femoral neck during growth determines its strength in old age. J. Bone Miner. Res. 22 (7), 1055–1061.*

shorter bone like the femoral neck. Similar observations have been reported in studies of the femoral neck (Fig. 11.3, right panel).

Thus, the total CSA of a tubular bone and its mineralized matrix mass are inversely associated; larger cross sections are assembled with less material relative to their total CSA, producing a lower apparent volumetric bone mineral density (vBMD); there is less bone within the periosteal envelope of a bigger bone, avoiding bulk. Smaller cross sections are assembled with more material relative to their size, producing a higher apparent vBMD; there is more bone within the periosteal envelope of a smaller bone, minimizing the liability to fracture of slenderness.

Bulk is avoided in larger cross sections by greater modeling-based endocortical resorption during growth. A larger medullary cavity is excavated so that thickening of the cortex by periosteal apposition is offset, thereby minimizing mass, yet radial displacement by this radial modeling drift achieves the same cortical bone area and compressive strength because the thinner "ribbon" of cortex is distributed around a larger perimeter. The radial drift of the cortex increases resistance to bending even though the cortex is thinner relative to the total CSA (Ruff and Hayes, 1988).

Thus, long bones are not drinking straws; they do not have a single cross-sectional diameter, a single cortical thickness, or medullary cavity diameter. Group means are used to express these dimensions but they obscure the diversity in structure and matrix mineral distribution so critical to determining diversity in bone strength. Diameters of a bone cross section

differ at each degree around the periosteal perimeter, creating differences in the external shape. Differences in the medullary diameters at corresponding points around the endocortical perimeter determine the shape of the medullary cavity, and the proximity of the periosteal and endocortical envelopes determines the cortical thicknesses around the perimeter of the cross section and the distances at which the cortical mass at each point around a cross section is placed from the neutral axis (Zebaze et al. 2005, 2007).

This diversity in bone size, shape, and mass distribution is achieved by differing degrees of focal formative and resorptive modeling at each point around the periosteal and endocortical perimeters. Intracortical remodeling assembles osteons, which are bone structural units with a central canal and concentric lamellae of differently oriented mineralized collagen fibers. A cement line delineates each osteon from the interstitial (interosteonal) bone matrix and other osteons.

An example of this regional specificity of remodeling is seen in studies of the femoral neck, the location of fractures associated with high morbidity and mortality. Remodeling upon the periosteal, intracortical, and endocortical surfaces varies according to the location chosen (Fig. 11.4, left). This heterogeneity produces the varying shape of the femoral neck cross sections. Greater periosteal apposition superiorly and inferiorly relative to mediolaterally produces the elliptical shape. Differences in periosteal apposition and endocortical resorption produce a thicker cortex inferiorly and a thinner cortex superiorly (Zebaze et al., 2007). The loss of bone during aging is also heterogeneous and varies depending on the location measured. It is greatest at the superior segment where the cortex is thinnest.

This principle of optimizing strength and minimizing mass is illustrated in a prospective study of the growth of a tibial cross section (Wang et al., 2005a, 2005b). In prepubertal girls, tibial cross-sectional shape was already elliptical at 10 years of age. During 2 years, focal periosteal apposition increased the ellipticity by adding twice the amount of bone anteroposteriorly than mediolaterally. Consequently, estimates of bending strength increased more in the anteroposterior (I_{max})

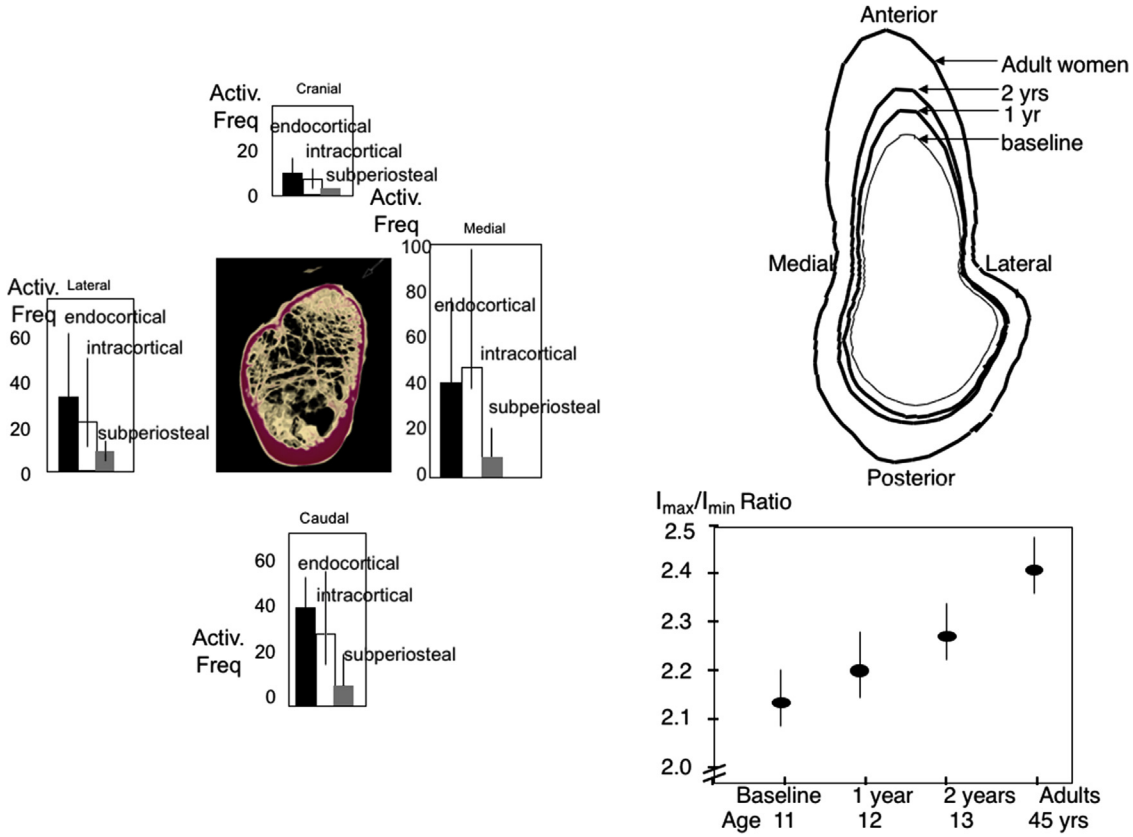

FIGURE 11.4 (Left) The femoral neck cross section. Activation frequency (*Activ. Freq*) of remodeling events differs on the periosteal, intracortical, and endocortical surface depending on the location studied. (Right) Bone mass distribution around the center of the tibial cross section. More bone is deposited anteriorly and posteriorly than medially and laterally during 2 years of growth, increasing the ellipticity of the cross section. Bending resistance increases more along the anteroposterior axis (I_{max}) than the mediolateral axis (I_{min}) as reflected in the increasing ratio. *Adapted from Wang, Q., Alen, M., Nicholson, P., Lyytikainen, A., Suurubuenu, M., Helkala, E., Suominen, H., Cheng, S., 2005a. Growth patterns at distal radius and tibial shaft in pubertal girls: a 2-year longitudinal study. J. Bone Miner. Res. 20 (6), 954–961, Wang, X.F., Duan, Y., Beck, T., Seeman, E.R., 2005b. Varying contributions of growth and ageing to racial and sex differences in femoral neck structure and strength in old age. Bone 36 (6), 978–986.*

than the mediolateral direction (I_{min}) (Fig. 11.4, right). Marrow area changed little, so more mass was distributed as a thicker cortex anteroposteriorly due to periosteal apposition without concurrent endocortical resorption. Resistance to bending increased by 44% along the principal axis (I_{max}) with a 22% increase in mass. If cortical thickness increased by the same amount of periosteal apposition at each point around the tibial perimeter, the amount of bone producing the same increase in bending resistance would be 205 mg, four-fold more than observed.

While it is intuitive that a bone with a larger CSA must be constructed with more periosteal bone than a smaller cross section, the contrary is observed. During 2 years, the absolute amount of bone deposited on the periosteal surface of the tibial cross section was similar in children with baseline tibial total CSA in the upper, middle, and lower tertile at 10 years of age. Thus, larger cross sections were assembled with less mass relative to their starting cross-sectional size, avoiding bulk, and smaller cross sections were assembled with more mass relative to their starting total CSA, offsetting the fragility associated with slenderness.

Deposition of similar amounts of bone on the periosteal surface of larger and smaller cross sections (and so less in relative terms on the former and more on the latter) was possible because the differences in bone size were established early, probably in utero (see later). Consequently, the deposition of an amount of bone on the periosteal surface of a larger cross section confers more bending resistance than the deposition of the same amount of bone on the periosteal surface of a smaller cross section, because resistance to bending is proportional to the fourth power of the distance from the neutral axis (Ruff and Hayes, 1988).

The increase in strength of a bone achieved by modifying its size and shape rather than increasing its mass is convincingly documented in racket sports. During growth, greater loading of the playing arm achieves greater bone strength by modifying its external size, its shape, and its internal architecture. Focal periosteal apposition and endocortical resorption at some locations, but endocortical bone formation at others, change the distribution of bone in space *without* a net change in its mass to accommodate loading patterns; apparent vBMD does not change; bending strength increases without increasing bulk (Haapsalo et al., 2000; Bass et al., 2002).

Trait variances in adulthood originate before puberty

Although adults have larger skeletons than children, differences in bone size and mass in adult life probably begin early in life. In a 3-year prospective study of growth in 40 boys and girls, Loro et al. reported that the variance at Tanner stage 2 (prepuberty) in vertebral CSA and volumetric trabecular BMD, femoral shaft CSA, and cortical area was no less than at Tanner stage 5 (maturity); 60%–90% of the variance at maturity was accounted for by the variance present before puberty. Thus, the magnitude of trait variances (dispersion around the age-specific mean) is largely established before puberty (Loro et al., 2000).

The ranking of individual values at Tanner stage 2 was unchanged during 3 years in girls. These traits tracked, so that an individual with a large vertebral or femoral shaft cross section, or higher vertebral vBMD or femoral cortical area, before puberty retained this position at maturity. The regression lines for each of the quartiles did not cross during 3 years. Similar observations were made in boys.

Similar observations have been reported using peripheral computed tomography of the tibia in 258 girls. The magnitude of variance at 10–13 years of age did not differ from that 2 years later, and did not differ from that of their premenopausal mothers. Likewise, in a study monitoring 744 women and men during 25 years, about 90% of the variance in cortical thickness in adulthood was accounted for by variance at completion of growth 25 years earlier (Garn et al., 1992). Similarly, studies from Tromso suggest that distal and ultradistal radial size and mass tracked during 6.5 years of follow-up of 5366 women and men ages 45–84 years (Emaus et al. 2005, 2006).

Finding that the magnitude of the trait variances at maturity is no different from the magnitude of their variances before puberty suggests that growth in larger and smaller bones occurs the same rate. (If larger bones deposit more bone during growth than smaller bones, variance will increase.) In addition, the constant variance and tracking also suggest that environmental factors are likely to contribute little to total variance of a trait in the population.

In infants and children at ages between 1 and 10 years, variances in diaphyseal diameter and muscle diameter were established at 1–2 years of age (Maresh, 1961). In a cross-sectional study of 146 stillborn fetuses of 20–41 weeks gestation, the percentage of a femur, tibia, and humerus diaphyseal cross section that was cortical area was about 80%–90% at 20 weeks gestation and remained so across the 20 weeks of intrauterine life, suggesting that as bone size increased during advancing intrauterine life, the proportion of bone within the cross section was established prior to 20 weeks gestation (Rodriguez et al., 1992).

The inference from the early establishment and constancy of trait variances is that genetic rather than environmental factors account for this variance. Studies in family members, twins, and birth cohorts followed for many decades and

studies of fetal limb buds grown in vitro support this view (Murray and Huxley, 1925; Pocock et al., 1987; Seeman et al., 1996).

This does not mean that traits *in an individual* are immutably fixed. This flawed notion confuses the proportion of the *population* variance in a trait attributable to genetic or environmental differences in that population with the effect of an environmental factor or disease on a trait in an individual. Muscle paralysis in utero, exercise during growth, or effects of disease in adulthood all have profound effects on bone structure in individuals (Bass et al., 2002; Pitsillides, 2006). Lifestyle changes influence the population mean of a trait as documented many times by secular increases in height, a highly heritable trait (Bakwin, 1964; Meredith, 1978; Cameron et al., 1982; Tanner et al., 1982; Malina and Brown, 1987). However, under stable conditions, lifestyle *differences* within a population make only a small contribution to trait variances compared with genetic *differences* in that population.

Sex and racial differences in bone structure

For the vertebrae, increasing bone size by periosteal apposition builds a wider vertebral body in males than in females and in some races than in others (Seeman, 1998). Trabecular number per unit area is constant during growth (Fig. 11.5, bottom left). Therefore, individuals with a low trabecular number in young adulthood are likely to have lower trabecular numbers in childhood (Parfitt et al., 2000). The age-related increase in trabecular density is the result of increased thickness of existing trabeculae (Fig. 11.5, top left). Before puberty there is no difference in trabecular density in boys and girls of either Caucasian or African American origin (Gilsanz et al 1988, 1991) (Fig. 11.5, right). This suggests that both vertebral body size and the mass within its periosteal envelope increase in proportion until Tanner stage 3.

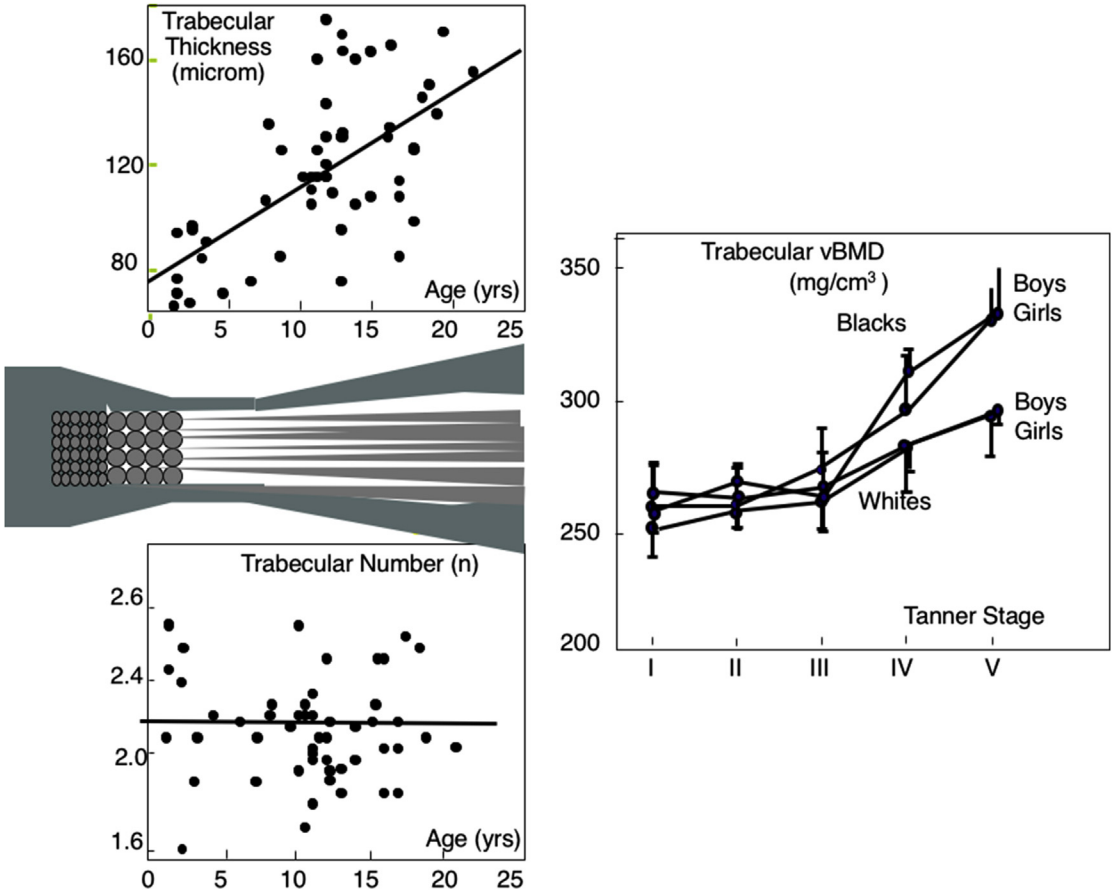

FIGURE 11.5 (Left) Trabecular volumetric bone mineral density (*vBMD*) increases with advancing age owing to an increase in trabecular thickness (top), not number (bottom). (Right) Before puberty, trabecular vBMD is no different by sex or race and increases at Tanner stage 3 similarly by sex within a race, but more greatly in blacks than in whites. *(Left) Adapted from Parfitt, A.M., Travers, R., Rauch, F., Glorieux, F.H., 2000. Structural and cellular changes during bone growth in healthy children. Bone 27, 487–494. (Right) Adapted from Gilsanz, V., Roe, T.F., Stefano, M., Costen, G., Goodman, W.G., 1991. Changes in vertebral bone density in black girls and white girls during childhood and puberty. N. Engl. J. Med. 325, 1597–1600.*

At puberty, trabecular density increases by race and sex, but there is no sex difference in trabecular density within a race. This increase is probably the result of the cessation of external growth in bone size but continued bone formation upon trabecular and endocortical surfaces, resulting in more bone within the periosteal surface of the bone—higher apparent vBMD. Thus, growth does not build a "denser" vertebral body in males than females, it builds a bigger vertebral body in males. Strength of the vertebral body is greater in young males than females because of size differences. Within a sex, African Americans have a higher trabecular density than whites due to a greater increase in trabecular thickness (Han et al., 1996). The mechanisms responsible for the racial dimorphism in trabecular density but lack of sexual dimorphism within a race are not known. The greater trabecular thickness in African Americans partly accounts for the lower remodeling rate in adulthood because there is less surface available upon which remodeling can occur (Han et al., 1996).

Sex differences in appendicular growth are largely the result of differences in timing of puberty (Fig. 11.6, left). Before puberty, there are already sex differences in diaphyseal diameter (Iuliano-Burns et al., 2008). As long bones increase in length by endochondral apposition, periosteal apposition widens the lengthening long bone. Concurrent endocortical resorption excavates the medullary cavity. As periosteal apposition is greater than endocortical resorption, the cortex thickens. In females, earlier completion of longitudinal growth with epiphyseal fusion and earlier inhibition of periosteal apposition produces a smaller bone.

Bone length continues to increase in males and periosteal apposition increases cortical thickness. However, cortical thickness is similar in males and females because endocortical apposition in females contributes to final cortical thickness (Garn, 1970; Bass et al., 1999). Cortical thickness is similar by race and sex (Fig. 11.6, right). What differs is the position of the cortex in relationship to the long axis of the long bone (Wang et al., 2005a, 2005b; Duan et al., 2005). It is not clear

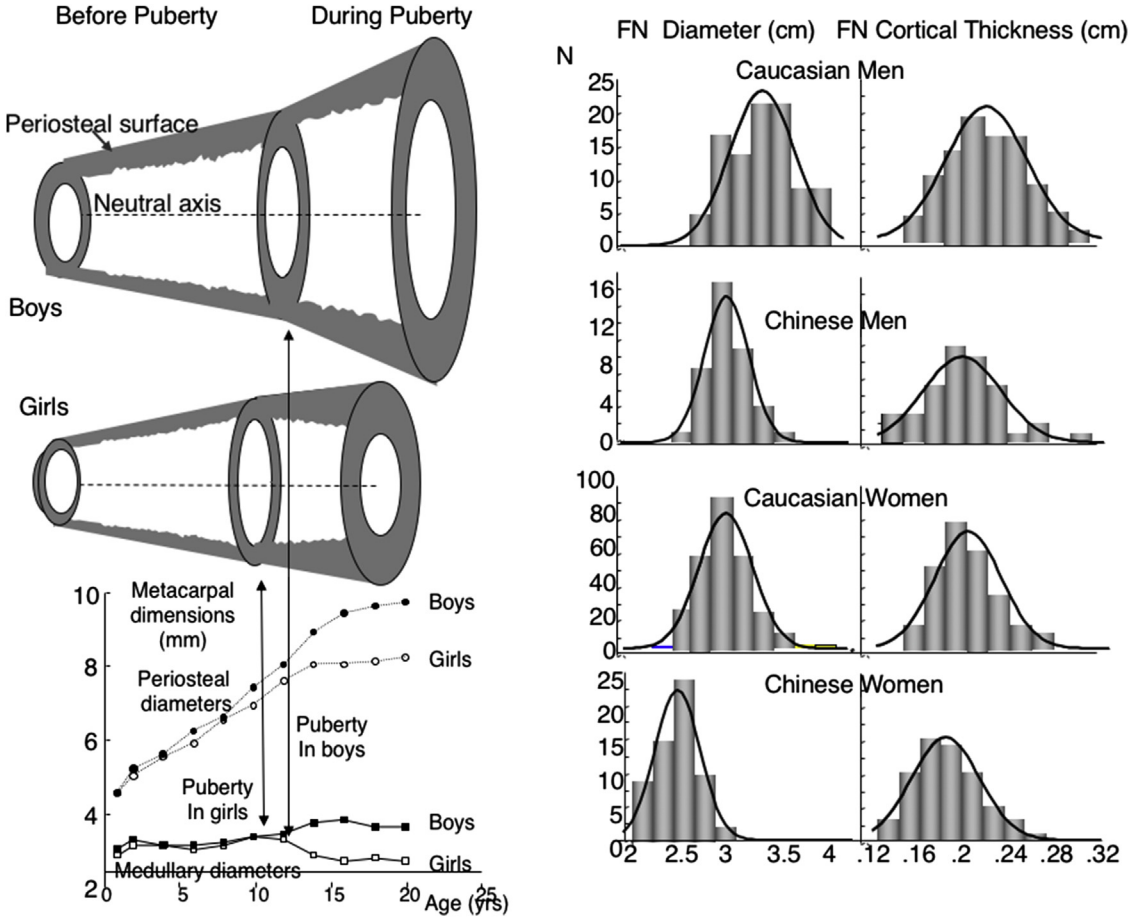

FIGURE 11.6 (Left) Long bone diameter is greater in males than females before puberty. Growth in length and width continues longer in males because puberty occurs later. Endocortical apposition in females contributes to cortical thickness so that final cortical thickness is similar in males and females but displaced further radially in males. (Right) Distribution of femoral neck (*FN*) diameter differs by sex and race but FN cortical thickness is similar by sex and race. *(Left) Adapted from Garn, S., 1970. The Earlier Gain and Later Loss of Cortical Bone. Nutritional Perspectives. Charles C. Thomas, Springfield, IL, pp. 3–120. (Right) E. Seeman with permission.*

whether the wider diaphysis in males than in females is the result of more rapid periosteal apposition in males, as commonly believed, or more protracted longitudinal growth at the same rate, as males enter puberty 1−2 years after females (Garn, 1970).

Bone remodeling by the basic multicellular unit

Osteocyte death in signaling bone remodeling

Bone, like roads, buildings, and bridges, develops fatigue damage during repeated loading, but only bone has a mechanism enabling it to detect the location and magnitude of the damage, remove it, replace it with new bone, and restore the bone's material composition while maintaining its micro- and macroarchitecture (Parfitt 1996, 2002).

Bone resorption is not necessarily bad for bone. On the contrary, the resorptive phase of remodeling removes old or damaged mineralized matrix. The formation phase of the remodeling cycle renews the material composition of bone and restores bone's microstructure provided that the volume of bone formed and deposited is the same as the volume of damaged bone removed. This process depends on the normal production, work, and life span of osteoclasts and osteoblasts. While these are the two executive cells of the BMU, the BMU consists of a range of cells that participate in the renewal of bone matrix composition, as discussed elsewhere (see chapters 4 and 10 for further detail).

It is likely that the osteocyte plays a pivotal role in bone modeling and remodeling. Osteocytes are the most numerous, longest-lived cells of bone. There are about 10,000 cells per cubic millimeter of mineralized bone matrix volume and each cell possesses about 50 neuron-like processes that connect osteocytes with one another and with flattened lining cells on the endosteal surface (Marotti et al., 1990) (Fig. 11.7A, see legend also).

The dense lacelike network of osteocytes with their processes ensures that no part of bone is more than several micrometers from a lacuna containing its osteocyte, suggesting that these cells are part of the machinery guarding the integrity of the composition and structure of bone (Parfitt, 2002). Microcracks sever osteocyte processes in their canaliculi, producing osteocyte apoptosis (Hazenberg et al., 2006) (Fig. 11.7B and C). Prevention of osteocyte death may be an attractive therapeutic target if they are the result of damage, if they become a form of damage themselves when they become apoptotic, or if they produce damage (O'Brien et al., 2004; Keller and Kneissel, 2005; Manolagas, 2006).

Apoptotic osteocytes, for example, may be a form of damage themselves, perhaps reducing the energy-absorbing/dissipating capacity of bone when lacunae mineralize. Estrogen deficiency and corticosteroid therapy result in their apoptosis (Manolagas, 2006). Osteocyte apoptosis may damage surrounding mineralized matrix, producing bone fragility (independent of bone loss). Corticosteroid-treated mice have large osteocyte lacunae surrounded by matrix with a 40% reduction in mineral and reduced elastic modulus (Lane et al., 2006). Genetic ablation of osteocytes produces bone fragility (Tatsumi et al., 2007). Whether the increased rate of remodeling in midlife in women is partly the result of osteocyte death is not known.

The number of dead osteocytes provides the topographical information needed to identify the location and size of damage (Verborgt et al., 2000; Taylor, 1997; Schaffler and Majeska, 2005) (Fig. 11.11C). Osteocyte apoptosis is likely to be one of the first events signaling the need for remodeling. It precedes osteoclastogenesis (Clark et al., 2005). In vivo, osteocyte apoptosis occurs within 3 days of immobilization and is followed within 2 weeks by osteoclastogenesis (Aguirre et al., 2006). In vitro, death of the osteocyte-like MLO-Y4 cells, induced by scratching, results in the formation of TRACP-positive (osteoclast-like) cells along the scratching path (Kurata et al., 2006).

Thus, just as the spider knows the location and size of its wriggling prey by signals sent along its vibrating web, the need for reparative remodeling is likely to be signaled by osteocyte death. This takes place via their processes connected to viable osteocytes and to flattened osteoblasts lining the three intracortical, endocortical, and trabecular components of the inner (endosteal) surface of bone upon which remodeling is initiated.

The bone remodeling compartment

Bone remodeling is initiated at points upon on the endocortical, trabecular, and intracortical components of the endosteal envelope. The endocortical and trabecular surfaces are adjacent to marrow. The intracortical surface is formed by the surface of Haversian and Volkmann's canals. While remodeling is initiated at points upon these surfaces, damage occurs deep to them, within the matrix of osteons or the interstitial (interosteonal) bone in the case of cortical bone or within hemiosteons in the case of trabecular bone. Information concerning the location and size of damage must reach these surfaces, and cells involved in remodeling must reach the site of damage beneath the endosteal surface. This anatomical

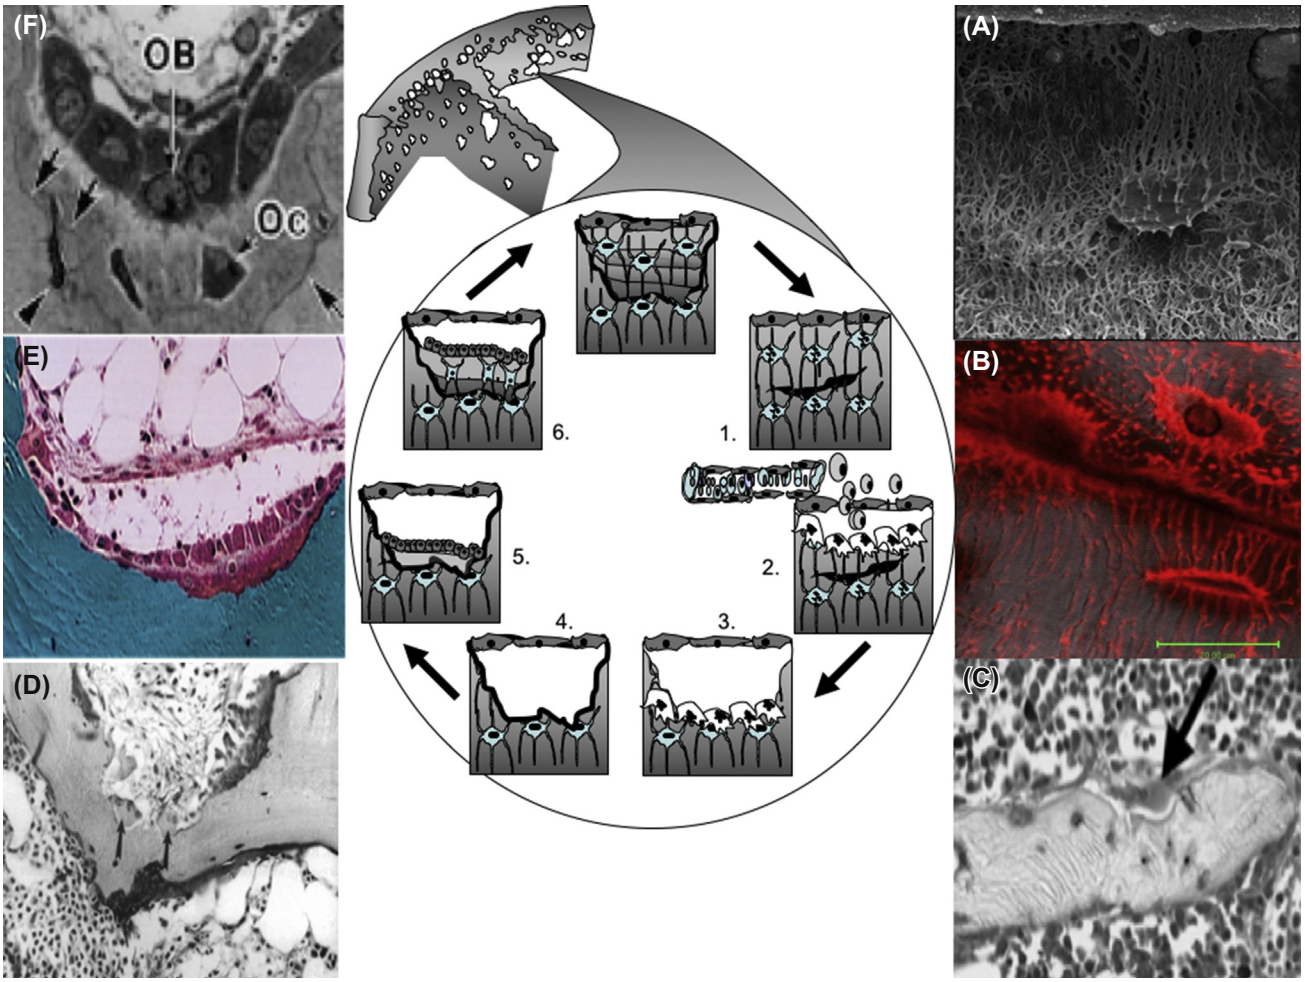

FIGURE 11.7 (A) Osteocytes are connected to one another and to lining cells on the endosteal surface adjacent to the marrow. (B) Damage to osteocytic processes by a microcrack produces osteocyte apoptosis. (C) The distribution of apoptotic osteocytes provides the topographical information needed to target osteoclasts (identified by arrow) to the damage. (D) Osteoclasts (arrows) resorb bone. (E) Osteoblasts deposit osteoid. (F) Some osteoblasts are entombed in the osteoid (arrows) they deposit. Central cartoons depict the remodeling events with (1) damage causing osteocytes to apoptose; (2) formation of a bone remodeling compartment with a vascular supply and osteoclasts resorbing bone; (3 and 4) osteoclasts resorbing damage; (5) a cement line being formed; and (6) bone formation following refilling of the cavity with entombment of osteoblasts that become osteocytes. *OB*, osteoblast; *Oc*, osteocyte. *(B) Courtesy J. Hazenberg. (C) Courtesy M. Schaffler. (F) From Suzuki, R., Domon, T., Wakita, M., 2000. Some osteocytes released from their lacunae are embedded again in the bone and not engulfed by osteoclasts during remodelling. Anat. Embrol. 202, 119–128.*

arrangement makes the flattened lining cells likely conduits transmitting the health status of the bone matrix to the bone marrow environment, which in turn is a source of the cells of the BMU, but not the only source.

Apoptotic osteocytes signal the location and size of the damage burden to the flattened lining cells of the endosteal surface, leading to the formation of a bone remodeling compartment (BRC), which confines and targets remodeling to the damage that is removed by osteoclasts (Hauge et al., 2001) (Fig. 11.7D). The regulatory steps between osteocyte apoptotic death and creation of the BRC are not known. Bone-lining cells express collagenase mRNA (Fuller and Chambers, 1995). An early event creating the BRC may be collagenase digestion of unmineralized osteoid to expose mineralized bone, a requirement for osteoclastic bone resorption.

The flattened bone-lining cells express markers of the osteoblast lineage, particularly lining cells forming the BRC canopy (Hauge et al., 2001; Parfitt, 2001). These canopy cells also express markers for growth factors and regulators of osteoclastogenesis, such as receptor activator of NF-κB ligand (RANKL), suggesting that the canopy has a central role in the differentiation of precursor cells of marrow stromal origin, monocyte–macrophage origin, and vascular origin toward their respective osteoblast, osteoclast, or vascular phenotype.

The multidirectional steps of the remodeling cycle

While the two classical events of remodeling—resorption of a volume of bone by osteoclasts and formation of a similar volume of bone by osteoblasts—occur sequentially (Hattner et al., 1965), the cellular and molecular regulatory events leading to these two fully differentiated functions may not be sequential. Some may be contemporaneous and multidirectional; osteoblastogenesis and its regulators determine osteoclastogenesis, and so the volume of bone to be resorbed, while osteoclastogenesis and the products of the resorbed matrix regulate osteoblastogenesis. Both pathways may be regulated to some extent by osteocytes and their products (e.g., sclerostin). How this cellular and molecular traffic is orchestrated from beginning to end remains unclear (see chapters 4 and 10 for further detail).

Signaling from apoptotic osteocytes to cells in the canopy expressing the osteoblast phenotype may influence further differentiation toward osteoblast precursors expressing RANKL and fully differentiated osteoblasts producing osteoid. Even at this stage, regulation of osteoclastogenesis and osteoblastogenesis occurs simultaneously through osteoblast precursors. In the MLO-Y4 cell line, damaged osteocyte-like cells have been reported to secrete macrophage colony-stimulating factor and RANKL (Kurata et al., 2006). Whether this occurs in human subjects in vivo is not known, but it raises the possibility that osteocytes participate in the differentiation of monocyte−macrophage precursor cells toward the osteoclast lineage. Both osteoblast and osteoclast precursors circulate and so may arrive at the BRC via the circulation and via capillaries penetrating the canopy (Eghbai-Fatourechi et al 2005, 2007; Fujikawa et al., 1996).

The contribution of precursors from the canopy or the marrow via sinusoids or capillaries is not well defined. Angiogenesis is essential to bone remodeling. Osteoprogenitor cells are associated with vascular structures in the marrow and several studies suggest there may be common progenitors giving rise to cells forming the blood vessels and the perivascular cells that can differentiate toward cells of multiple lineages (Doherty et al., 1998; Howson et al., 2005; Sacchetti et al., 2007; Matsumoto et al., 2006; Kholsa, 2007; Otsura et al., 2007; Khosla et al., 2008).

Little is known about the factors determining the volume of bone resorbed or how resorption stops after the damaged region has been resorbed. Osteoclasts phagocytose osteocytes and this may be one way the signal for resorption is removed (Elmardi et al., 1990). Products from the osteoclasts, independent of their resorption activity, and products from the resorbed matrix partly regulate osteoblastogenesis and bone formation (Suda et al., 1999; Martin and Sims, 2005; Lorenzo, 2000). Sclerostin, a negative regulator of bone formation, is an osteocyte product that inhibits bone formation and its inhibition is permissive for bone formation.

After the reversal phase, osteoblasts deposit osteoid, partly or completely filling the cavity (establishing the size of any negative BMU balance) (Fig. 11.7E). Osteoblasts deposit type I collagen, which is configured as the lamellae that undergo primary and secondary mineralization. How the osteoblasts change polarity to produce the differently oriented collagen fibers from lamella to lamella is not known. Most osteoblasts die, others become lining cells, while others are entombed in the osteoid they form, leaving reconstruction and "rewiring" of the osteocytic canalicular communicating system for later mechanotransduction, damage detection, and repair (Fig. 11.7F) (Han et al., 2004).

Perhaps the most fundamental and challenging question remains unanswered. Why is remodeling initiated at a given location and at a given time? While it is commonly stated that remodeling is initiated by "damaged" or "old" bone, the definitions of "damaged" and "old" remain enigmatic. Damage at the nano- or microstructural level has not been categorized in morphological terms, so the causes of damage, the biomechanical effects, and the biochemical and structural means of detecting, signaling, and repairing different types of damage remain uncertain (Akkus et al., 2004; Burr et al., 1998; Danova et al., 2003; Diab et al., 2006; Diab T and Vashisha D 2005; Garnero et al., 2006; Landis 2002; Ruppel et al., 2006; Silva et al., 2006; Taylor et al., 1997).

Bone remodeling and microstructure during young adulthood, menopause, and advanced age

Young adulthood: reversible bone loss and microstructural deterioration

Remodeling is balanced during young adulthood; the same volumes of bone are removed and eventually replaced at specific locations upon the endocortical, intracortical, and trabecular components of bone's endosteal envelope (Hattner et al., 1965). There is no net focal gain or loss of bone so that the external and internal dimensions of the mineralized bone matrix volume remain unchanged. Remodeling also occurs upon the outer (periosteal) surface but to a minimal extent (Orwoll 2003; Blizoites et al., 2006).

The resorption of a volume of bone, its replacement with an identical volume of osteoid, and primary and secondary mineralization of osteoid are not instantaneous events. The resorptive phase of remodeling takes ~3 weeks, the reversal

phase takes ~1 week, the formation phase takes ~3 months, and completion of mineralization takes many months, if not years (Baron et al., 1984; Hattner et al., 1965; Parfitt, 1996).

Remodeling occurs simultaneously at different locations but it is asynchronous. BMUs at different locations are at different phases of their remodeling cycle. While remodeling is balanced, the deficit in matrix and its mineral content is *focally* transient and fully reversible. However, as concurrent events are asynchronous, there is a *globally* ever-present deficit in matrix and its mineral content formed by the BMUs at different stages of their remodeling cycle. The more rapid the remodeling, the greater the number of BMUs, and so the greater size of the reversible deficit in matrix and its mineral content.

In morphological terms, the ever-present reversible global deficit in matrix and its mineral content consists of BMUs in their resorption phase, BMUs with cavities in their reversal phase, cavities containing osteoid that has undergone primary mineralization, and other cavities containing matrix at various stages of secondary mineralization (Parfitt, 1996). More BMUs are at varying stages of their formation or mineralization phase than in their resorption or reversal phase because the matrix formation phase is longer than the resorption phase and the matrix mineralization phase is very much longer than the matrix deposition phase. As secondary mineralization is so much slower than the matrix deposition, the ever-present global deficit in mineralized bone matrix volume is largely the result of a deficit in the mineral content of the matrix, not the matrix. New osteons in cortical bone or hemiosteons in trabecular bone are fully reconstructed by the cellular activity of osteoblastic bone formation many months before they become fully mineralized.

In premenopausal women, the ever-present global deficit is ~10% of the total mineralized bone matrix volume. After menopause, when remodeling rate increases, the deficit is ~20% of the total mineralized bone matrix volume. Of the 20% of the skeleton being remodeled—"turned over"—annually, not all is reversible because of the emergence of the remodeling imbalance and the appearance of the irreversible deficit in bone matrix and its mineral content.

The recognition of the existence of the reversible and irreversible deficits in matrix volume and its mineral content and the differing time course of completion of matrix resorption, matrix deposition, and the much slower secondary mineralization of the matrix is important because each event contributes differently to aspects of the pathogenesis of menopause and age-related loss of bone matrix, its mineral content, and so bone's material and structural strength and whole-bone strength.

This "deconstruction" into the reversible and irreversible deficits of bone matrix and mineral content is also relevant to understanding the morphological changes produced by antiresorptive and anabolic therapy, particularly when these two classes of drugs are combined. These treatments have opposite effects on matrix mineral density and so have effects on material and microstructural strength not captured by the BMD measurement, and indeed obscured by the measurement, which is used as a surrogate of "bone strength." Several examples of the effects of the reversible and irreversible deficits in matrix and mineral follow here and in the section concerning modeling and remodeling during drug therapy.

The reversible deficit in matrix and its mineral content produces no permanent microstructural deterioration before menopause. If remodeling is rapid, the presence of many excavated cavities may increase bone fragility independent of the temporary small deficit in matrix and its mineral content produced by the delay and slowness of the formation phase. These cavities form stress "risers" or stress "concentrators," which are likely to contribute to the pathogenesis of fractures (Hernandez, 2006).

Before menopause, remodeling is balanced and the deficit in matrix and mineral at a given location is transitory, yet several studies suggest that bone loss occurs before menopause. For example, Riggs et al. reported that women lose 37% and men 42% of the total trabecular bone before age 50 years and 6% and 15% of lifetime cortical bone is lost (Riggs et al 1986, 2007; Gilsanz et al., 1987). However, a prospective study of female twins remaining premenopausal or entering peri- or postmenopause did not support the occurrence of bone loss or microstructural deterioration before menopause (Bjørnerem et al., 2018).

The loss of bone (measured as a decrease in BMD) may be an artifact produced by an increase in medullary cavity fat, which attenuates photons less than water or cells, producing a seeming decline in BMD giving the impression of bone "loss" (Bolotin and Sievänen, 2001). Alternatively, a remodeling imbalance may exist before menopause but is below the detection limits of current methods. If bone loss does occur before menopause, the structural and biomechanical consequences are likely to be less than those of bone loss later in life because the remodeling rate is slow, and trabecular bone loss probably proceeds by reduced bone formation and thinning rather than increased bone resorption with perforation and loss of connectivity. Thinning is less deleterious to loss of strength than perforation and loss of connectivity (Van der Linden et al., 2001). Moreover, continued periosteal apposition partly offsets endocortical bone loss, shifting the cortices radially, maintaining cortical area and resistance to bending (Szulc et al., 2006).

Menopause: reversible and irreversible bone loss and microstructural deterioration

At the time of menopause, there is an early accelerated phase of bone loss and an accelerated decrease in BMD. The worsening of the reversible deficit in matrix and mineral is the net result of the concurrent appearance of many more BMUs in their resorptive phase than the BMUs generated before menopause only now entering their refilling phase. The deficit in matrix and mineral produced by perturbation of steady-state surface level remodeling is fully reversible.

If the increase in the rate of bone remodeling was the only effect of menopause, BMD would decrease to a level determined by the higher rate of remodeling at the new steady state with BMUs in varying states of incompleteness of their remodeling cycle. No further bone loss would occur. Bone fragility would increase as a function of numbers of stress concentrators. If estrogen deficiency was reversed and remodeling returned to its premenopausal rate, BMD would be fully restored to its premenopausal level and there would be no permanent microstructural deterioration. This is not the case.

The percentages of the endosteal surface participating in bone resorptive activity and in formative activity at other locations are increased because the birth rate of BMUs increases after menopause. This alone does not determine whether bone is irreversibly lost from the skeleton. Whether bone loss occurs depends on the presence of a remodeling imbalance at the level of each BMU. Menopause is accompanied by the appearance of remodeling imbalance; less bone is deposited than was resorbed during each remodeling transaction. This differs from the reversible deficit and reversible microstructural deterioration produced by the normal delay and slowness of the refilling phase of remodeling.

Remodeling imbalance with less bone deposited than formed may occur in a range of ways. The most common and demonstrated by histomorphometry is a reduction in *both* the volumes of bone resorbed and the volumes deposited by each BMU, but a greater reduction in the volume of bone formed (Lips et al., 1978; Vedi et al., 1984). The decrease in resorption by the BMU is reflected in a smaller resorption cavity and an age-related increase in interstitial thickness (Croucher et al., 1991; Ericksen et al., 1999). (If resorption depth increased, interstitial wall thickness, the distance between cement lines of adjacent hemiosteons in trabecular bone, should decrease.) The reduction in the volume of bone resorbed results in the formation of smaller osteons, as the diameter of the resorption cavity defines the outer diameter of the osteon to be reassembled, while the reduction in the volume of bone deposited in the smaller cavity produces fewer lamellae and a larger central Haversian canal (porosity).

Another mechanism producing remodeling imbalance is an increase (not decrease) in the volume of bone resorbed and a decrease in the volume of bone formed due to an increase in the life span of osteoclasts and decrease in the life span of the osteoblasts, respectively (Manolagas Bonyadi et al., 2003; Nishida et al., 1999; Stenderup et al., 2001; Oreffo et al., 1998). The observation that menopause is accompanied by reduced numbers of trabeculae not thinning is consistent with larger cavities perforating these trabeculae (Aaron et al., 1987; Bjornerem et al., 2018). The observation of reduced cavity depth is consistent with a reduction in bone resorption. The differing observations can be reconciled if the increased life span of osteoclasts produced by estrogen deficiency is transitory (Ericksen et al 1986, 1999; Manolagas, 2000; Compston et al., 1995).

The factor driving the early accelerated bone loss is the perturbation of the surface extents of resorption and formation, not remodeling imbalance. Whether the early accelerated loss of bone at menopause is partly due to a reduction in the volume of bone formed by BMUs generated just *before* menopause is uncertain, because osteoblasts of these BMUs may not yet have a reduced life span. The reduction in osteoblast life span may emerge only during menopause.

Remodeling returns to steady state 6−12 months postmenopause at a higher remodeling rate than the steady-state remodeling before menopause, but at a slower rate than in early menopause. This slowing is not the result of slowing of the rate of remodeling. On the contrary, the rate of remodeling continues to be rapid. Bone loss is driven by the size of the remodeling imbalance and the birth rate of the new BMUs, but no longer by perturbation of the surface extents of resorption and formation. Now, the great many new BMUs generated in early menopause refill incompletely, and concurrently, a similarly large number of BMUs in their resorptive phase are generated**.** The rates of increase in cortical porosity, decrease in trabecular density due to reduced numbers of trabeculae, and reduction in matrix mineral density accelerate in women transitioning from peri- to postmenopause, and then decelerate (Bjørnerem et al., 2018) (Fig. 11.8).

Whatever the mechanisms producing remodeling imbalance, the imbalance in the volumes of bone resorbed and deposited by each BMU is the necessary and sufficient morphological basis for bone loss, microstructural deterioration, and bone fragility. Bone can no longer accommodate its loading circumstance by adaptive modeling and remodeling because each time a remodeling event occurs in an attempt to maintain bone's material composition, there is a loss of bone and microstructural deterioration. Most importantly, the loss of strength is out of proportion to the bone loss producing this deterioration; an increase in porosity of a compact structure like cortical bone reduces resistance to bending to the seventh power of the rise in porosity. A rise in porosity of an already porous structure like cortical bone reduces its resistance to bending to the third power (Schaffler and Burr, 1988).

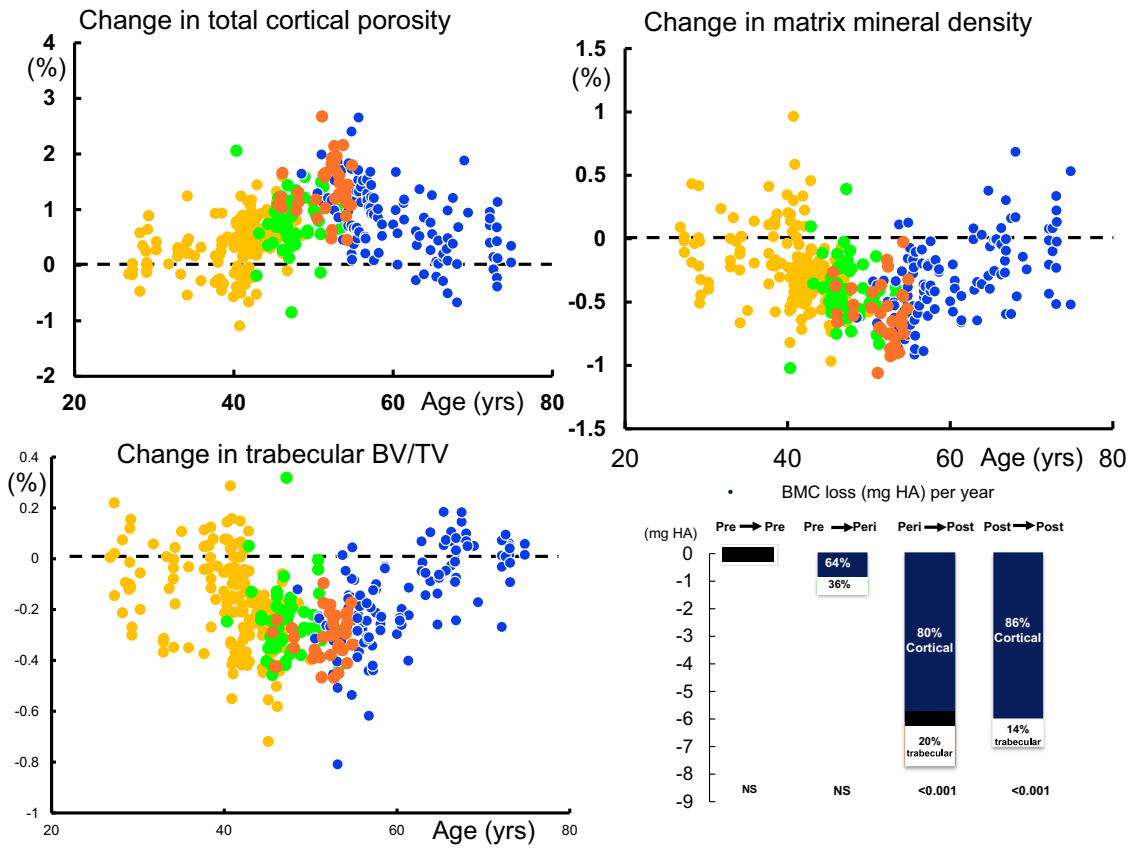

FIGURE 11.8 Annual changes in distal tibia total cortical porosity, trabecular bone volume/total volume (*BV/TV*), and matrix mineral density as a function of baseline age in women remaining premenopausal (*light orange dots* [light gray in print version]), becoming perimenopausal (*green dots* [medium gray in print version]), becoming postmenopausal (*dark orange dots* [dark gray in print version]), and remaining postmenopausal (*blue dots* [black in print version]). The bottom right shows the amount of tibial cortical and trabecular bone loss as a percentage of annual loss of total bone mineral content (*BMC*; mg hydroxyapatite [*HA*]) in women remaining premenopausal (*Pre* → *Pre*), becoming perimenopausal (*Pre* → *Peri*), moving from peri- to postmenopausal (*Peri* → *Post*), and remaining postmenopausal (*Post* → *Post*). *P* values within each group tested whether the total annual loss was different from zero.

Thus, BMD may decrease only into the so-called "low normal" range or osteopenic range, but bone fragility is present and is obscured by these modest reductions in BMD, which misleadingly suggest fracture risk is low. Fracture risk is lower than in women with BMD within the osteoporosis range (T score < -2.5 SD), but osteopenia or normal BMD in a postmenopausal woman is no assurance of absence of fracture risk; on the contrary, most fractures in the community arise among women and men with osteopenia (Siris et al., 2004).

Advanced age: the predominance of cortical bone loss

Modeling and remodeling are surface-dependent cellular events. For remodeling to occur there must be a surface upon which it is initiated. The larger the surface area, the greater the likelihood that remodeling can be initiated by events occurring deep to that surface, whether this event is matrix damage, osteocyte death, or other still undefined factors. Trabecular bone is fashioned as thin plates with a large surface area and a high surface area/matrix volume configuration. This is an advantage for matrix damage repair because damage can be easily signaled to the trabecular surface and the initiated remodeling can then easily be targeted to return to the matrix damage, remove it, and replace it with new bone. Hence, trabecular bone is more readily "turned over," a liability when remodeling becomes unbalanced. Indeed, when this occurs, rapid loss of complete trabeculae removes them and their surface so that trabecular remodeling diminishes as trabeculae disappear. In addition, loss of strength is greater with perforation of trabeculae, as found in women, rather than thinning, as occurs in men (Van der Linden, 2001) (Fig. 11.9).

As trabeculae are lost with their surfaces, bone loss from this compartment slows as less trabecular surface is available for resorption, but remodeling upon the endocortical and intracortical surfaces continues and increases as the endocortical

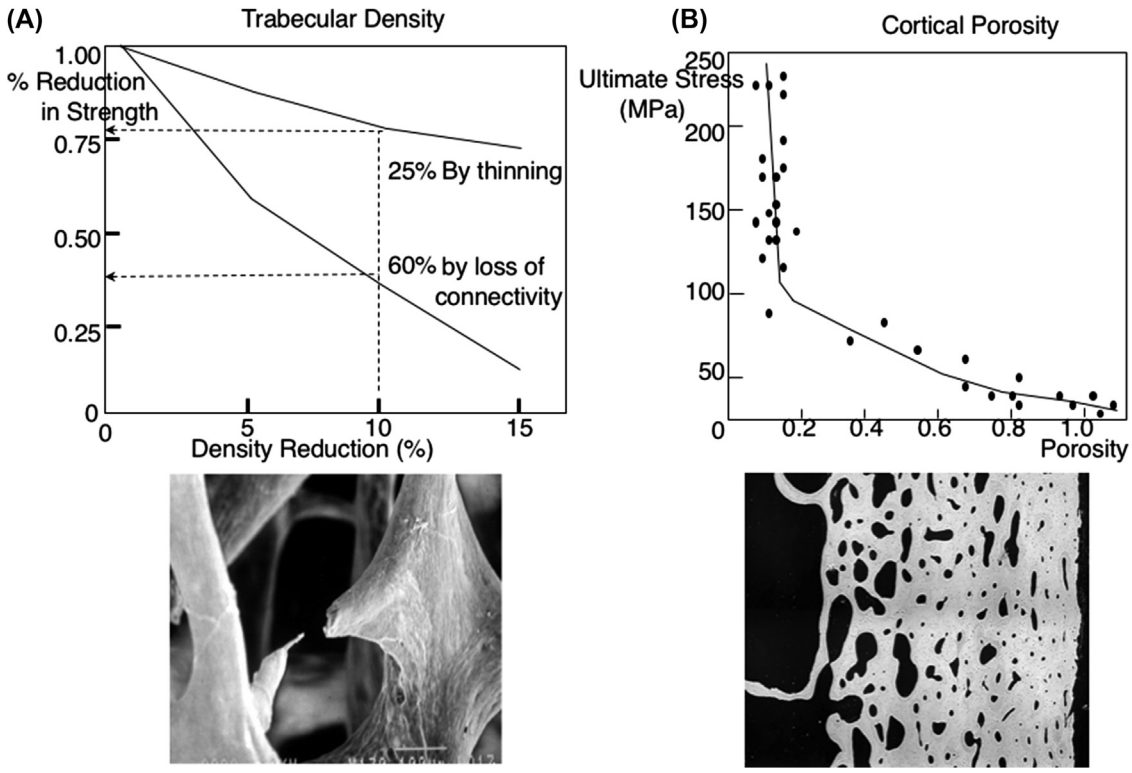

FIGURE 11.9 (A) Reduction in strength produced by a 10% deficit in trabecular density is greater when this deficit is produced by loss of trabecular connectivity than by thinning. Image shows loss of connectivity (Mosekilde et al., 1990). (B) A small increase in cortical porosity by a few percentage points is associated with a decline in ultimate stress and reduction in toughness. Scanning electron microscopic image of irregularly shaped enlarged pores in cortical bone. *(A) Adapted from Van der Linden, J.C., Homminga, J., Verhaar, J.A.N., Weinans, H., 2001. Mechanical consequences of bone loss in cancellous bone. J. Bone Miner. Res. 16, 457–465. (B) Adapted from Martin, R.B., 1984. Porosity and specific surface of bone. CRC Critical Rev. Biomed. Eng. 10, 179–221; and Yeni, Y.N., Brown, C.U., Wang, Z., Norman, T.L., 1997. The Influence of bone morphology on fracture toughness of the human femur and tibia. Bone 21, 453–459.*

surface undergoes bone resorption, so that its surface area increases like the folds of a curtain (Parfitt, 1984; Brown et al., 1987; Arlot et al., 1990; Foldes et al., 1991). The main source of bone loss is intracortical remodeling initiated upon the surface of the myriads of Haversian canals traversing the cortex (Martin, 1984; Brockstedt et al., 1993; Yeni et al., 1997). Increased porosity is mainly due to increased size of existing canals that coalesce, forming irregularly shaped pores (canals seen in cross section). As the canals enlarge, the surface area of the canals also enlarges as does the surface area/matrix volume configuration, making cortical matrix accessible to being turned over and lost by the unbalanced remodeling (Bui et al., 2013). Total bone surface area either does not change (increasing in cortical bone, decreasing in trabecular bone) or increases (in regions of cortical bone only) so that late in life, bone loss is more cortical than trabecular in origin (Zebaze et al., 2010).

Increased intracortical remodeling of cortex adjacent to the medullary canal fragments the cortex, causing it to "trabecularize"; the cortical fragments look like trabecular bone and the porosity is erroneously "seen" as part of an enlarging medullary canal. Apportioning the intracortical porosity to the medullary compartment underestimates the age-related increase in cortical porosity and the trabecularized cortical fragments are regarded as trabecular bone within the seemingly expanded medullary canal, leading to an underestimation of the decrease in trabecular density with age (Zebaze et al., 2010). Both errors underestimate fracture risk in individuals and so fail to signal the imperative to initiate treatment.

Solutions to these problems have been found by segmenting a corticotrabecular outer and inner transitional zone using non-threshold-based image analysis. This approach allocates and confines cortical porosity to this "third" compartment, rather than erroneously expanding the medullary canal void, and cortical fragments to the outer transitional zone and partly to the inner transitional zone, which also contains true trabecular fragments (Zebaze et al., 2013).

As age advances and rapid unbalanced remodeling continues due to permanent estrogen deficiency and perhaps emerging secondary hyperparathyroidism, the extent of coalescence of pores increases, so the number of intracortical pores decreases, but the total area of porosity increases, as reported in patients with hip fractures (Bell et al., 1999). Cortical

porosity reduces the ability of bone to limit crack propagation so that bone cannot absorb the energy imparted by the impact of a fall. This energy is released in the worst possible way, by fracture (Martin, 1984; Yeni et al., 1997). The continued unbalanced remodeling at a similar intensity removes the same volume of bone from an ever-decreasing amount of bone, accelerating the rate of bone loss and microstructural deterioration (Zebaze et al. 2013).

While the unbalanced remodeling produces bone loss and microstructural deterioration, remodeling is a transaction. Older, more completely mineralized bone is replaced with a smaller volume of younger bone that is less completely mineralized. This results in a decrease in mean matrix mineral density and an increase in the heterogeneity in the degree of mineralization of adjacent osteons and the interstitial (interosteonal) bone between osteons (which is more fully mineralized) (Boivin and Meunier, 2002; Boivin et al., 2003). This heterogeneity may limit microcrack propagation because more energy is needed to propagate a microcrack through a heterogeneously than a homogeneously mineralized material (Ural and Vashishth, 2014). However, interstitial (interosteonal) bone is less remodeled and becomes more highly mineralized and cross-linked with advanced glycation end products like pentosidine, both of which reduce the ductility of the matrix, facilitating microcrack propagation (Bailey et al., 1999; Banse et al., 2002; Nalla et al., 2004; Qui et al., 2005; Yeni et al., 1997; Viguet-Carrin et al., 2006).

The net effects of reduced periosteal apposition and endosteal bone loss

Over 80 years ago, Fuller Albright suggested that osteoporosis was a disorder of reduced bone formation (Albright et al., 1941). Research into the pathogenesis of bone fragility has focused on the role of bone resorption. During aging, reduced bone formation plays a central role in producing remodeling imbalance and so net bone loss takes place from the three components of the endosteal surface and reduced periosteal bone formation.

As age advances bone modeling by periosteal apposition continues, but much more slowly than during growth and much more slowly than endosteal bone loss. The net effect is an imperceptibly small increase in bone size but a reduction in total mineralized bone matrix volume and microstructural deterioration, with eventual almost complete loss of trabecular bone, cortical thinning, and a reduction in the number of cortical pores, but an increase in the cortical porosity as enlarging pores coalesce, so that all that is left is an eggshell rim of cortical bone (Balena et al., 1992; Seeman et al., 2003; Szulc et al., 2006).

Periosteal apposition is believed to increase as an adaptive response to compensate for the loss of strength produced by endocortical bone loss, so there will be no *net* loss of bone, no cortical thinning, and no loss of bone strength (Ahlborg et al., 2003). While this is often claimed, there are formidable challenges in identifying the existence of periosteal apposition during adulthood, its site specificity, its magnitude, and sex differences. In cross-sectional studies, secular changes in bone size may obscure or exaggerate periosteal apposition. Secular increases in stature are variously reported in one or both sexes, in some races but not others, and in the skeleton of the upper or lower body or both (Bakwin, 1964; Meredith, 1978; Cameron et al., 1982; Tanner et al., 1982; Malina and Brown, 1987).

These secular trends can produce misleading inferences when increments or lack of increments in bone diameters are used as surrogates of periosteal apposition. For example, in cross-sectional studies, the absence of an increment in periosteal diameter across age may not mean periosteal apposition failed to occur. Earlier born individuals (the elderly in a cross-sectional sample) are likely to have been shorter and to have had more slender bones than later born individuals (young normals in a cross-sectional sample). When periosteal apposition occurs, earlier born persons (forming the older subjects in a cross-sectional sample) with more slender bones have an increase in bone diameter that comes to equal that in later born persons (who have not yet had age-related periosteal apposition), leading to the flawed inference that there was no periosteal apposition.

When comparisons are made between sexes (or races) in cross-sectional studies, if the truth is that periosteal apposition is greater in men than in women but men have a secular increase in bone size and women do not, then the secular increase in men will blunt the increment in bone width across age in men and make it appear that the age-related increase in vertebral and femoral neck diameters (and so periosteal apposition) is similar in women and men.

Longitudinal studies are also problematic because changes in periosteal apposition during aging are small (Balena et al., 1992). The precision of methods to determine bone diameter, usually bone densitometry, and problems with edge detection when BMD is changing, limit the credibility of these measurements. Nevertheless, in one prospective study of over 600 women, Szulc et al. reported that endocortical bone loss occurred in premenopausal women with concurrent periosteal apposition (Szulc et al., 2006) (Fig. 11.10). As periosteal apposition was less than endocortical resorption, the cortices thinned but there was no *net* bone loss because the thinner cortex was now distributed around a larger perimeter, conserving total bone mass. Resistance to bending increased despite bone loss and cortical thinning, because this same amount of bone was now distributed farther from the neutral axis. So bone mass alone is a poor predictor of strength,

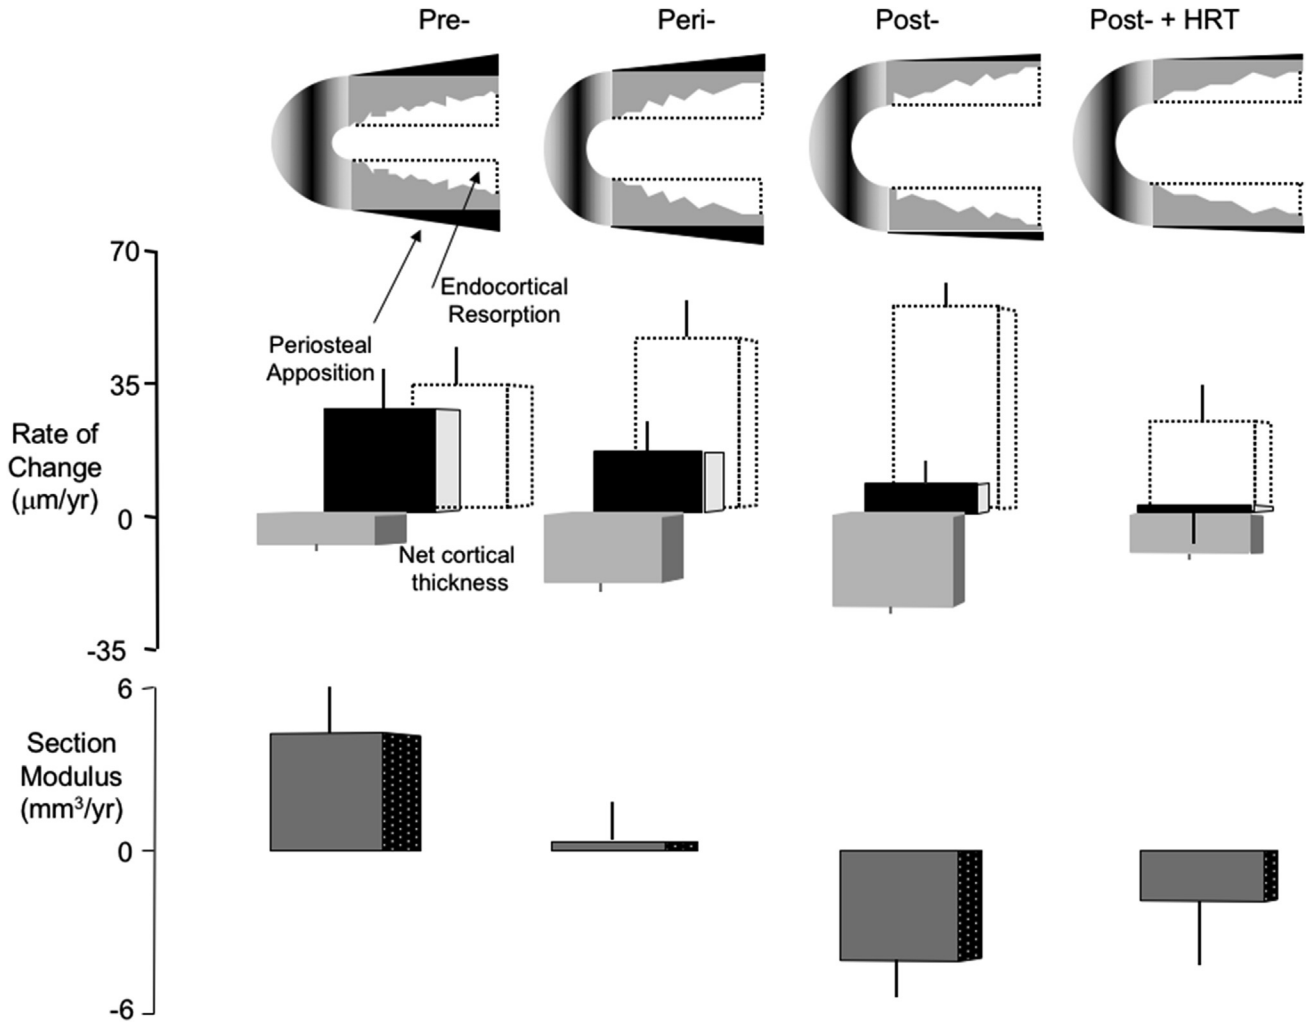

FIGURE 11.10 The amount of bone resorbed by endocortical resorption (*open bar*) increases with age. The amount deposited by periosteal apposition (*black bar*) decreases. The net effect is a decline in cortical thickness (*gray bar*). In premenopausal women, the thinner cortex is displaced radially, increasing section modulus (Z). In perimenopausal women Z does not decrease, despite cortical thinning, because periosteal apposition still produces radial displacement. In postmenopausal women, Z decreases because endocortical resorption continues, periosteal apposition declines, and little radial displacement occurs. In women treated with hormone replacement therapy (*HRT*), resorption is decreased with no effect on periosteal apposition. Z is less reduced than in untreated women. *Adapted from Szulc, P., Seeman, P., Duboeuf, F., Sornay-Rendu, E., Delmas, P.D., 2006. Bone fragility: failure of periosteal apposition to compensate for increased endocortical resorption in postmenopausal women. J. Bone Miner. Res. 21, 1856−1863.*

because resistance to bending is determined by the spatial distribution of the bone and increases as a fourth-power function of the radial distance a volume of bone is positioned from the neutral axis.

Endocortical resorption increased during the perimenopausal period, yet periosteal apposition decreased: it did not increase as expected if periosteal apposition is compensatory. The cortices thinned as periosteal apposition declined further. Nevertheless, bending strength remained unchanged, despite bone loss and cortical thinning, because periosteal apposition was still sufficient to shift the thinning cortex outward (Fig. 11.10).

Bone fragility emerged after menopause when acceleration in endocortical bone resorption and deceleration in periosteal apposition produced further net cortical thinning. As periosteal apposition was now minimal, there was little outward displacement of the thinning cortex, so cortical area now declined as did resistance to bending. Endocortical resorption was reduced but not abolished in women receiving hormone replacement therapy, while periosteal apposition was no different from that of untreated women; cortical thinning was reduced and the resistance to bending occurred, but less than in untreated women.

Periosteal envelope is not an exclusively bone-forming surface. During growth, bone resorption is critical for the in-wasting that produces the fan-shaped metaphyses (Rauch et al., 2001). Bliziotes and colleagues report that bone

resorption occurs in adult nonhuman primates (Blizoites et al., 2006). Femur specimens from 16 intact adult male and female nonhuman primates showed that periosteal remodeling of the femoral neck in intact animals was slower than in cancellous bone but more rapid than at the femoral shaft. Gonadectomized females showed an increase in osteoclast number on the periosteal surface compared with intact controls. If these data are correct, adult skeletal dimensions may decrease in size as age advances.

Sexual dimorphism in trabecular and cortical bone loss

A greater proportion of women than men sustain fragility fractures. Men have a larger skeleton than women so that resistance to bending is greater in men. Bone loss in both sexes is the result of remodeling imbalance but remodeling rate does not increase in midlife in men. If there is a transitory increase in the volume of bone resorbed by each BMU in women, this does not seem to be the case in men. So, trabecular thinning occurs in men, trabecular perforation with greater loss of trabecular strength occurs in women (Aaron et al., 1987; Van der Linden et al., 2001). Net trabecular bone loss across age is reported to be only slightly greater in women than in men (Riggs et al., 2004), or is similar (Aaron et al., 1987; Meunier et al., 1990; Kalender et al., 1989; Mosekilde and Mosekilde, 1990; Seeman, 1997; Seeman et al., 2001). However, measurement error is likely to produce this observation because greater intracortical remodeling with trabecularization of the cortex in women underestimates their loss of trabecular bone. Cortical porosity increases less in men than in women because remodeling rate is lower in men and so crack propagation in cortical bone is probably better resisted in men than in women. Research is needed because cortical porosity is underestimated by imaging methods that use threshold-based image analysis (Zebaze et al., 2013).

Thus, several methodological issues leave the question of the morphological basis of sex differences in bone fragility unanswered (Seeman et al., 2004). The absolute risks for fracture in women and men of the same age and BMD are similar (Kanis et al., 2001, 2005). If this is correct, then the reason fewer men than women suffer fractures in their lifetime is likely to be that fewer men than women have material and structural properties that cause bone fragility, such as high cortical porosity and low trabecular density. Structural failure occurs less often in men because the relationship between load and bone strength is better maintained in men than in women (Riggs et al., 2006; Bouxsein et al., 2006).

The heterogeneous material and structural basis of bone fragility in patients with fractures

Patients with fractures are grouped by having "one or more minimal trauma fractures" or sustaining a fall from "no greater than the standing position." However, the pathogenesis and structural basis of the bone fragility underlying the fractures are heterogeneous. Patients with fractures may have high, normal, or low remodeling rates (Brown et al., 1984; Arlot et al., 1990; Delmas, 2000). Some have a negative BMU balance due to reduced formation, increased resorption, or both, or no negative BMU balance (Ericksen et al., 1990). Some patients with fractures have increased, while others have reduced, matrix mineral density (Ciarelli et al., 2003) (Fig 11.11). Some patients have reduced osteocyte density, others do not (Qui et al 2003, 2005). Contemporary therapeutics gives no consideration to selecting a treatment based on the underlying pathogenesis or structural abnormalities of bone fragility. Consequently, there are no data to support the notion that selecting treatment according to the causes of bone fragility will lead to reducing the number needed to treat to avert one person from having a fracture.

Bone modeling, remodeling, and drug therapy

Antiresorptive therapy reduces the reversible but not the irreversible deficit in mineralized matrix volume

The effects of antiresorptive therapy are the reciprocal of the effects of menopause in several ways. When an antiresorptive agent is administered, the early accelerated increase in BMD is largely due to the rapid reduction in the reversible deficit in matrix and its mineral content. At the time of administration, the number of BMUs in their resorptive phase decreases in proportion to the antiresorptive efficacy of the drug. Bisphosphonates reduce remodeling by 50%–60% (as estimated using remodeling markers). The net effect of fewer new BMUs excavating resorption cavities and the many more resorption cavities excavated shortly before treatment concurrently entering their refilling phase is the rapid early net increase in BMD and reduction in cortical porosity reported during the first 6–12 months of treatment (Seeman, 2010).

The rise in BMD is often mistakenly interpreted as an increase in bone "mass" or "volume" and a restoration of microstructural deterioration. This is not the case; the incomplete refilling of cavities excavated just before treatment is the

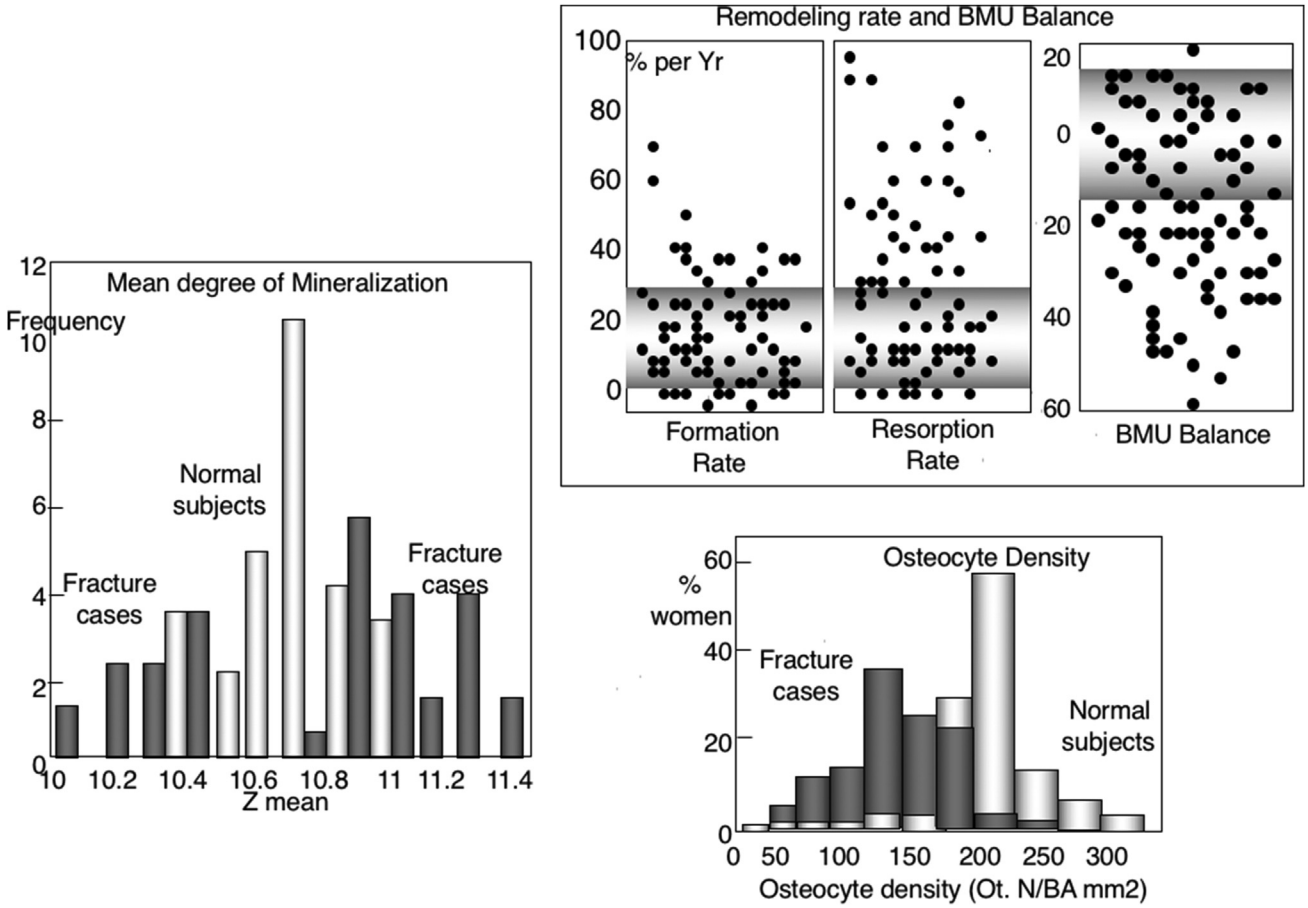

FIGURE 11.11 Bone fragility in patients with fractures has a heterogeneous pathogenesis and structural basis. Patients have tissue mineral density in the upper or lower part of the normal distribution. Some have reduced or normal osteocyte density. Formation and resorption rates may be lower normal or high; bone balance in the basic multicellular level (*BMU*) may be normal or negative. *Adapted from Ciarelli, T.E., Fyhrie, D.P., Parfitt, A.M., 2003. Effects of vertebral bone fragility and bone formation rate on the mineralization levels of cancellous bone from white females. Bone 32, 311–315. Qui, S., Rao, R.D., Saroj, I., Sudhaker, I., Palnitkar, S., Parfitt, A.M., 2003. Reduced iliac cancellous osteocyte density in patients with osteoporotic vertebral fracture. J. Bone Miner. Res. 18, 1657–1663. Eriksen et al. (1990).*

same in a treated and a placebo group. The reason BMD increases in the treated group is that fewer cavities are being excavated than are being incompletely refilled. BMD decreases in the control group because similar numbers of cavities are being excavated and incompletely refilled. In the treated group there is no change in the external or internal dimensions of bone; the periosteal perimeter does not increase, as occurs during growth or anabolic therapy; the endocortical perimeter does not decrease, as occurs during endocortical apposition using anabolic therapy; and trabeculae do not thicken.

There may be focal trabecular thickening at the remodeled location as incomplete refilling of the resorption cavity occurs due to the reversible component of the deficit. The irreversible deficit is not corrected, so that there is no focal restitution of the dimensions of a trabecular plate or cortical thickness to the level before menopause, because the remodeling imbalance is not corrected. Thickening above the premenopausal level would require overfilling of the resorption cavity. As antiresorptives may reduce the size of the resorption cavity, it is plausible that refilling or overfilling might occur (Allen et al., 2010). Even so, antiresorptives cannot reconstruct the skeleton because the remodeling rate is suppressed. Only about 5%–7% of the skeleton is remodeled annually.

The trabecular and cortical "thickening" often reported using imaging methods is an artifact produced by an increase in matrix mineral density (part of the reversible deficit in mineral), which leads to edge detection as photons are attenuated by the same deficit matrix that is now more densely mineralized (Seeman, 2010). Nevertheless, incomplete refilling of cavities may reduce stress risers and this may partly account for the rapid reduction in vertebral fracture risk achieved when remodeling is suppressed by antiresorptive agents.

As steady-state remodeling is restored at the new slower rate determined by the drug's antiresorptive efficacy, bone loss continues because the unsuppressed unbalanced remodeling continues to deteriorate the bone. Total bone matrix volume

decreases despite treatment. Moreover, matrix mineral density of the declining matrix volume increases due to continued secondary mineralization, which is part of the *reversible* deficit in *mineral*. So BMD continues to increase, obscuring the decrease in total bone matrix volume, and this increase may be mistaken as an increase in bone matrix mass or volume and a reversal of microstructural deterioration (Fig. 11.12).

The only antiresorptive that virtually abolishes bone loss is denosumab, because it is widely distributed and reduces osteoclast synthesis from its precursors and reduces the life span of osteoclasts existing at the time of treatment. Denosumab profoundly suppresses serum C-terminal telopeptide of type I collagen (CTX), so there is almost complete separation of the frequency distribution curves of serum CTX in treated and untreated subjects (Zebaze et al., 2014). This is not the case when alendronate is administered. About half of the women receiving alendronate had serum CTX no different from that of untreated controls, probably because of continued cortical bone loss despite alendronate treatment. Bisphosphonates bind avidly to mineral and fail to penetrate deep peri-Haversian cortical matrix (Smith, 2003). The concentrations of bisphosphonates are lower in cortical than in trabecular bone. When an osteoclast imbibes deeper cortical matrix its resorptive activity is not inhibited. In studies of nonhuman primates, ibandronate reduces remodeling upon endocortical and trabecular, but not Haversian canal, surfaces and improves trabecular, not cortical, bone strength (Smith et al., 2003).

As reported in human subjects and nonhuman primates, upon the return of steady state at a slow remodeling rate in the second 6 months of therapy, continued intracortical remodeling with alendronate probably accounts for cortical porosity no longer being lower than in controls by 12 months (Zebaze et al., 2014). With weak antiresorptive agents like calcium supplements or selective estrogen receptor modulators, the rate of remodeling is only modestly reduced relative to pretreatment, perhaps by 20%−30%; so after steady state is restored from its initial perturbed state, bone loss and microstructural deterioration continue, but only slightly more slowly than prior therapy (Reid et al., 2006; Silverman et al., 2012).

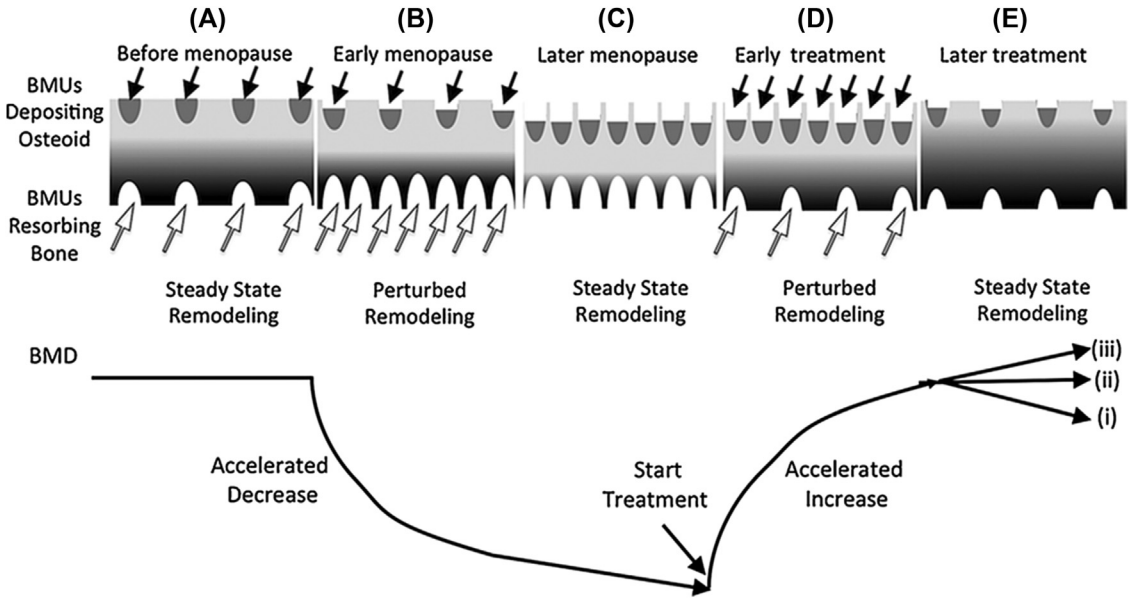

FIGURE 11.12 (A) Before menopause, remodeling is slow and in steady state. Similar numbers of sites are excavated (*white arrows*) and completely refilled (*black arrows*). No net bone loss occurs. (B) During early menopause, surface level remodeling is perturbed as more basic multicellular units (BMUs) resorb bone and each resorbs more bone (*white arrows*), while concurrently, the fewer cavities excavated before menopause now refill but do so incompletely (*black arrows*). Bone mineral density (*BMD*) decreases rapidly (bottom). (C) During later menopause, surface level remodeling returns to steady state but at a higher rate. The number of BMUs excavating bone approximately equals the number excavated in early menopause, only now refilling but doing so incompletely. Bone loss continues but more slowly. (D) During early antiresorptive therapy remodeling now becomes perturbed at the surface level but in a reciprocal fashion to early menopause. Fewer BMUs excavate smaller cavities (*white arrows*), while the many more BMUs excavating in later menopause refill incompletely (*black arrows*). BMD increases rapidly. (E) During later antiresorptive therapy, remodeling returns to steady state at the surface level at a slower rate, much like premenopause, but remodeling is unbalanced. The fewer and smaller cavities excavated during early antiresorptive treatment refill incompletely as similarly few new BMUs excavate smaller cavities. (i) If the negative BMU balance remains, BMD slowly declines from its higher level. (ii) If BMU balance is restored, there is no change in BMD. (iii) If remodeling remains unbalanced, secondary mineralization increases BMD, obscuring continued structural deterioration and the slow decrease in bone matrix volume.

With protracted remodeling suppression beyond the first 3 years, there is continued slow increase in BMD due to slow completion of secondary mineralization, which may take years (Akkus, 2004). Increases in matrix mineral density should become asymptotic with full mineralization of matrix after about 3−5 years of treatment (Dempster et al., 2018). During denosumab therapy there is continued increase in BMD reported after 5 years of treatment. This is not an anabolic effect of this antiresorptive agent. Studies of nonhuman primates suggest that age-related bone modeling upon the endocortical surface remains obscured by rapid remodeling prior to treatment and becomes detectable when remodeling is markedly suppressed by denosumab (Ominsky et al., 2015). Whether this occurs during treatment in human subjects remains uncertain.

Anabolic therapy: restoring the irreversible deficit in mineralized matrix volume and microstructural deterioration by remodeling- and modeling-based bone formation

Thus, the reversible deficit in matrix produced by the slowness of its deposition (∼3 months) and the slowness of matrix mineralization (taking ∼2 years), both respond to antiresorptive therapy. Slowing remodeling allows completion of the deposition of matrix and its complete mineralization. The irreversible deficit is not responsive to antiresorptive therapy. Reconstruction of the skeleton, "curing" bone fragility, requires anabolic therapy. Anabolic agents produce modeling- or remodeling-based bone formation.

Modeling-based bone formation occurs upon quiescent bone surfaces. Remodeling-based bone formation occurs within BMUs present at the time of treatment or by the initiation of new BMUs. Of necessity, the latter is preceded by the initial resorptive phase of remodeling removing mineralized bone by excavating a cavity within cortical bone or upon trabecular surfaces. Refilling of the cavity may correct the remodeling imbalance. If achieved, this will allow continued remodeling without causing microstructural deterioration. This will not reconstruct the skeleton.

Overfilling of existing and newly created cavities is needed to begin reconstruction of the skeleton, but this will result in focal reconstruction only. This approach is limited in scope because, at best, only 10%−20% of the skeleton is remodeled annually. Thus, reconstruction of an already deteriorated microstructure is a formidable challenge and probably requires sustained modeling-based bone formation.

Modeling upon the periosteal surface increases bone's total cross-sectional area, modeling upon the intracortical surface reduces intracortical porosity, modeling upon the endocortical surface thickens the cortex and increases its CSA. Modeling upon trabecular surfaces thickens them and may improve their connectivity, provided some connectivity is preserved at the time of treatment. Modeling upon surfaces of trabeculae abutting the cortex may "corticalize" them, thickening the cortex in a way that is the opposite of cortical trabecularization and cortical thinning from "within" the cortex during aging. Corticalization of trabeculae is similar to the formation of the metaphyseal cortex, which is the result of the coalescence of trabeculae emerging from the periphery of the growth plate (Cadet et al., 2003).

If successful, modeling produces an absolute increase in mineralized bone matrix volume, an increase in periosteal perimeter, a decrease in endocortical perimeter and medullary area, cortical thickening, a reduction in cortical porosity, and an increase in trabecular density. This differs from the increase in mineralized matrix density of a slowly diminishing total bone matrix volume produced by remodeling suppression using antiresorptive agents: both treatments increase BMD, but the morphological basis of the increase in BMD is of course very different and is likely to have different effects on bone strength.

About 80% of the total osteoid formed by parathyroid hormone (PTH) (1−34)- or PTH(1−84)-mediated bone formation is remodeling based. This is likely to be the same using abaloparatide, a peptide acting on the PTHR1 receptor that shares some of its amino acid sequence with PTH(1−34) and PTH-related protein (PTHrP) (Miller et al., 2016; Martin and Seeman, 2017). The proportion of the remodeling-based bone formation derived from anabolic agents acting on existing BMUs and newly generated BMUs resulting from PTH(1−34) treatment is uncertain, but the more rapid the remodeling, the greater the surface extent of remodeling, and the larger the number of existing BMUs at various stages of remodeling available to PTH.

During the resorptive phase of a remodeling cycle, PTH is likely to promote osteocyte and osteoblast precursor production of RANKL, osteoclastogenesis, bone resorption, and an increase in cortical porosity, until production of local factors from osteoclasts and the matrix they resorb influences bone formation. PTH acting on BMUs in their reversal phase may promote differentiation of osteoblast lineage cells into mature osteoid-producing forms. PTH acting on BMUs in their formation phase is likely to increase matrix production by inhibiting osteoblast apoptosis. Of necessity, BMU-based bone formation must follow resorption; the earlier increase in resorption markers is not a signal of the closure of a mythological "anabolic window." Excavated cavities upon endocortical or trabecular surfaces may refill or overfill, the latter thickening cortices and trabeculae focally.

Periosteal apposition is modest during adulthood and is advantageous because of the disproportionate increase in bending strength achieved by a small increment in bone diameter. However, there is no evidence that intermittent PTH produces measurable changes in periosteal circumference, even though there is evidence of increased apposition using quadruple labeling procedures (Lindsay et al., 2006).

Modeling-based bone formation upon intracortical canal surfaces may reduce canal diameter focally. However, many studies suggest that cortical porosity increases during early intermittent PTH therapy. Even though this increase in porosity is likely to be transient, bone fragility may increase transiently. Whether this occurs is not known. Trabecular thickening is likely to increase connectivity, provided some connectivity is present, but thickening may remain undetected by noninvasive imaging methods (that depend on photon attenuation by mineral) because replacement of older mineralized matrix with newly synthesized osteoid transmits rather than attenuates photons.

Abaloparatide, a peptide with partial amino acid homology to PTH(1−34) and PTHrP, has been reported to reduce the incidence of vertebral and nonvertebral fractures (Miller et al., 2016). There is no evidence quantifying the proportions of any anabolic effect due to existing BMUs at the time of treatment, newly generated BMUs in response to treatment, or modeling-based bone formation. A claim is made that the anabolic effect occurs with relatively less resorptive effect than observed using PTH(1−34). This is partly based on finding less of an increase in serum CTX relative to the increase in procollagen type 1 N-terminal propeptide (P1NP) in clinical trials in human subjects. The higher ratio of P1NP to CTX is inferred to be a surrogate of greater net bone formation relative to resorption, which in turn is responsible for the 1%−2% greater gain in BMD with abaloparatide than with PTH(1−34). These inferences are problematic for several reasons that are discussed elsewhere (Seeman, 2016; Martin and Seeman, 2017).

About 80% of the intracortical, endocortical, and trabecular components of the endosteal surface are quiescent and provide a vast surface area upon which osteoid can be deposited. Sclerostin antibodies (Scl-Abs) like romosozumab block the action of sclerostin, an inhibitor of bone formation. The anabolic effect is largely modeling based and is accompanied by a transient reduction in circulating serum CTX, suggesting that there is also a reduction in bone resorption. Ominsky et al. (2017) quantified the bone modeling and remodeling activity on bone surfaces in OVX rats administered vehicle or Scl-Ab (25 mg/kg) twice a week for 5 weeks, and in adolescent cynomolgus monkeys administered vehicle or Scl-Ab (30 mg/kg) subcutaneously every 2 weeks for 10 weeks. In OVX rats, Scl-Ab increased modeling eightfold from 7% to 63% of the bone surface. In cynomolgus monkeys, Scl-Ab increased modeling-based formation on trabeculae from 0.6% to 34% and on the endocortical surface from 7% to 77%. Scl-Ab did not increase remodeling-based bone formation despite decreased resorption surface in both species.

These observations have been confirmed by unpublished data reported by Chavassieux et al. (JBMR, 2019). The effects of 210 mg romosozumab on iliac crest histomorphometry at 2 and 12 months in postmenopausal women with osteoporosis were reported. For histomorphometry, 29 women had quadruple labeling at 2 m and 70 double labeling at 12 m. For microcomputed tomography (microCT), 28 women were evaluable at 2 m, and 71 at 12 m. At 2 months, bone formation rate increased in cancellous bone by 328% and by 233% upon endocortical surfaces. At 2 and 12 months, eroded surface decreased in cancellous and endocortical bone. At 12 months, wall thickness, bone mass, and trabecular and cortical thickness increased with romosozumab. At 2 months, microCT showed a decrease in trabecular separation; at 12 months, trabecular BMD, matrix density, and bone volume increased. There is robust evidence of vertebral and nonvertebral fracture risk reduction that appears to be more effective than that obtained with antiresorptive therapy or PTH(1−34) (Saag et al., 2017; Kendler et al., 2018). Details of the anti-fracture efficacy are presented elsewhere (Reid, 2015; Ramchand and Seeman, 2018).

Combined antiresorptive and anabolic therapy

Combining antiresorptive and anabolic therapy makes sense. The justification for any additional cost and exposure to the side effects of two drugs is evidence of greater fracture risk reduction than achieved by either drug alone. A prospective randomized blinded placebo-controlled trial is a formidable challenge to execute and has never been done. A lower level of evidence comes from animal experiments demonstrating that combined therapy increases the breaking strength of bone ex vivo more greatly than either drug alone. Only one study comparing PTH(1−34)/alendronate and PTH(1−34)/osteoprotegerin (OPG) versus PTH(1−34) alone has been reported. While trabecular bone volume increased more greatly than PTH(1−34) alone, bone strength assessed ex vivo in this study of rodents was not greater than that produced by PTH(1−34) alone (Samadfam et al., 2007).

Short of evidence of improved bone strength is morphological data showing that combined therapy produces a greater net increase in the volumes of bone deposited upon the periosteal surface and the three (intracortical, endocortical, and trabecular) components of the endosteal surface than therapy with either drug alone. Combined therapy has not been

reported to produce a greater periosteal perimeter, a smaller endocortical perimeter, increased cortical thickness and area, lower cortical porosity, or thicker, more connected, or greater numbers of trabeculae than therapy with either drug alone.

Most comparator studies have been done using changes in BMD, bone remodeling markers, or bone microstructure as the outcome. This approach is fraught with challenges because a change in BMD may be the result of a change in bone matrix volume, its mineral content, or both, and often, these traits change in the opposite direction, even with single therapy. For example, antiresorptives slow unbalanced remodeling; matrix volume continues to decrease and microstructure continues to deteriorate, but matrix mineral density increases, producing a net increase in BMD of the deteriorating structure. PTH(1−34) increases bone matrix volume but decreases its matrix mineral density as remodeling-based bone formation replaces older more mineralized bone with younger less mineralized bone. BMD has been reported variously to increase, decrease, or remain unchanged. Thus, the behavior of these traits even during single-drug therapy makes inferences about the effects on bone strength challenging, but more so when these drugs are combined.

Indeed, combined therapy has been reported to blunt the BMD response to PTH in some, but not all, studies. Blunting is held to be due to antiresorptive treatment suppressing remodeling so that remodeling-based bone formation by PTH(1−34) is prevented. Scrutiny of the data does not support this notion. If blunting of the BMD response was due to fewer BMUs, then blunting should be *more* severe with coadministration of PTH(1−34) with zoledronate, denosumab, or OPG than with alendronate. The opposite is reported (Tsai et al., 2015), and many studies report additive effects (Seeman and Martin, 2015). Blunting is not *greater* with denosumab/PTH(1−34) than with alendronate/PTH, even though denosumab suppresses remodeling more greatly than alendronate. Additive effects on BMD are reported with PTH/denosumab relative to PTH(1−34) alone (Tsai et al., 2015; Leder et al., 2014) and comparing PTH/OPG versus PTH (Kostenuik et al., 2001).

The difficulties using bone densitometry are only partly overcome by independently measuring changes in matrix mineral density and microstructure, because image acquisition and analysis using high-resolution peripheral computed tomography also depends on photon attenuation by a region's mineral content. Challenges in the interpretation of the effects of combined therapy are illustrated in the study by (Tsai et al., 2015; Leder et al., 2014).

These investigators report that combined therapy increased cortical vBMD. However, PTH reduced cortical vBMD, while denosumab had no detectable effect, leaving unexplained the increased cortical vBMD using combined therapy. Combined therapy increased cortical matrix mineral density, yet PTH decreased it, and denosumab had no detectable effect, again leaving unexplained the increased cortical matrix density using combined therapy. Combined therapy had no effect on porosity, yet PTH increased it, while denosumab had no detectable effect, leaving the combined effect unexplained. Finally, combined therapy increased cortical thickness, PTH had no detectable effect, but denosumab increased it; the opposite of what was expected.

The findings reasonably to be expected are as follows: for cortical vBMD combined therapy should have no net effect, because PTH increases porosity and reduces matrix mineral density; denosumab does the reverse. Combined therapy therefore should also have no net effect on cortical porosity or matrix mineral density, but should increase cortical thickness. Failure to detect an increase in cortical thickness is probably the result of replacement of mineralized bone with younger bone. Finding an increase in cortical thickness with denosumab is likely to be due to an edge detection error, as antiresorptives increase matrix mineral density, they do not thicken cortices. Most pores are <100 μm. At a resolution of 130 μm, voxels containing a pore or part of a pore also contain matrix and so attenuate photons above the threshold designated as "porosity."

Conclusion

Deterioration of the cellular machinery of modeling and remodeling compromises the many qualities of bone conferred by its material composition and structural design. For the past 60 years, the bone strength conferred by these qualities and the bone fragility resulting from their deterioration have been inferred using BMD. This was a good beginning because it provided a quantitative measure of fracture risk, but BMD is insensitive; most fractures occur in individuals with modest deficits in BMD. These individuals have fragile bones caused by microstructural deterioration. BMD does not capture this fragility because the loss of strength produced by microstructural deterioration is disproportionate to the bone loss producing it and the modest reductions in BMD. There is progress in image acquisition and quantification of microstructure, but whether measurement of microstructural deterioration improves detection of individuals at imminent risk for a first fracture and whether treatment allocation based on the severity of microstructural deterioration reduces the number of persons that need to be treated to avert one event remain unknown. Answers to these questions are needed because longevity and the burden of fractures are increasing. Antiresorptive agents neither reverse existing microstructural deterioration nor abolish its progression. These drugs only slow continued microstructural deterioration and reduce vertebral

and hip fracture risk by ~50%. For nonvertebral fractures, 80% of all fractures, the risk reduction is only 20%–30%. Teriparatide, the only anabolic agent widely available for clinical use, produces predominantly remodeling-based bone formation and transitory cortical porosity but may have better vertebral and nonvertebral anti-fracture efficacy than antiresorptives. The recently marketed abaloparatide reduces vertebral and nonvertebral fractures and is also likely to produce remodeling-based bone formation. Neither drug reduces the risk of hip fracture, the most devastating fracture. Modeling-based bone formation using romosozumab, an Scl-Ab, has antivertebral and nonvertebral fracture efficacy within 12 months. Whether anabolic agents in combination with antiresorptive agents offer better anti-fracture efficacy than either drug alone is not known. The challenge of reducing the burden of fractures remains an unmet need.

Chapter outline

Characteristics of the aged skeleton

Human

The proportion of elderly humans among the global population is now higher than at any time in history. Old age is a major risk factor for several chronic diseases, including osteoporosis, and increases exponentially the risk of fractures (Almeida et al., 2017; Niccoli and Partridge, 2012). Soon after the attainment of peak bone mass the balance between bone formation and bone resorption begins to progressively tilt in favor of the latter, in both women and men (Looker et al., 1998). This process is slowed by the presence of sex steroids and accelerates following menopause. The rate of bone loss due to the menopause is followed, within 5−10 years, by a slower phase of bone loss (Black and Rosen, 2016; Seeman, 2013). This later phase occurs also in men and causes structural deterioration of cortical bone, a significant portion of which is due to increased intracortical porosity (Bala et al., 2015). Postmenopausal women have greater cortical porosity than men over the age of 50 (Nirody et al., 2015; Shanbhogue et al., 2016). It is unknown, however, whether this difference is due to decreased estrogen levels. Importantly, about 80% of fractures occur in the appendicular skeleton, at regions containing large amounts of cortical bone.

A histological hallmark of aged human bone is decreased wall width, an index of the reduced amount of work performed by teams of osteoblasts (Lips et al., 1978; Parfitt, 1990). This is due primarily to an insufficient number of osteoblasts relative to the need for the replacement of bone created by increased osteoclastic resorption (Manolagas, 2000). Another common histologic feature of aged human bone is decreased osteocyte density (Manolagas and Parfitt, 2010; Qiu et al., 2002b). The decrease in osteocyte lacunar density in cortical bone with age correlates with microcrack accumulation (Vashishth et al., 2000). In contrast, a dense osteocyte network is associated with better bone material quality (Kerschnitzki et al., 2013). Mineralization of osteocyte lacunae, a process known as micropetrosis, may contribute to the decrease in osteocytes with age (Busse et al., 2010; Frost, 1960). Micropetrosis may be one potential outcome of osteocyte death; however, the conditions that cause it are unclear. Be that as it may, it is now abundantly clear that the integrity or lack thereof of the osteocyte network plays a major role in skeletal health and disease.

Rodents

Like humans, both female and male mice lose bone mass and strength with age. Aging female mice do not experience menopause, but become acyclic while retaining functional levels of estrogens (Almeida et al., 2017; Ucer et al., 2017). Androgen levels in aged male mice are maintained at a 20-fold higher level than in females (Nilsson et al., 2015). Yet, both female and male mice exhibit all of the major features of skeletal aging, including the decline of cancellous and cortical bone mass and the development of cortical porosity by 18 months of age (Almeida et al., 2007b; Ferguson et al., 2003; Glatt et al., 2007; Halloran et al., 2002; Jilka et al., 2010; Ucer et al., 2017). In C57BL/6J (B6) mice the accrual of bone mass occurs up to 6−7 months of age, and soon after bone mineral density starts to slowly decline at a constant rate until the end of life. Micro-computed tomography (microCT) analysis performed at about 12 months (equivalent to 40 years in humans; Dutta and Sengupta, 2016) shows that the marrow begins to expand and additional bone is slowly added to the periosteum, but the former exceeds the latter, leading to a thinner and more fragile cortex. The number of osteoclasts also decreases in cancellous bone with advancing age.

The structural and cellular features of aged bone in mice have been well characterized. Old age causes a decline in osteoblast number, bone formation rate, and wall width, which is seen in cancellous and endocortical bone surfaces of both female and male mice (Almeida et al., 2007b; Tiede-Lewis et al., 2017; Ucer et al., 2017). Osteoclast number, however, also declines with age in the cancellous compartment (Almeida et al., 2007b). Thus, an insufficient number of osteoblasts must be the key mechanism for the unbalanced remodeling and the age-dependent loss of cancellous bone.

It has been argued earlier that the endosteal surface of adult mice undergoes osteoclastic modeling but not basic multicellular unit (BMU)-based remodeling. Several lines of evidence refute this idea. Specifically, the endosteal surface of both 7- and 21-month-old B6 mice exhibits scalloped cement lines, which are associated with fluorochrome labeling, indicating that BMU-based remodeling of the endosteal surface persists with advancing age. Moreover, administration of osteoprotegerin to adult mice ablates both endosteal bone resorption and formation. The same is true in adult rats, as shown by histologic analysis of 12-month-old female Fischer-344 rats (Erben, 1996) and a strong inhibitory effect of risedronate on endosteal fluorochrome labeling in 15-month-old ovariectomized Sprague−Dawley rats (Baumann, 1995). The loss of bone at the endosteal surface is caused by inadequate filling of resorption cavities due to an increase in osteoclasts and decrease in osteoblasts (Li et al., 2015; Ucer et al., 2017). As is the case in humans (Han et al., 1997; Power et al., 2003), cortical thinning with aging in mice is due to loss of bone from the endosteal surface that exceeds the amount of bone added to the periosteal surface.

Another feature of skeletal aging in both female and male mice is an increase in cortical porosity (Ferguson et al., 2003; Jilka et al., 2014; Tiede-Lewis et al., 2017). Like humans, aged female mice exhibit higher cortical porosity than aged males (Piemontese et al., 2017). In female B6 mice, the number and size of pores are much higher in the femoral cortex of 21-month-old mice than in 7-month-old young adults. Large pores are especially prominent in the metaphyseal cortex. Unbalanced remodeling is most evident near the endosteal surface and leads to the penetration of the endosteal boundary and the trabecularization of the endocortical part of the cortex, similar to the situation in humans. In young adult mice, cortical capillaries formed during development persist in the cortex, and osteons arise only occasionally from these capillaries (Piemontese et al., 2017; Schneider et al., 2009). With advancing age, however, osteons exhibit several histologic hallmarks of remodeling activity, including osteoclasts and fluorochrome-labeled bone matrix adjacent to scalloped cement lines. Histologic and microCT imaging studies in aged mice suggest that new osteons may arise from preexisting cortical capillaries, from redirection of endosteal BMUs from the endosteal surface into the cortex in tandem with vascular invasion from the marrow, or from both mechanisms. However, murine osteons do not exhibit the numerous concentric lamellae that characterize the much larger osteons of human bone. Instead, they resemble rabbit osteons (Pazzaglia et al., 2015). The highly organized networks seen in humans are not present in murine osteons, perhaps due to the lack of a preexisting haversian system. Nevertheless, this is probably a consequence of body size rather than phylogenetic determinants.

Interestingly, genetic background greatly influences the gain or loss of murine cortical bone mass during growth, in old age, or following sex steroid deficiency (Li et al., 2005; Piemontese et al., 2017; Price et al., 2005). In contrast, genetic background does not influence trabecular bone loss (Piemontese et al., 2017). This and the evidence that an increase in bone resorption accounts for the loss of cortical, but not cancellous, bone with age, indicates that distinct molecular mechanisms underlie the age-dependent dysregulation of endosteal and trabecular remodeling in mice.

Bone cell aging

Cellular aging is frequently described as a decline in function due to the accumulation of damage to lipids, proteins, and DNA (Droge, 2002). Damage of long-lived cells, together with the cellular response to damage, is thought to be involved

in the functional deterioration of many tissues with advancing age (55). Mesenchymal progenitors and osteocytes are long-lived cells and, most likely, are more prone to suffer the damaging effects of aging. The declining osteoblast number in the aging skeleton has been attributed to a decrease in the number of mesenchymal stem cells (MSCs), defective proliferation/differentiation of progenitor cells, or diversion of these progenitors toward the adipocyte lineage (Almeida and O'Brien, 2013; Kassem and Marie, 2011).

The loss of functional adult stem/progenitor cells (Rossi et al., 2008; Sharpless and DePinho, 2007) might contribute to the defective regenerative capacity of different tissues with age. Indeed, old mice exhibit a reduction in the number, proliferative capacity, or differentiation potential of distinct stem cells such as germ-line (Ryu et al., 2006; Zhang et al., 2006), neuronal (Kuhn et al., 1996; Molofsky et al., 2006), hematopoietic (Morrison et al., 1996), and muscle progenitor cells (Conboy et al., 2003; Shefer et al., 2006). Genetic mutations, epigenetic changes, and the extrinsic environmental milieu alter stem cell function with aging (Goodell and Rando, 2015).

Osteocytes orchestrate bone resorption and formation via the production of receptor activator of nuclear factor κB (NF-κB) ligand (RANKL), sclerostin (Sost), and other factors. Osteocytes formed during growth are still present in the cortical bone of skeletally mature and of aged mice (Piemontese et al., 2017). Findings indicate that aging of osteocytes can affect their expression profile and, consequently, alter both bone resorption and bone formation (Farr et al., 2016; Piemontese et al., 2017).

Osteoblast progenitors

MSCs are generally defined by their ability to self-replicate and differentiate into chondrocytes, osteoblasts, and adipocytes (Caplan, 1991; Friedenstein et al., 1974). MSCs are found in the bone marrow and in the perivascular niche in multiple human organs (Crisan et al., 2008). Mesenchymal cells in the bone marrow of long bones in mice express smooth muscle α-actin, myxovirus resistance-1, leptin receptor, and/or collagen II, and give rise to osteoblasts on the bone surfaces (Grcevic et al., 2012; Ono et al., 2014; Park et al., 2012; Zhou et al., 2014). Of note, cells expressing leptin receptor are the source of the majority of osteoblasts and osteocytes in adult mice. However, the effects of aging in these or other adult skeletal MSC populations remain unknown.

Because of the very limited number of MSCs, and the laborious procedures required to isolate pure populations, cultures of bone marrow stromal cells from humans and rodents are commonly used as surrogates for progenitor cells. These cultures have been used to elucidate changes in MSCs with aging in both humans and rodents (Coipeau et al., 2009; Kasper et al., 2009; Sethe et al., 2006; Stenderup et al., 2003). Changes in the behavior of bone marrow−derived MSCs with aging, such as loss of potential to proliferate and differentiate, loss of capacity to form bone in vivo, and increased senescence, have been also reported (Coipeau et al., 2009; Kasper et al., 2009; Sethe et al., 2006; Stenderup et al., 2003). Multipotent cells derived from adipose tissue similarly show an age-dependent loss of self-renewal capacity as well as an increased propensity for adipogenesis (Huang et al., 2010). Furthermore, cultures of MSCs from patients with Hutchinson−Gilford progeria syndrome, a disease characterized by accelerated aging, exhibit defective ability to differentiate (Scaffidi and Misteli, 2008). Similar findings have been reported in murine models of progeria (Chen et al., 2013; Diderich et al., 2012).

The transcription factor Osterix1 (Osx1) is required for osteoblast differentiation. Bone marrow mesenchymal progenitor cells expressing Osx1 give rise to all osteoblast and adipocytes in bone (Horowitz et al., 2017; Xiong et al., 2011), suggesting that expression of Osx1 marks a bipotent progenitor. In a mouse model in which Osx1-expressing cells are labeled with a fluorescent protein, the number of these cells in the bone marrow greatly decreases between adulthood and old age (Kim et al., 2017). Moreover, the cells from old mice exhibit decreased proliferation and several markers of cellular senescence, as determined in freshly isolated cells. Notably, the decline in the number of Osx1-expressing cells with age is associated with a decrease in type H capillaries at the distal end of the arterial network, which are critical for the maintenance of perivascular osteoprogenitors (Kusumbe et al., 2014). Aging leads to an increase in the expression of peroxisome proliferator-activated receptor γ—the master transcription factor for adipogenesis—in Osx1-expressing progenitor cells (Kim et al., 2017), in line with their propensity to differentiate toward adipocytes. Indeed, an increase in marrow adipocytes is a well-established consequence of skeletal aging in humans and mice (Horowitz et al., 2017). It remains unclear, however, whether any of the changes noted in osteoblast progenitors contribute to the decrease in bone formation with age and whether they are functionally related to skeletal involution.

Osteocytes

Depending on their anatomical location, osteocyte life span in humans can range from a few months to several decades. Osteocytes are as old as the bone matrix in which they are embedded and this depends on the rate of remodeling at that site.

Within cancellous bone and remodeling cortical bone, a subset of osteoblasts becomes embedded in bone matrix with each remodeling cycle, thereby generating a fresh population of osteocytes within the new packet of bone. Osteocytes near the periosteum are derived from the osteoblasts that continuously expand the periosteum via modeling. As mentioned earlier, osteocyte survival and number decline with age in rodents and humans (Jilka et al., 2013; Noble et al., 1997; Qiu et al., 2002a). In aged mice, there is a concomitant and dramatic decrease in dendrite number per osteocyte. This effect is more severe in females compared with males (Tiede-Lewis et al., 2017). A loss of dendrites with age is also seen in neuronal cells and is associated with impaired nervous system function in a variety of disorders such as Parkinson's and Alzheimer's disease (Koleske, 2013; McNeill et al., 1988). Dendrite loss in neuronal disorders has been linked to defective autophagy (Coleman, 2013; Tang et al., 2014). Interestingly, young mice with defective autophagy in osteocytes show an aging bone phenotype, including reduced trabecular and cortical bone volume, increased cortical porosity, and loss of dendrites (Piemontese et al., 2016). Nevertheless, it remains unknown whether loss of dendrites is causally related to the low bone mass in this model or in wild-type aged mice.

Because of the difficulty in isolating pure populations of osteocytes, there has been little quantitative information on molecular damage in osteocytes from aged mice. Based on the evidence that osteocytes control bone resorption via RANKL and bone formation via sclerostin, reduced osteocyte number might lead to altered production of these factors, leading to changes in bone remodeling. The levels of sclerostin decrease in cortical bone with age (Piemontese et al., 2017). However, the low sclerostin levels should promote Wnt signaling and thereby osteoblast formation; yet osteoblast number is reduced with age. In contrast to sclerostin, RANKL expression levels in cortical bone increase with age, consistent with the increase in endocortical bone resorption. The increase of RANKL along with an increase in other cytokines, chemokines, and metalloproteinases indicates that aging alters the synthetic capacity of osteocytes.

Although the cellular and molecular mechanisms responsible for the increase in cortical porosity with age remain unclear, there is evidence to suggest that osteocytes are the mediators of this effect. Increased osteocyte apoptosis, perhaps in response to age-dependent bone microdamage, is thought to contribute to the development of cortical porosity (Bentolila et al., 1998; Cardoso et al., 2009; Jilka and O'Brien, 2016). This notion is based on evidence that apoptotic osteocytes release factors that stimulate RANKL production by neighboring viable osteocytes. The age-dependent increases in RANKL and cortical porosity are exacerbated in female mice with apoptosis-resistant osteocytes (Jilka et al., 2014), probably due to accumulation of damaged osteocytes that cannot complete the apoptotic death program. Senescent osteocytes might be also involved in the activation of de novo intracortical remodeling via the senescence-associated secretory phenotype (SASP) (see section on "Cellular senescence"). As of this writing, there is no explanation for the lower porosity in male compared with female mice, in the face of a seemingly equivalent increase in osteocyte senescence in both sexes. Similarly, the highly variable magnitude and preferential development of cortical porosity near the metaphyses remain unexplained. In addition, it remains unclear why these mechanisms have different effects on the rate of remodeling in cancellous versus cortical bone.

Molecular mechanisms of aging

The time-dependent accumulation of cellular damage is widely considered the general cause of aging (Gems and Partridge, 2013; Lithgow and Kirkwood, 1996; Vijg and Campisi, 2008). Nevertheless, the sources of aging-caused damage, the compensatory responses that attempt to reestablish homeostasis, the interconnection between the different types of damage and compensatory responses, and the optimal means to intervene exogenously to delay aging remain unknown. Nonetheless, several cellular and molecular hallmarks of aging have been identified (Kennedy et al., 2014; Lopez-Otin et al., 2013). A hallmark should ideally fulfill the following criteria: it should manifest during normal aging, its experimental aggravation should accelerate aging, and its experimental amelioration should delay aging. Below, we review evidence that aging hallmarks such as mitochondrial dysfunction, cell senescence, and loss of proteostasis contribute to skeletal involution with old age.

Mitochondrial dysfunction

The mitochondrial free radical theory of aging proposes that as cells and organisms age, the efficacy of the respiratory chain diminishes, thus reducing ATP generation and increasing electron leakage and production of reactive oxygen species (ROS) (Green et al., 2011; Harman, 1956). The respiration-produced free radicals cause damage to macromolecules, resulting in cellular and tissue loss of function observed during aging (Balaban et al., 2005; Droge, 2002). The majority of cellular ROS are generated by the mitochondria during oxidative phosphorylation. H_2O_2 is the most stable and abundant form of ROS and is produced from the conversion of superoxide by superoxide dismutase enzymes (Balaban et al., 2005;

Chance et al., 1979; D'Autreaux and Toledano, 2007). ROS are also produced in other cellular compartments by NADPH oxidases, lipoxygenases, and other enzymes, in response to growth factors and cytokines (Janssen-Heininger et al., 2008). To prevent excessive ROS production, cells scavenge ROS by multiple mechanisms, including superoxide dismutases and catalase as well as thiol-containing oligopeptides with redox-active sulfhydryl moieties. The most abundant of the last are glutathione and thioredoxin (Dickinson and Forman, 2002).

Several lines of evidence have called into question the idea that an increase in ROS limits life span at the organismal level. Specifically, mouse models of increased mitochondrial ROS and oxidative damage do not exhibit accelerated aging (Van Remmen et al., 2003; Zhang et al., 2009). In addition, increased ROS may prolong life span in lower organisms (Doonan et al., 2008; Mesquita et al., 2010). In line with these observations, ROS can trigger proliferation and survival in response to physiological signals and stress conditions (Sena and Chandel, 2012). Nevertheless, many other studies indicate that oxidative stress is responsible for age-related pathologies, including diabetes, cardiovascular disease, cancer, and neurodegeneration (Dai et al., 2014; Lee et al., 2010; Schriner et al., 2005; Wanagat et al., 2010). A reevaluation of these apparent contradictory lines of evidence posits that the primary effect of ROS is the activation of compensatory homeostatic responses. Above certain threshold levels, ROS betray their original homeostatic purpose and exacerbate, rather than ameliorate, the age-associated damage (Hekimi et al., 2011; Salmon et al., 2010). This new conceptual framework accommodates seemingly conflicting evidence regarding the positive, negative, or neutral effects of ROS on aging.

It has been well established that ROS play a role in osteoclast differentiation and bone resorption (Garrett et al., 1990). RANKL and macrophage colony-stimulating factor—the two critical cytokines for osteoclast generation—promote mitochondrial biogenesis and the accumulation of H_2O_2 in osteoclasts, and H_2O_2 stimulates osteoclastogenesis (Bartell et al., 2014; Garrett et al., 1990; Ha et al., 2004; Ishii et al., 2009; Lee et al., 2005). The increase in H_2O_2 by proosteoclastogenic cytokines is due to an Akt-mediated inhibition of FoxO transcription factors, which causes a decrease in the expression of antioxidant enzymes (Bartell et al., 2014; Liu et al., 2005; Tan et al., 2015). Importantly, lowering H_2O_2 generation in osteoclasts, by overexpressing human catalase targeted to the mitochondria, reduces osteoclast numbers and increases bone mass (Bartell et al., 2014).

As in other tissues, skeletal aging is associated with an increase in ROS levels in bone cells (Almeida et al., 2007b; Jilka et al., 2010; Lean et al., 2003, 2005; Manolagas, 2010). The loss of bone mass caused by sex steroid deficiency in mice is also associated with an increase in ROS (Almeida et al., 2007b; Lean et al., 2003; Manolagas, 2010; Yamasaki et al., 2009). These findings raised the possibility that elevated ROS may be a common mechanism of the adverse effects of sex steroid deficiency and old age on bone; and that sex steroid deficiency may accelerate the effects of aging. Studies involving administration of antioxidants or decreasing mitochondrial levels of H_2O_2 (by expressing a mitochondria-targeted catalase transgene) have revealed that mitochondrial ROS are required for the increase in osteoclast number and the loss of bone caused by ovariectomy or orchidectomy. Surprisingly, however, mitochondrial ROS in osteoclasts do not contribute to the adverse effects of aging on either cortical or cancellous bone. Attenuation of H_2O_2 generation in cells of the mesenchymal lineage, on the other hand, ameliorates the age-dependent decline in mineralizing surfaces and prevents the loss of cortical bone. Together, these studies have indicated a major role of ROS in the bone loss associated with aging and estrogen deficiency. Yet, the evidence that distinct cell types are implicated in the effects of ROS within each condition suggests that the cellular and molecular mechanisms responsible for the loss of bone mass with aging and estrogen deficiency are distinct.

Oxidative stress decreases the life span of an osteoblast, as evidenced by the observation that administration of antioxidants abrogates osteoblast apoptosis in ovariectomized or aged mice (Almeida et al., 2007b; Jilka et al., 2010). ROS also inhibit the Wnt/β-catenin signaling pathway, which is indispensable for osteoblastogenesis during development and adulthood (Baron and Kneissel, 2013). Wnt proteins bind to the Frizzled/low-density lipoprotein (LDL) receptor—related protein 5 (LRP5) or LRP6 receptor complex, thereby preventing the degradation of the transcriptional coactivator β-catenin (Clevers and Nusse, 2012). In the nucleus β-catenin associates with the T cell factor (TCF) lymphoid-enhancer binding factor family of transcription factors and regulates the expression of Wnt target genes. In the setting of oxidative stress or nutrient depletion, FoxOs divert the limited pool of active β-catenin from TCF- to FoxO-mediated transcription in diverse cell types, including osteoblasts, colon cancer cells, and hepatocytes (Almeida et al., 2007a; Hoogeboom et al., 2008; Liu et al., 2011). In murine models of targeted deletion of FoxOs in osteoblast progenitors FoxOs restrain the pro-proliferative effects of Wnt signaling and attenuate bone formation (Iyer et al., 2013). Likewise, FoxOs in enteroendocrine progenitors or in neuronal progenitors suppress β-catenin/TCF-mediated transcription and proliferation (Paik et al., 2009; Talchai et al., 2012). Thus, diversion of β-catenin from TCF- to FoxO-mediated transcription in response to stressful conditions, such as increased ROS and growth factor deficiency, may represent a pathogenetic mechanism for osteoporosis. Support for this idea is provided by the evidence that mice that lack FoxOs in the osteoblast lineage maintain high bone mass throughout life (Iyer et al., 2013).

Cellular senescence

Cellular senescence is a process in which cells stop dividing and initiate a gene expression pattern known as SASP (Campisi, 2013; Kuilman et al., 2010; Lopez-Otin et al., 2013; Newgard and Sharpless, 2013). An increase in senescent cells occurs in most tissues with age; however, its impact on age-related diseases and longevity has remained unknown until recently. Senescent cells can be identified by several features, including cell cycle arrest, DNA damage foci that contain phosphorylated histone H2AX, activated ataxia−telangiectasia mutated (ATM) kinase ATM(Ser^{1981}), p53 binding protein, activated p53 (phospho-Ser^{15}), elevated levels of the cell cycle inhibitor $p21^{CIP1}$ or $p16^{INK4a}$, and high senescence-associated β-galactosidase activity. Although none of these markers is, in and of itself, specific or universal for all senescent types, there is a clear consensus that senescent cells express most of them (Campisi, 2013; Childs et al., 2015; Munoz-Espin and Serrano, 2014). Another characteristic of senescent cells is a resistance to apoptosis. Notably, postmitotic cells also exhibit key characteristics of senescence. For example, neurons in various parts of human and mouse brains are known to accumulate high amounts of DNA damage (Sedelnikova et al., 2004) along with other senescence-associated markers, including heterochromatinization, accumulation of GATA4 and activation of NF-κB, synthesis of proinflammatory interleukins, and senescence-associated β-galactosidase activity (Jurk et al., 2012). Senescence-like features are similarly seen in adipocytes of mice on a high-fat diet (Minamino et al., 2009).

Selective elimination of senescent cells expressing p16 in mice, through an INK-ATTAC or p16-3MR transgene, has revealed that senescent cells reduce organismal life and health span (reviewed in Childs et al., 2017). For example, genetic depletion of senescent cells rejuvenates the hematopoietic stem cells (HSCs), counters frailty and the loss of renal function in aged mice, diminishes cancer relapse, and prevents the development of atherosclerosis and osteoarthritis (Baar et al., 2017; Chang et al., 2016; Childs et al., 2016; Demaria et al., 2017; Jeon et al., 2017). The evidence that genetic ablation of senescent cells counters the effects of aging has prompted a rush to the discovery of small molecules that can selectively kill senescent cells (Baker et al., 2011; Zhu et al., 2015). These drugs, called senolytics, have the potential to be novel antiaging agents. Ablation of senescent cells using senolytics delays age-related pathologies in naturally aged mice, similar to the elimination of senescence with genetic means (Baar et al., 2017; Baker et al., 2011, 2016; Jeon et al., 2017; Ogrodnik et al., 2017; Schafer et al., 2017).

In vitro studies using serially passaged bone marrow−derived stromal cells have suggested that cells from aged humans become senescent at earlier passages compared with cells from young individuals (Stenderup et al., 2003; Zhou et al., 2008). However, because serial passaging by itself causes replicative senescence (Hayflick and Moorhead, 1961), it has remained unclear whether osteoblast progenitors become senescent with old age in vivo. As we discussed earlier, studies using freshly isolated osteoprogenitor cells have elucidated that the age-related decline in number of these cells is associated with several markers of senescence, including DNA damage foci, G1 cell cycle arrest, activated p53, and elevated levels of $p21^{CIP1}$. Markers of senescence, including elevated p16 and expression of the SASP, were also present in osteocyte-enriched bone fractions from old mice. Elimination of p16-expressing cells in 20-month-old mice, using the INK-ATTAC transgene or senolytics, increases bone mass (Farr et al., 2017). This effect is associated with a decrease in osteoclasts and an increase in osteoblasts at the endocortical surfaces.

One of the causes of senescence is DNA damage. Of all DNA lesions, DNA double-strand breaks are the most harmful. DNA double-strand breaks can be induced by radiation, radiomimetic chemicals, or ROS, but also during DNA replication when a polymerase encounters a single-strand lesion at a replication fork (Jackson, 2002). DNA double-strand breaks pose problems for cells because their immediate and efficient repair by ligation is often constrained by their physical separation and/or the need to process damaged DNA termini (Mine-Hattab and Rothstein, 2012; Soutoglou and Misteli, 2008). In the absence of repair, damaged cells can be eliminated by apoptosis. Alternatively, mitotically active cells respond to DNA double-strand breaks by becoming senescent. DNA damage triggers a repair response known as the DNA damage response (DDR). This response is characterized by the activation of ATM and the recruitment of RAD-3-related kinase (or ATR) (Rouse and Jackson, 2002) to the site of damage, leading to phosphorylation of Ser^{139} of histone H2AX molecules adjacent to the site of DNA damage. The phosphorylation of histone H2AX activates the transducer kinases Chk1 and Chk2, which converge on p53/p21 and p16 (Smogorzewska and de, 2002). In addition, the DDR stimulates the SASP by upregulating GATA4 and NF-κB (Kang et al., 2015).

Markers of DNA damage increase with age in both osteoprogenitors and osteocytes and are associated with cell senescence (Kim et al., 2017; Piemontese et al., 2017). While it remains unclear whether DNA damage is indeed the cause of skeletal cell senescence, DNA damage induced by irradiation causes changes in osteoprogenitors that are similar to the ones seen with aging (Kim et al., 2017). In addition, DNA damage due to focal irradiation in long bones causes senescence of osteoblast lineage cells, decreases bone formation, and leads to bone loss in mice (Chandra et al., 2017). Additional support for the deleterious effects of DNA damage on the skeleton is provided from the phenotype of murine models of

progeroid syndromes due to defective DNA damage repair. For example, a mouse model of trichothiodystrophy (Diderich et al., 2012; Nicolaije et al., 2012; Wijnhoven et al., 2005) exhibits features of accelerated aging, including loss of trabecular and cortical bone mass and a reduction in bone strength, from 9 months onward. Similar observations have been made in a murine model of Werner syndrome (Brennan et al., 2014). Bone marrow–derived osteoblastic cell cultures from these models exhibit increased senescence (Chen et al., 2013; Saeed et al., 2011). Nevertheless, caution should be exercised in interpreting results from progeroid mice, as several of these models exhibit impaired growth, poor health, and short life spans (Chen et al., 2013; Niedernhofer et al., 2006; Saeed et al., 2011). Furthermore, not all the cellular features of natural aging are replicated in the progeroid models. Specifically, the loss of trabecular bone mass in several progeroid models is associated with an increase in osteoclast number, which is not seen with natural aging (Almeida et al., 2007b; Brennan et al., 2014; Chen et al., 2013; Saeed et al., 2011).

Together these lines of evidence implicate cellular senescence in the loss of bone mass with age. Future work should elucidate the cell targets and the molecular mechanisms mediating the effects of senescence in skeletal aging. These studies should also clarify the extent to which elimination of cell senescence ameliorates the loss of bone mass with age.

Loss of autophagy

Proteostasis, the process by which cells control the abundance and folding of the proteome, is maintained by proteolytic systems, such as the ubiquitin–proteasome system and the autophagy–lysosomal system, both of which decrease in old age (Cuervo, 2008; Morimoto and Cuervo, 2014). These changes occur in age-related diseases characterized by the accumulation of intracellular or extracellular protein aggregates, including neurodegeneration. These observations have led to the idea that a decline in proteostasis is a common mechanism of aging.

Autophagy is a quality control system that removes defective organelles or protein aggregates to maintain the health and viability of the cell (Yang and Klionsky, 2010). However, under stress conditions, for example, hypoxia or nutrient deprivation, autophagy increases to break down cellular components that can be reused as an energy source. During macroautophagy large components of the cytoplasm, including protein aggregates and mitochondria, are surrounded by a double-membrane structure to form a vacuole known as an autophagosome. This structure then fuses with the lysosome to allow the degradation of its components. Autophagosome formation is controlled by a ubiquitin-like protein known as LC3 (Geng and Klionsky, 2008), which, in turn, is activated by the E1-like enzyme Atg7 and is eventually conjugated to phosphatidylethanolamine in the double-membrane structure. This process is dependent on Atg7, and genetic inactivation of Atg7 effectively abrogates autophagy (Komatsu et al., 2007). Other forms of autophagy include chaperone-mediated autophagy and microautophagy (Levine and Kroemer, 2008). Chaperone-mediated autophagy targets proteins containing a specific five-amino-acid motif directly to the lysosome for degradation. Microautophagy is characterized by invagination of the lysosomal membrane to engulf small portions of the cytoplasm. Because macroautophagy is the most prevalent form of autophagy in many cell types, hereafter, we will use the general term autophagy to refer to this particular process.

Many organisms show signs of decreased autophagic capacity with aging in tandem with the accumulation of damaged cellular components, suggesting that a decline in autophagy may contribute to organismal aging (Cuervo, 2008; Hansen et al., 2018; Lopez-Otin et al., 2013). Specifically, expression of autophagy-related genes declines in muscle tissue from aged humans and in the hypothalamus, muscle, liver, and osteoarthritic bone chondrocytes from aged rodents (Carames et al., 2015; Carnio et al., 2014; Cuervo and Dice, 2000). Furthermore, suppression of autophagy in neurons or myocytes mimics the effects of aging on the nervous or muscle tissue, respectively (Carnio et al., 2014; Komatsu et al., 2007).

Deletion of ATG7 in osteoblasts and osteocytes decreases cancellous and cortical bone mass (Onal et al., 2013). These changes are associated with lower osteoclast and osteoblast numbers in cancellous bone. In addition, ROS levels are increased in the bones of mice lacking autophagy in osteocytes. This is probably due to the accumulation of damaged mitochondria, which in turn produce more ROS. Nevertheless, autophagy exerts positive effects on the skeleton by mechanisms other than suppression of H_2O_2 levels in the mitochondria of osteoblasts and osteocytes (Piemontese et al., 2016). Strikingly, deletion of Atg7 in the entire osteoblast lineage using an Osx1-Cre transgene causes fractures and decreases bone mass. The low-bone-mass phenotype is more pronounced than the one of mice in which ATG7 is deleted from mature osteoblasts and osteocytes (Piemontese et al., 2016). Lack of autophagy in early progenitors of osteoblasts alters osteocyte cell body morphology and reduces the extent of osteocyte cellular projections, suggesting that autophagy contributes to the transition of osteoblasts into osteocytes.

A critical role for autophagy in bone homeostasis is further supported by evidence that mice with deletion of ATG5 or the focal adhesion kinase family–interacting protein of 200 kDa (FIP200) in cells of the osteoblast lineage have compromised autophagy and low bone mass (Liu et al., 2013; Nollet et al., 2014).

Autophagy is important for the long-term health of stem cells as well as fully differentiated long-lived cell types. For example, autophagy is required for the maintenance of the HSC compartment in adult mice (Mortensen et al., 2011; Warr et al., 2013). The FoxO transcription factors are critical for the expression of autophagy genes and the induction of autophagy in response to stress in HSCs and other cell types (Warr et al., 2013; Zhao et al., 2008). It is possible that autophagy plays a similar role in the maintenance of MSCs in bone and this may underlie changes in MSC behavior with age.

In conclusion, suppression of autophagy in the osteoblast lineage is sufficient to replicate in young adult mice the skeletal changes observed in aged wild-type mice. Future studies will be required to identify the molecular mechanisms by which autophagy in cells of the osteoblast lineage controls bone remodeling and bone mass and whether autophagy does indeed decline with age in osteocytes or other cell types of the lineage.

Contribution of bone extrinsic mechanisms to skeletal aging

Loss of sex steroids

A decrease in estrogen levels at menopause, or both estrogens and androgens in elderly men, causes an imbalance between bone resorption and formation, leading to loss of bone mass and strength and increased risk of osteoporotic fractures (Almeida et al., 2017; Khosla, 2010; Manolagas, 2000; Manolagas et al., 2013; Vanderschueren et al., 2014). Within 5−10 years after menopause, the slope of the decline of bone mass in women slows and becomes indistinguishable from the slope of bone loss seen in elderly males. This slower phase of bone loss in both sexes later in life affects primarily the cortical compartment and is characterized by cortical thinning as well as increased cortical porosity (Nicks et al., 2012; Zebaze et al., 2010). Consequently, after the age of 65 most fractures are nonvertebral and predominantly occur at cortical sites (Zebaze et al., 2010).

Estrogens and androgens slow the rate of bone remodeling, and estrogen or androgen deficiency accelerates it. In addition, cell and biochemical studies have revealed that the antiremodeling effects of these two hormones result from their ability to restrain the birth rate of osteoclasts and shorten their life span (Almeida et al., 2017; Hughes et al., 1996; Manolagas, 2000, 2010, 2013). Conditional deletion models of the estrogen receptor α or the androgen receptor have provided critical new insights into the cellular targets of sex steroid action in vivo (Almeida et al., 2013; Chiang et al., 2009; Maatta et al., 2013; Martin-Millan et al., 2010; Nakamura et al., 2007; Notini et al., 2007; Sinnesael et al., 2012; Ucer et al., 2015). This body of work, reviewed elsewhere (Almeida et al., 2017), has produced two seminal but unexpected findings. First, the effects of estrogens and androgens on the cancellous bone compartment are mediated via different cell types. In females, estrogens protect against the loss of cancellous bone via direct actions on cells of the osteoclast lineage. In males, on the other hand, androgens protect against the loss of cancellous bone via actions on mature osteoblasts or osteocytes. Second, in both females and males, estrogens alone protect against the resorption of cortical bone, via actions on osteoprogenitors. In males, the estrogens responsible for this effect derive from the aromatization of androgens. In support of this conclusion, administration of estrogens to orchidectomized B6 mice prevents the loss of cortical thickness, while administration of dihydrotestosterone has no effect (Ucer et al., 2017). Notably, in men, estrogens account for ~70% and testosterone for at most ~30% of the protective effect of sex steroids on bone resorption (Khosla, 2015), remarkably consistent with the fact that the skeleton is ~80% cortical and ~20% cancellous.

Because of the abrupt decline in ovarian function at menopause in women and a slower decline of both androgen and estrogen levels in men with advancing age, the two conditions inexorably overlap, making it impossible to dissect their independent contributions to the cumulative anatomic deficit. Experiments using B6 mice ovariectomized at 4 or 18 months of age have elucidated that at least up to the age of 19.5 months mice remain functionally estrogen sufficient (Ucer et al., 2017). Six weeks following the loss of ovarian function at either age, we observed the expected decrease in uterine weight and increase in body weight in both young and old mice. Nonetheless, femoral cortical thickness and vertebral cancellous bone volume declined and cortical porosity increased in the estrogen-sufficient mice between 5.5 and 19.5 months of age. These findings clearly show that in mice the adverse effects of aging are independent of sex steroid status.

The canonical inhibitor of NF-κB kinase β/NF-κB pathway plays a seminal role in the SASP (Salminen et al., 2012). As discussed earlier under "Cellular senescence," the transcription factors GATA4 and NF-κB are major activators of the SASP (Kang et al., 2015). GATA4 protein levels, NF-κB activity, and the expression of common SASP genes are increased in both bone marrow stromal cells and osteocytes from old B6 mice (Farr et al., 2016; Kim et al., 2017; Piemontese et al., 2017). In line with these findings, the number of osteoclasts formed in cocultures of macrophages with

bone marrow−derived stromal cells is higher when stromal cells originate from old mice compared with cells from young mice (Cao et al., 2005; Kim et al., 2017). Estrogens suppress NF-κB activation via direct interactions of the estrogen receptor α with NF-κB (De Bosscher et al., 2006; Stice and Knowlton, 2008). Moreover, some of the same cytokines of the SASP have been implicated in the loss of cortical bone caused by estrogen deficiency (Almeida et al., 2017). It is, therefore, quite likely that in the aged skeleton, senescence of mesenchymal lineage cells and the SASP, driven by NF-κB activation, are the predominant mechanism of the increased osteoclast number and resorption in the endosteal surface. Because NF-κB is also upregulated by estrogen deficiency, the two pathologies may act in concert. In other words, NF-κB may be a key molecular nexus where the two pathologies intersect, and as a result estrogen deficiency accelerates the adverse effects of aging on cortical bone in both sexes.

Lipid peroxidation and declining innate immunity

ROS-induced oxidative damage causes lipid peroxidation and thereby produces highly reactive degradation products, including oxidized phosphatidylcholine, malondialdehyde (MDA), and 4-hydroxynonenal (Witztum and Lichtman, 2014). These neoepitopes interact with amino groups of proteins and other lipids to create oxidation-specific epitopes (OSEs). The same neoepitopes occur on apoptotic cell bodies. OSEs are part of a larger group of proinflammatory molecules, collectively known as damage-associated molecular patterns (DAMPs), that are produced in response to cellular stressors, including oxidative stress. DAMPs share structural homology with another group of moieties present on microbes and collectively known as pathogen-associated molecular patterns (PAMPs). Because of their shared molecular signatures, PAMPs and DAMPs bind to evolutionarily conserved pattern recognition receptors (PRRs) of the innate immune system.

Natural antibodies (nAbs) of the innate immune system are the first line of defense against microbial pathogens. nAbs are produced by B-1 lymphocytes and are predominantly of the IgM class. The antigen binding sites of nAbs are generated by rearrangement of germ-line-encoded variable-region genes in the complete absence of foreign antigen exposure, hence the term "natural" as opposed to antibodies produced by the "adaptive" immune system. As opposed to the adaptive immune system, nAbs have only a limited repertoire of binding specificities (Ehrenstein and Notley, 2010; Vas et al., 2013). nAbs are soluble PRRs that recognize OSEs and block their adverse effects.

When OSEs are not neutralized and/or their production is excessive, relative to the capacity of the innate immune system, the physiologic response is overwhelmed and becomes instead a disease-causing mechanism (Witztum and Lichtman, 2014). A series of clinical studies has provided compelling evidence that anti-OSE-specific IgM antibodies made by B-1 cells play a role in the development of disease in humans, as they do in mice (Binder et al., 2016; Griffin et al., 2011). Indeed, OSE-specific natural IgM antibodies protect against cardiovascular disease (Tsiantoulas et al., 2014), and titers of IgM antibody against oxidized LDL (OxLDL) and MDA−LDL are inversely correlated with cardiovascular disease (Karvonen et al., 2003; Tsimikas et al., 2007). In particular, anti-PC (phosphocholine) IgM levels are inversely correlated with cardiovascular disease risk in patients with systemic lupus erythematous (Anania et al., 2010; Gronwall et al., 2012), stroke (Fiskesund et al., 2010), and heart attacks (de Faire et al., 2010; Fiskesund et al., 2012; Gronlund et al., 2009; Imhof et al., 2015). Notably, in humans, B-1 cells decline with age (Griffin et al., 2011), raising the possibility that declining levels of nAbs against OSEs contribute to the pathogenesis of age-related diseases.

Hyperlipidemia leads to atherogenesis by promoting the formation of oxidized forms of LDL and phospholipids. These oxidation-modified moieties, in turn, induce potent inflammatory responses in the subendothelial matrix of the arteries, thereby triggering the pathogenetic changes that are ultimately responsible for the generation of the atherosclerotic lesions (Steinberg and Witztum, 2010). Consistent with this mechanism, genetic animal models of hyperlipidemia exhibit disruption of normal lipoprotein regulation and metabolism. Indeed, B6 mice maintained on an atherogenic high-fat diet, or genetically modified B6 mice lacking the LDL receptor or its ligand (ApoE), develop hyperlipidemia and atherosclerosis as a result of reduced clearance of non−high-density lipoproteins (Tintut and Demer, 2014).

Osteoporosis and atherosclerosis are epidemiologically linked (Makovey et al., 2009; Tintut and Demer, 2014). Moreover, bone mineral density and LDL-cholesterol levels are inversely correlated in mice as well as rats (Liu et al., 2016; Tintut and Demer, 2014). Diet-induced hyperlipidemia adversely affects bone growth and bone mineral density in these models. In line with the evidence for an adverse effect of lipids on bone, lipid accumulation has been demonstrated by histochemical staining in the subendothelial spaces of haversian canals from patients with osteoporosis (Tintut et al., 2004). Based on this evidence, it has been hypothesized that, similar to the situation in the subendothelial space of the vasculature, lipids accumulating in the subendothelial spaces of the haversian canals undergo nonenzymatic modifications, such as oxidation by ROS, rendering them capable of inducing inflammatory responses. Oxidized lipids may then induce

bone loss by inhibiting the differentiation of bone-forming osteoblasts and promoting the differentiation of bone-resorbing osteoclasts (Almeida et al., 2009; Liu et al., 2016).

Witztum and colleagues have generated transgenic mice that overexpress a single-chain variable fragment of the IgM nAb E06 (Que et al., 2018). The fragment is secreted from liver and macrophages and achieves sufficient plasma levels to inhibit macrophage uptake of OxLDL. High-fat diet—fed LDL receptor—null mice expressing E06 develop less atherosclerosis compared with controls. Importantly, high-fat diet—induced bone loss is also attenuated in mice expressing the E06 transgene due to an increase in osteoblast number and bone formation (Ambrogini et al., 2018). More strikingly, E06-scFv increases bone mass in mice fed a normal diet. Moreover, the levels of anti-PC IgM decrease in aged mice. These results indicate that OSEs chronically occurring with or without a high-fat diet in mice exert a restraining effect on bone formation. Moreover, the age-related bone loss might be due in part to diminished innate immune system defense against OSEs. Taken together with the evidence that the same nAbs prevent atherosclerosis, these discoveries demonstrate that anti-OSE nAbs may well represent a novel therapeutic approach against atherosclerosis and osteoporosis simultaneously.

Decreased physical activity

Mechanical strains are critical signals for bone mass accrual and strength (Frost, 2003). Mechanical loading tilts the balance between bone formation and resorption in favor of the former, by stimulating bone formation and suppressing bone resorption (Robling et al., 2006; Rubin and Lanyon, 1985; Zhao et al., 2013). For example, exposure to frequent high-impact loading increased bone mass in the dominant arm of tennis players (Ireland et al., 2013; Jones et al., 1977). Conversely, unloading due to lack of ambulation or weightlessness during space flights causes a marked reduction in bone mass, due to decreased bone formation and increased bone resorption (Lang et al., 2004; LeBlanc et al., 1990). A decrease in physical activity with aging, most likely, contributes to skeletal fragility. Exercise that is beneficial to bone in premenopausal women is typically not effective in elderly women (Korpelainen et al., 2006; Vainionpaa et al., 2007). Likewise, in animals the stimulatory effects of loading on bone are greater in growing or young adult animals compared with older ones (Holguin et al., 2014; Meakin et al., 2014; Razi et al., 2015; Rubin et al., 1992; Turner et al., 1995). These findings indicate that with aging, there is reduced responsiveness of the skeleton to mechanical loading (Srinivasan et al., 2012).

Osteocytes are thought of as critical mediators of the effects of mechanical loading by virtue of their location and connectivity with one another and with cells at the bone surface. Because osteocyte dendrites are critical for mechanotransduction (Burra et al., 2010), reduced dendrite connectivity may contribute to the impaired bone response to mechanical loading in aged animals. In addition, altered cell proliferation and decreased Wnt signaling have been implicated in the age-related decline in bone mechanoresponsiveness. The importance of Wnt signaling in loading-induced bone formation is well documented. Mechanical loading in young adult animals downregulates Sost/sclerostin at sites of subsequent bone formation and stimulates canonical Wnt signaling (Lara-Castillo et al., 2015; Moustafa et al., 2012; Robinson et al., 2006; Robling et al., 2008). Moreover, the osteogenic response to loading in mice is disrupted by overexpression of Sost, deletion of Lrp5, or heterozygous deletion of β-catenin in bone cells (Javaheri et al., 2014; Sawakami et al., 2006; Tu et al., 2012; Zhao et al., 2013). Activation of Wnt signaling by mechanical loading is impaired in bone of aged mice (Holguin et al., 2016). Meakin et al. reported that osteoblasts from old mice are less proliferative after in vitro stretching, and that tibial compression in old mice produces a smaller increase in periosteal osteoblast number than in young mice (Meakin et al., 2014). The age-related decline in osteoprogenitor number might contribute to the deficient response of the skeleton to mechanical loading (Kim et al., 2017).

Future directions

Research in animal models has revealed that the rate of physiological aging can be ameliorated by a variety of behavioral, genetic, and pharmacological means. There is great enthusiasm that this can also be accomplished in humans. Most importantly, decreased rate of aging in animal models is often accompanied by a delay (and decreased severity) of a number of age-associated diseases. This evidence strongly suggests that therapeutic interventions that can either delay the onset or decrease the rate of aging could have a beneficial effect on the health of the elderly. As a result, there is a race to develop drugs that may alleviate several degenerative diseases simultaneously. Current antiosteoporotic treatments have limited impact on public health, despite their effectiveness at the individual level. It is, therefore, imperative to elucidate mechanisms of skeletal aging so that osteoporosis is added to the list of degenerative diseases that are amenable to treatment with antiaging drugs.

Chapter outline

Introduction

It has been over 150 years since the term "collagen" was first adopted in the English language. This ropelike structure that yields gelatin upon boiling made its early appearance in evolution in primitive animals such as jellyfish, coral, and sea anemones (Bergeon, 1967). Today, the collagen family of proteins has grown to 28 different types and is used as a versatile biomaterial for delivery of drugs as well as for cosmetic purposes.

The work of Nageotte in the early 1920s used acid solubilization to reveal the fibers that histologists had earlier described in sections of connective tissues (Nageotte, 1927); X-ray diffraction and then electron microscopy characterized those fibers that made up the collagen molecule. In addition to collagens involved in fibril formation, several other groups

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00013-0

of nonfibrillar collagen have been discovered. Among these, some are involved in the formation of membranes that surround tissues, such as basement and Descemet's membranes, the cuticle of worms, and the skeleton of sponges. During those 150 years our understanding of collagen has evolved with advances in techniques and technology. This led to the discovery that collagens mediate adulthood extracellular matrix (ECM) remodeling and are needed for aging to be delayed (Ewald et al., 2015). The importance of collagen production in diverse antiaging interventions implies that ECM remodeling is a generally essential signature of longevity assurance.

In this chapter, we are focusing on fibrillar collagens and, in particular, collagen type I, the most abundant extracellular protein, especially in bone where it is essential for bone strength and in soft connective tissues where it confers compliance, flexibility, and resilience. We will discuss the structure and biosynthesis, regulation, and degradation of type I collagen and associated proteins that maintain its homeostasis and recent insights into the organization of regulatory elements in type I collagen genes, many of which are based on studies in transgenic mice. Then we will address how collagen synthesis is regulated by cytokines and growth factors.

The accepted definition of collagens is "structural proteins of the extracellular matrix which contain one or more domains harboring the conformation of a collagen triple helix" (Myllyharju and Kivirikko, 2004; van der Rest and Garrone, 1991). The triple-helix motif is composed of three polypeptide chains whose amino acid sequence consists of Gly−X−Y repeats. Because of this particular peptide sequence, each chain is coiled in a left-handed helix, and the three chains assemble in a right-handed triple helix, where Gly residues are in the center of the triple helix and the lateral chains of X and Y residues are on the surface of the helix (van der Rest and Garrone, 1991). In about one-third of the cases, X is a proline and Y is a hydroxyproline; the presence of hydroxyproline is essential to stabilize the triple helix and is a unique characteristic of collagen molecules. At the time of this review, 28 different types of collagens have been described, which are grouped in subfamilies depending on their structure and/or their function. The Roman numerals denoting collagen types follow the order in which they were reported. For each collagen type, the α chains are identified with Arabic numerals (Myllyharju and Kivirikko, 2001). Although a standard nomenclature has been agreed on, the representation of the collagen names can be sometimes confusing. Throughout this chapter, we will address the unassembled collagen molecules as procollagens, the mouse genes as Col1a1 or Col1a2 (lower case), and the human genes in capital letters (COL1A1 or COL1A2).

The family of fibrillar collagens

Types I, II, III, V, and XI and the newly described types XXIV and XXVII collagens (Boot-Handford et al., 2003; Koch et al., 2003) form the group of fibrillar collagens. The characteristic feature of fibrillar collagens is that they consist of a long continuous triple helix that self-assembles into highly organized fibrils. These fibrils have a very high tensile strength and play a key role in providing a structural framework for body structures such as skeleton, skin, blood vessels, intestines, or fibrous capsules of organs. Type I collagen, which is the most abundant protein in vertebrates, is present in many organs and is a major constituent of bone, tendons, ligaments, and skin. Type III collagen is less abundant than type I collagen, but its distribution essentially parallels that of type I collagen with the exception of bones and tendons, which contain virtually no type III collagen. Moreover, type III collagen is relatively more abundant in distensible tissues, such as blood vessels, than in nondistensible tissues. Type V collagen is present in tissues that also contain type I collagen. Type II collagen is a major constituent of cartilage and is also present in the vitreous body. Like type II, type XI and type XXVII collagens are present in cartilage. However, unlike other collagens, type XXVII appears to express in epithelial cells of cochlea, lung, gonad, and stomach (Boot-Handford et al., 2003), suggesting that its function in these epithelial layers cannot depend on the copolymerization with other collagens. Collagen type XXIV displays unique structural features of invertebrate fibrillar collagens and is expressed predominantly in bone tissue (Matsuo et al., 2006).

Bone formation is a complex and tightly regulated genetic program that involves two distinct pathways at different anatomical locations (de Crombrugghe et al., 2001; Karsenty and Wagner, 2002; Olsen et al., 2000). In intramembranous ossification, mesenchymal cells condense and differentiate directly into mainly collagen type I−producing osteoblasts, whereas in endochondral bone formation, a cartilage model that is initially rich in type II and type XI collagens, which are secreted by chondrocytes, is replaced by an ostium rich in collagen type I matrix. Cartilage formation in endochondral skeletal elements is initiated by the condensation of chondrogenic mesenchymal cells followed by the overt differentiation of cells in these condensations. After undergoing a unilateral form of proliferation, these cells gradually become hypertrophic. At the same time, cells around the condensations form the perichondrial layer that gives rise to the osteoblast-forming periosteum and ultimately to cortical bone. The process of cartilage replacement by a bone matrix involves invasion by preosteoblasts in the periosteum as well as blood vessels and hematopoietic cells of the zone of hypertrophic chondrocytes. Expression of the genes for collagen type I and those for collagen types II and XI follows distinct

transcriptional codes that control osteoblastogenesis and chondrogenesis (Bridgewater et al., 1998; de Crombrugghe et al., 2001; Karsenty and Wagner, 2002; Lefebvre et al., 2001; Lefebvre and de Crombrugghe, 1998). In addition to fibrillar collagens, collagen type X has been implicated in the morphogenic events of hypertrophic cartilage prior to its replacement by bone. Although knockout mice for collagen X showed no apparent phenotype (Rosati et al., 1994), significant reduction in the amount and quality of bone minerals was evident (Paschalis et al., 1996).

Collagen types XXIV and XXVII display mutually exclusive patterns of expression in the developing and adult mouse skeleton. Gene expression studies have shown that, whereas Col24a1 transcripts accumulate at ossification centers of the craniofacial, axial, and appendicular skeleton, Col27a1 activity is instead confined to the cartilaginous anlagen of skeletal elements (Boot-Handford et al., 2003; Koch et al., 2003; Pace et al., 2003). In addition, structural considerations have suggested that collagens XXIV and XXVII are likely to form distinct homotrimers (Koch et al., 2003). Together these observations have been interpreted to indicate that these newly discovered fibrillar collagens may participate in the control of important physiological processes in bone and cartilage, such as collagen fibrillogenesis and/or matrix calcification and mineralization (Boot-Handford et al., 2003; Koch et al., 2003; Pace et al., 2003).

Structure, biosynthesis, transport, and assembly of type I collagen

Structure

Fibril-forming collagens are synthesized in precursor form, procollagens. Each molecule of type I collagen is typically composed of two α1 chains and one α2 chain (α1(I)2−α2(I)) coiled around one another in a characteristic triple helix. Both the α1 chain and the α2 chain consist of a long helical domain preceded by a short N-terminal peptide and followed by a short C-terminal peptide (for reviews, see Myllyharju and Kivirikko, 2001, 2004, and van der Rest and Garrone, 1991).

The mechanism that controls the 2:1 stoichiometry of the collagen chains in type I collagen is not well understood. It is evident that a number of type I collagen molecules can be formed by three α1 chains (α1(I)3). The homotrimeric type I collagen isotype containing three pro-α1(I) collagen chains (α1(I)3) is a minor isotype, whose role is not well understood. Homotrimers are found embryonically (Jimenez et al., 1977; Rupard et al., 1988), in small amounts in skin (Uitto, 1979), in certain tumors and cultured cancer cell lines (Moro and Smith, 1977; Rupard et al., 1988), and also during wound healing (Haralson et al., 1987). Mesangial cells, which do not synthesize collagen type I in vivo, produce homotrimeric type I collagen in culture, further suggesting that homotrimers play a role in wound healing (Johnson et al., 1992). The collagen I α2-deficient mouse, otherwise known as the oim mouse (osteogenesis imperfecta [OI] model), is homozygous for a spontaneous nucleotide deletion in the Col1a2 gene, resulting in a frameshift altering the carboxy propeptide of the pro-Col1a2 chain. Although the carboxy propeptide is not present in mature type I collagen, it is responsible for association of the Col1a2 chain with the Col1a1 chains during assembly of the triple helix (Chipman et al., 1993; Deak et al., 1983; McBride et al., 1997) (see sections on collagen diseases).

Type I collagen is secreted as a propeptide, but the N telopeptide and the C telopeptide are cleaved rapidly by specific proteases, ADAMTS- 2 and bone morphogenetic protein 1 (BMP-1), respectively, so that shorter molecules assemble to form fibrils (Canty and Kadler, 2005). In fibrils, molecules of collagen are parallel to one another (Fig. 13.1); they overlap one another by multiples of 67 nm (distance D), with each molecule being 4.4 D (300 nm) long; there is a 40-nm (0.6 D) gap between the end of a molecule and the beginning of the next (see Fig. 13.1). This quarter-staggered assembly explains the banded aspect displayed by type I collagen fibrils in electron microscopy. In tissues, type I collagen fibrils can be parallel to one another and form bundles (or fibers), as in tendons, or they can be oriented randomly and form a complex network of interlaced fibrils, as in skin. In bone, hydroxyapatite crystals seem to lie in the gaps between collagen molecules.

Regulation of transcription

In humans the gene coding for the α1 chain of type I collagen is located on the long arm of chromosome 17 (17q21.3−q22; chromosome 11 in mouse), and the gene coding for the α2 chain is located on the long arm of chromosome 7 (7q21.3−q22; chromosome 6 in mouse). Both genes have very similar structures (Chu et al., 1984; D'Alessio et al., 1988), and this structure is also very similar to that of genes coding for other fibrillar collagens (Vuorio and de Crombrugghe, 1990). The difference in size between the two genes (18 kb for the Col1a1 gene and 38 kb for the Col1a2 gene) is explained by differences in the sizes of the introns.

The triple-helical domain of the α1 chain is coded by 41 exons, which code for Gly−X−Y repeats, and by two so-called joining exons. These joining exons code in part for the telopeptides and in part for Gly−X−Y repeats, which

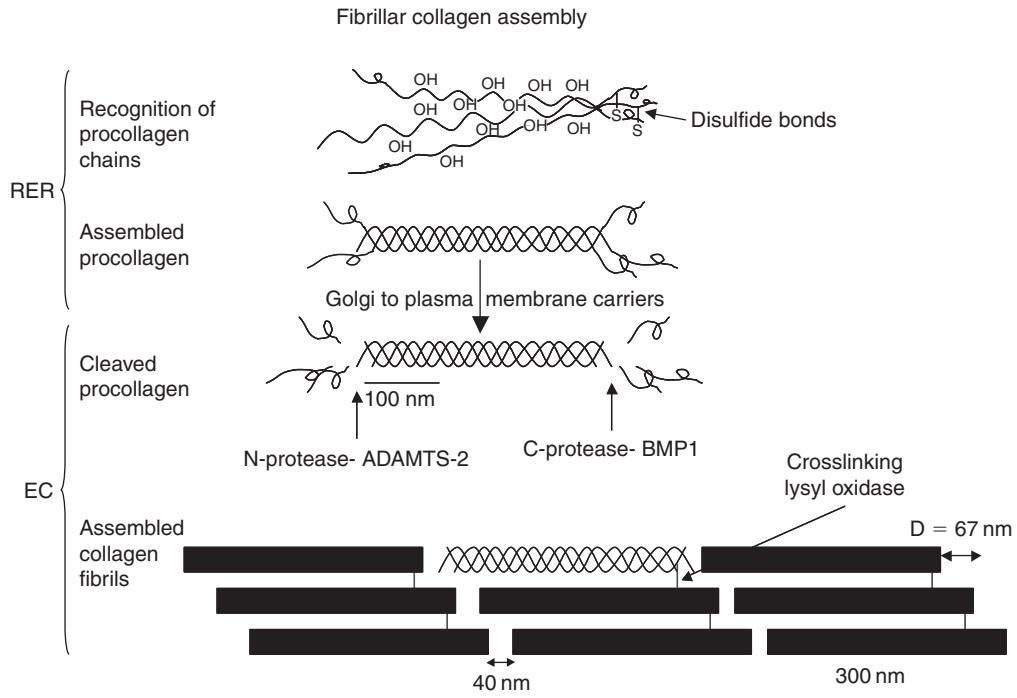

FIGURE 13.1 Schematic diagram of collagen assembly depicting the recognition of the α chains in the rough endoplasmic reticulum (*RER*) and the helix formation strengthened by the hydroxylated proline and lysine residues (*OH*). The collagen is then transported by the Golgi to plasma membrane vesicles to the extracellular space (*EC*) where the propeptides are removed by proteinases and the fibrils are assembled into collagen fibers that are cross-linked by lysyl oxidase. *ADAMTS-2*, a disintegrin and metalloproteinase with thrombospondin motifs-2; *BMP1*, bone morphogenetic protein-1.

are part of the triple-helical domain. The triple-helical domain of the α2 chain is coded by 42 exons, plus two joining exons. The corresponding exons coding for the triple-helical domain of the α1 chain and for the triple-helical domain of the α2 chain have similar lengths (Table 13.1). The only exception is that exons 34 and 35 in Col1a2, which are 54 bp long each, correspond to a single 108-bp 34/35 exon in the a1 gene. Except for the two joining exons, each exon starts exactly with a G codon and ends precisely with a Y codon, and all the exons are 54, 108 (54 3 2), 162 (54 3 3), 45, or 99 bp long (see Table 13.1). This organization suggests that exons coding for triple-helical domains could have originated from the amplification of a DNA unit containing a 54-bp exon embedded in intron sequences. Exons of 108 and 162 bp would result from a loss of intervening introns. Exons of 45 and 99 bp would result from recombinations between two 54-bp exons (Vuorio and de Crombrugghe, 1990).

For both the α1 chain and the α2 chain, the C propeptide plus the C telopeptide are coded by four exons (exons 48−51 of the Col1a1 gene, exons 49−52 of the Col1a2 gene). The first of these exons codes for the end of the triple-helical domain, the C-terminal telopeptide, and the beginning of the C-terminal propeptide. The three other exons code for the rest of the C-terminal propeptide. The C-terminal propeptide has a globular structure that is stabilized by two intrachain disulfide bonds (see Fig. 13.1). It contains three (α2 chain) and four (α1 chain) additional cysteine residues that form interchain disulfide bonds. The formation of disulfide bonds precedes the triple-helix formation and plays an essential role in the intracellular assembly of the three α chains (see sections on translational and posttranslational modifications). Prdm5 is a member of a family of transcriptional regulators that predominantly bind exonic regions of collagen genes and associate with RNA polymerase II to sustain collagen I transcription. Prdm5 targets all mouse collagen genes as well as several small leucine-rich proteoglycan (SLRP) genes. Prdm5 controls both collagen I transcription and fibrillogenesis by binding inside the Col1a1 gene body and maintaining RNA polymerase II occupancy. In vivo, Prdm5 loss results in delayed ossification involving a pronounced impairment in the assembly of fibrillar collagens (Galli et al., 2012).

The signal peptide, the N propeptide, and the N telopeptide of the 1 chain, as well as of the α2 chain, are coded by the first six exons. The N propeptide of the α1 chain contains a cysteine-rich (10-cysteine-residue) globular domain, a short triple-helical domain, and a short globular domain, which harbors the N-terminal peptidase cleavage site (see Fig. 13.1). The N-terminal propeptide of the α2 chain does not contain a cysteine-rich domain but a short globular domain. The 3′-untranslated region (UTR) of both the Col1a1 gene and the Col1a2 gene contains more than one polyadenylation site,

TABLE 13.1 Sizes of exons coding for the triple-helical domain of type I collagen[a].

Exon	Size (bp)	Exon	Size (bp)	Exon	Size (bp)
7	45	21	108	35	54
8	54	22	54	36	54
9	54	23	99	37	108
10	54	24	54	38	54
11	54	25	99	39	54
12	54	26	54	40	162
13	45	27	54	41	108
14	54	28	54	42	108
15	45	29	54	43	54
16	54	30	45	44	108
17	99	31	99	45	54
18	45	32	108	46	108
19	99	33	54	47	54
20	54	34	54	48	108

[a]In the pro-α1(I) collagen gene, exons 33 (54 bp) and 34 (54 bp) are replaced by a single 108-bp 33/34 exon. The two joining exons (exons 6 and 49) are not considered in this table (see text for details).

which indicates that mRNAs with different sizes will be generated. As in many other genes, the functional role of the different polyadenylation sites is still unknown.

Control of translation

After being transcribed, the pre-mRNA undergoes exon splicing, capping, and addition of a poly(A) tail, which gives rise to a mature mRNA. These mature mRNAs are then translated in polysomes, and the resulting proteins undergo extensive posttranslational modifications before being assembled into a triple helix and released in the extracellular space (for reviews, see Lamande and Bateman, 1999; Myllyharju and Kivirikko, 2001).

Signal peptides are cleaved from the chains when their N-terminal end enters the cisternae of the rough endoplasmic reticulum (ER). Both the pro-α1 chain and the pro-α2 chain undergo hydroxylation and glycosylation, and these modifications are essential for the assembly of type I collagen chains in a triple helix. About 100 proline residues in the Y position of the Gly−X−Y repeats, a few proline residues in the X position, and about 10 lysine residues in the Y position undergo hydroxylation, respectively, by a prolyl 4-hydroxylase, a prolyl 3-hydroxylase, and a lysyl hydroxylase. Hydroxylation of proline to hydroxyproline is critical to obtain a stable triple helix, and at 37°C, stable folding in a triple-helical conformation cannot be obtained before at least 90 prolyl residues have been hydroxylated. These hydroxylases have different requirements to be active, and, in particular, they can act only when prolyl or lysyl residues occupy the correct position in the amino acid sequence of the α chain and when peptides are not in a triple-helical configuration. Moreover, these enzymes require ferrous ions, molecular oxygen, α-ketoglutarate, and ascorbic acid to be active. This requirement for ascorbic acid could explain some of the consequences of scurvy on wound healing. When lysyl residues become hydroxylated, they serve as a substrate for a glycosyltransferase and for a galactosyltransferase, which add glucose and galactose, respectively, to the E−OH group. As for hydroxylases, glycosylating enzymes are active only when the collagen chains are not in a triple-helical conformation. Glycosylation interferes with the packaging of mature molecules into fibrils, and increased glycosylation tends to decrease the diameter of fibrils.

While hydroxylations and glycosylations described previously occur, after a mannose-rich oligosaccharide is added to the C propeptide of each pro-α chain, C propeptides from two α1 chains and one α2 chain associate, with the formation of intrachain and interchain disulfide bonds. After prolyl residues have been hydroxylated, and the three C propeptides have associated, a triple helix will form at the C-terminal end of the molecule and then extend toward the N-terminal end (see Fig. 13.1). This propagation of the triple-helical configuration occurs in a "zipper-like" fashion (Prockop, 1990). If prolyl

residues are not hydroxylated or if interchain disulfide bonds are not formed between the C propeptides, the α chain will not fold into a triple helix. Although the functions of the C-terminal sequences, which have been associated with initiation of triple-helix formation, are thought to be well established, those of the N-terminal propeptide are poorly understood (Bornstein, 2002). The N propeptide of type I procollagen, as released physiologically by procollagen N-protease (ADAMTS-2), contains a globular domain largely encoded by exon 2 in the Col1a1 gene and a short triple helix that terminates in a non-triple-helical telopeptide sequence, which separates this helix from the major collagen helix. Bornstein and colleagues generated a mouse with a targeted deletion of exon 2 in the Col1a1 gene, thus replicating the type IIB splice form of type II procollagen in type I procollagen (Bornstein et al., 2002); surprisingly, homozygous mutant mice were essentially normal. In particular, none of the steps in collagen biogenesis thought to be dependent on the N propeptide were defective. However, there was a significant, but background-dependent, fetal mortality, which suggested a role for the type I collagen N propeptide in developmental processes.

Toman and colleagues have gone even further to demonstrate that propeptide may not be necessary for the selection and folding of procollagen. They engineered type I collagen genes that encode the N and C telopeptides with the entire triple-helical domain and showed that these sequences are sufficient for the assembly of a triple helix in *Saccharomyces cerevisiae* (Olsen et al., 2001). Other fibrillar collagens (types II, III, V, and XI) have similar structures and thus would be expected to fold into triple helices without the propeptide regions in an analogous system.

Intracellular transport

The transport of newly synthesized secretory proteins begins at their site of synthesis, the ER, a network of dynamically interconnected membrane tubules and cisternae (Fig. 13.1). All vesicles then detach from the ER through membrane fission and move to the ER−Golgi intermediate compartment. From there, carriers containing secretory cargoes are transported forward to the Golgi complex.

The newly formed triple-helical forms are then stabilized by heat shock protein 47 (Hsp47), a molecular chaperone of type I collagen molecules (Nagai et al., 2000; Tasab et al., 2000). This protein belongs to the serine protease inhibitor (serpin) superfamily containing a serpin signature sequence. Hsp47 resides in the ER, as inferred from the presence of a carboxyl-terminal RDEL sequence similar to the ER retrieval signal, KDEL. After folding, proteins enter the exit sites of the ER, where they are sorted into large pleomorphic budding vesicles that are generated through the membrane-bending properties of coat protein complex II (COPII). Disrupting the Hsp47 gene in mice resulted in embryonic lethality in mice by 11.5 days postcoitus and caused a molecular abnormality in procollagens (Nagai et al., 2000). Type I procollagen chains containing propeptides accumulated in the tissues, but the mature collagen chains normally processed were scarcely observed, suggesting that HSP47 is essential as a collagen-specific molecular chaperone for the proper processing of procollagen molecules, and the Hsp47 gene is needed for the normal development of mouse embryo (Nagai et al., 2000). However, the transfer from ER to the Golgi was unexplained since the mean fibrillar collagen, when formed into a trimer, adopts a rigid, rodlike structure of >300 nm in length and could not fit into a generic COPII vesicle of 60−90 nm diameter.

A genome-wide screen was performed in *Drosophila* tissue culture S2 cells to identify transport components (Bard et al., 2006). This screen revealed a number of previously unidentified genes required for transport and Golgi organization (TANGO genes). TANGO1 was shown to transport carriers without following the cargo into the vesicle itself. Thus, the mechanism of TANGO1-mediated cargo loading of collagen VII into COPII carriers (j.cell. 2008.12.025). A null allele of Mia3 in the mouse. Melanoma inhibitory activity member 3 (MIA3/TANGO1) is an evolutionarily conserved ER resident transmembrane protein.

Mia3 knockouts display a chondrodysplasia that causes dwarfing of the fetus, peripheral edema, and perinatal lethality. Thus far, our understanding of Mia3 (*Drosophila melanogaster* homolog of the vertebrate gene MIA3, also known as TANGO1) in escorting all collagens examined to date, including collagens I, II, III, IV, VII, and IX, but not other ECM components, such as fibronectin or aggrecan, indicates that this protein plays a unique role within the cell to facilitate the nucleation of large ER transport vesicles. However, collagen secretion indeed still occurs in Mia3-null cells. Either an alternate independent pathway of egress remains open to large ECM cargoes, or these proteins can still exit via large COPII vesicles (Wilson et al., 2011). Interestingly, studies in mice focusing on liver fibrogenesis and hepatic stellate cell (HSC) function noted that the loss of MIA3/TANGO1 resulted in retention of procollagen I in the ER and promotion of the unfolded protein response. In vivo this was manifest as a reduction in hepatic fibrosis following liver injury and a dysregulation in HSC homeostasis leading to enhanced apoptosis (Maiers et al., 2017). A critical role for correct intracellular transport of procollagen I has also been highlighted in HSCs deficient in the ER oxidase 1α enzyme (ERO1α), which mediates protein modifications crucial to the transport of secreted proteins. Silencing of ERO1α caused impaired secretion of collagen type I and intracellular accumulation severely inhibiting cell proliferation (Fujii et al., 2017). It is notable that

mutations in the ubiquitous COPII component Sec23a or in the transport protein particle complex subunit TRAPPC2 (which is involved in trafficking between the ER and the Golgi complex) can selectively affect osteocytes and chondrocytes, resulting in craniolenticulosutural dysplasia (Boyadjiev et al., 2006) and spondyloepiphyseal dysplasia tarda (Gedeon et al.,1999), respectively.

After passing through the Golgi complex and reaching the *trans*-Golgi network (TGN), different cargoes are packaged in specialized membranous carriers, within which they are shipped out to the plasma membrane. There they are secreted into the extracellular space, where removal of the N and C propeptides from procollagens I, II, and III is catalyzed by specific Zn^{2+}-dependent metalloendopeptidases, procollagen N- and C-proteinase, respectively (Prockop, 1998). Procollagen C-proteinase, also known as BMP-1, is a member of the astacin family of proteases and triggers spontaneous self-assembly of collagen molecules into fibrils, giving rise to mature collagen molecules (Kadler, 2004; Kadler et al., 1990). Cleavage of the propeptide decreases the solubility of collagen molecules dramatically. Thus a major extracellular function of C propeptides is thought to prevent fibril formation, while N propeptides influence fibril shape and diameter (Hulmes, 2002).

The free propeptides are believed to be involved in feedback regulation of the synthesis of types I and III collagens by fibroblasts in culture (Wiestner et al., 1979). However, the mechanism of this inhibition remained elusive despite attempts by several groups to characterize it.

Fibrillogenesis

In the extracellular space, the molecules of mature collagen assemble spontaneously into quarter-staggered fibrils; this assembly is directed by the presence of clusters of hydrophobic and of charged amino acids on the surface of the molecules. Fibril formation has been compared with crystallization in that it follows the principle of "nucleated growth" (Prockop, 1990). Once a small number of molecules have formed a nucleus, it grows rapidly to form large fibrils. During fibrillogenesis, some lysyl and hydroxylysyl residues are deaminated by a lysine oxidase, which deaminates the «-NH_2 group, giving rise to aldehyde derivatives. These aldehydes will associate spontaneously with «-NH_2 groups from a lysyl or hydroxylysyl residue of adjacent molecules, forming interchain cross-links. These cross-links will increase the tensile strength of the fibrils considerably (see Fig. 13.1). In vitro studies have shown that procollagen molecules and their various structural domains have a remarkable capacity to control all stages of collagen assembly, from intracellular assembly to extracellular suprafibrillar assembly at a micrometer scale. The in vivo process is much more complex, but we are beginning to understand some of this in particular cell types. Kadler and coworkers have shown that GPCs are indeed present in vivo in embryonic tendon fibroblasts and that some GPCs contain 28-nm-diameter collagen fibrils. Moreover, GPCs are targeted to novel plasma membrane protrusions, which they have termed "fibripositors" (fibril depositors). What was intriguing in this study is the fact that procollagen can be converted to collagen within the confines of the cell membrane, which is consistent with the observation of collagen fibrils in some GPCs and the known intracellular activation of BMP-1 in the TGN compartment (Canty-Laird et al., 2012). In addition, fibripositors were shown to be always oriented along the tendon axis, which establishes a link between intracellular transport and the organization of the ECM (Canty et al., 2004). Interestingly, fibripositor formation is not a constitutive process in procollagen-secreting cells. It is absent in postnatal development despite active procollagen synthesis, and occurs only during a narrow window of embryonic development when tissue architecture is being established. It is not known whether this phenomenon occurs in other types of specialized collagen-secreting cells. More recently, the Kadler group has shown that fibripositors are specialized sites of fibril assembly and fibril transport. The fibripositors form an extended mechanical interface between the cytoskeleton and extracellular collagen fibrils. This interface serves to transmit cell-derived tensioning force to the tissue, which is critical in maintaining fibril alignment. The dynamic transport of new collagen fibrils occurs at the plasma membrane and this process is driven by nonmuscle myosin II, since inhibition of dynamin-dependent endocytosis with dynasore blocked fibricarrier formation and caused accumulation of fibrils in fibripositors (Kalson et al., 2013).

Assembly

The final assembly of fibrillar collagen involves the direct interaction of several molecules, which include other collagens, SLRPs, and others. These interactions shape the diameter of the fibrils (Kuc and Scott, 1997; Vogel and Trotter, 1987) and patterning of the final matrix. SLRPs are a group of secreted proteins, including decorin, biglycan, fibromodulin, lumican, and keratocan, among others, that play major roles in tissue development and assembly, especially in collagen fibrillogenesis (Iozzo, 1999). Biglycan and decorin are highly expressed in extracellular bone matrix and there is now substantial evidence to support an increasing role for biglycan and decorin in influencing bone cell differentiation and proliferative

activity (Waddington et al., 2003). The ability of decorin and biglycan to interact with collagen molecules and to facilitate fibril formation has implicated these macromolecules in important roles in the provision of a collagenous framework in bone, which eventually allows for mineral deposition. Initial mineral deposition is proposed to occur within or near the gap zones along the collagen fibers, and the structural architecture of the collagen fibers along with interacting noncollagenous proteins is likely to play a key role in directing placement of the mineral crystals (Dahl and Veis, 2003).

Molecular modeling techniques have led to the proposal that decorin and biglycan adopt an open-horseshoe structure (Weber et al., 1996) where the inner cavity interacts with a single triple-helical molecule. The generation of mutated forms of decorin has demonstrated the importance of leucine-rich sequences 4− to 6 in mediating this interaction (Kresse et al., 1997). In addition, reduction in the disulfide bridges at the C- and N-terminal ends of decorin also abolished interaction with type I collagen (Ramamurthy et al., 1996) and this led to the proposal that the disulfide loop at the C terminus binds to adjacent collagen fibrils, thereby facilitating the lateral assembly and stabilization of the fibrils.

Interestingly, molecular analysis data have put forward the idea that decorin exists as a dimer in solution (Scott et al., 2003), and if this is the case in vivo, then the nature of this interaction will be important when considering the mechanistic role of decorin in fibril assembly. The glycosaminoglycan moieties of decorin and biglycan have also been deemed to play an important role in collagen fibrillogenesis, where the interaction of glycosylated forms of these SLRPs with collagen appeared to be greater than that of nonglycosylated forms (Bittner et al., 1996). Adding to the macro- and microstructural information of collagen type I, three important studies using high-resolution mapping, crystallographic techniques, and modeling have highlighted the spatial arrangement and packaging of the collagen molecules in fibrils and fibril domain architecture. These investigations have helped to evolve our understanding of cell−collagen−matrix interactions via the presentation of organized domains and provide novel solutions and information relevant to the functional interactions of decorin in assembly and matrix metalloproteinases (MMPs) in collagenolysis (Orgel et al., 2006; Sweeney et al., 2008; Varma et al., 2016). Further evidence for the role of decorin and biglycan in bone formation is provided by targeted deletion of the genes. The biglycan-knockout (Bgn 2/2) mouse (Xu et al., 1998), unlike the Dcn 2/2 mouse (Danielson et al., 1997), showed no gross skin abnormalities but rather a reduction in bone density. These mice were seen to develop an osteoporotic phenotype, failing to achieve peak bone mass, owing to decreased bone formation, with significantly shorter femurs (Ameye et al., 2002). Within these animals lower osteoblast numbers and osteoblast activity were observed. In vitro experiments demonstrated that the number and responsiveness of bone marrow stromal cells to transforming growth factor β (TGFβ), and hence osteogenic precursor cells, decreased dramatically with age, but apoptosis rates increased (Chen et al., 2002a,b). The effects were not confined only to the skeletal tissues. Within the teeth the transition of predentin to dentin appeared to be impaired and the thickness of the enamel was dramatically increased (Goldberg et al., 2002). Taken together these results would suggest that biglycan plays an important role in the formation of mineralized tissue. Furthermore, despite high sequence identity and somewhat similar patterns of localization, decorin and biglycan are not interchangeable in function and do not have the ability to rescue each other's knockout phenotypes. Notably, Bgn 2/2 and Dcn 2/2 double-knockout animals revealed that the effects of both gene deficiencies were additive in the dermis and synergistic in bone (Corsi et al., 2002). The lack of both genes caused a phenotype with severe skin fragility and osteopenia, resembling a rare progeroid variant of Ehlers−Danlos syndrome.

Consequences of genetic mutations on type I collagen formation

OI (also known as "brittle bone disease") is a genetic disease characterized by an extreme fragility of bones. Genetic studies have shown that it is due to a mutation in the coding sequence of either the pro-COL1A1 gene or the pro-COL1A2 gene, and more than 150 mutations have been identified (for review, see Byers, 2001). Most severe cases of OI result from mutations that lead to the synthesis of normal amounts of an abnormal chain, which can have three consequences (Marini et al., 2007). First, the structural abnormality can prevent the complete folding of the three chains in a triple helix, e.g., if a glycine is substituted by a bulkier amino acid that will not fit in the center of the triple helix. In this case, the incompletely folded triple-helical molecules will be degraded intracellularly, resulting in a phenomenon known as "procollagen suicide." Second, some mutations appear not to prevent folding of the three chains in a triple helix, but presumably prevent proper fibril assembly. For example, Prockop's group has shown that a mutation of the pro-Col1a1 gene that changed the cysteine at position 748 to a glycine produced a kink in the triple helix (Kadler et al., 1991). Finally, some mutations will not prevent triple-helical formation or fibrillogenesis but might modify the structural characteristics of the fibrils slightly and thus affect their mechanical properties. In all these cases, the consequences on the mechanical properties of bone are probably similar. Mild forms of OI most often result from a functionally null allele, which decreases the production of normal type I collagen. Null mutations are usually the result of the existence of a premature stop codon or of an abnormality in mRNA splicing. In these cases, the abnormal mRNA appears to be retained

in the nucleus (Johnson et al., 2000). A mouse model of OI has been obtained by using a knock-in strategy that introduced a $Gly^{349} \rightarrow Cys$ mutation into the pro-Col1a1 gene (Forlino et al., 1999). This model faithfully reproduced the human disease. Another spontaneous mouse mutation, the oim/oim mouse, analogous to human type III OI, carries a spontaneous deletion of G at nucleotide 3983 in the α2 chain of collagen type I, which alters the reading frame to result in the final 48 amino acids of the COOH-terminal propeptide generating a new stop codon, with addition of an extra amino acid (Chipman et al., 1993). In these mice, collagen type I is made of α(I)3 homotrimers in place of the normal α1(I)2 α2(I)1 heterotrimers (Chipman et al., 1993; Kuznetsova et al., 2004; Miles et al., 2002), which results in marked skeletal fragility, with thinning of the long bones and reduced mechanical strength (Chipman et al., 1993; Pereira et al., 1995). An additional organ pathology has been described by Phillips and coworkers, namely a glomerulopathy characterized by abnormal renal collagen deposition (Brodeur et al., 2007; Phillips et al., 2002). Interestingly, data have also provided an insight into a fourth mechanism potentially resulting in OI. Here, a mutation at the signal peptide cleavage site of collagen type I, a domain not well characterized, caused reduced production and the intracellular retention of collagen I, leading to a severe OI phenotype (Lindert et al., 2018). This study is consistent with the notion that mechanisms influencing intracellular transport of collagen I may exert a profound impact on bone and other connective tissues in which collagen type I plays an important structural role.

Ehlers–Danlos syndrome types VIIA and VIIB are two rare dominant genetic diseases characterized mainly by an extreme joint laxity. They result from mutations in the pro-COL1A1 gene (Ehlers–Danlos syndrome type VIIA) or in the pro-COL1A2 gene (Ehlers–Danlos syndrome type VIIB) that interfere with the normal splicing of exon 6, and a little fewer than 20 mutations have been described. These mutations can affect the splice donor site of intron 7 or the splice acceptor site of intron 5; in the latter case, there is efficient recognition of a cryptic site in exon 6 (Byers et al., 1997). Thus, these mutations induce a partial or complete excision of exon 6. They do not appear to affect the secretion of the abnormal procollagen molecules, but they are responsible for the disappearance of the cleavage site of the N-terminal propeptide and thus for the presence of partially processed collagen molecules in fibrils that fail to provide normal tensile strength to tissues (Byers, 2001). Nevertheless, these mutations seem to affect the rate of cleavage of the N-terminal propeptide rather than completely prevent it, which explains why the phenotype is less severe than for patients who do not have a functional N-proteinase (Ehlers–Danlos syndrome type VIIC).

Collagen type I degradation and catabolism

The absolute requirement to critically regulate collagen type I synthesis and assembly in health is paralleled by the necessity to control the level and deposition of collagen type I once produced at the level of degradation and catabolism (for reviews see Fields 2013; Van Doren 2015; Zigrino et al., 2016). Furthermore, work over the past 5–10 years has begun to unravel the molecular pathways mediating degradation of collagen (Mi et al., 2017; Sprangers et al., 2019). These studies have shown that several key intracellular and extracellular pathways exist, and both mechanisms are important for maintaining collagen homeostasis. Different pathways for extracellular and intracellular degradation are employed by a wide range of tissue and cell types (i.e., bone, cartilage, and skin). There are at least three main types of enzymes that possess collagenolytic activity, including the MMPs (Nagase et al., 2006), cathepsins (Novinec et al., 2013), and neutrophil elastase (Fields, 2013). One of the most typical vertebrate collagenases and the most studied with respect to collagen type I cleavage is MMP-1 (Arakaki et al., 2009; Fields, 2013). MMP-1 cleaves collagen type I into one-quarter- and three-quarter-length fragments (Lauer-Fields, 2002). Once cleaved, a number of factors appear to influence further collagenolysis and sequential degradation. These include conformational dynamics and the mechanism by which the MMPs disrupt the stable collagen triple helix (Adhikari, 2012), cross-linking (Kwansa et al., 2014), cell surface binding that facilitates collagen unwinding (Adhikari et al., 2011), and the presence of membrane-bound proteases such as MT1-MMP (Yañez-Mó et al., 2008). Several other MMPs, such as MMP-2, MMP-8, MMP-9, MMP-12, MMP-13, and MMP-14, are also known to degrade collagen, but in general the precise modes of action of many have not been studied in detail. For MMP-12, the catalytic domain has been studied, and it recognizes, binds, and cleaves at specific sites in the triple helix in regions of relatively less proline, notably between Gly^{775} and Leu/Ile^{776} in the α1 and α2 collagen chains, respectively, in a manner that is characteristic of the unique collagenolytic activity of MMP collagenases (Bigg et al., 2007; Tam et al., 2004; Taddese et al., 2010).

It is clear that correct proteolytic processing and collagenolysis are critical in development and for normal tissue homeostasis, and abnormalities in these processes or their dysregulation in disease and aging can significantly contribute to many severe pathologies (reviewed in 2017 by Amar et al.,). It has also become apparent that many studies aimed at defining the molecular mechanism(s) have taken advantage of animal systems or in vitro analysis. For instance, in models of diabetes in rodents, reduced MMP (MMP-2 and MMP-9) activity was noted to be associated with increased collagen

deposition and stromal growth (Santos et al., 2017), and an imbalance in MMP/tissue inhibitor of metalloproteinases (TIMP) levels (creating reduced MMP-1 and MMP-3) appears to be responsible for the elevated collagen type I production in an in vitro model of chronic liver disease using HSCs (Robert et al., 2016). Enhanced type I collagen levels can directly promote fibroblast differentiation by altering integrin expression in models of cardiac fibrosis (Hong et al., 2017). Abnormally high collagen turnover by enhanced MMP activity can be equally disruptive such as aortic aneurysms, where elevated MMP-3, MMP-9, and MMP-12 are present and associated with collagen degradation (Klaus et al., 2017). Another important aspect of dysregulated collagen catabolism is the direct impact excessive levels of collagen type I can exert on cells via surface receptors. Studies have shown type I collagen promotes differentiation, proliferation, and scar formation by cardiac and ligament fibroblasts and astrocytes via interactions with specific integrins, cadherins, and SPARC (secreted protein acidic and cysteine rich) (Hara et al., 2017; Hong et al., 2017; Rosset et al., 2017), and plays a proinflammatory role by altering the release of cytokines by monocytes (Schultz et al., 2016). These data provide an insight into the distinct and pivotal role of collagen type I in regulating critical cell functions and the deleterious impact resulting from failure of correct collagen type I degradation and homeostasis. A greater understanding of role of MMPs and the molecule mechanisms that underlie their distinct roles in collagenolysis will enable the development of selective, specific, or targeted approaches for the effective treatment of an array of human conditions.

Collagen type I and bone pathologies

Because type I collagen is the most abundant protein in bone and because mutations in the COL1A1 gene are a major cause of OI, this gene has been considered a strong candidate for susceptibility to osteoporosis (Ralston and de Crombrugghe, 2006). Indeed polymorphisms in both the promoter (Garcia-Giralt et al., 2002) and the first intron of COL1A1 (Grant et al., 1996) have been associated with changes in bone mineral density (BMD). The polymorphism of intron 1 is located in a binding site for the transcription factor Sp1 and has been associated with various osteoporosis-related symptoms such as bone density and fractures (Grant et al., 1996; Uitterlinden et al., 1998), postmenopausal bone loss (Harris et al., 2000; MacDonald et al., 2001), bone geometry (Qureshi et al., 2001), bone quality (Mann et al., 2001), and bone mineralization (Stewart et al., 2005). The osteoporosis-associated Sp1 polymorphism causes increased Sp1 binding, enhanced transcription, and abnormally high production of COLIA1 mRNA and protein (Mann et al., 2001), which result in an imbalance between the COLIA1 and the COLIA2 chains. This is thought to lead to impairment of bone strength and reduced bone mass in carriers of the Sp1 polymorphism (Stewart et al., 2005). Retrospective meta-analyses of previous studies have indicated that the Sp1 polymorphic allele is associated with reduced BMD and with vertebral fractures (Efstathiadou et al., 2001; Mann and Ralston, 2003). In a large prospective meta-analysis of more than 20,000 participants from several European countries in the GENOMOS study, homozygotes for the Sp1 polymorphism were found to be associated with lower BMD at the lumbar spine and femoral neck and a predisposition to vertebral fractures (Ralston et al., 2006). In this study, however, the BMD association was observed only for homozygotes of the Sp1 polymorphism, in contrast to previous studies in which heterozygotes also showed a reduction in BMD (Mann and Ralston, 2003). It should be noted that the association between COLIA1 alleles and vertebral fracture reported in GENOMOS and other studies was not fully accounted for by the reduced bone density, suggesting that the Sp1 allele may also be a measure of bone quality. Furthermore, the existence of an extended haplotype defined by the Sp1 polymorphism and other promoter polymorphisms has been proposed to exert stronger effects on BMD than the individual polymorphisms (Garcia-Giralt et al., 2002; Stewart et al., 2006). Evidence has been presented that suggests that the promoter polymorphism at position 21,663 interacts with the transcription factor NMP4, which plays a role in osteoblast differentiation by interacting with Smads (Garcia-Giralt et al., 2005).

Although collagen type I assembly stipulates a heterotrimer assembly, a homotrimer assembly appears to occur in fetal tissues, fibrosis, and cancer (Han et al., 2010). Genetic studies indicate that collagen (I) homotrimers may be detrimental to bone structure, as in the mouse model of OI (oim), in which only $(\alpha 1)3$ homotrimers are present and the bone contains smaller and more tightly packed apatite crystals, but has a lower BMD due to altered collagen organization and bone structure (Vanleene et al., 2012).

However, the homotrimer can reduce the risk of tendon/ligament rupture, possibly because of the laxity in the fibrils. Translational mechanisms may also play a role in collagen (I) homotrimer biosynthesis, as nonmuscle myosin has been reported to coordinate cotranslational translocation of collagen (I) heterotrimers (Cai et al., 2010). However, disassembly of nonmuscle myosin filaments appeared to result in collagen (I) homotrimer production in lung fibroblasts but not in scleroderma skin fibroblasts, indicating that translational control may be specific to particular cell or tissue types. Collagen (I) homotrimer is resistant to proteolytic degradation by MMPs through its resistance to local unwinding at the MMP cleavage site (Han et al., 2010) and may therefore persist in tissues during remodeling and contribute to tissue sclerosis. In

cancer, invasive cancer cells may use homotrimers for building MMP-resistant invasion paths, supporting local proliferation and directed migration of the cells, whereas surrounding normal stromal collagens are cleaved.

Transcriptional regulation of type I collagen genes

Expression of the pro-Col1a1 gene and the pro-Col1a2 gene is coordinately regulated in a variety of physiological and pathological situations. In many of these instances it is likely that the control of expression of these two genes is mainly exerted at the level of transcription, suggesting that similar transcription factors control the transcription of both genes.

This section considers successively the proximal promoter elements of these genes and then the nature of cell-specific enhancers located in other areas of these genes, including intronic sequences. Information about the various DNA elements has come from transient expression experiments in tissue culture cells, in vitro transcription experiments, and experiments in transgenic mice. In vitro transcription experiments and, in large measure, transient expression experiments identify DNA elements that have the potential of activating or inhibiting promoter activity. These DNA elements can be used as probes to detect DNA-binding proteins. However, transient expression and in vitro transcription experiments do not take into account the role of the chromatin structure in the control of gene expression. Transgenic mice are clearly the most physiological system to identify tissue-specific elements; the DNAs that are tested are integrated into the mouse genome and their activities are presumably also influenced by their chromatin environment. In transgenic mice experiments, reporter genes such as green fluorescent protein, luciferase, or the *Escherichia coli* β-galactosidase offer the advantage that their activity is indicative of promoter activation and location of the expression. All three transgenes can be detected in vivo without having to kill the mouse. In addition, X-Gal histochemical stain for β-galactosidase can identify the cell types in which the transgene is active by histology.

Transient transfection experiments using various sequences upstream of the transcription start site of either the pro-α1(I) or the pro-α2(I) promoter, cloned upstream of a reporter gene, and introduced into fibroblasts have delineated positive *cis*-acting regulatory segments in these two sequences that were designated as minimal proximal promoters. Footprint experiments and gel-shift assays performed using these regulatory elements as DNA templates have also characterized sequences that interact with DNA-binding proteins to modulate the expression of the two genes.

Proximal promoters of type I collagen genes

Transcription factors binding to the pro-α1(I) proximal promoter

In the pro-α1(1) collagen gene, a close homology exists between human and mouse promoters. Brenner and colleagues demonstrated by progressively deleting the mouse pro-Col1a1 promoter that sequences downstream of 2181 bp are needed for high-level transient transfection (Brenner et al., 1989). Therefore, the sequence between 2220 and 1110 has been used as the proximal promoter (Fig. 13.2) and contains binding sites for DNA-binding factors that also bind to the proximal pro-Col1a2 promoter (Ghosh, 2002). These DNA elements include an RFX consensus binding site surrounding the transcription start site (−11 to +10) that contains three methylation sites, rather than one in the COL1A2 gene RFX-binding site. RFX1 interacts weakly with the unmethylated COL1A1 site, and binds with higher affinity to the methylated site (Sengupta et al., 2005).

RFX1 represses the unmethylated COL1A1 less efficiently than COL1A2, while RFX5 interacts with both collagen type I genes with similar binding affinity and represses both promoters equally.

The mouse pro-Col1a1 proximal promoter includes a binding site for the CCAAT-binding protein CBF between 290 and 2115 (Karsenty and de Crombrugghe, 1990). A second CCAAT box located slightly more upstream is, however, unable to bind CBF, suggesting that sequences surrounding the CCAAT motif also have a role in CBF binding. Similar results were observed in the human COL1A1 promoter (Saitta et al., 2000). DNA transfection experiments with the pro-Col1a1 promoter showed that point mutations in the CBF-binding site decreased promoter activity (Karsenty and de Crombrugghe, 1990). The CBF-binding site is flanked by two identical 12-bp repeat sequences that are binding sites for Sp1 and probably other GC-rich binding proteins (Nehls et al., 1991). In transient transfection experiments, a mutation in the binding site that prevents the binding of Sp1 surprisingly increased the activity of the promoter, and overexpression of Sp1 decreased the activity of the promoter (Nehls et al., 1991). It is possible that several transcription factors with different activating potentials bind to overlapping binding sites and compete with one another for binding to these sites; the overall activity of the promoter could then depend on the relative occupancy of the different factors on the promoter DNA. Substitution mutations in two apparently redundant sites between 2190 and 2170 and between 2160 and 2130 that abolished DNA binding resulted in an increase in transcription (Karsenty and de Crombrugghe, 1990). Formation of a

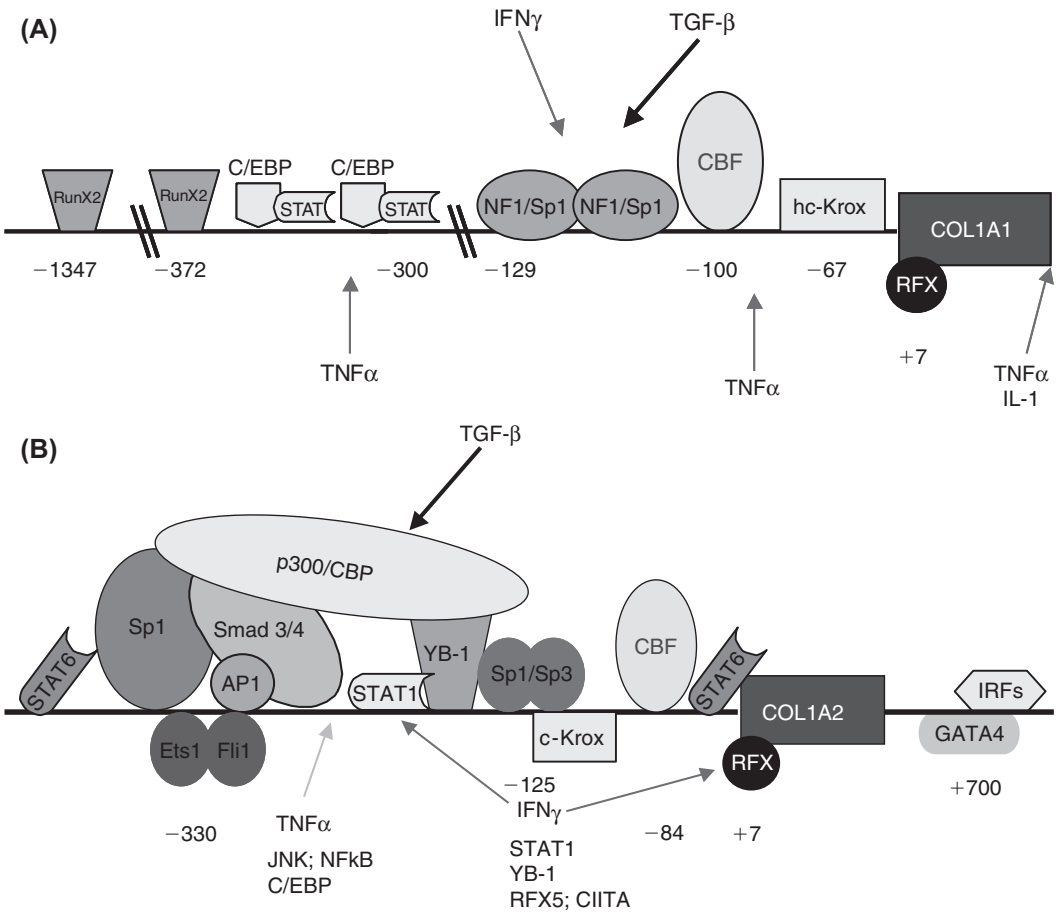

FIGURE 13.2 Schematic diagrams illustrating the known transcription factors that bind to the proximal promoter of the human and murine (A) Col1a1 and (B) Col1a2 promoters. Also shown are the cytokines that modulate the expression of these genes. The data are accumulated from several papers as cited in the text. *AP1*, activator protein 1; *CBF*, CCAAT-binding factor; *CBP*, CREB-binding protein; *C/EBP*, CCAAT/enhancer-binding protein; *CIITA*, class II, major histocompatibility complex, transactivator; *hc-Krox*, human collagen Krox; *IFNγ*, interferon-γ; *IL-1*, interleukin 1; *IRF*, interferon regulatory factor; *JNK*, Jun N-terminal kinase; *NF1*, nuclear factor 1; *NF-κB*, nuclear factor κB; *STAT*, signal transducer and activator of transcription; *TGF-β*, transforming growth factor β; *TNFα*, tumor necrosis factor α; *YB-1*, Y-box binding factor.

DNA−protein complex with these two redundant elements in the pro-Col1a1 promoter was also shown to be completed by the sequence of the pro-Col1a2 promoter between 2173 and 2143, suggesting that both type I promoters contained similar binding sites (Karsenty and de Crombrugghe, 1991). A member of the Krox family, designated c-Krox, binds to these two sites in the pro-Col1a1 promoter (Galera et al., 1994). In addition, c-Krox binds to a site located near the CCAAT box in the pro-Col1a1 promoter and to three GC-rich sequences in the pro-Col1a2 proximal promoter, located between 2277 and 2264 bp, between 2175 and 2143 bp, and near the CCAAT box, respectively (Galera et al., 1996). More recently, c-Krox has been shown to exert its action by synergistic association with SP1 (Kypriotou et al., 2007).

The Col1a1 promoter region spanning bp 29 to 256 bound purified recombinant YY1, and the corresponding binding activity in nuclear extracts was supershifted using a YY1-specific antibody. Mutation of the TATA box to TgTA enhanced YY1 complex formation. YY1 functions as a positive regulator of constitutive activity in fibroblasts. Although YY1 is not sufficient for transcriptional initiation, it is a required component of the transcription machinery in this promoter (Riquet et al., 2001).

A RunX2/Cbfa1-binding element is present in the Col1a1 promoter of mouse, rat, and human at approximately position 2372 (Kern et al., 2001). This site binds RunX2/Cbfa1 only weakly and does not act as a *cis*-acting activator of transcription when tested in DNA transfection experiments. These may interact with the upstream osteoblast-specific element (OSF2) site at 21,347 (Kern et al., 2001), as discussed under "Upstream elements in the pro-*Col1a1* gene" later.

A study exploring the impact of hypoxia on human cartilage identified the role of Sp3 transcription factor in down-regulating collagen type I by binding to a region in the human COL1A1 promoter (between −2300 and −1816) upstream

of the initiation site. This motif contains two GC boxes and the data support the competition between Sp1 and Sp3 for binding, and the accumulation of Sp3 in response to cartilage hypoxia switches from Sp1 binding, a positive regulator toward transcriptional suppression via Sp3 (Duval et al., 2016).

It is likely that the transcriptional function of various transcription factors and eventually their DNA-binding properties offer opportunities for regulation by intracellular signaling pathways. These pathways are triggered by a variety of cytokines such as tumor necrosis factor α (TNFα), which exerts its inhibitory action on Col1a1 expression through nuclear factor κB (NF-κB) (Rippe et al., 1999).

Factors binding to the pro-COL1A2 proximal promoter

Several functional *cis*-acting elements have been identified in the approximately 400-bp proximal promoter of the mouse pro-Col1a2 gene (154−2350 bp) and the human minimal sequence between 152 and 2378 bp. The first transcription factor found to bind to this promoter was the ubiquitous CCAAT-binding protein CBF. This transcription factor is formed by three separate subunits, named A, B, and C, which have all been cloned and sequenced (Maity and de Crombrugghe, 1998). All three subunits are needed for CBF to bind to the sequence containing the CCAAT box located between 284 and 280 and activate transcription in both human and mouse genes (see Fig. 13.2B). In vitro data suggest that the A and C subunits first associate to form an A−C complex and that this complex then forms a heteromeric molecule with the B subunit (Sinha et al., 1995). Mutations in the CCAAT box that prevent the binding of CBF decrease the transcriptional activity of the pro-Col1a2 proximal promoter three to five times in transient transfection experiments of fibroblastic cell lines (Coustry et al., 1995). Purified CBF as well as CBF composed of its three recombinant subunits also activate the pro-Col1a2 promoter in cell-free nuclear extracts previously depleted of CBF (Coustry et al., 1995). Two of the three subunits of CBF contain transcriptional activation domains. More recently, a single substitution of T to an A in vivo in the presence of an upstream enhancer of the human sequence suggested that CBF is involved in patterning of the collagen type I expression in the dorsoventral as well as the rostrocaudal axis of mouse skin fibroblasts (Tanaka et al., 2004).

In addition to the binding site for CBF, footprinting experiments and gel-shift studies identified other binding sites in the first 350 bp of the mouse pro-Col1a2 promoter. Three GC-rich sequences, located at about 2160 bp (between 2176 and 2152 bp) and 2120 bp (between 2131 and 2114 bp) have been shown to interact with DNA-binding proteins by footprint experiments and gel-shift assays (Hasegawa et al., 1996). A deletion in the mouse promoter encompassing these three footprinted sequences completely abolished the transcriptional activity of the pro-Col1a2 proximal promoter in transient transfection experiments using fibroblastic cell lines. The corresponding regions in the human pro-COL1A2 promoter were also protected in in vivo and in vitro footprinting experiments (Ihn et al., 1996) and bound transcriptional activators. However, gel-shift assays performed using the human pro-COL1A2 promoter have suggested that a *cis*-acting element located at 2160 bp represents a repressor element (Ihn et al., 1996), implying that interactions between proteins interacting with the activator elements at 2300, 2125, and 280 bp and proteins binding to a repressor element at 2160 bp regulate this gene. More recently it was shown that CUX1, a CCAAT displacement protein, is associated with reduced expression of type I collagen both in vivo and in vitro and that enhancing the expression of CUX1 results in effective suppression of type I collagen by interfering with CBF binding (Fragiadaki et al., 2011).

Sp1 and Sp3 have been shown to bind the TCCTCC motif located between 2123 and 2128 bp; both transcription factors activate this promoter (Ihn et al., 2001) (see Fig. 13.2B). Furthermore, proteins that bind to the two proximal segments also bind to the most upstream GC-rich segment, at 2300 bp, with the exception of CBF, suggesting a redundancy among functionally active DNA segments of the pro-COL1A2 proximal promoter.

TGFβ mediates its action in the human promoter through the combination of the ubiquitous transcription factor Sp1, the Smad3/4 complex, and the coactivators p300/CREB-binding protein (CBP) in what is termed a TGFβ-responsive element (TβRE) (Zhang et al., 2000). This segment contains three GC-rich motifs between 2330 and 2255, capable of binding Sp1, CCAAT/enhancer-binding protein (C/EBP), activator protein 1 (AP1), and Smad complexes (Chen et al., 1999, 2000a,b; Kanamaru et al., 2003; Tamaki et al., 1995; Zhang et al., 2000). Interaction among these nuclear factors is synergistic and requires binding of Sp1 and Smad3/4 to the GC-rich elements and the downstream CAGAC Smad site, respectively (Ghosh et al., 2000; Poncelet and Schnaper, 2001; Zhang et al., 2000). At the turn of this century, there was a great debate over whether Smads are more important than AP1 in the proximal promoter. This was resolved some 10 years later when it was shown that TGFβ also activates the COL1A2 gene via a noncanonical (Smad-independent) signaling pathway, which requires enhancer/promoter cooperation involving exchange of c-Jun/JunB transcription factor occupancy of a critical enhancer site, resulting in the stabilization of enhancer/promoter coalescence (Ponticos et al., 2009). A report exploring the effects of hypoxia and TGFβ on the COL1A2 gene has added to the potential role of Smads, in particular Smad3, in regulating collagen expression. These studies in human mesangial cells suggest that under hypoxic conditions and in the

presence of TGFβ, hypoxia-inducible factor 1α (HIF-1α) and Smad3 can form transcriptional complexes and preferentially enhance binding to one of the three hypoxia response elements within the human COL1A2 promoter at position −335 bp (Baumann et al., 2016). The authors suggest that this novel interaction provides a mechanism that accounts for the synergy observed between HIF and TGFβ in kidney fibrosis.

TNFα and interferon-γ (IFN-γ) suppress matrix production. In contrast to the single DNA element that mediates TGFβ stimulation of the COL1A2 proximal promoter, both TNFα and IFN-γ have been shown to inhibit COL1A2 transcription by interfering with the formation of the TGFβ-induced complex, and by stimulating the interaction of negative factors with responsive DNA elements located 5′ and 3′ of it. This so-called "cytokine responsive element" plays an important role in maintaining homeostasis. Involvement of AP1 and NF-κB in transducing the inhibitory action of TNFα on COL1A2 gene expression has been shown using immortalized fibroblasts from mice that lack either the AP1 activator Jun N-terminal kinase 1 (JNK1) or the NF-κB essential modulator NEMO. Specifically, the loss of JNK1 prevented the TNFα antagonism of TGFβ, but preserved TNFα inhibition of constitutive COL1A2 expression. TGFβ antagonism by TNFα involves JNK1 phosphorylation of c-jun, leading to off-DNA competition of the latter molecule for Smad3 binding to the cognate DNA site and/or for interaction with the p300/CBP coactivators (Kouba et al., 1999; Verrecchia et al., 2001, 2002).

Binding of IFN-γ to its receptors leads to tyrosine phosphorylation of janus kinase (JAK) tyrosine kinases and this in turn results in signal transducer and activator of transcription (STAT1) phosphorylation. In COL1A2, STAT1 activation results in competition with Smad3 for interaction with p300/CBP (Inagaki et al., 2003). In addition, JAK1 can also activate transcription factor Y-box binding factor (YB-1); this activation results in both inhibition of constitutive promoter activity through YB-1 binding of the 2125TC box and antagonism of TGFβ signals through YB-1 competition with Smad3 and/or p300/CBP (Ghosh et al., 2001; Higashi et al., 2003). For more details, see "Growth factors" and "Cytokines."

Est1/Fli1 have also been shown to bind the same sequence with opposite effects on collagen type I transcription. A functional Ets transcription factor was identified in COL1A2 in close proximity of Sp1 sites. Ets1 stimulated, whereas Fli1 inhibited, promoter activity. Sp1 binding was essential for inhibition of Fli1. Moreover, overexpression of Fli1 in dermal fibroblasts led to a decrease in COL1A2 mRNA and protein levels (Czuwara-Ladykowska et al., 2001). Furthermore, TGFβ treatment of dermal fibroblasts leads to dissociation of Ets1 from the CBP/p300 complexes and alters their response to TGFβ in favor of matrix degradation (Czuwara-Ladykowska et al., 2002).

Furthermore, a CpG motif at 17 bp has been shown to be preferentially methylated and bound by RFX proteins in cells acquiring a collagen I—negative state. Cell transfection experiments in conjunction with DNA-binding assays have assigned positive or negative properties to each of the proteins binding to the proximal promoter of pro-COL1A2 (Sengupta et al., 2002). The degree of methylation at the 17 CpG site, on the other hand, has been shown to modulate the binding affinity of RFX proteins and, consequently, their ability to downregulate promoter activity by recruiting associated proteins that interfere with the assembly of positively acting transcriptional complexes (Xu et al., 2003, 2004).

Structure and functional organization of upstream segments of type I collagen genes

Upstream elements in the pro-*Col1a1* gene

In complete contrast with its high-level activity in transient expression and in vitro transcription experiments, the 220-bp pro-Col1a1 proximal promoter is almost completely inactive in stable transfection experiments and in transgenic mice (Rossert et al., 1996). By increasing the length of this promoter, evidence from different groups showed that the 2.3-kb human promoter linked to different transgenes resulted in a high degree of tissue-specific expression of the reporter gene in bone, tail, and skin. However, this expression of the transgene was not identical to that of the endogenous gene (Slack et al., 1991). Indeed, in later experiments using embryos from the same mice, in situ hybridization assays showed no expression of the transgene in perichondrium and in skeletal muscle, implying that additional sequences might be needed to obtain expression of the gene in all type I collagen—producing cells (Liska et al., 1994). In newborn mice carrying a 3.6-kb rat Col1a1 promoter linked to a chloramphenicol acetyltransferase (CAT) reporter gene, high levels of transgene expression were found in extracts of bone, tooth, and tendon (Bogdanovic et al., 1994; Pavlin et al., 1992). Similarly, the mouse 3.6-kb promoter fused to β-galactosidase transgene resulted in a similar pattern, but localized to three distinct *cis*-acting sequences that directed expression in the skin, bone, and tendon (Rossert et al., 1995). The skin element was between 2220 and 2900 bp. The bone element was further delineated to 117 bp between 21,656 and 21,540 bp, and the tendon to a sequence between 22,300 and 23,600 bp (Rossert et al., 1996) (Fig. 13.3). These experiments suggested a modular arrangement of separate *cis*-acting elements that activate the pro-Col1a1 gene in different type I collagen-

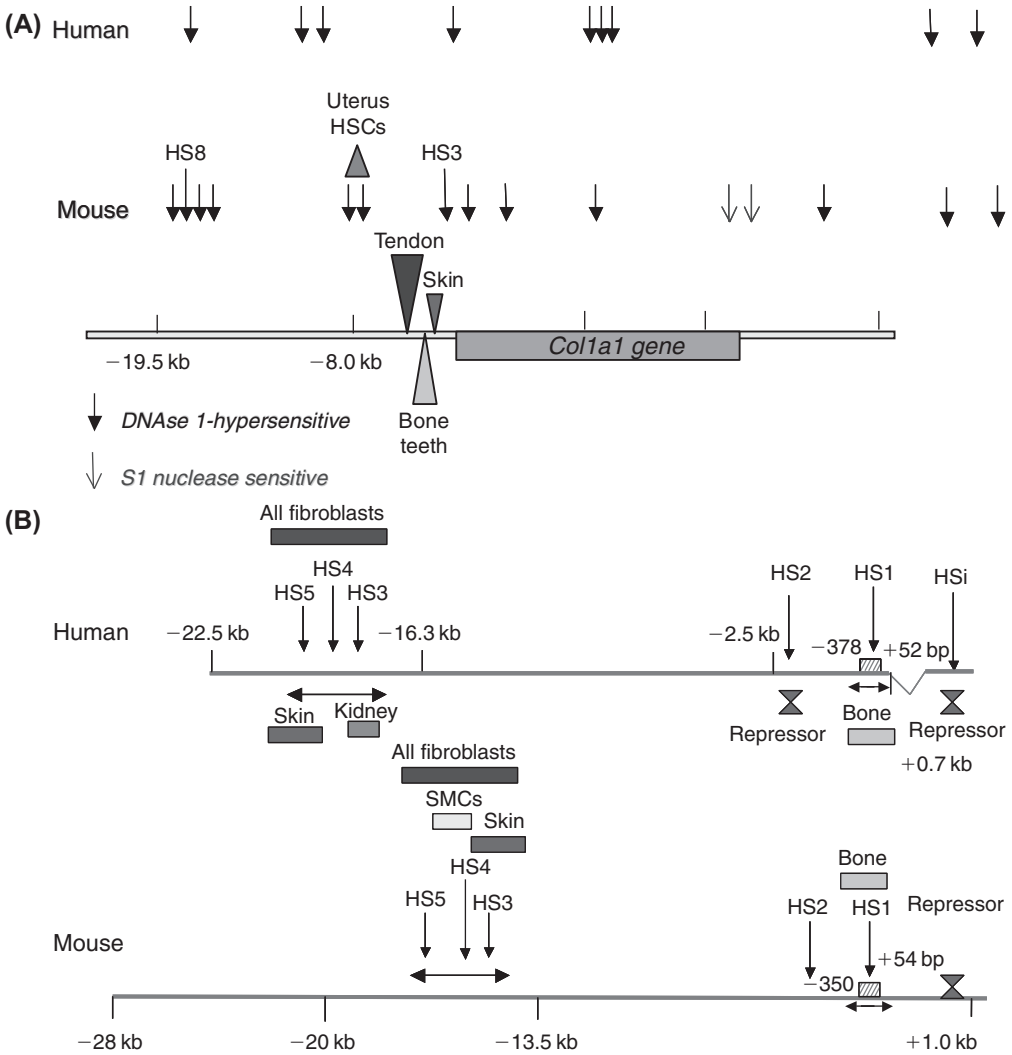

FIGURE 13.3 DNase I hypersensitive sites (*HS*) of the human and murine (A) Col1a1 and (B) Col1a2 genes depicted by *vertical arrows*, which indicate the position within the gene where the sequence may be involved in transcriptional regulation. Areas of high homology in the promoter (0.85%) are indicated by *horizontal arrows*. Also indicated are the regions in which *cis*-acting sequences have been shown to be expressed in transgenic mice, and the tissues or cells in which they are expressed, and which are called "elements" SMCs, smooth muscle cells.

producing cells. The direct consequence of such a modular arrangement is that it should be possible to selectively modulate the activation of type I collagen genes in well-defined subpopulations of type I collagen−producing cells. Perhaps the best illustration of a *cis*-acting element responsible for the activation of the mouse pro-Col1a1 gene is the osteoblast element. This 117-bp segment is very well conserved among species. In the mouse promoter, located between 21,656 and 21,540 bp, is a minimal sequence able to induce high levels of expression of the reporter gene exclusively in osteoblasts. In these mice the transgene becomes active at the same time during embryonic development when osteoblasts first appear in the different ossification centers. This so-called "osteoblast-specific element" can be divided into three subsegments that have different functions. The 29-bp A segment, which is located most 5′ (21,656−21,628 bp), is required to activate the gene in osteoblasts. A deletion of the A element or a 4-bp mutation in the TAAT sequence of this segment completely abolished the expression of the reporter gene in osteoblasts of transgenic mice. The C segment, which is located at the 3′ end of the 117-bp sequence (21,575−21,540 bp), is required to obtain consistent high-level expression of the reporter gene in transgenic mice (Rossert et al., 1996). When this C segment was deleted, the lacZ gene was expressed at very low levels and only in a small proportion of transgenic mice. The function of the intermediary segment (B segment) is still poorly understood, but it could be to prevent a promiscuous expression of the gene and, in particular, expression of the gene in the nervous system.

In addition to the 117-bp region, a consensus Cbfa1-binding site, termed oxidation-specific epitope 2 (OSE2), is present at approximately 21,347 bp of the rat, mouse, and human genes (Kern et al., 2001). RunX2/Cbfa1 can bind to this site, as demonstrated by electrophoretic mobility shift assay and supershift experiments using an anti-Cbfa1 antibody. Mutagenesis of the Col1a1 OSE2 at 21,347 bp reduces the activity of a Col1a1 promoter fragment - to threefold. Moreover, multimers of this OSE2 at 21,347 bp confer osteoblast-specific activity to a minimum Col1a1 collagen promoter fragment in DNA transfection experiments. However, this region did not confer expression in transgenic mice, suggesting that other specific factors contribute to expression of collagen type I in osteoblasts. Indeed, Osterix (Osx), a zinc finger transcription factor, was found to be essential for bone formation and to act downstream of RunX2/Cbfa1. It was shown to bind to segment C of the osteoblast element. The tendon element was found to be a combination of sequences between 23.2 and 23.6 kb termed TSE1 and TSE2 (Terraz et al., 2002). Gel-shift experiments of this region showed that scleraxis, which is a basic helix−loop−helix transcription factor that is expressed selectively in tendon fibroblasts, binds TSE2, whereas TSE1 binds NFATc (nuclear factor of activated T cells) transcription factors (Lejard et al., 2007).

In pursuit of the controlling regions of this gene, a chromatin structure analysis of the human COL1A2 gene has revealed the presence of several proximal and distal 5′ and 3′ DNase I hypersensitive sites (HSs) (Barsh et al., 1984). Breindl's team used the same technique and mapped a 55-kb sequence spanning the mouse gene, including 24 kb of 5′- and 13 kb of 3′-flanking sequences (Salimi-Tari et al., 1997). Nine HSs were found, seven of which were in the promoter sequence (HS3−HS9) up to 220 kb (see Fig. 13.3A). All of these HSs were present in collagen type I−producing cells except for HS8. When these sequences were fused to a reporter gene in transgenic animals, they revealed an additional *cis*-acting sequence in uterine smooth muscle cells between 27 and 28 kb (Krempen et al., 1999) and in liver stellate cells (Yata et al., 2003).

Upstream elements of the mouse pro-*Col1a2* gene

The activity of the mouse 350-bp pro-Col1a2 proximal promoter in transgenic mice is very low compared with that of the corresponding endogenous gene. Although this low-level activity appears to be present selectively in fibroblasts and mesenchymal cells (Niederreither et al., 1992), the precise sequences and the factors responsible for this tissue specificity have not yet been identified. An element located 13.5−17 kb upstream of the start site of transcription, and named "far-upstream enhancer," increased the levels of expression of the lacZ and luciferase reporter genes considerably when it was cloned upstream of the 350-bp mouse pro-Col1a2 proximal promoter. Moreover, this element by itself contributed to the tissue-specific expression of a reporter gene. Indeed, when it was cloned upstream of a minimal promoter that has no tissue-specific expression by itself, i.e., the first 220 bp of the pro-Col1a1 proximal promoter, it conferred a tissue-specific expression to the lacZ reporter gene in transgenic mice (Bou-Gharios et al., 1996). The enhancer was reduced in size to 1.5 kb between −15.5 and −17 kb and was shown to depend on HS4 around 250 bp to drive the expression. Interestingly, in transgenic mice harboring the lacZ reporter gene cloned downstream of a pro-Col1a2 promoter segment containing the far-upstream enhancer, fibroblastic cells expressed the lacZ reporter gene at very high levels, but only a subset of osteoblastic cells expressed this reporter gene, and odontoblasts and fully differentiated tendon fibroblasts did not (Bou-Gharios et al., 1996; Li et al., 2017), suggesting that a *cis*-acting element active in all osteoblasts is missing from this promoter/enhancer sequence. Other than this heterogeneous expression of the lacZ reporter gene in bone, the lack of expression of the lacZ gene in odontoblasts suggests that other elements exist that control expression in these cells and strongly supports a modular organization of different regulatory domains in the mouse pro-Col1a2 promoter, as described for the pro-Col1a1 promoter.

To verify the transgene staining results, both luciferase and β-galactosidase activity in tissue homogenate was measured, because the transgenic line used harbored both β-galactosidase and luciferase transgenes. Although β-galactosidase staining was no longer present in many tissues by the time transgenic mice were weaned, luciferase activity of the same tissues remained significantly higher than in controls. The endogenous mRNA level followed the overall trend of the transgene, and very little transgene mRNA was detected by 3 months of age. The skin showed the highest level of endogenous mRNA during development, which was matched by transgene expression (Ponticos et al., 2004a, b), and although mRNA level dropped by day 10 after birth, the transgene remained significantly high until 3 weeks of age, suggesting perhaps a specific role of this enhancer in the dermis.

The role of the enhancer in the regulation of the collagen type I gene was also revealed by measuring activation of the transgenes after injury to tissues, either by injection of fibrogenic cytokines such as TGFβ1 or by physical injury. Such challenge appears to stimulate a significant increase in transcription of both the endogenous collagen gene and the transgenes. Although mRNA levels of collagen have been shown to diminish in many tissues after birth and throughout adulthood (Goldberg et al., 1992), acute injury reactivates the lacZ transgene to a level that is visually apparent

(Ponticos et al., 2004a, b). This finding makes such transgenic animals an important tool and provides a model to address questions about the nature of cells that are active in fibrosis. For example, in muscular dystrophy, where fibrosis bears the hallmark of the disease (Morrison et al., 2000), this model can be used to identify those cells that are active in producing collagen type I as shown with glomerulosclerosis (Chatziantoniou et al., 1998) and the Tsk mouse model bred with these transgenic mice (Denton et al., 2001). More importantly, this will allow us to test the direct effects of various antifibrotic agents on the cells that are actively synthesizing collagen type I.

In the human COL1A2 gene, six distinct DNase I−HSs were mapped within 22 kb upstream and around the start site of transcription. Their spatial arrangement, cell type specificity, and relative availability to DNase I digestion are comparable to those of the mouse gene (Antoniv et al., 2001). The more striking finding of the chromatin survey was the identification of three strong cell-type-specific HSs (HS3−5), at a location comparable to those of the mouse far-upstream enhancer and residing within nearly identical sequences (see Fig. 13.3B). DNase I footprinting correlated areas of sequence identity with 12 distinct binding sites of nuclear proteins, the majority of which are likely not to be tissue specific. Using transgenic analysis, it was found that the proximal 2378 promoter contains elements that drive tissue-specific transcription in subsets of fibroblastic and osteoblastic cells, and this activity is significantly augmented when the proximal promoter is linked to the far-upstream enhancer. The results of the human transgenes thus indicate that the predominant function of the upstream element is to broaden and intensify tissue-specific transcription from the proximal promoter. Unlike the mouse enhancer that was active only in a subset of osteoblasts, the human sequence was active in all osteoblasts and it is most likely that the osteoblast element resides in the proximal promoter (Antoniv et al., 2001). Focusing on the mouse Col1a2 gene, a study by Marongiu et al. has identified a potentially new long-range autoregulatory mechanism controlling collagen transcription. The group investigated FOXL2, a member of the evolutionarily conserved forkhead box transcription factors, and found, using chromatin immunoprecipitation experiments followed by genomic DNA sequencing (ChIP-seq) and electrophoretic mobility shift assays, that this factor bound to a DNA element ∼65 kb upstream of the collagen gene. This region was found to contain a putative forkhead transcription factor binding site (ACAAACA), thereby providing a mechanism antagonizing transcription from the promoter. These experiments were centered on studies of the mouse reproductive system and therefore whether this represents a general automodulatory process governing Col1a2 transcription or is a tissue-restricted process is unclear as of this writing (Marongiu et al., 2016).

Delineating the mode of action of tissue-specific elements

The mode of action of the different lineage-specific transcription elements and their postulated cognate-binding proteins is still unknown, but studies of HSs (Antoniv et al., 2001; Bou-Gharios et al., 1996) and in vivo footprinting experiments (Chen et al., 1997) strongly suggest that the chromatin structure of discrete areas in the regulatory regions of type I collagen genes is different in cells when these genes are being transcribed actively, compared with cells in which they are silent. These experiments suggest that, in intact cells, transcription factors such as CBF bind to the proximal promoters of type I collagen genes only in cells in which the genes are transcribed actively (Coustry et al., 2001). Although in vivo footprint experiments show a protection of the CCAAT box in different fibroblastic cell lines, such a protection does not exist in cell lines that do not produce type I collagen. Similarly, HSs corresponding to the far-upstream enhancer of the pro-Col1a2 promoter can be detected only in cells that express type I collagen. The importance of chromatin structure is also highlighted by comparison of transient and stable transfection experiments. When a chimeric construct harboring the pro-Col1a1 osteoblast-specific element cloned upstream of a minimal promoter and of the lacZ reporter gene was transfected stably in different cell lines, it was expressed in the ROS17/2 osteoblastic cell line, but not in two fibroblastic cell lines or in a cell line that does not produce type I collagen. In contrast, in transient transfection experiments, the same chimeric construction was expressed at high levels by all cell lines. These results suggest a model in which the binding of a lineage-specific transcription factor to specific enhancer segments of type I collagen genes would result in opening the chromatin around the promoter and allow ubiquitous transcription factors to bind to the proximal promoter and to activate transcription of the genes.

The discovery of the far-upstream enhancer raised the question of whether the enhancer could confer tissue specificity on its own, and if individual elements of the proximal promoter contribute differently to COL1A2 transcription in vivo. A series of mutations introduced into each of the transcription factors' binding sites within the proximal promoter, such as the three Sp1 sites, GC-rich Sp1/Sp3-binding sites, and the CBF-binding site, reduced transgene activity, providing strong evidence that these protein interactions operate in vivo as well, and in concert with the enhancer-bound complex (Tanaka et al., 2004). The unique expression pattern of transgenic mice harboring mutations in the binding site of transcription factor CBF/NFY led to loss of lacZ expression in the ventral and head regions of the dermis, as well as in the muscles of the forelimbs. The patterning of specific cell lineages implies that CBF/NFY may be essential for COL1A2 activity in those

cells that do not express the transgene. These transgenic data therefore raise the intriguing possibility that CBF/NFY may be implicated in patterning COL1A2 expression in some mesenchyme cell lineages through a yet-to-be-defined mechanism. The results suggested cooperativity between the far-upstream enhancer and the proximal promoter in assembling tissue-specific protein complexes. They confirmed in vitro observations indicating that interactions among proximal promoter elements are required for optimal transcription. They also indicated that transcription factors binding to individual promoter elements are responsible for distinct properties of COL1A2 expression in vivo (Ramirez et al., 2006). More importantly, the upstream enhancer was shown to play a part in the fibrotic process of connective tissue disease, such as diffuse cutaneous systemic sclerosis (SSc), where the accumulation of JunB in the COL1A2 enhancer in fibroblast DNA resulted in altered mammalian target of rapamycin (mTOR)/protein kinase B (AKT) signaling and a failure of proteolytic degradation of collagen, which underpins the aberrant overexpression of type I collagen in this disease (Ponticos et al., 2015).

In the enhancer sequence of the mouse Col1a2 gene, the first tissue-specific element to be characterized was a vascular smooth muscle cell (vSMC) element: a 100-bp sequence at about 216.6 kb upstream of the transcription start site regulates collagen expression exclusively in vSMCs (Ponticos et al., 2004a, b). This expression was shown to be activated through the binding of the homeodomain protein Nkx2.5, and further potentiated by the presence of GATA6. In contrast, this element was repressed by the binding of the zinc finger protein δ-EF1/ZEB1. A model of regulation was proposed in which the activating transcription factor, Nkx2.5, and the repressor, δ-EF1/ZEB1, compete for an overlapping DNA-binding site. This element is important in understanding the molecular mechanisms of vessel remodeling and is a potential target for intervention in vascular diseases in which there is excessive deposition of collagen in the vessel wall.

Role of the first intronic elements in regulating collagen type I

First intron of the pro-*COL1A1* gene

Different negative or positive regulatory segments have been identified within the first intron, but most of the transcription factors binding to these regulatory segments are still unknown. A sequence of the first intron of the human COL1A2 gene located about 1600 bp downstream of the transcription start site binds AP1, and a mutation that abolished this binding diminished the expression of a reporter gene in transient transfection experiments (Liska et al., 1990) This AP1 was also found to mediate the repressive effect of ras in fibroblasts (Slack et al., 1995). Another segment of the first intron of the human gene, which extends from 820 to 1093 bp, has been shown to inhibit the activity of a reporter gene in transient transfection experiments (Liska et al., 1992). This sequence contains two binding sites for an Sp1-like transcription factor, and mutations in these two Sp1-binding sites tended to increase the activity of the reporter gene (Liska et al., 1992). An Sp1-binding site is also located at about 1240 bp, in the human gene, and a frequent G-to-T polymorphism in this Sp1-binding site (G1242T) has been linked with low BMD and increased risk of osteoporotic vertebrate fracture (Grant et al., 1996), which suggests that it may be important for normal levels of type I collagen synthesis by osteoblasts.

The phenotype of Mov 13 mice suggested that the first intron of the pro-α1(I) collagen gene could play a role in the expression of this gene. These mice, which harbor a retrovirus in the first intron of the pro-Col1a1 gene (Harbers et al., 1984), express this gene in osteoblasts and odontoblasts, but not in fibroblastic cells (Schwarz et al., 1990). Nevertheless, the presence of tissue-specific regulatory elements in the first intron of the pro-Col1a1 gene has long been controversial. Two groups have reported that, in transgenic mice harboring the proximal promoter of either the human or the rat pro-Col1a1 gene, the pattern of expression of the reporter gene was the same whether or not these mice harbored the first intron of the pro-Col1a1 collagen gene (Sokolov et al., 1993). In contrast, data obtained by in situ hybridization in transgenic mice harboring 2.3 kb of the human pro-Col1a1 proximal promoter suggested that the first intron of this gene was necessary to obtain high-level expression of the transgene in the dermis of skin (Liska et al., 1994). Only mice harboring the first intron, in addition to the 2.3-kb proximal promoter segment, expressed the human growth hormone reporter gene at high levels in skin. To clarify this issue, Bornstein's group generated knock-in mice with a targeted deletion of most of the first intron (Hormuzdi et al., 1998). Mice homozygous for the mutated allele developed normally and showed no apparent abnormalities. Nevertheless, in heterozygous mice, the mutated allele was expressed at normal levels in skin, but at lower levels in lung and muscle, and its levels of expression decreased with age in these two tissues more than in wild-type mice. Thus, the first intron does not play a role in the tissue-specific expression of the pro-Col1a1 gene, but it seems to be important for maintaining normal transcriptional levels of this gene in certain tissues (Hormuzdi et al., 1999).

First intron of the pro-*COL1A2* gene

The first intron of the mouse pro-Col1a2 gene has also been shown to contain a tissue-specific enhancer in transient transfection experiments (Rossi and de Crombrugghe, 1987). In transgenic mice, however, the presence of this tissue-specific enhancer apparently had no effect on the pattern of expression of a CAT reporter gene (Goldberg et al., 1992). However, transgenic analysis of the human gene suggested that, despite the homologies between the two genes, species-specific differences have been reported regarding the function of individual *cis*-acting elements, such as the first intron sequence (Antoniv et al., 2005). In vitro DNase I footprinting of the sequence corresponding to the open chromatin site identified a cluster of three distinct areas of nuclease protection that span from nucleotide 1647 to 1759 of the COL1A2 gene. These areas contain consensus sequences for GATA and interferon regulatory factor (IRF) transcription factors. Gel mobility shift and chromatin immunoprecipitation assays corroborated this finding by documenting binding of GATA4 and IRFs 1and 2 to the first intron sequence (Antoniv et al., 2005). Moreover, a short sequence encompassing the three footprints was found to inhibit expression of transgenic constructs containing the COL1A2 proximal promoter and far-upstream enhancer in a position-independent manner. Mutations inserted into each of the footprints restored transgenic expression to different extents. These results therefore indicated that the intronic sequence corresponds to a repressor element, the activity of which seems to be mediated by the concerted action of GATA and IRF proteins (see Fig. 13.2B). Furthermore, GATA4 was found to bind the promoter sequence of HS2 at 22.3 kb in the COL1A2 gene. Overexpression of this transcription factor inhibited the expression of the transgene as well as the endogenous gene in fibroblasts (Wang et al., 2005). The presence of a common repressor transcription factor in both HS2 and HS intron led to the suggestion that the "switch-off" of collagen in adults may occur via cooperation of the intronic sequence and HS2 to block the enhancer activity from exerting its effect through its cooperation with the proximal promoter in HS1 (Ramirez et al., 2006).

ChIP-seq with chromatin of mouse calvarial cells has been used to identify Osx/Sp7 interaction sites (Hojo et al., 2016). Osx was previously shown to be a transcription factor completely required for osteoblast differentiation and for bone formation (Nakashima *et al.* 2002). In this ChIP-seq study one major peak of Osx/Sp7 interaction in the chromatin of the Col1a1 gene was localized in the segment that was previously identified to be osteoblast specific in transgenic mice (Rossert et al., 1996; Bedalov et al., 1995). Other peaks of Osx/Sp7 interactions were also identified farther upstream of the sequence previously identified as osteoblast specific. The same ChIP-seq study also provided evidence that Osx/Sp7, which belongs to the Sp1 family of transcription factors, was itself not strongly binding to a GC-rich DNA target, unlike the other members of the SP1 family, but interacted as a coactivator with another DNA-binding protein, most likely a member of the Dlx family of transcription factors (Hojo et al., 2016). ChIP-seq is a powerful method to identify interaction sites for specific transcription factors in the genome of specific cell types. These sites can then further be characterized either by reporter assays in vivo in transgenic mice or by transfection of tissue culture cells. In addition, ChIP-seq can be used to characterize epigenomic modifications of histones or other chromatin proteins in the genome of specific cells.

In other ChIP-seq experiments interactions of the Runx2 transcription factor, which is also required for osteoblast differentiation and for bone formation, with the Col1a1 gene were examined (Wu et al., 2014). A major site of interactions was found at a promoter-proximal site of this gene. This study compared the interactions of Runx2 in the genome of a preosteoblastic cell line at three stages of osteoblast differentiation.

Posttranscriptional regulation of type I collagen

Even if the control of expression of type I collagen genes appears to be mainly exerted at the level of transcription, type I collagen production is also regulated at a posttranscriptional level. For example, TGFβ and IFN-γ modulate not only the levels of transcription of type I collagen genes, but also the stability of the corresponding mRNAs. Similarly, activation of HSCs is associated with a dramatic increase in the stability of the pro-Col1a1 mRNA. Run-on experiments have shown that the half-life of this mRNA was increased about 15-fold in activated rat HSCs compared with quiescent ones (Stefanovic et al., 1997). Several lines of evidence indicate that expression of the genes coding for the two collagens I and III is controlled predominantly posttranscriptionally at the mRNA level, as the 3′-UTR of the collagen family mRNA has been shown to be a target for mRNA-binding protein. Heterogeneous nuclear ribonucleoproteins (hnRNPs) A1, E1, and K substantially participate in the coordinative upregulation of collagen I and III synthesis, which is involved in mRNA stabilization (Lindquist et al., 2000). Indeed, all three COL1A1, COL1A2, and COL3A1 3′-UTRs contain hnRNP K-like consensus motifs and do actually bind it. COL1A1 and COL1A2 contain a classical CU-rich hnRNP E1-binding site, and it is also able to bind hnRNP E1, although not in COL3A1, which lacks a more extended CU-rich region. Furthermore, these mRNA-binding proteins have been shown to increase in fibrotic conditions and are suggested to coordinate expression of

type I and III collagens by common posttranscriptional mechanisms targeted at the mRNA 3′-UTR level (Thiele et al., 2004).

The sequence of the mouse pro-Col1a1 mRNA surrounding the start codon could also play a role in regulating mRNA stability. This sequence has been shown to form a stem−loop structure, and mutations that prevent its formation decreased the stability of the mRNA dramatically (Stefanovic et al., 1999). Indeed, the 5′-UTRs of COL1A1, COL1A2, and COL3A1 mRNAs are involved in such translational control. These 5′ stem−loops, together with their cognate binding proteins, should help coordinate translation and couple the translation apparatus to the rest of the collagen biosynthetic pathway (Stefanovic and Brenner, 2003).

MicroRNAs (miRNAs) mediate the posttranscriptional regulation of gene expression by binding to partially complementary sites in the 3′-UTR of target mRNA. The formation of miRNA−mRNA duplexes leads to mRNA degradation or translational repression (Ambros, 2003) The first miRNAs that were shown to be involved in collagen regulation were members of the miR-29 family. TGF is activated and triggers the downregulation of miR-29 in cardiac fibroblasts and consequent upregulation of the expression of collagens and other ECM proteins involved in fibrosis (pnas.0805038105). This was also evident in other fibrotic disease. Moreover, miR-185 and miR-98 have been shown to regulate TGFβ and collagen type I in hypertrophic scar tissue fibroblasts. miR-185 loss of function resulted in elevated TGFβ1 and collagen expression, suggesting miR-185 might serve as a potential therapeutic target for scarring. miR-98 was shown to directly target the Col1A1 3′-UTR, resulting in reduced expression, and therefore likely to have an impact on scar formation. In addition to miRs that directly interact and inhibit collagen and TGFβ, the study of keloid fibroblasts has highlighted the role of miR-21in promoting Col1A1 production via the targeting of Smad7. Negatively regulating the expression of the inhibitory Smad, Smad 7, appears to alter the TGFβ/Smad7 signaling pathway favoring increased collagen production and keloid scarring. Similarly, downregulation of miRNA let-7a or miR-196a was shown to contribute to scarring in SSc by the intrinsic activation of TGFβ (jimmunol.1200822) and the expression of miR-21 or miR-145 and decreased mRNA levels of Smad7 or Smad3, respectively. Similarly, the cytokine decreased the expression of miR-29b and increased α1(I) collagen mRNA. Accordingly, these miRNAs may contribute to the pathogenesis of SSc via the regulation of Smad7, Smad3, and α1(I) collagen (Zhu et al., 2012).

Critical factors involved in type I collagen gene regulation

Various cytokines, hormones, vitamins, and growth factors can modify type I collagen synthesis by osteoblasts and/or fibroblasts. The effects of these molecules have been studied mainly in vitro by using either bone organ cultures or cell cultures. However, in some instances the in vivo effects of these factors on type I collagen synthesis have also been studied. A degree of complexity is due to the fact that some factors can act on type I collagen synthesis but can also act indirectly by modifying the secretion of other factors, which will themselves affect type I collagen synthesis. For example, TNFα will inhibit type I collagen production through the NF-κB pathway, but it will also induce the secretion of prostaglandin E_2 (PGE_2) and of interleukin 1 (IL-1), which themselves affect type I collagen production. Furthermore, PGE_2 will induce the production of insulin-like growth factor 1 (IGF-1), which also modifies the rate of type I collagen synthesis.

Growth factors

Transforming growth factor β

In mammals, the TGFβ family consists of three members (TGFβ1, TGFβ2, and TGFβ3), which have similar biological effects but different spatial and temporal patterns of expression. These three molecules are part of a large family, the TGFβ superfamily, which also contains proteins such as BMPs, activins/inhibins, and growth and differentiation factors, as well as Nodal and its related proteins (Chang et al., 2002; Massague and Chen, 2000). Members of the TGFβ family are multifunctional proteins that regulate cell proliferation and differentiation, ECM modification, angiogenesis, apoptosis, and immunosuppression (Feng and Derynck, 2005; Jones et al., 2006; Schier and Shen, 2000). A TGFβ protein exerts its function by binding to and bringing together on the cell surface type I and II receptors to form a ligand−receptor complex (Leask and Abraham, 2004). Five members of type II and seven members of type I receptors (Activin receptor-like kinase 1−7) have been characterized in mammals (Graham and Peng, 2006). Upon phosphorylation by the type II receptor, the type I receptor phosphorylates and activates Smads, which are intracellular signaling molecules for members of the TGFβ superfamily. Phosphorylated Smads are released from the receptors and form oligomeric complexes with a common-partner Smad, Smad4, and translocate into the nucleus where they bind to specific DNA sequences called Smad-binding elements and act as transcription factors to regulate the transcription of target genes. Smad2 and Smad3

respond to TGFβs, Activins, Nodal, and Lefty, whereas Smad1, Smad5, and Smad8 mediate BMP signaling (Miyazawa et al., 2002). Several transcription factors and transcriptional coactivators have been shown to cooperate with Smad complexes, such as Sp1, AP1, PEBP2/CBF, TFE-3, ATF-2, and CBP/p300 (reviewed in Attisano and Wrana, 2000).

TGFβs are secreted by many cell types, including monocytes/macrophages, lymphocytes, platelets, fibroblasts, osteoblasts, and osteoclasts (Leask and Abraham, 2004). Synthesis by bone cells is quantitatively important because, in vivo, the highest levels of TGFβ are found in platelets and bone (Seyedin et al., 1985). Nearly all cells, including osteoblasts and fibroblasts, have TGFβ receptors (Verrecchia and Mauviel, 2007).

The three mammalian TGFβ isoforms are synthesized as homodimeric proproteins (pro-TGFβ) that have a mass of 75 kDa. The dimeric propeptides are cleaved from the mature TGFβ 24-kDa dimer in the *trans*-Golgi by furin-type enzymes. Mature TGFβ1 then associates noncovalently with a dimer of its N-terminal propeptide (also called LAP, for latency-associated peptide). This complex is referred to as the small latent complex (Annes et al., 2003). Early in the assembly of TGFβ and LAP, disulfide linkages are formed between cysteine residues of LAP and specific cysteine residues in another protein, the latent-TGFβ-binding protein (LTBP), to form the large latent complex (Annes et al., 2003). The LTBP is removed extracellularly by either proteolytic cleavage by various proteases, such as plasmin, thrombin, plasma transglutaminase, or endoglycosylases, or by physical interactions of the LAP with other proteins, such as thrombospondin-1, which is able to transform latent TGFβ1 into active TGFβ1 in vitro. Analysis of mice harboring a targeted disruption of the thrombospondin-1 gene suggests that it probably plays an important role in vivo (Crawford et al., 1998). In particular, the phenotype of thrombospondin-1-null mice was relatively similar to that of TGFβ1-null mice, and fibroblasts isolated from the former mice had a decreased ability to activate TGFβ1. Nevertheless, thrombospondin-1 is probably not the only molecule that activates TGFβ in vivo (Abdelouahed et al., 2000).

The four LTBPs (LTBP1−4) belong to the LTBP/fibrillin family of large extracellular glycoproteins (Todorovic et al., 2005). LTBP1, LTBP3, and LTBP4 form a subgroup within the family, because they covalently interact with latent TGFβ and have an important role as regulators of TGFβ function: LTBPs facilitate the secretion of latent TGFβ, direct its localization in the ECM, and regulate the activation of the cytokine. In mice ablation of the Ltbp3 gene and attenuation of Ltbp4 expression both result in developmental defects associated with reduced TGFβ activity (Dabovic et al., 2002; Sterner-Kock et al., 2002), further demonstrating that Ltbp3 and Ltbp4 modulate extracellular TGFβ levels in a specific and nonredundant manner.

The role of TGFβ on type I collagen synthesis has been demonstrated both in vivo and in vitro. In vivo, subcutaneous injections of platelet-derived TGFβ in newborn mice increased type I collagen synthesis by dermal fibroblasts with formation of granulation tissue (Roberts et al., 1986). Injections of platelet-derived TGFβ onto the periostea of parietal bone of newborn rats stimulated bone formation, and thus accumulation of ECM (Noda and Camilliere, 1989). Transgenic mice that overexpressed mature TGFβ1 developed hepatic fibrosis and renal fibrosis (Sanderson et al., 1995). Increased expression of TGFβ2 in osteoblasts in transgenic mice resulted in an osteoporosis-like phenotype with progressive bone loss. The bone loss was associated with an increase in osteoblastic matrix deposition and osteoclastic bone resorption (Erlebacher and Derynck, 1996). Conversely, expression of a dominant-negative TGFβ receptor mutant in osteoblasts led to decreased bone remodeling and increased trabecular bone mass (Filvaroff et al., 1999). In humans, mutations in the LAP of TGFβ1 cause Camurati−Engelmann disease, a rare sclerosing bone dysplasia inherited in an autosomal-dominant matter. It is unclear whether these mutations impair the ability of the LAP to inhibit TGFβ activity or cause accelerated degradation of TGFβ (Janssens et al., 2000; Kinoshita et al., 2000).

More recently, transgenic mice expressing a kinase-deficient type II TGF receptor (T-RIIΔk) in fibroblasts demonstrated unexpected skin and lung fibrosis (Denton et al., 2003). Moreover, the fibrotic phenotype of explanted dermal fibroblasts from the T-RIIΔk-deficient transgenic mice showed that expression of the mutant receptor leads to multilevel activation of the TGFβ ligand−receptor axis and that activation depends on endogenous T-RI receptor kinase activity (Denton et al., 2005). This paradoxical increased activity of the TGFβ ligand−receptor axis in these transgenic mice occurs despite previous findings that the kinase-deficient TGFβ receptors are dominant-negative inhibitors of signaling in several experimental systems, when expressed at high levels compared with wild-type receptors. Further evidence that TGFβ and its signaling pathways significantly influence collagen gene regulation is manifested in Smad3 2/2 mice exposed to a single dose of 30−50 Gy of γ-irradiation. These mice showed significantly less epidermal acanthosis and dermal influx of mast cells, macrophages, and neutrophils and decreased expression of TGFβ compared with skin from wild-type littermates, suggesting that inhibition of Smad3 could decrease tissue damage and reduce fibrosis after exposure to ionizing radiation (Flanders et al., 2002). Conversely, C57BL/6 mice with bleomycin-induced lung fibrosis receiving an intratracheal injection of a recombinant adenovirus expressing Smad7 demonstrated suppression of type I procollagen mRNA, reduced hydroxyproline content, and no morphological fibrotic responses in the lungs, indicating that gene transfer of Smad7 prevents bleomycin-induced lung fibrosis (Nakao et al., 1999). More recently, using mice with a targeted deletion of

Smad3, Roberts et al. (2006) demonstrated that lack of Smad3 prevents the epithelial-to-mesenchymal transition of lens epithelial cells following injury, and attenuates the development of fibrotic sequelae. Together, these various experimental approaches demonstrate the direct implication of Smad3 and TGFβ and molecular changes in collagen type I in fibrotic diseases.

In vitro, TGFβ stimulates the synthesis of most of the structural components of the ECM by fibroblasts and osteoblasts, including type I collagen (for a review, see Leask and Abraham, 2004). It also decreases ECM degradation by repressing the synthesis of collagenases and stromelysins and by increasing the synthesis of TIMPs. It increases lysyl-oxidase activity, which may favor interchain cross-linking in collagen fibrils (Feres-Filho et al., 1995). Finally, it stimulates the proliferation of both fibroblasts and osteoblasts, in contrast to its inhibitory effect on the proliferation of epithelial cells. Moreover, TGFβ may have a role in controlling the lineage-specific expression of type I collagen genes during embryonic development, because there is an excellent temporal and spatial correlation between the activation of type I collagen genes and the presence of immunoreactive TGFβ in the extracellular environment (Niederreither et al., 1992). As noted earlier, Fli1 is a key transcriptional repressor of the *COL1A2* gene. Interestingly, TGFβ induces a sequential displacement of Fli1 from the COL1A2 promoter by posttranslational modifications. The molecular mechanism underlying this process has been delineated and involves the TGFβ-induced phosphorylation of Fli1 leading to the dissociation of the transcriptional repressor protein complex composed of Fli1, histone deacetylase (HDAC), and p300. Thus by alleviating the chromatin remodeling by histone deacetylation, the repressor complex that occupies the COL1A2 promoter (at −404 to −237) is disassembled, leading to transcriptional activation (Asano et al., 2013).

Another way in which TGFβ exerts its action is at a pretranslational level, by increasing mRNA levels of the pro-Col1a1 and pro-Col1a2 transcripts. This increase in type I collagen mRNA levels can be caused by an increase in the transcription rate of type I collagen genes and/or by an increase in procollagen mRNA stability, with the relative contribution of these two mechanisms depending on cell type and on culture conditions. The second effect is through Smad proteins as indicated later: The effect of TGFβ on transcription of the human pro-COL1A2 gene involves Smad complexes (reviewed by Ramirez et al., 2006). This effect is mediated through a sequence of the promoter located between 2378 and 2183 bp upstream of the start site of transcription and is called the TβRE, as demonstrated by transfection experiments (Inagaki et al., 1994). Footprinting experiments performed with this sequence revealed two distinct segments interacting with DNA-binding proteins (Inagaki et al., 1994). It contains two binding sites for Sp1, as well as a binding site for C/EBP (Greenwel et al., 1997; Inagaki et al., 1994). The DNA sequence between 2271 and 2250 contains a CAGA box that binds Smad 3/Smad4 complexes (Chen et al., 1999; Zhang et al., 2000), as well as a binding site for AP1 (Chung et al., 1996). Data have shown that Smad 3/Smad4 complexes can bind to the CAGA box and mediate TGFβ-induced stimulation of the pro-COL1A2 gene, in cooperation with Sp1 proteins (Zhang et al., 2000). Other studies have suggested a role of AP1 in mediating the effects of TGFβ (Chung et al., 1996). This Smad/AP1 interaction was later found to take place "off DNA" (Verrecchia et al., 2001). The transcriptional coactivator CBP/p300, which can bind to Smad complexes, also plays an important role in mediating the effects of TGFβ on the transcriptional activity of the pro-COL1A2 gene (Ghosh et al., 2000). Thus, TGFβ probably activates the transcription of the pro-COL1A2 gene through the binding of a multimeric complex, which includes Smad3/Smad4, Sp1, CBP/p300, and possibly AP1. More recently, using Affymetrix microarrays to detect cellular genes whose expression is regulated by TGFβ through Smad3, Chen et al. identified the gene for early growth response factor-1 (EGR-1) as a Smad3-inducible gene (Chen et al., 2006a,b). It was also found that TGFβ enhanced endogenous Egr-1 interaction with a consensus Egr-1-binding-site element and with GC-rich DNA sequences of the human COL1A2 promoter in vitro and in vivo. Furthermore, forced expression of Egr-1 by itself caused dose-dependent upregulation of COL1A2 promoter activity and further enhanced the stimulation induced by TGFβ (Chen et al., 2006a,b). Other transcriptional coactivators such as the steroid receptor coactivator-1 may also participate in TGFβ effects (Dennler et al., 2005).

In the rat pro-Col1a1 gene, a TβRE has been described at about 1.6 kb upstream of the start site of transcription (Ritzenthaler et al., 1993) and between 2174 and 284 bp in the human pro-α1 collagen gene (Jimenez et al., 1994). The latter sequence contains an Sp1-like binding site, but neither of these two sequences seems to contain a potential Smad-binding site. In addition to direct action of TGFβ, part of the profibrotic properties may be indirect, mediated by increased production of a cysteine-rich protein called connective tissue growth factor (CTGF) (Leask and Abraham, 2003).

Connective tissue growth factor

CTGF (also called CCN2), a member of the CCN family of matricellular proteins, has long been known to promote differentiation and proliferation of chondrocytes and osteoblasts (for a review, see Takigawa et al., 2003). CCN2 promotes fibroblast proliferation, matrix production, and granulation tissue formation, as well as cell adhesion and migration.

Experiments using recombinant CTGF and neutralizing antibodies targeting CTGF have suggested that CTGF mediates at least some of the effects of TGFβ on fibroblast proliferation, adhesion, and ECM production, including collagen and fibronectin (Crean et al., 2002; Weston et al., 2003). Moreover, an expression vector encoding CTGF transfected into fibroblasts can activate a reporter driven by the type I collagen promoter, suggesting that a CTGF response element exists in the promoter of type I collagen (Shi-wen et al., 2000). Perhaps the most significant recent insights into the specific physiological roles of CCN2 have come from the generation of mutant mice lacking CCN2 (Ivkovic et al., 2003). Ccn2 2/2 mice display severely malformed rib cages and die soon after birth owing to a failure to breathe. These mice exhibit impaired chondrocyte proliferation and proteoglycan production within the hypertrophic zone. Excessive chondrocytic hypertrophy and a concomitant reduction in endochondral ossification are also observed. Further support for the idea that CCN2 regulates bone formation in development comes from studies of transgenic mice that overproduce CCN2 under the control of the mouse type XI collagen promoter. These mice develop normally but show dwarfism within a few months of birth owing to a reduced bone density (Nakanishi et al., 2001). The molecular basis for this deformity has not yet been explored; however, a possible explanation is that CCN2 overexpression results in abnormally premature ossification, before proper chondrocyte maturation.

CCN2 is constitutively expressed in fibrotic and embryonic fibroblasts independent of TGFβ (Chen et al., 2006a,b; Holmes et al., 2001, 2003). Experiments using Ccn2 2/2 mouse embryonic fibroblasts (MEFs) have shown that loss of CCN2 results in an inability of TGFβ to induce expression of approximately one-third of those mRNAs induced in Ccn2 1/1 MEFs (Shi-wen et al., 2006). Consistent with the fact that CCN2 is required for only a subset of TGF responses, Ccn2 2/2 MEFs show no impairment of the generic Smad pathway, emphasizing the relative selectivity of CCN2-dependent action. In contrast to the lack of effect of loss of CCN2 expression on basal type I collagen and α-smooth muscle actin expression, the ability of TGFβ to induce these proteins is impaired in Ccn2 2/2 MEFs (Shi-wen et al., 2006).

Expression of the CTGF gene in fibroblasts is strongly induced by TGFβ but not by other growth factors, and intradermal injections of TGFβ in neonatal mice induced an overexpression of CTGF in skin fibroblasts (Frazier et al., 1996; Igarashi et al., 1993). The ability of TGFβ to induce CCN2 also requires protein kinase C and the Ras/MEK/ERK MAP kinase cascade (Chen et al., 2002a,b; Stratton et al., 2002). As in the case of other TGFβ-responsive promoters that do not require the transcription factor AP1, the induction of CCN2 by TGFβ is antagonized by hyperactive AP1 or JNK (Leask et al., 2003) because of the ability of active Jun to bind to Smads off DNA and inhibit Smads from interacting with the target DNA sequences (Verrecchia et al., 2001). The role of CTGF in scarring and fibrosis regulating collagen type I also appears to be via mediating the activity of other factors such as adenosine or by modulating critical signaling pathways such as the AKT/mTOR pathways. For instance, activation of the adenosine (2A) receptor was shown to suppress the expression of the transcriptional repressor Fli1, yet induce the secretion of CTGF. Together, the release of the inhibitory activity of Fli1 (able to suppress both collagen type I and CTGF) and the elevation in CTGF level resulted in a significant enhancement of collagen type I production (Chan et al., 2013). In addition, the targeting of the CTGF 3′-UTR by an endogenous miRNA (miR-143-3p) reduced CTGF levels and inhibited collagen expression. This observation was further refined to reveal that reducing CTGF concomitantly attenuated AKT/mTOR signaling, and suggested that restraining the AKT/mTOR pathway by targeting CTGF represents a mechanism to effectively block collagen ECM production (Mu et al., 2016). Interestingly, platelet-derived growth factor receptor β also uses the AKT/mTOR signaling pathway to promote collagen (1α2) expression in an in vitro model of tubulointerstitial fibrosis (Das et al., 2017).

Although a specific CTGF receptor has yet to be identified, CTGF appears to perform many of its functions through integrins, heparan sulfate-containing proteoglycans, and the low-density lipoprotein receptor-related protein (Gao and Brigstock, 2003; Segarini et al., 2001; Weston et al., 2003).

Fibroblast growth factor

Fibroblasts growth factors (FGFs) comprise a family of 23 genes encoding structurally related proteins divided into six subfamilies of FGFs (Ornitz and Marie, 2002). The most recent member is FGF23, which is mainly produced by osteocytes in bone and acts as a hormone primarily to inhibit phosphate reabsorption in the proximal tubules of the kidney (Liu et al., 2007; Razzaque and Lanske, 2007). Most members of the FGF family bind to four distinct FGF receptor tyrosine kinase molecules (FGFRs) and activate the receptors. Historically, FGF2 (basic FGF) was the first FGF ligand to be isolated from growth-plate chondrocytes (Sullivan and Klagsbrun, 1985). Subsequently, Fgf2 gene expression has also been observed in periosteal cells and in osteoblasts (Hurley et al., 1999; Sabbieti et al., 1999). FGF signaling affects the expression and activity of several transcription factors that are required for calvarial osteogenesis. In rat or mouse calvarial cells, FGF2 activates osteocalcin transcription. This activity is inhibited by the transcription factor MSX2 and is activated by DLX5

(Newberry et al., 1997, 1999). FGF2 can upregulate Twist expression in mouse calvarial mesenchyme (Rice et al. 2000). Twist-heterozygous mice show altered FGFR protein expression (Rice et al., 2000), suggesting that Twist acts upstream of FGF signaling pathways. In addition, Twist could be a potential transcriptional regulator that mediates the negative effect of FGF2 on type I collagen expression in calvarial cells (Fang et al., 2001). Thus, FGF/FGFR, MSX, and Twist functionally interact to control cranial suture development in a coordinated manner. FGF2 production by calvarial osteoblasts is upregulated by FGF2 itself and by parathyroid hormone (PTH), PGE_2, and TGFβ. Thus, the balance between high and low levels of endogenous FGF2 may constitute a mechanism to control proliferation and ensure normal cranial vault development (Moore et al., 2002).

Bone resorption by osteoclasts is required to maintain the shape of craniofacial bones during development. It is therefore significant that FGF2 can increase the formation of osteoclast-like cells and activate mature osteoclasts through FGFR1 (Chikazu et al., 2000). In addition, FGF2 increases the expression of metalloproteinases, collagenases 1 and 3 (Newberry et al., 1997; Tang et al., 1996; Varghese et al., 2000), TIMPs 1 and 3 (Varghese et al., 1995), and stromelysin-3, which regulates collagenase activity in calvarial cells (Delany and Canalis, 1998). These mechanisms may control bone matrix degradation and remodeling by FGFs during calvarial expansion. Targeted deletion of FGF2 causes a relatively subtle defect in osteoblastogenesis, leading to decreased bone growth and bone density. However, no defects in chondrogenesis were observed (Montero et al., 2000).

Insulin-like growth factor

IGF-1 is synthesized by many cells, including cells of the osteoblastic lineage, as well as chondroblasts and osteoclasts (Rajaram et al., 1997). IGF-1 plays an important role in regulating peak BMD and bone size (Mohan and Baylink, 2005; Mohan et al., 2003). The IGFs interact with specific cell surface receptors, designated type 1 and type 2 IGF receptors (IGF-1R and IGF-2R). Most of the actions of IGF-1 and IGF-2 are mediated by the IGF-1R, which is a transmembrane receptor with tyrosine kinase activity.

The IGFs in serum and other extracellular environments are bound to specific IGF-binding proteins (IGFBPs), which represent a family of six secreted proteins with a common domain organization. Each IGFBP has unique properties and exhibits specific functions. IGFBPs 2− to 5 are present in bone; IGFBPs 4 and 5 are expressed at the highest levels. Unlike IGFBP-4, which has an inhibiting effect on IGF actions, IGFBP-5 has a potentiating effect, both in vivo and in vitro, probably by binding directly to sites that are independent of the IGF receptor (Govoni et al., 2005).

IGF-1 and IGF-2 can stimulate osteoblast and fibroblast proliferation and increase type I collagen production by these cells. Their effect on type I collagen production by osteoblasts has been demonstrated by using both fetal rat calvariae and osteoblastic cells, and it is related to an increase in corresponding mRNA transcripts (McCarthy et al., 1989; Thiebaud et al., 1994; Woitge and Kream, 2000). IGF-1 can also promote osteogenic differentiation and Col1a2 synthesis via induction of the mRNA-binding La ribonucleoprotein 6 gene (LARP6). Here, IGF-1 treatment of primary osteoblasts caused an increase in LARP6, which bound to the Col1a2 mRNA, promoting expression. Although in this study the precise mechanism by which LARP6 binding promoted COL1A2 expression was not delineated, a previous series of experiments by another group had noted that IGF-1 rapidly increased LARP6 expression, which was able to bind to the 5′ stem−loop motif structures of both the COL1a1 and the COL1a2 mRNAs. This suggested that increased synthesis of collagen would result from alterations in mRNA stability/accessibility or the ability of LARP6 to enhance or coordinate its translation into the heterotrimeric collagen type I molecule (Blackstock et al., 2014).

In vivo, administration of IGF-1 to hypophysectomized rats increased mRNA transcripts for pro-Col1a1 and pro-Col1a2 genes in parietal bones (Schmid et al., 1989). Furthermore, in calvariae of mice in which the Igf1 gene was disrupted, there was a reduced rate of collagen synthesis. By using the Cre-LoxP model to disrupt IGF-1 in all Col1a2-expressing cells it was demonstrated that locally produced IGF-1 plays a critical role in embryonic and postnatal growth. Local IGF-1 from Col1a2-producing cells is required for bone matrix mineralization during embryonic development and postnatal growth (Govoni et al., 2007). Moreover, to determine the effects of locally expressed IGF-1 on bone remodeling, a transgene was produced in which murine IGF-1 cDNA was cloned downstream of a gene fragment comprising 3.6 kb of 5′ upstream regulatory sequence and most of the first intron of the rat Col1a1 gene. Transgenic calvariae showed an increase in osteoclast numbers per bone surface, as well as increased collagen synthesis and cell proliferation. Femur length, cortical width, and cross-sectional area were also increased in transgenic femurs, whereas femoral trabecular bone volume displayed little change. Thus, broad overexpression of IGF-1 in cells of the osteoblast lineage increased indices of bone formation and resorption (Jiang et al., 2006). Furthermore, in calvariae of mice in which the IGF-1 gene was disrupted, there was a reduced rate of collagen synthesis (Woitge and Kream, 2000).

Cytokines

Tumor necrosis factor α

TNFα is a cytokine secreted mainly by monocytes/macrophages, but osteoblasts seem to be able to produce TNFα under certain conditions (Gowen et al., 1990). After being cleaved from its propeptide, TNFα undergoes trimerization and binds to type I receptors, which transduce most of the effects of TNFα, or to type II receptors, which activates them and transmits signals to the nucleus via different transcription factors.

TNFα levels are elevated in various bone disorders, such as rheumatoid arthritis and osteoporosis (Beutler and Cerami, 1988; Pacifici, 1996). In bone tissue, TNFα inhibits osteoblast function and increases osteoclastogenesis, thus favoring net matrix destruction (Centrella et al., 1988; Chou et al., 1996; Panagakos et al., 1996). Similarly, TNFα stimulates fibroblast and osteoblast proliferation and inhibits the production of ECM components, including type I collagen and its modifying enzyme, lysyl oxidase (Kouba et al., 1999; Pischon et al., 2004; Verrecchia et al., 2000), as well as the transcription factor Sox9 (Murakami et al., 2000), and increases collagenase production and thus ECM degradation (Iraburu et al., 2000).

In vivo, inoculation of nude mice with TNFα-producing cells decreased type I collagen production in skin and liver, impaired wound healing, and decreased TGFβ1 synthesis in skin (Houglum et al., 1998). TNFα also increases PGE_2 and interleukin 1 production by osteoblasts and fibroblasts, which themselves modulate type I collagen synthesis.

In dermal fibroblasts, inhibition of collagen synthesis in fibroblasts by TNFα is associated with a decrease in mRNA levels for the pro-Col1a1 and pro-Col1a2 transcripts and in the transcription of type I collagen genes (Solis-Herruzo et al., 1988). Inagaki et al. (1995) showed that TNFα increases the binding of a protein complex that recognizes the negative *cis*-acting element located immediately next to the TβRE, and postulated that TNFα counteracts the TGFβ-elicited stimulation of collagen gene expression through overlapping nuclear signaling pathways. Kouba et al. (1999) characterized this specific TNFα-response element between nucleotides 2271 and 2235 relative to the transcription initiation site and termed it TαRE. Electrophoretic mobility supershift assays identified the NF-κB family members NF-κB1 and RelA as transcription factors binding the TαRE and mediating TNFα repression of COL1a2 promoter activity. By using a gene-knockout approach, the same group showed that, in primary fibroblasts from NEMO-knockout mice, lack of NF-κB activation prevented repression of basal COL1a2 gene expression by TNFα. Similar regulatory mechanisms take place in dermal fibroblasts transfected with dominant-negative forms of IKK-α, a critical kinase upstream of NF-κB (Verrecchia et al., 2002). More interestingly, the antagonist activities of TGFβ and TNFα in COL1a2 may be the result of steric interactions between transcription factors binding to TβRE and TαRE, respectively (Greenwel et al., 2000; Verrecchia et al., 2001).

The inhibitory effects of TNFα on the rat pro-Col1a1 proximal promoter were shown to be mediated by a sequence located between 2378 and 2345 bp through the binding of proteins of the C/EBP family, such as C/EBPδ and p20C/EBPβ (Iraburu et al., 2000). Other TNFα response elements have been identified within the pro-Col1a1 gene between 2101 and 238 bp and between 68 and 86 bp, in dermal fibroblasts and HSCs, respectively (Hernandez et al., 2000; Mori et al., 1996). The latter *cis*-acting element binds proteins of the Sp1 family, whereas the proteins binding to the former have not been identified (Hernandez et al., 2000; Mori et al., 1996). Using two lines of transgenic mice harboring a growth hormone reporter gene under the control of either at 2.3 kb, the human pro-COL1A1 proximal promoter plus the first intron, or at 440 bp, this promoter plus the first intron, Chojkier's group reported that different *cis*-acting elements mediate the inhibitory effects of TNFα, depending on the tissue (Houglum et al., 1998). In skin, the inhibitory effect of TNFα on the activity of the reporter gene was mediated through a *cis*-acting element located between 22.3 kb and 2440 bp (Buck et al., 1996). In contrast, this inhibitory effect of TNFα was mediated in liver through an element located between 2440 and 11,607 bp (Houglum et al., 1998).

Interferon γ

IFN-γ is a cytokine produced both by monocytes/macrophages and by type 1 helper T cells. IFN-γ binds to the IFN-γ receptor complex (IFNGR1 and IFNGR2), followed by the activation of receptor-associated JAK, which in turn phosphorylates and activates STAT1. Once phosphorylated, STAT1 molecules dimerize and translocate to the nucleus where they modulate target gene transcription either by direct interaction with specific sequences or through protein−protein interactions (Darnell et al., 1994; Horvai et al., 1997).

In vitro, IFN-γ decreases osteoblast and fibroblast proliferation and type I collagen synthesis by these cells. This effect seems to be caused both by a decrease in type I collagen mRNA stability (Czaja et al., 1987; Kahari et al., 1990) and by a decrease in the transcription rate of the pro-Col1a1 gene (Diaz and Jimenez, 1997; Yuan et al., 1999). Transfection studies

using different segments of the human pro-COL1A1 proximal promoter have shown the existence of an IFN-γ response element between 2129 and 2107 bp that can bind transcription factors NF1 and members of the Sp1 family (Yuan et al., 1999). However, mutations in NF1 and Sp1 sites, which abrogate the binding of these factors, repress the basal COL1A1 promoter activity but are unable to abrogate the IFN-γ-mediated inhibition, suggesting that NF1 and Sp1 are not involved in this inhibitory action of IFN-γ (Yuan et al., 1999). The activation of major histocompatibility complex II by IFN-γ requires activation of a trimeric DNA-binding transcriptional complex, the RFX5 complex, containing RFXB (also called RFXANK or Tvl-1), RFXAP, and RFX5 protein. RFX5 was later shown to bind to the collagen transcription start site and repress collagen gene expression (Sengupta et al., 2002). Moreover, two studies have provided further evidence for the role of the RFX5 repressor complex in suppressing COL1A2 transcription and have noted a prominent role of epigenetics in this mode of regulation of collagen synthesis. Both studies identified components of the HDAC complex (SIRT1 and SIN3B) acting upon RFX5, altering its acetylation status. In smooth muscle cells IFN-γ repressed COL1A2 transcription by downregulating the sirtuin SIRT1, leading to acetylation, preventing nuclear expulsion and degradation and thereby modulating RFX5 repressor activity. IFN-γ also promoted the recruitment of SIN3B to the COL1A2 transcription start site, where it cooperated with G9a, a histone H3K9 methyltransferase, to effect a repressive chromatin structure. Taken together these studies strongly suggest that IFN-γ coordinates the assembly of a potent repressor complex containing RFX5, HDACs, Sirt1, Sin3B, and G9a on the COL1A2 promoter. In the human COL1A2 gene, an IFN-γ response element has been identified between 2161 and 125 bp by using transfection experiments in dermal fibroblasts (Higashi et al., 1998). Similar to the action of TNFα, Ulloa et al. (1999) reported that IFN-γ abrogates the TGFβ stimulation of TβRE-containing reporter constructs in fibrosarcoma cells by inducing the level of Smad7 via the JAK−STAT1 signaling pathway. To account for the antagonistic action of IFN-γ and TGFβ on the expression of the COL1a2 gene, however, evidence suggests another mechanism involving p300/CBP. This evidence indicates that IFN-γ-activated STAT1 sequesters the endogenous p300 and reduces its interaction with Smad3, thus inhibiting the TGFβ/Smad-induced collagen gene transcription (Ghosh et al., 2001). Moreover, Higashi et al. (2003) showed that YB-1 binds to the IFN-γ responsive element at 2165 to 2150 and mediates transcriptional repression of COL1A2. YB-1 was used successfully as a therapeutic target to downregulate collagen type I as a strategy to treat liver fibrosis in vivo. This effect was potentiated by the addition of exogenous IFN-γ (Inagaki et al., 2005).

Other cytokines

Interleukin 1

IL-1 is a cytokine secreted mainly by monocytes/macrophages, but also by other cells, including fibroblasts, osteoblasts, synoviocytes, and chondrocytes. Two forms of IL-1 have been described, IL-1α and IL-1β, which have little primary structure homology but bind to the same receptor and have similar biological activities (Stylianou and Saklatvala, 1998).

IL-1 modulates the type I collagen synthesis at different levels, and the variations may be attributable to cell type, species, and age differences, but, at this writing, the molecular mechanisms by which IL-1 modulates type I collagen gene transcription are not clear. In vitro, IL-1 has an inhibitory effect on type I collagen production by osteoblasts, which is due to an inhibition of type I collagen gene transcription (Harrison et al., 1990). Nevertheless, it can be masked when low doses of IL-1 are used, as this cytokine stimulates the production of PGE_2, which in turn can modulate type I collagen synthesis. Slack et al. (1995) have suggested that the inhibitory effects of IL-1 on the transcription of the human pro-COL1A1 collagen gene by osteoblasts could be mediated through the binding of AP1 to the first intron of the gene (Slack et al., 1995), but this has not been confirmed. In vitro, IL-1β inhibits the expression of the COL1A2 in human lung fibroblasts at the transcriptional level by a PGE_2-independent effect, as well as through the effect of endogenous fibroblast PGE_2 released under the stimulus of the cytokine (Diaz et al., 1993). More recently, in SSc fibroblasts, pre-IL-1α was shown to form a complex with IL-1β-binding proteins that are translocated into the nuclei of fibroblasts via HAX-1 (HS1-associated protein X-1) and IL-1 receptor type II to increase production of collagen and IL-6 (Kawaguchi et al., 2006). In contrast, the biological impact of IL-1β on tendon fibroblasts showed that the presence of IL-1β significantly decreased the level of collagen type I mRNA. These effects were found to be mediated by selective upregulation of the EP(4) receptor, which is a member of the G-protein-coupled receptors that transduces the PGE_2 signal via the p38 MAP kinase pathway (Thampatty et al., 2007).

Interleukin 13

IL-13 is a major inducer of fibrosis. Indeed, IL-13 induces expression of TGF 2 β1 in macrophages. The increase in TGFβ expression requires both TNFα and signaling through the IL-13 receptor α2 (IL-13Ra2) to activate an AP1 variant, which stimulates the TGFβ promoter. Prevention of IL-13Ra2 expression, IL-13Ra2 gene silencing, or blockade of IL-13Ra2

signaling leads to marked downregulation of TGFβ1 production and collagen deposition in bleomycin-induced lung fibrosis (Fichtner-Feigl et al., 2006). Thus, IL-13Ra2 signaling during prolonged inflammation could be an important therapeutic target for the prevention of TGFβ1-mediated fibrosis. Evidence has also suggested that IL-13 can mediate the increased deposition of collagen type I via TGFβ (Firszt et al., 2014) and independent of the action of TGFβ via STAT6. By showing a direct effect of IL-13 on collagen expression using specific STAT6 small interfering RNAs and miR-135b, an endogenous miRNA that targets STAT6, and methylation inhibitors, the authors were able to show a clear role for STAT6 and epigenetic mechanisms regulating IL-13-mediated collagen production (O'Reilly et al., 2016).

Interleukin 4

IL-4 is secreted by type 2 helper T cells and by mastocytes. In vitro, IL-4 increases type I collagen production by human fibroblasts by increasing both transcriptional levels of type I collagen genes and the stability of the corresponding mRNAs (Serpier et al., 1997). In bronchial fibroblasts, IL-4 positively regulates pro-COL1A1 transcription by direct promoter activation and increases the TIMP2/MMP-2 ratio, thereby supporting the profibrotic effect of this cytokine. Furthermore, a combined action of SP1, NF-κB, and STAT6 contributes to the IL-4-mediated COL1A2 gene activation. An AP2 site adjacent to a STAT6 consensus motif, TTC N(3/4) GCT, is located within 205 bases of the transcription start site and seems to support the moderate IL-4 induction of COL1A1 gene expression (Bergeron et al., 2003; Buttner et al., 2004).

Interleukin 6 IL-6 has been shown to induce collagen type I and is elevated in patients with SSc (Kawaguchi et al., 1999) and in cultured HSCs (Nieto, 2006). Two studies have indicated that IL-6 can regulate collagen type I via STAT3 by two distinct mechanisms. First, IL-6 induction of STAT3 (phospho-STAT3/S727) led to noncanonical STAT3 activation and to increased TGFβ and collagen expression (Li et al., 2015). Second, at both the transcriptional level, through the upstream elements of the COL1A2 enhancer and their interaction with the proximal promoter, and the posttranscriptional level, where IL-6 *trans* signaling and high levels of STAT3 activation led to increased COL1A2 protein expression by (Papaioannou et al., 2018).

Other interleukins

IL-10 is secreted mainly by monocytes/macrophages and inhibits type I collagen gene transcription and type I collagen production by skin fibroblasts (Reitamo et al., 1994). In addition, several other cytokines have also been reported to regulated type I collagen production, for instance, IL-17, IL-18, and the IL-12 family of cytokines, such as IL-23. Although the molecular mechanisms responsible for changes in collagen have not been fully explored, they often show alterations in the levels of transcription factors, upstream signaling pathways, and miRNA expression. For example, IL-18 appears to involved in the activation of the ERK signaling cascade leading to the induction of the collagen type I transcriptional repressor Ets1 (Kim et al., 2010). With respect to IL-17, this cytokine exerts a direct impact on the expression of TGFβ type II receptors (TGFβRIIs) via JNK-dependent signaling pathways, with the resultant upregulation and stabilization of TGFβRII leading to enhance Smad2/3 signaling and the induction of collagen gene expression (Fabre et al., 2014). The dysregulation in IL-23 signaling reported in fibrosis and contributing to increased collagen production has been attributed to an IL-23-dependent imbalance between two miRNAs (miR-4458 and miR-18a) that target type I collagen, and in particular the IL-23 downregulation of miR-18a resulting in collagen upregulation (Nakayama et al., 2017).

Oncostatin M is produced mainly by activated T cells and monocytes/macrophages and belongs to the hematopoietic cytokine family. It is mitogenic for fibroblasts and stimulates type I collagen production by fibroblasts by increasing transcriptional levels of type I collagen genes (Ihn et al., 1997). Transfection studies performed using different segments of the human pro-α2(I) collagen gene have shown that a 12-bp segment located between 2131 and 2120 bp, and that contains a TCCTCC motif, mediated the stimulatory effects of oncostatin M (Ihn et al., 1997).

Arachidonic acid derivatives

PGE_2, a product of the cyclooxygenase pathway, is synthesized by various cell types, including endothelial cells, monocytes/macrophages, osteoblasts, and fibroblasts. Its production by fibroblasts is increased by IL-1 and TNFα. PGE_2 has a biphasic effect on type I collagen synthesis by bone organ cultures and by osteoblastic cells (Ono et al., 2005). At low concentrations, it increases type I collagen synthesis, whereas at higher concentrations it decreases type I collagen synthesis. PGE_2 induces the production of IGF-1 by osteoblastic cells, and part of the stimulatory effect of low doses of PGE_2 on type I collagen production seems to be indirect, mediated by a stimulation of IGF-1 production (Raisz et al., 1993a, b). Nevertheless, part of this stimulatory effect is independent of IGF-1 production and persists after blocking the

effects of IGF-1 (Raisz et al., 1993a, b). It is notable that when PGE_2 is added to fibroblasts in culture, it inhibits type I collagen synthesis and decreases the levels of the corresponding mRNAs. Most of the effects of PGE_2 are mediated through an increase in cAMP levels (Sakuma et al., 2004) and the activation of collagen synthesis by low doses of PGE_2 could be caused by such a mechanism, because cAMP analogs can also increase collagen synthesis in bone (Fall et al., 1994). In contrast, the inhibitory effect of PGE_2, which has been shown to be caused by an inhibition of transcription of type I collagen genes, is not mediated through a cAMP-dependent pathway but through a pathway involving the activation of protein kinase C (Sakuma et al., 2004). A study using an osteoblastic cell line transfected stably with various segments of the rat pro-Col1a1 promoter cloned upstream of a CAT reporter gene has shown that PGE_2 acts through an element located more than 2.3 kb upstream of the start site of transcription (Raisz et al., 1993a, b). A more recent study using fibroblasts transfected transiently with a construct containing 220 bp of the mouse pro-Col1a1 proximal promoter has shown that PGE_2 can also act through a *cis*-acting element located within this promoter segment (Riquet et al., 2000).

Hormones and vitamins

Corticosteroids

It has been known for many years that the administration of corticosteroids to patients results in osteoporosis and growth retardation. In mice, corticosteroids have also been shown to decrease collagen production in calvariae (Advani et al., 1997). In vitro, incubation of fetal rat calvariae with high doses of corticosteroids, or with lower doses but for a prolonged period of time, decreased the synthesis of type I collagen (Canalis, 1983; Dietrich et al., 1979); this inhibitory effect could also be observed with osteoblastic cell lines (Hodge and Kream, 1988). Moreover, cortisol increases interstitial collagenase transcript levels by posttranscriptional mechanisms in osteoblastic cells (Delany et al., 1995a, b). Nuclear run-off experiments performed using osteoblasts derived from fetal rat calvariae showed that glucocorticoids downregulate transcriptional levels of the pro-Col1a1 gene, as well as the stability of the corresponding mRNA (Delany et al., 1995a, b). Because corticosteroids inhibit the secretion of IGF-1, part of their inhibitory effect on type I collagen synthesis could be indirect, but calvariae from IGF-1-null mice maintain their responsiveness to glucocorticoids (Woitge and Kream, 2000).

When added to fibroblasts in culture, corticosteroids usually decrease type I collagen synthesis by acting at a pretranslational level, which is in agreement with their in vivo effect on wound healing (Cockayne et al., 1986). Stable transfection experiments using the mouse pro-Col1a2 proximal promoter fused to a CAT reporter gene and transfected into fibroblasts have shown that sequences located between 22,048 and 2981 bp and between 2506 and 2351 bp were important for the corticosteroid-mediated inhibition of transcription (Perez et al., 1992). However, the *cis*-acting element(s) responsible was not sufficient to block the effect alone (Meisler et al., 1995), and further experiments from the same group indicated that glucocorticoids coordinately regulate procollagen gene expression through TGFβ elements. Depression of procollagen gene expression by glucocorticoids through the TGFβ element is mediated by decreased TGFβ secretion, possibly involving a secondary effect on regulatory proteins encoded by noncollagenous protein genes (Cutroneo and Sterling, 2004).

BMD decreases by 2%−4.5% after just 6 months of glucocorticoid administration to healthy men, but subsequently the rate of bone loss declines (LoCascio et al., 1990). Considerable evidence indicates that glucocorticoid-induced bone loss occurs in two phases in both humans and mice: an early, rapid phase in which bone mass is lost because of excessive bone resorption and a slower, later phase in which bone is lost because of inadequate bone formation (LoCascio et al., 1990; Weinstein et al., 1998). Transgenic mice overexpressing 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) using the osteoclast-specific murine tartrate-resistant acid phosphatase promoter (Reddy et al., 1995) exhibited decreased cancellous osteoclasts after glucocorticoid administration and were protected from the glucocorticoid-induced early, rapid loss of BMD (Jia et al., 2006), suggesting that direct effects of glucocorticoids on osteoclasts are more important than these mediators in the early, rapid loss of bone mass that follows glucocorticoid administration. Similarly, when an osteoblast-specific 2.3-kb Col1a1 promoter drives 11β-HSD2 expression in mature osteoblasts, 11β-HSD2 should metabolically inactivate endogenous glucocorticoids in the targeted cells, thereby reducing glucocorticoid signaling; collagen synthesis rates were lower in calvarial organ cultures of transgenic mice than in wild-type. Furthermore, the inhibitory effect of 300 nM hydrocortisone on collagen synthesis was blunted in transgenic calvariae. Trabecular bone parameters measured by microcomputed tomography were also reduced in L3 vertebrae, but not femurs, of 7- and 24-week-old transgenic females. This effect was not seen in male mice, suggesting that endogenous glucocorticoid signaling is required for normal vertebral trabecular bone volume and architecture in female mice (Sher et al., 2004).

Thyroid hormones

Thyroid hormones have been shown to inhibit type I collagen production by cardiac fibroblasts, and this effect was associated with a decrease in the levels of pro-Col1a1 mRNA (Chen et al., 2000a,b). Transfection studies have shown that thyroid hormones modulate transcriptional levels of the pro-Col1a1 gene through a *cis*-acting element located between 2224 and 115 bp (Chen et al., 2000a,b). In addition, thyroid hormone (T3) regulates the FGFR1 promoter in osteoblasts through a thyroid receptor-binding site at position 2279/2264 (O'Shea P et al., 2007). With respect to chondrocyte differentiation, a study has indicated that thyroid hormone receptor-associated protein 3 negatively regulates SOX9 transcriptional activity as a cofactor of a SOX9 transcriptional complex during chondrogenesis (Sono et al., 2018).

Parathyroid hormone

PTH binds to specific receptors in osteoblasts and upregulates the expression of receptor activator of NF-κB ligand, a protein essential for osteoclast development and survival. PTH signaling occurs via a PTH receptor 1/cAMP/protein kinase A/CREB cascade. Runx2 may contribute to the osteoblast specificity of PTH signaling (Fu et al., 2006) by downregulating osteoprotegerin expression (Boyle et al., 2003). In vitro, PTH inhibits type I collagen synthesis by osteoblastic cell lines as well as by bone organotypic cultures (Kream et al., 1986). This inhibitory effect is associated with a decrease in the levels of procollagen mRNAs (Kream et al., 1986). When calvariae of transgenic mice harboring a 1.7-, 2.3-, or 3.6-kb segment of the rat pro-Col1a1 proximal promoter were cultured in the presence of PTH, there was a parallel decrease in the incorporation of [^{3}H]proline and in the activity of the reporter gene, suggesting that the pro-Col1a1 promoter contains a *cis*-acting element located downstream of 21.7 kb, which mediates the inhibition of the pro-Col1a1 gene expression induced by PTH (Bogdanovic et al., 2000; Kream et al., 1993). Furthermore, the effect of PTH on the levels of expression of the reporter gene were mimicked by cAMP and potentiated by a phosphodiesterase inhibitor, suggesting that the inhibitory effects of PTH are mediated mainly by a cAMP signaling pathway (Bogdanovic et al., 2000).

Vitamin D

The classic role of the vitamin D endocrine system is to stimulate calcium absorption in the intestine, thus maintaining normocalcemia and indirectly regulating bone mineralization (van Driel et al., 2004). The actions of vitamin D are mediated through the vitamin D receptor (VDR), which acts as a ligand-activated transcription factor to regulate the expression of target genes. The VDR heterodimerizes with retinoid X receptor (RXR) and associates with the transcriptional complex on promoters of target genes. In vitro, the active metabolite of vitamin D3, $1,25(OH)_2D_3$, has been shown to inhibit type I collagen synthesis by bone organ cultures and by osteoblastic cells, and this inhibitory effect is caused by an inhibition of the transcription of type I collagen genes (Bedalov et al., 1998; Harrison et al.,1989). Transfection studies performed with the rat pro-Col1a1 proximal promoter led to the identification of a vitamin D-responsive element between 22.3 and 21.6 kb (Pavlin et al., 1994). Nevertheless, when transgenic mice harboring a 1.7-kb segment of the rat pro-Col1a1 promoter cloned upstream of a CAT reporter gene were treated with $1,25(OH)_2D_3$, the levels of expression of the CAT reporter gene decreased, which suggests that a vitamin D-response element is located downstream of 21.7 kb (Bedalov et al., 1998). Similarly, when calvariae from these transgenic mice were cultured in the presence of $1,25(OH)_2D_3$, it inhibited reporter gene expression (Bedalov et al., 1998). It is of note that part of the effects of vitamin D on type I collagen could be mediated through an inhibition of the production of IGF-1, because vitamin D has been shown to inhibit IGF-1 production and increase the concentrations of inhibitory IGFBP-4 (Scharla et al., 1991). Indeed, the effects of $1,25(OH)_2D_3$ on release of the IGFs were independent of bone resorption and support the conclusion that $1,25(OH)_2D_3$ modulated the production and secretion of IGF-1 and IGF-2 in calvarial cells (Linkhart and Keffer, 1991). The results of these and similar studies on PTH in calvarial cells suggest that PTH, TGFβ, and $1,25(OH)_2D_3$ differentially regulate mouse calvarial cell IGF-1 and IGF-2 production. Furthermore, IGFBP-5 has been shown to reduce the effects of $1,25(OH)_2D_3$ by blocking cell cycle progression at G0/G1 in osteoblasts and by decreasing the expression of cyclin D1. Moreover, IGFBP-5 can interact with VDR to prevent RXR:VDR heterodimerization and IGFBP-5 may attenuate the $1,25(OH)_2D_3$-induced expression of bone differentiation markers (Schedlich et al., 2007).

Many studies have reported an inverse relationship between vitamin D and PTH concentrations, where PTH plateaued at concentrations of 25OHD between 75 and 100 nmol/L (30−40 ng/mL). Biochemical markers of bone metabolism are increasingly used in the management of patients with osteoporosis and other metabolic bone diseases.

Among bone formation markers is procollagen type 1 amino-terminal propeptide (P1NP), which is released into the circulation during bone formation. Bone resorption markers include carboxy-terminal cross-linked telopeptide of type I collagen (CTX). CTX is a degradation product of type I collagen and is released into the circulation during bone resorption

(Vasikaran et al., 2011). The Bone Marker Standards Working Group recommends P1NP and CTX as reference standard markers of bone formation and resorption (Vasikaran et al., 2011; Stokes et al., 2011). In humans, many studies have reported deficiencies or insufficiencies in vitamin D, even in equatorial countries (Tan et al., 2013), and a confusing picture of the markers of bone turnover, P1NP and CTX, and vitamin D levels, which may be influenced by reduced PTH, has emerged.

Chapter 14

Collagen cross-linking and bone pathobiology

David M. Hudson, MaryAnn Weis and David R. Eyre
Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, United States

Chapter outline

Introduction

Lysyl oxidase (LOX)-mediated covalent cross-links between individual collagen molecules are essential for the strength of collagen fibrils. They appeared at the dawn of metazoan evolution (Rodriguez-Pascual and Slatter, 2016) and can be argued to have been a critical step in allowing larger animals to evolve (Boot-Handford and Tuckwell, 2003). Divergencies in the content, placement, and chemical stability of these intermolecular cross-links have clearly evolved to modulate the properties of collagen fibrils in different tissue types.

Collagen accounts for about a third of all protein in the human body (Verzár, 1964) and is the main organic component of bone (Myllyharju and Kivirikko, 2004; Eyre, 1980). Fibrillar collagen molecules consist of three polypeptide α-chains, each about 1000 residues of a single repeating Gly−Xaa−Yaa primary amino acid sequence, which folds into the defining triple-helical conformation of a collagen molecule. Variations in the extensive posttranslational modifications of the major fibril-forming collagen type I contribute to the structural and functional differences between tissues (Eyre et al., 1984a,b;

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00014-2

Hudson and Eyre, 2013). Indeed, cross-linking chemistry differs fundamentally between skin, tendon, and bone type I collagen, with distinct changes continuing during tissue growth and maturation (Light and Bailey, 1979).

LOXs initiate fibrillar collagen cross-linking, in the sole enzymatic step, by forming aldehyde side-chains from specific telopeptide lysine and hydroxylysine residues. From then on, further reactions are driven by the local protein environment at the cross-linking sites. All the fibril-forming collagens (types I, II, III, V, and XI) can have up to four cross-linking loci per molecule, one per telopeptide domain and two placed symmetrically at opposite ends of the triple helix. Certain chains (α2(I), α1(V), α2(V), α1(XI) and α2(XI)) lack C-telopeptide cross-linking lysines. Upon collagen fibril assembly, the triple-helical cross-linking lysines align and spontaneously react with telopeptide lysine and hydroxylysine aldehydes in adjacent molecules staggered axially by 4D periods (where D = 67nm, the axial stagger of adjacent collagen molecules packed in a fibril). The mature cross-linking chemistry in bone collagen is distinctive, with products containing both lysine and hydroxylysine aldehyde precursors (Fig. 14.1).

Advances in collagen cross-link analysis

Mature cross-link analysis

The content of pyridinoline cross-links, readily quantified by their natural fluorescence, has been used as a gold standard for assessing collagen cross-linking quality for decades (Eyre et al., 1984a). Specifically, high-performance liquid chromatography-based assays were developed to measure the quantitative distribution of hydroxylysyl pyridinoline (HP) and lysyl pyridinoline (LP) across tissues and collagen genetic types (Eyre et al., 1984b; Wu and Eyre, 1985; Fujimoto, 1977). Variances in the total amount and/or HP/LP ratio of these trifunctional residues have been one of the traditional measures of collagen quality and pathobiology (Eyre et al., 1984a,b). Although informative, the content of pyridinolines is only a fraction of the total LOX-mediated cross-links in most tissues, including bone.

Even mature bone contains more divalent cross-links and more pyrrolic cross-links than total pyridinolines. Trivalent pyrrole cross-links are measured in collagenous tissues using a colorimetric assay. Ehrlich's reagent (*p*-dimethylaminobenzaldehyde) reacts with pyrrole residues to yield a quantifiable pink color (Scott et al., 1981). Pyrrole cross-links appear to be limited mostly to fibrillar collagens of bone and load-bearing tendons (Hanson and Eyre, 1996; Horgan et al., 1990).

Divalent cross-link analysis

Divalent cross-linking amino acids were originally profiled in tissues as tritiated products after sodium borotritide reduction on the amino acid analyzer, with quantitation relative to nonreducible cross-links by ninhydrin detection (Eyre, 1987; Avery et al., 2009). Mass spectrometric approaches have begun to supplement the traditional methods of amino acid analysis and N-terminal sequencing for studying divalent collagen cross-links (Hudson et al., 2017; Eyre et al., 2004; Kalamajski et al., 2014; Terajima et al., 2014; Naffa et al., 2016).

Electrospray mass spectrometry

Early mass spectrometric methods were used to structurally characterize collagen cross-links beginning in the 1960s (Blumenfeld and Gallop, 1966; Schneider et al., 1967). However, using ion-trap mass spectrometry, collagen cross-linked peptides could be identified by their peptide fragmentation patterns (Fig. 14.2) (Eyre et al., 2004). Collagen peptides can be generated for mass spectrometric analysis using several approaches, including sodium dodecyl sulfate–polyacrylamide gel electrophoresis of whole chains and CNBr peptides and in-gel protease digestion (e.g., trypsin, endo-Asp) or bacterial collagenase digestion followed by liquid chromatography, or directly from urine after Sep-Pak enrichment (Eyre et al., 2008). By using sequence-specific antibodies for detection followed by mass spectrometric analysis, heterotypic cross-links between α-chains of different collagen types were identified (Eyre et al., 2008).

Cross-link formation

Bone collagen cross-linking

The distinctive profile of mature cross-links in bone collagen is controlled by the partial hydroxylation of lysine residues at both telopeptide and triple-helical cross-linking sites (Fig. 14.3). Telopeptide lysines at both ends are about 50%

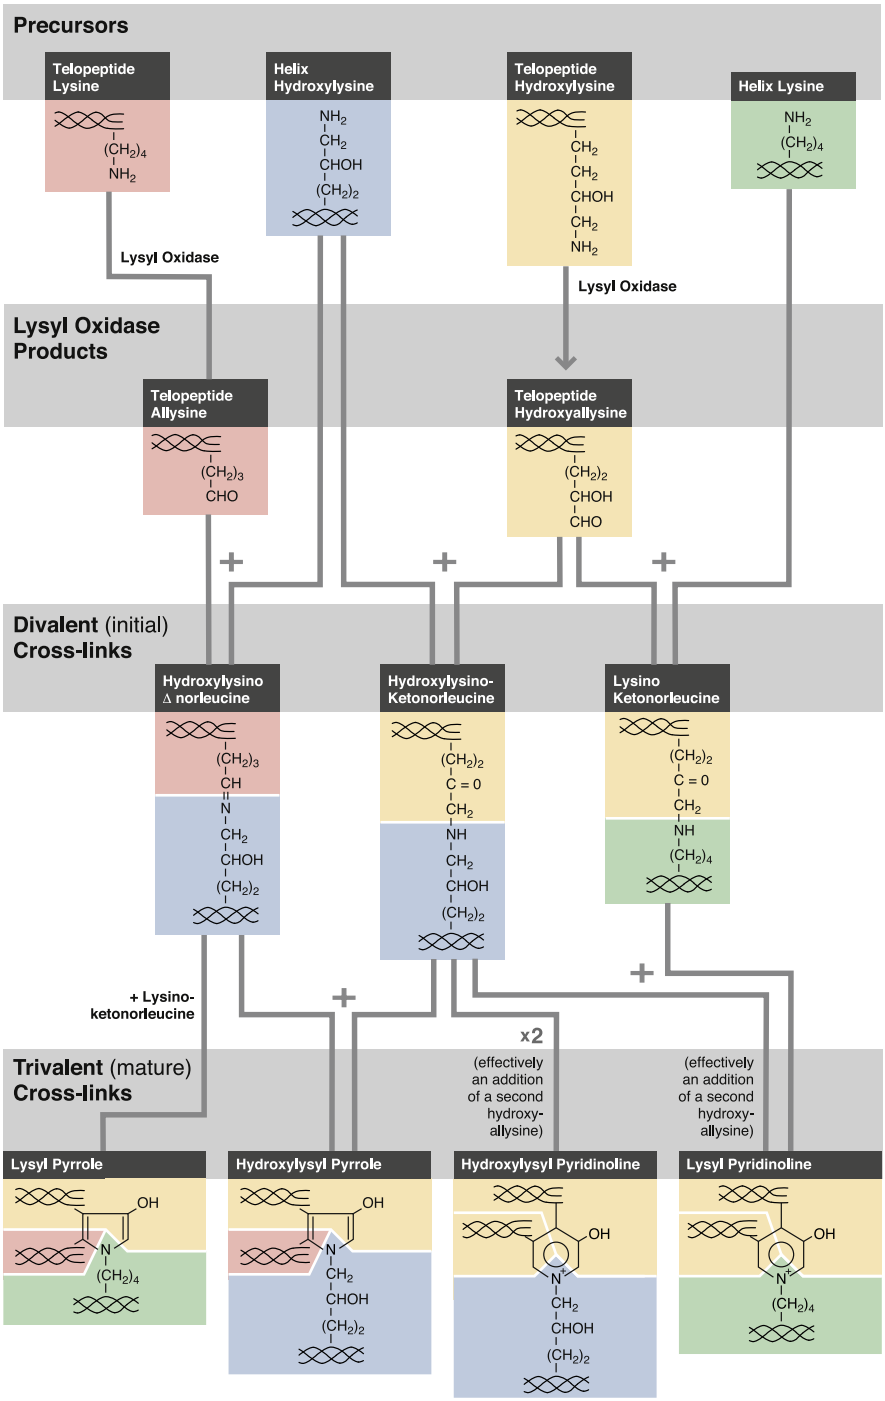

FIGURE 14.1 Lysyl oxidase–derived collagen cross-linking pathway in bone. Type I collagen cross-linking in bone is unique in using both lysine (allysine) and hydroxylysine (hydroxyallysine) aldehyde precursors in the telopeptide domains. In growing fibrils, the aldehydes interact with specific lysine or hydroxylysine residues at helical sites (K87 and K930) in neighboring collagen molecules. The resulting divalent cross-links are the predominant cross-links found in bone. These initial divalent cross-links can add an additional telopeptide aldehyde (from a second divalent cross-link) to form trivalent (mature) cross-links. In adult human bone, the trivalent cross-links are a mixture of about equal amounts of pyridinolines and pyrroles.

hydroxylated (human, bovine) compared with 0% in skin type I collagen and 100% in cartilage type II collagen (Eyre et al., 2008). This results in a unique pattern of both divalent and mature, trivalent cross-linked peptides from bone collagen including a mixture of mature pyrrole and pyridinoline structures (Hanson and Eyre, 1996). The formation of the trifunctional cross-links requires the precise lateral packing of collagen molecules in the native staggered structure that

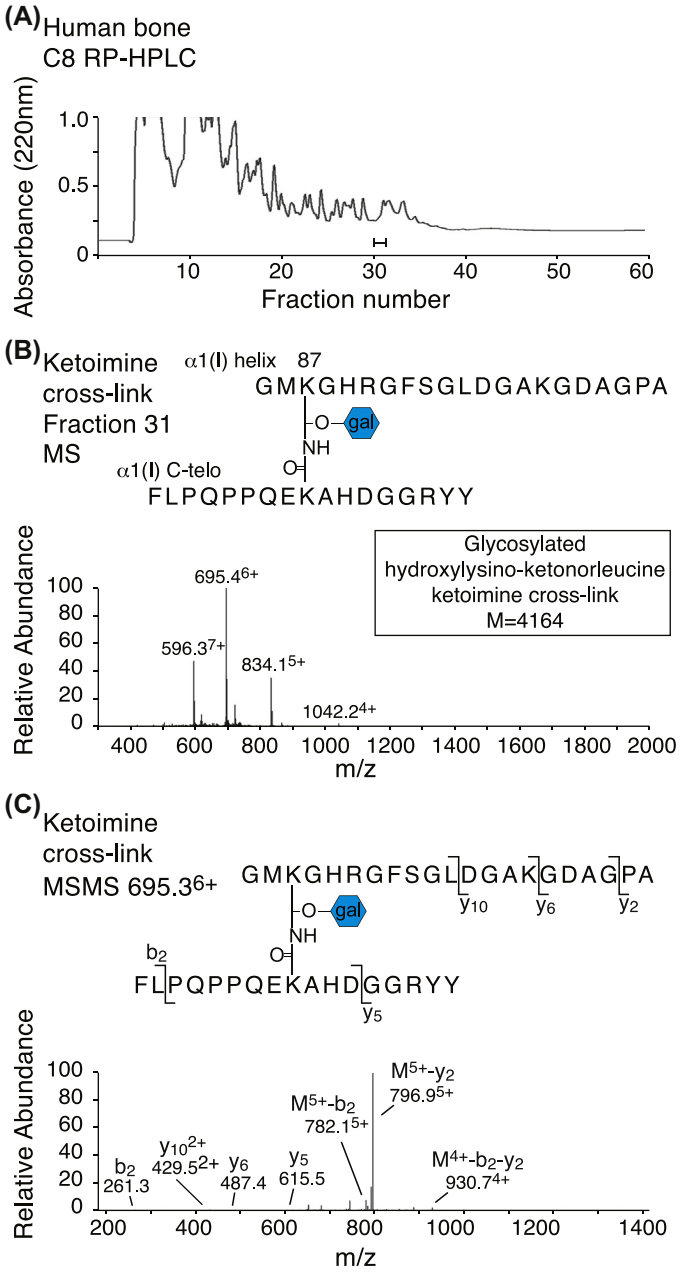

FIGURE 14.2 The identification of a divalent cross-linked peptide from bone collagen (Lys-87 to C-telopeptide) using mass spectrometry. (A) Reverse-phase high-performance liquid chromatography resolution of cross-linked peptides from human bone collagen digested with bacterial collagenase. (B) Mass spectrometry (*MS*) profile of fraction 31 reveals a glycosylated (galactosyl-) ketoimine structure from human bone (596.3^{7+}, 695.4^{6+}, 834.1^{5+}, and 1042.2^{4+}). (C) Tandem MS fragmentation spectrum of the parent ion (695.3^{6+}) confirms the mass of the glycosylated ketoimine cross-link.

provides the appropriate nearest-neighbor intermolecular relationships for reactions to occur. The well-characterized chemical pathway of cross-linking interactions in bone collagen is shown in Fig. 14.1.

Cross-link structures

Divalent cross-links

The predominant cross-links in mature bone collagen are divalent residues (Eyre et al., 1984a; Eyre, 1981, 1987). With increasing age the mean sum of divalent cross-links (dihydroxylysinonorleucine [DHLNL] and hydroxylysinonorleucine

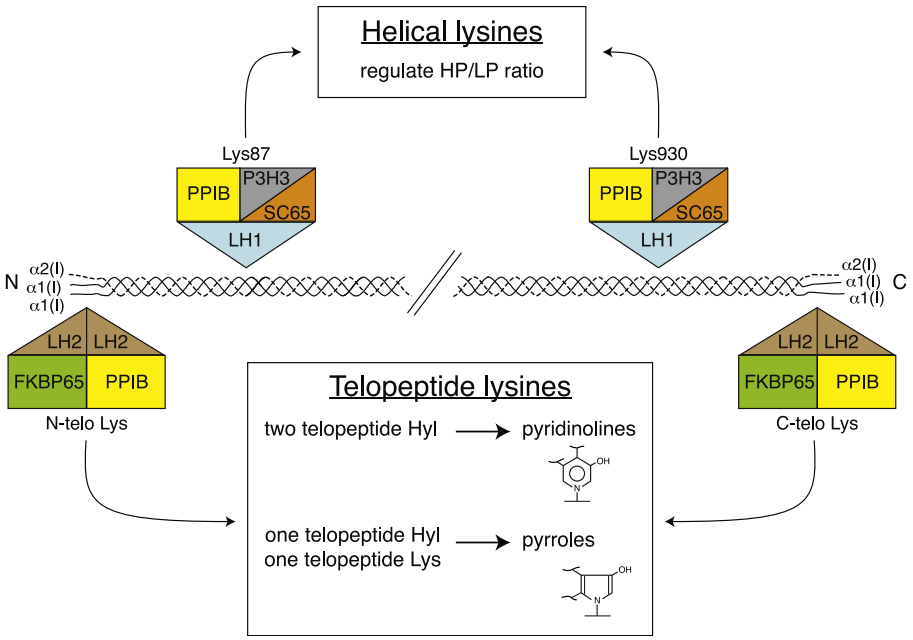

FIGURE 14.3 Regulation of collagen cross-linking in bone by the lysyl hydroxylase (*LH*) complexes. The four lysine sites of cross-linking are symmetrically located in type I collagen (two telopeptide sites and two triple-helical sites). The LH1 complex (LH1, PPIB, SC65, P3H3) catalyzes the hydroxylation of helical lysines 87 and 930. The LH2 complex (LH2 dimer, PPIB, FKBP65) catalyzes the hydroxylation of N- and C-telopeptide lysines. The pattern of lysyl hydroxylation determines the chemical nature of the cross-links, which varies between tissue types. In bone collagen, LH2 partially hydroxylates the telopeptide lysines and LH1 partially hydroxylates the two helical-site lysines of both α-chains. This pattern is a distinguishing post-translational feature of bone type I collagen compared with type I collagen of skin, tendon, and other soft tissues. *FKBP65*, 65-kDa FK506-binding protein; *HP*, hydroxylysyl pyridinoline; *Hyl*, hydroxylysine; *LP*, lysyl pyridinoline; *P3H3*, prolyl 3-hydroxylase 3; *PPIB*, cyclophilin B (peptidyl-prolyl isomerase B); *SC65*, synaptonemal complex 65.

[HLNL]) decreases from 1.9 mol/mol in young bone (13 years) to 0.8 mol/mol in adult bone (41 years) (Eyre, 1987). This decrease coincides with cross-link maturation from bifunctional to trifunctional structures. It is important to note that the physiological bone cross-links, such as dehydro-DHLNL and dehydro-HLNL, and their respective ketoamine forms are reduced to stable secondary amines, DHLNL and HLNL, upon borohydride treatment, allowing their quantitation after acid hydrolysis. Several studies have applied mass spectrometry to further investigate the divalent cross-links in normal tissue (Terajima et al., 2014) and in mouse models that alter tendon (Kalamajski et al., 2014), skin and bone cross-linking chemistry (Hudson et al., 2017).

Pyridinium cross-links

Telopeptide hydroxylysines are a prerequisite for pyridinoline formation (Bank et al., 1999), and the degree of helical cross-linking lysine hydroxylation determines the ratio of HP to LP (Eyre and Wu, 2005). HP and LP each show molecular site and α-chain selectivity in their concentrations (Hanson and Eyre, 1996). Their levels in urine relative to creatinine offer a convenient measure of bone resorption (Beardsworth et al., 1990). Even more specific to osteoclastic bone resorption are the NTx and CTx urine and serum immunoassays directed at short type I collagen telopeptide fragments that were protected by the cross-links through to excretion (Hanson et al., 1992; Singer and Eyre, 2008).

Pyrrole cross-links

Pyrroles are the product of an interaction between a telopeptide lysine aldehyde, a telopeptide hydroxylysine aldehyde, and a triple-helical-domain lysine or hydroxylysine. We believe pyrrole formation involves an interaction between an initial ketoimine and an aldimine divalent cross-link, analogous to that proposed between two divalent cross-links to form HP and LP (Eyre and Oguchi, 1980). This mechanism produces the trivalent structure and releases one triple-helical domain donor sequence. The highest pyrrole cross-link levels will occur when the telopeptide lysines are 50% hydroxylated as they roughly are in normal human bone collagen (Hanson and Eyre, 1996). There is evidence that the content of pyrrole cross-links is positively associated with bone strength (Knott and Bailey, 1998), perhaps by aiding in the assembly of the highly

ordered mineral nanocrystal/protein composite of normal bone. Thus the ratio of pyrrole/pyridinoline cross-links has been shown to be associated with bone quality, with a lower pyrrole content and altered trabecular organization in osteoporotic bone compared with control bone (Banse et al., 2002).

Pyridinoline and pyrrolic cross-linked peptides in urine

The 3-hydroxy pyrrole cross-linking structures, unlike pyridinolines, are labile to acid hydrolysis and so cannot be measured in the same tissue acid hydrolysates as pyridinolines. They can, however, be recovered in cross-linked peptides from mild, proteolytic digests of bone matrix (Hanson and Eyre, 1996) and also in cross-linked peptides excreted in urine as products of osteoclastic bone resorption along with their pyridinoline counterparts.

Fig. 14.4 shows an example of liquid chromatography–mass spectrometry analysis of the urinary pool of cross-linked peptides from osteoclastic resorption that were derived from the N-telopeptide cross-linking site. The results shown reveal a mix of pyridinoline- and pyrrole-linked, otherwise identical trivalent peptides from the main site of pyrrole cross-linking (Hanson and Eyre, 1996). The resulting estimate of pyridinoline-to-pyrrole ratio can provide a potentially useful, noninvasive index of the posttranslational quality of a patient's bone.

Histidine-containing collagen cross-links and other maturation products

It is becoming increasingly evident that the diversity in biomechanical properties between different collagen-rich tissues is very much a function of evolved differences in cross-linking chemistry. Although beyond the scope of this review, collagen cross-linking variations include the apparent involvement of histidine residues in the pathway of lysine aldehyde cross-linking in skin collagen (Yamauchi et al., 1987); an arginine-bound adduct, arginoline, from divalent ketoimine cross-links in cartilages (Eyre et al., 2010); and the sulfilimine cross-links created by the enzyme peroxidasin between specific hydroxylysine and methionine residues in all forms of type IV collagen that are crucial for the biological function of basement membranes (Vanacore et al., 2009; Bhave et al., 2012).

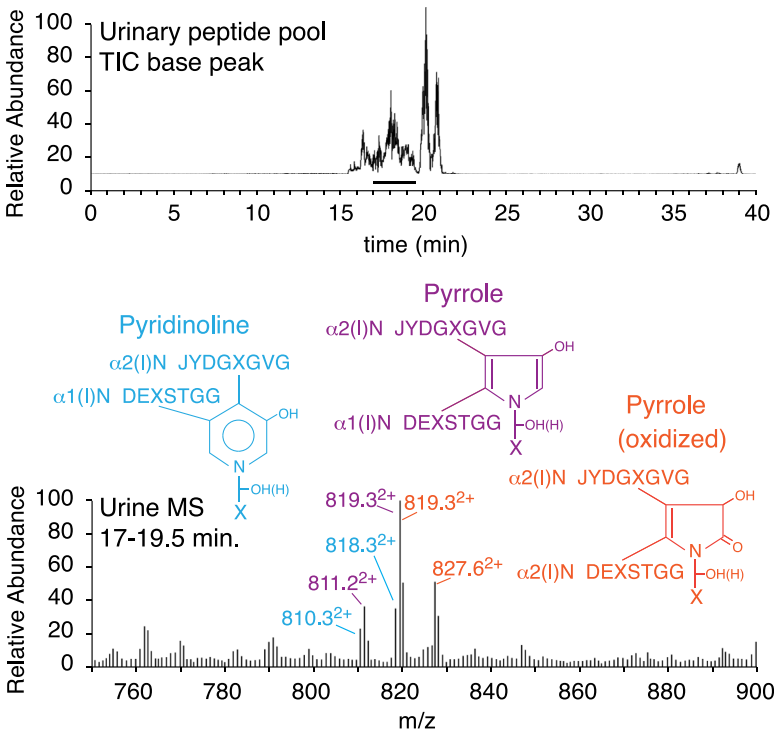

FIGURE 14.4 Liquid chromatography–mass spectrometry (LC–MS) analysis of cross-linked collagen peptides in human urine. The top shows the total ion current (*TIC*) elution profile of peptides on reverse-phase LC and the bottom the ion-trap mass spectral analysis of the *underlined* peptide component peak. The pool of peptides was initially enriched for analysis by ion-exchange and reverse-phase cartridge extraction. The structures shown were identified by their MS/MS fragmentation patterns on tandem mass spectrometry and fitting of the masses of the trivalent cross-linking residues shown. The 3-hydroxy pyrrole ring is readily oxidizable to the +16 Da oxo C2 ring form (819.3^{2+} and 827.6^{2+}), and so gives two pairs of peptides for the lysyl- and hydroxylysyl-derived variants.

In recent work, we have shown that the stable maturation product histidinohydroxylysinonorleucine (HHL), believed to form naturally in the lysine aldehyde pathway of cross-linking that dominates in skin, cornea, and other soft tissue collagens (Yamauchi et al., 1987), is an artifactual product of acid hydrolysis. It is a reaction product formed at sites of C-telopeptide allysine aldol in species with a neighboring C-telopeptide histidine residue (Eyre et al., 2019). This and other evidence is consistent with a role for nearby histidines in catalyzing cross-link formation. Histidine incorporation into mature cross-linking structures is seen only after borohydride reduction (HHMD, histidinohydroxymerodesmosine) or acid hydrolysis (HHL), not on mass spectral analysis of proteolytic digests of tissue collagen (Eyre et al., 2019).

Glycosylations and glycations

Enzymatic glycosylation

Hydroxylysine glycoside content can vary significantly between tissues and collagen types. Bone type I collagen is particularly limited. Only one site, hydroxylysine (Hyl)-87, in each α-chain appears to be fully glycosylated, and Gal-Hyl dominates over Glc-Gal-Hyl. The Gal-Hyl residue participates in cross-link formation with α1(I) C-telopeptide aldehydes (Hanson and Eyre, 1996). Additional partial glycosylation sites include Hyl-174 and Hyl-219 in both α-chains, but only at low occupancy (Terajima et al., 2014; Pokidysheva et al., 2013).

Enzymatic glycosylation is a specific and regulated intracellular modification of nascent collagen α-chains in the endoplasmic reticulum (ER) prior to triple-helix formation (Myllyharju and Kivirikko, 2004; Kivirikko and Myllyla, 1982). The predominant hydroxylysyl galactosyltransferase for bone type I collagen, glycosyltransferase 25 domain 1, is encoded by the GLT25D1 gene (Schegg et al., 2009; Sricholpech et al., 2011). Interestingly, a member of the lysyl hydroxylase (LH) family, the multifunctional LH3, is the principal galactosyl−hydroxylysyl glucosyltransferase in basement membrane collagen (Rautavuoma et al., 2004; Ruotsalainen et al., 2006) and potentially bone type I collagen biosynthesis (Sricholpech et al., 2011).

Tissue-dependent variations in cross-link glycosylation

The ratio of glycosylated to nonglycosylated cross-links can reflect maturational age, tissue type, and even disease state of a collagen sample. Such variation was demonstrated by a 2014 study of adult bovine bone collagen peptides using tandem mass spectrometry (Terajima et al., 2014). Glycosylated pyridinolines and pyrroles were more prevalent than their non-glycosylated forms, and the Gal form dominated. Divalent cross-links were mostly glycosylated too, but with about equal Gal and Glc-Gal forms. The results suggest a steric selectivity for the Gal-Hyl-87 ketoimine cross-link being incorporated into the trivalent structure.

This is consistent with a preference for nonglycosylated pyridinolines being formed during type II collagen maturation in cartilage (Eyre et al., 2008). Divalent ketoimines containing Glc-Gal-Hyl-87 are the primary cross-links in fetal cartilage, whereas nonglycosylated HP is the main pyridinoline in adult articular cartilage (Eyre et al., 2008). An attached disaccharide may therefore sterically hinder a ketoimine cross-link from being the precursor of Glc-Gal HP. A preference for nonglycosylated > Gal > Glc-Gal precursors is indicated.

Potential functions

Potentially, glycosyl groups on bone collagen could either aid or interfere with fibril mineralization. A role for type I collagen overglycosylation in the pathogenesis of osteogenesis imperfecta (OI) has been suggested (Bateman et al., 1984; Tenni et al., 1993; Taga et al., 2013). Altered levels of bone collagen glycosylation have been noted in several musculoskeletal disorders, including postmenopausal osteoporosis (Michalsky et al., 1993), osteosarcoma, and osteofibrous dysplasia (Lehmann et al., 1995). Although in general the functional effects of sugar residues on collagen α-chains are unclear, a broad spectrum of roles have been proposed. They include activities in matrix remodeling (Yang et al., 1993; Jürgensen et al., 2011), collagen fibrillogenesis (Notbohm et al., 1999; Bätge et al., 1997; Torre-Blanco et al., 1992), collagen cross-linking (Rautavuoma et al., 2004; Ruotsalainen et al., 2006; Wang et al., 2002; Moro et al., 2000), and bone mineralization (Sricholpech et al., 2012).

Nonspecific glycations

Among the known and proposed cross-links in collagens, perhaps the least understood but most speculative pathologically are those identified as advanced glycation end products (AGEs). Collagens are frequently cited targets for these adventitious sugar additions since they are typically very long-lived proteins with half-lives ranging for humans from about

5 years in bone (Manolagas, 2000) and 10 years in skin (Avery and Bailey, 2006) to 100 years or more in tendon (Thorpe et al., 2010; Heinemeier et al., 2013) and cartilage (Verzijl et al., 2000). Interestingly, whereas LOX-controlled collagen cross-links appear to plateau in content at a relatively young tissue age (Haut et al., 1992; Eyre et al., 1988), these nonenzymatic cross-links seem to increase steadily over time and cause host tissues to stiffen (Bank et al., 1998; Snedeker and Gautieri, 2014).

Being generally stochastic in nature, AGE cross-linking is proposed to result from randomly accumulated lysine, and perhaps arginine, side-chain glycation adducts that by their placement have potential to go on to form intra- and intermolecular cross-links (Monnier et al., 2005). There is evidence, however, that collagen glycations and AGE formation sites are not random, but will tend to occur at restricted sites (Reiser et al., 1992; Hudson et al., 2018).

Advanced glycation end products

AGEs are formed following the reaction of the carbonyl of a reducing sugar (commonly glucose) with a lysine residue (Fig. 14.5). This nonenzymatic process is the first step in the classical Maillard reaction pathway. The initial product is a relatively unstable Schiff base with the ε-amine of the lysine, which Amadori rearranges to the ketoimine fructosyllysine. This can undergo dehydration, condensation, fragmentation, and cross-linking to form various AGE products. The most prominent is glucosepane, formed by dehydration, carbonyl migration along the sugar carbon chain, and arginine side-chain addition. For this to produce interchain or intrachain protein cross-links, arginine and lysine side-chains need to be 7 Å or less apart (Dai et al., 2008). Several potential sites of glucosepane formation in collagen type I fibrils have been predicted on theoretical grounds (Gautieri et al., 2014; Collier et al., 2015, 2016), but direct analytical proof on connective tissue samples is limited at best. The potential for hydroxylysine as well as lysine residues to be glycated in collagens tends also to have been largely ignored.

Types of advanced glycation end products

From the analysis of complete protease hydrolysates, glucosepane is by far the most prevalent of the potential AGE cross-links in connective tissues (Biemel et al., 2002). Although many more glycation-based structures and potential cross-links have been predicted from experiments in vitro (Snedeker and Gautieri, 2014; Monnier et al., 2005; Sell and Monnier, 2012), their natural tissue levels and significance are less clear. For example, most AGEs arise as monovalent side-chain

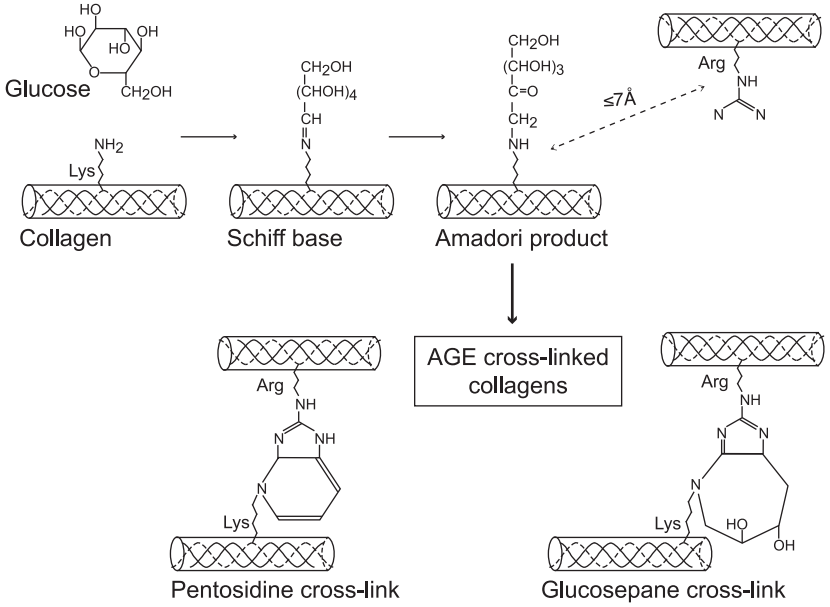

FIGURE 14.5 Glycation products as potential collagen cross-links in bone. The covalent attachment of glucose to collagens and other long-lived proteins leads to advanced glycation end products (*AGEs*) that include candidate cross-links. The Maillard reaction pathway is initiated when the carbonyl of a reducing sugar (commonly glucose) reacts with lysine residues (commonly collagen). The relatively unstable initial Schiff base Amadori rearranges to the ketoimine fructosyllysine. This product can undergo dehydration, condensation, fragmentation, and cross-linking to form various AGE products, which include glucosepane and pentosidine. Such pathological cross-links are thought to contribute to age-related soft tissue stiffening, but the significance for bone is largely unknown.

modifications, which include the arginine product, ornithine; the lysine adduct, fructosyllysine; and the lysine product, carboxymethyllysine. The last has been proposed to cause tissue damage through its ability to chelate transitional metals that can produce reactive oxygenated species (Saxena et al., 1999).

Glucosepane can in theory form intrachain, interchain, and intermolecular collagen cross-links. Based on quantitation in whole-tissue proteolytic digests, glucosepane has been proposed to be the most significant AGE cross-link in older tissues (~0.3 mol/mol of collagen (age 80 skin) (Monnier et al., 2005). Pentosidine, the fluorescent AGE, is quantitatively minor (0.019 mol/mol of collagen (age 80 bone) (Viguet-Carrin et al., 2009). However, to put this in perspective, even if all the measured tissue glucosepane was in collagen as intermolecular cross-links, the levels reached are still an order of magnitude lower than those of the main LOX-based cross-links introduced at synthesis.

Potential consequences

Diabetes mellitus seems to accelerate the age-related decline in bone quality. Increased risk of bone fractures has long been associated with both type 1 and type 2 diabetes (Vestergaard et al., 2009). Bone biopsies from patients with type 1 diabetes revealed a positive association between bone fracture incidence and pentosidine content (Farlay et al., 2016). However, despite decades of research, the pathogenesis of the skeletal effects in diabetes is still poorly understood.

Cross-linking lysine-modifying enzymes

Lysyl hydroxylases

The LH isoenzymes (LH1−3) are encoded by procollagen-lysine, 2-oxoglutarate 5-dioxygenases (*PLOD1−3*). These LH isoenzymes catalyze the hydroxylation of specific collagen lysine residues in a reaction requiring several cofactors (Fe^{2+}, 2-oxoglutarate, O_2, and ascorbate). Unlike prolyl hydroxylation, the extent of lysine hydroxylation varies significantly between tissues and collagen types.

The exact substrate sequence specificity of each isoenzyme has not been fully resolved. It is becoming increasingly clear, however, that LH1 is mainly responsible for catalyzing the hydroxylation of lysine residues within the triple-helical sequence Gly-Xaa-Lys of type I collagen, with particular preference for the cross-linking sites. LH2 is responsible for hydroxylating cross-linking lysine residues in the telopeptide sequences Xaa-Lys-Gly, Xaa-Lys-Ala, and Xaa-Lys-Ser of fibrillar collagens. *PLOD2* encodes two splice variants of LH2, a short form termed LH2a and a long form with an extra exonic 21 amino acids termed LH2b. It has long been thought that LH2b is responsible for collagen telopeptide lysine hydroxylation in bone (Yamauchi and Shiiba, 2008) and hence is the splice variant that controls expression of a hydroxylysine−aldehyde cross-linking tissue phenotype. However, findings in our laboratory are consistent with each splice variant having a unique tissue-specific function. Indeed, although LH2b is ubiquitously expressed in many tissues (Yeowell and Walker, 1999), we suspect that its predominant activity is in bone, tendon, and ligaments, and LH2a is the likely active isoform in connective tissues other than bone.

LH3 is the only multifunctional PLOD isoenzyme, which not only has LH activity, but also hydroxylysyl−galactosyltransferase and galactosylhydroxylysyl−glucosyltransferase activities (Wang et al., 2002). The LH activity of LH3 may be more important functionally for basement membrane collagens, such as type IV collagen, than for fibrillar collagens (Ruotsalainen et al., 2006).

Consequences of lysyl hydroxylase gene mutations

The kyphoscoliotic type of Ehlers−Danlos syndrome (EDS VIA) is caused by homozygous or compound heterozygous mutations in *PLOD1*. *Plod1*-null mice, which exhibit muscle hypotonia and aortic ruptures but not kyphoscoliosis or skin laxity, have a milder phenotype than the human *PLOD1* mutations (Takaluoma et al., 2007; Steinmann et al., 2002). A lack of helical lysine hydroxylation will systemically alter normal collagen cross-linking. In bone, for example, the HP/LP ratio is severely reduced due to the disruption of HP formation. Mutations in *PLOD2* have been identified in Bruck syndrome, an autosomal recessive disorder characterized by bone fragility and congenital joint contractures (Ha-Vinh et al., 2004). Mutations in *PLOD3* have been shown to cause epidermolysis bullosa simplex and other severe connective tissue defects (Salo et al., 2008). The *Plod3*-null mouse is embryonically lethal, which was attributed to an intracellular accumulation of type IV collagen lacking Glc-Gal-Hyl (Rautavuoma et al., 2004). However, if Glc-Gal-Hyl was also lost from some tissue fibrillar collagens, their cross-linking chemistry and supramolecular assembly may also have been affected.

Lysyl oxidases

LOX is responsible for the oxidative deamination of side-chain lysine and hydroxylysine primary amine substrates to produce reactive aldehydes (Siegel et al., 1970). The LOX-driven conversion of telopeptide lysine and hydroxylysine residues to allysines is the sole enzymatic step driving collagen cross-linking chemistry (Siegel and Fu, 1976). This enzyme reaction occurs outside the cell, specifically on the extracellular matrix substrates elastin and collagen (Eyre et al., 1984a). Five additional, LOX-like (LOXL) isoenzymes have been identified in eukaryotes (Grau-Bové et al., 2015; Wordinger and Clark, 2014). Despite all having a similar, highly conserved catalytic domain, two LOXL subfamilies can be classified, LOXL2/L3/L4 and LOX/L1/L5 (Grau-Bové et al., 2015). The former is proposed to influence collagen IV cross-linking in basement membranes and the latter to be involved in chordate/vertebrate-specific matrix remodeling (Grau-Bové et al., 2015).

A range of disease states, from glaucoma to thoracic aortic aneurysm and dissection, have been associated with mutations in the *LOX* and *LOXL* genes (Lee et al., 2016; Thorleifsson et al., 2007). The $Lox^{-/-}$ mice are perinatal lethal and exhibit cardiovascular instability with arterial and diaphragmatic ruptures (Hornstra et al., 2003; Maki, 2002). Desmosine cross-links in elastin were shown to be reduced by approximately 60% in the aorta and lungs of these knockout mice (Maki, 2002).

Heritable disorders and mouse models

Heritable disorders

OI, also known as brittle bone disease, is a generalized connective tissue disorder characterized by low bone mass and bone fragility. An array of systemic features is associated with the disease, but none are as pronounced as the skeletal phenotype. Approximately 90% of OI cases are caused by dominantly inherited mutations in the type I collagen gene *COL1A1* or *COL1A2*. The most common of these mutations substitute glycine residues with bulkier or charged residues. Generally, severity increases the more C-terminal the mutation is located, consistent with triple-helix folding from the C terminus, but with many site-related inconsistencies, suggesting a regional severity model (Marini et al., 2007).

In 2006, the first recessively inherited OI, caused by CRTAP mutation, was characterized (Morello et al., 2006). A long list of additional genes quickly followed (Table 14.1) (Kang et al., 2017; Eyre and Weis, 2013). The new insights into OI pathological mechanisms also revealed previously unappreciated genes that regulate collagen cross-linking chemistry and homeostasis. A decade later, new genes linked to rare musculoskeletal disorders, including OI, Bruck syndrome, and EDS, continued to emerge. Many of the new OI-causing genes (>10) encode proteins with essential roles in collagen post-translational modification, cross-linking, and mineralization, and some function as collagen chaperones and transporters through the ER and Golgi. The expanding list of OI-causing genes includes X-linked, dominant, and recessive variants that affect osteoblast function without any detected effect on collagen cross-linking. Although beyond the present scope, several comprehensive reviews cover them (Cundy, 2012; Forlino and Marini, 2016; Marini et al., 2017).

Collagen posttranslational modifications

CRTAP, LEPRE1, PPIB

An association between a collagen posttranslational modification and OI was discovered from studying the cartilage-associated protein (CRTAP)-null mouse (Morello et al., 2006). This led to the identification of other OI-causing genes encoding subunits of the prolyl 3-hydroxylase enzyme complex, which is composed of CRTAP, cyclophilin B (also called peptidylprolyl isomerase B; PPIB), and prolyl 3-hydroxylase 1 (P3H1) in a 1:1:1 ratio (Vranka et al., 2004). P3H1 (*LEPRE1*) and CRTAP (*LEPREL3*) are both members of the leprecan family of genes; however, only P3H1 has enzyme activity. P3H1 is the enzyme responsible for 3-hydroxylation of specific Pro residues in the X-position of the collagen Gly-Xaa-Yaa triplet repeat, to form 3-hydroxyproline (3*S*,2*S*-L-hydroxyproline; 3Hyp) (Vranka et al., 2004; Ogle et al., 1962; Ogle et al., 1961). The other two proteins in the enzyme complex, PPIB and CRTAP, act as a peptidylprolyl isomerase and an essential "helper" protein, respectively. Disruption of the P3H1 complex results in the loss or reduction of prolyl 3-hydroxylation at two sites in type I collagen, α1(I)Pro986 and α2(I)Pro707 (Morello et al., 2006).

Gene mutations that disrupt expression of any protein in the P3H1 complex (P3H1, CRTAP, and PPIB) have been shown to cause recessive OI (Morello et al., 2006; Barnes et al., 2006, 2010; Cabral et al., 2007; van Dijk et al., 2009). A common consequence of the gene mutations includes altered bone collagen cross-linking (Eyre and Weis, 2013). Bone from the *Crtap*-null mouse and a *LEPRE1*-mutant OI patient had abnormally high HP/LP ratios and overhydroxylated

TABLE 14.1 Noncollagen genes in which mutations cause osteogenesis imperfecta variants or related bone collagen abnormalities.

Gene	Protein	Phenotype	Bone collagen abnormalities
CRTAP *LEPRE1* *PPIB*	CRTAP P3H1, prolyl hydroxylase CYPB, cyclophilin B } P3H1 Complex	Mild to severe OI, reduced mineral density	α1(I)P986 and α2(I)P707 under prolyl-3-hydroxylation, high HP/LP (CRTAP and LEPRE1), low HP/LP (PPIB)
TMEM38B	TRIC-B	Bone fragility, moderate/severe OI	Reduced helical Lys hydroxylation, increased telopeptide hydroxylation
FKPB10 *PLOD2*	FKBP65 LH2, lysyl hydroxylase 2	Bruck syndrome: bone fragility, joint contractures	Lack of telopeptide hydroxylysines produces skin-like cross-links
LEPREL2 *LEPREL4*	P3H3 Sc65	Low bone mass, skin fragility	Low HP/LP, reduced helical Lys hydroxylation, altered divalent cross-links
MBTPS2	SP2, site-2 metalloprotease	Moderate/severe X-linked OI	Reduced helical Lys-87 hydroxylation and glycosylation
BMP1	Procollagen type I C-propeptidase	High mineral density, mild to severe OI	Defective C-propeptide removal, potential cross-linking defects
SERPINH1	HSP47, heat shock protein 47	Moderate/severe OI, bone fragility	High HP/LP and abnormal arrangement of cross-linking bonds
IFITM5	Bril, osteoblast-specific small transmembrane protein	Normal to severe OI, bone fragility	Altered mineralization, no other collagen abnormalities
SERPINF1	PEDF, pigment epithelium-derived factor	Moderate/severe OI, low mineral density, osteoid seams	Failed mineralization, no other collagen abnormalities

HP, hydroxylysyl pyridinoline; *LP*, lysyl pyridinoline; *OI*, osteogenesis imperfecta.

telopeptide lysines (Eyre and Weis, 2013). In contrast, bone and tendon from the *PPIB*-null mouse and bone from a *PPIB*-mutant OI patient had abnormally low HP/LP ratios but overhydroxylated telopeptide lysines in type I collagen (Eyre and Weis, 2013; Terajima et al., 2016). How an absent P3H1 complex can bring about these differential effects on collagen cross-linking is not fully clear. If it delays triple-helix folding, then helix lysine overmodification (higher HP/LP) might be expected. In the case of PPIB, which is a vital component of several ER complexes, including the LH1 complex (Cabral et al., 2014), both the P3H1 complex and LH1 activity are knocked down. The overhydroxylation of telopeptide lysines in the absence of a P3H1 complex is harder to explain, but may involve recently recognized interactions between prolyl 3-hydroxylase and LH complexes in the ER (see "SC65 and P3H3"). The effects on cross-linking are therefore most likely due mainly to an absence of the P3H1 complex and consequences of ER distress, not the absence of 3Hyp residues at α1(I) P986 and α2(I)P707 (Cabral et al., 2014; Pyott et al., 2011).

Solid-phase binding studies do, however, support a role for 3Hyp in collagen intermolecular recognition and binding during assembly (Hudson et al., 2012). Loss of prolyl 3-hydroxylation in CRTAP, P3H1, and PPIB forms of OI could potentially disrupt the fundamental short-range order in the supramolecular assembly within collagen fibrils of bone (Hudson et al., 2012). A compromised polymeric architecture might hinder the ordered hydroxyapatite nanocrystal growth within collagen fibrils (Eyre and Weis, 2013).

TMEM38B

TMEM38B encodes the ER-membrane monovalent cation channel TRIC-B. Mutations in *TMEM38B* have been shown to cause moderately severe recessive OI (Volodarsky et al., 2013; Shaheen et al., 2012). Disruption of TRIC-B-driven intracellular calcium homeostasis was proposed to dysregulate collagen synthesis and cause OI (Cabral et al., 2016). Type I collagen exhibited altered posttranslational modifications as a consequence of altering the function and expression of vital modifying enzymes. For example, cross-linking lysine hydroxylation was reduced in the helix and increased in telopeptides (Cabral et al., 2016). Much like P3H1 complex mutations, TMEM38B defects were proposed to cause intracellular accumulation of collagen, which resulted in ER stress and the unfolded protein response.

PLOD2 and FKBP10

PLOD2 and *FKBP10* mutations have both been linked to Bruck syndrome (Bank et al., 1999; Ha-Vinh et al., 2004). *FKBP10* encodes the 65-kDa FK506-binding protein FKBP65, a collagen chaperone protein with peptidylprolyl isomerase activity (Ishikawa et al., 2008). *FKBP10* mutations were also shown to cause both Bruck syndrome with severe OI (Kelley et al., 2011; Schwarze et al., 2013; Alanay et al., 2010) and Kuskokwim syndrome with minimal skeletal defects (Barnes et al., 2013). Notably, an *FKBP10* homozygous null mutation, which yields bone collagen with only lysine aldehyde-derived cross-links, does not seem to affect cartilage or ligament collagen (Bank et al., 1999). The lack of telopeptide hydroxylysines precludes pyridinoline formation in bone, and results in skin-like cross-links. The reduction of hydroxyallysine-derived cross-links observed in bone collagen is phenocopied in patients with *PLOD2* and *FKBP10* mutations (Bank et al., 1999; Schwarze et al., 2013). Interestingly, the *Fkbp10*-null mouse exhibited severe embryonic growth defects and did not survive birth (Lietman et al., 2014). The *Plod2*-null mouse is also embryonic lethal (Hyry et al., 2009); however, a zebrafish model carrying a biallelic nonsense mutation in *plod2* displayed severe musculoskeletal abnormalities resembling Bruck syndrome (Gistelinck et al., 2016). The bone collagen defects in *PLOD2* and *FKBP10*–derived Bruck syndrome can be detected as abnormal ratios of HP/LP in patients' urine (Schwarze et al., 2013). Indeed, biochemical data revealed that FKBP65 was part of an enzyme complex with LH2, as a deficiency of FKBP65 resulted in reduced telopeptide cross-linking lysine hydroxylation (Schwarze et al., 2013; Barnes et al., 2012). Consequently, FKBP65-deficient bone produced skin-like collagen cross-links with complete absence of pyridinolines (Schwarze et al., 2013).

SC65 and P3H3

Synaptonemal complex 65 (SC65 or P3H4) is another member of the leprecan gene family and a homolog of CRTAP. Like CRTAP, SC65 has no known enzymatic activity and appears to also function as a "helper" protein. SC65 operates in an enzymatic multiprotein complex, comprising LH1, PPIB, and prolyl 3-hydroxylase 3 (P3H3) (Heard et al., 2016). Although no known human mutation has yet been described, two *Sc65*-null mice have been characterized as having low bone mass and skin fragility (Heard et al., 2016; Gruenwald et al., 2014). *P3h3*-null mouse skin was similarly characterized as having a lack of structural integrity and fragile collagen fabric (Hudson et al., 2017). Both the *Sc65*-null and the *P3h3*-null mice were found to have decreased collagen lysine hydroxylation and abnormal cross-linking (Hudson et al., 2017).

The ratio of mature HP/LP cross-links in bone of both *Sc65*-null and *P3h3*-null mice was reversed compared with wild-type, consistent with the level of lysine underhydroxylation seen in individual chains at cross-linking sites. This was the first direct evidence of an ER complex controlling collagen modification that combines both a lysyl- and a prolyl-hydroxylase activity.

Mechanistically, lysine underhydroxylation at the helical-domain cross-linking sites altered the divalent aldimine cross-link chemistry of the mutant collagen. In normal skin, fully glycosylated Hyl-87 preferentially forms an intermolecular aldimine cross-link with a C-telopeptide lysine aldehyde. However, in the *Sc65*-null and *P3h3*-null mice, the type I collagen LH1 substrate sites are underhydroxylated and subsequently underglycosylated. As a result, the C-telopeptide lysine aldehydes preferentially form intramolecular aldol cross-links (as opposed to intermolecular aldols). We predict that under normal conditions the presence of the disaccharide on Hyl-87 favors aldimine formation with a single C-telopeptide aldehyde. This glycosylated aldimine then sterically hinders intramolecular aldol formation with the second α1(I) C-telopeptide aldehyde of the molecule, which favors intermolecular aldol formation. So, the net effect of underhydroxylated Lys-87 is fewer aldol intermolecular cross-links. A very similar underhydroxylation of triple-helical domain lysines occurs in human EDS VIA and *Plod1*-null mouse tissues (Takaluoma et al., 2007; Steinmann et al., 2002; Eyre et al., 2002), suggesting that *P3H3* and *SC65* mutations may cause as yet undefined EDS variants.

MBTPS2

The regulated intramembrane proteolysis of transmembrane proteins is an essential cellular process that releases functional protein domains into signaling pathways (Lal and Caplan, 2011). *MBPTS2* (membrane-bound transcription factor peptidase, site 2) encodes the serine protease S2P (site-2 metalloprotease), which spans the Golgi membrane (Ye et al., 2000). Missense mutations in MBTPS2 have been shown to cause moderately severe X-linked OI (Lindert et al., 2016). S2P was found to have impaired function, which ultimately resulted in reduced secretion of type I collagen in fibroblast cultures. Type I collagen also exhibited altered posttranslational modifications with decreased lysine hydroxylation and glycosylation on the K87 cross-linking lysines of both α-chains (Lindert et al., 2016). The main contributor to the bone phenotype from loss of S2P may be the impaired activation of several transcription factors fundamental to normal bone development (Lindert et al., 2016).

Collagen processing

Bone morphogenetic protein 1

Bone morphogenetic protein 1 is the type I procollagen C-propeptide protease. Homozygous missense mutations in *BMP1* have been shown to cause a recessively inherited form of OI with a severe skeletal phenotype (Martinez-Glez et al., 2012). Missense mutations at the type I collagen propeptide cleavage site result in a phenotypically similar but less severe form of OI characterized by unusually high mineral density bone (Lindahl et al., 2011, Cundy et al., 2018). Although not established, retention of the type I collagen C-propeptide presumably disrupts fibril assembly and could alter collagen cross-linking (Eyre and Weis, 2013). It is tempting to speculate that the retained propeptide could alter collagen fibril three-dimensional packing so that the ratio of bone mineral to collagen and bone density are increased.

Collagen chaperone

SERPINH1

SERPINH1 encodes heat shock protein 47 (HSP47), an ER-resident and collagen-specific chaperone protein. HSP47 functions as a quality control protein that prevents premature aggregation of native procollagen molecules during transport through the ER (Widmer et al., 2012). Mutations in *SERPINH1* cause OI with severe skeletal deformity (Christiansen et al., 2010). Loss of HSP47 chaperone function resulted in protein misfolding and intracellular retention of type I collagen with subsequent ER stress (Drogemuller et al., 2009). The importance of *SERPINH1* was highlighted by the embryonic lethality observed in *Hsp47*-null mice (Nagai et al., 2000). An OI dachshund with a loss-of-function mutation in *SERPINH1* (Drogemuller et al., 2009) revealed bone collagen cross-linking abnormalities consistent with a defective molecular assembly and posttranslational chemistry (Lindert et al., 2015). Mutations in *SERPINH1* yield brittle bones with a high HP/LP ratio, telopeptide lysine overhydroxylation, and resulting overabundance of stable pyridinoline cross-links (Eyre and Weis, 2013).

Bone mineralization

IFITM5

Mutations in *IFITM5* yield an autosomal dominant form of OI with a moderate to severe skeletal phenotype (Glorieux et al., 2000). The *IFITM5* gene encodes interferon-induced transmembrane protein 5 (IFITM5), a 14.8-kDa transmembrane protein thought to function in early bone mineralization (Moffatt et al., 2008). The *IFITM5*-null mouse had stunted growth with smaller long bones (Hanagata et al., 2011). No defects in collagen posttranslational chemistry have been found in the bone of mice expressing the type V OI-causing IFITM5 mutation (Lietman et al., 2015).

SERPINF1

OI caused by homozygous null mutations in *SERPINF1* result in bone mineralization defects without any known effect on collagen structure (Glorieux et al., 2002). *SERPINF1* encodes pigment epithelium-derived factor (PEDF), a member of the serine protease inhibitor serpin superfamily (Rauch et al., 2012). PEDF is a 50-kDa glycoprotein known as a potent inhibitor of angiogenesis (Becker et al., 2011). PEDF has been shown to bind to type I collagen from bone and is thought to help regulate bone angiogenesis and matrix remodeling (Tombran-Tink and Barnstable, 2004). Indeed, the absence of PEDF results in large quantities of unmineralized osteoid and an abnormal lamellar pattern on histology of patient bone (Homan et al., 2011). It is likely that the bone phenotype is the result of a dysregulated step in the mineral deposition machinery.

Implications for bone fragility and mineral deposition

Abnormal collagen cross-linking emerges as a recurring theme in many of these rare musculoskeletal disorders. We end with a hypothesis that the abnormal collagen cross-linking seen in bone from many variants of OI is a responsible contributor to the underlying brittleness. Clearly, collagen strength rests heavily on its cross-linking, but other properties of bone, including ductility and resistance to microdamage and crack propagation, may depend on the unique pattern of LOX-mediated cross-links that characterize normal bone collagen of higher vertebrates. The placement of cross-links and the chemical lability of a significant fraction of them (those formed from lysine aldehydes) may be required to produce a malleable framework in which highly ordered hydroxyapatite nanocrystals can grow optimally within the fibrils (Eyre and Weis, 2013).

Fig. 14.6 illustrates this concept of labile, aldimine cross-links breaking as mineral crystallites grow in the interior of bone collagen fibrils. If, as the data suggest, lysine aldehyde and hydroxylysine aldehyde cross-links are each distributed in an orderly (nonrandom) pattern in the packed collagen lattice, this could channel a parallel, ordered growth of

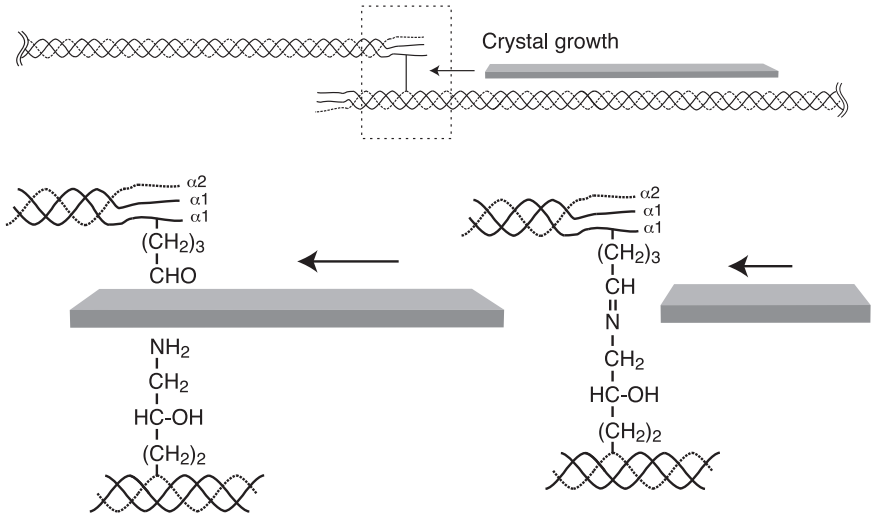

FIGURE 14.6 Illustrated concept that labile (aldimine) cross-links break as part of the orderly growth of hydroxyapatite crystal in mineralizing collagen fibrils.

hydroxyapatite crystals. In theory, for human bone, up to half the initial divalent cross-links (aldimines) would break, reverting back to their aldehyde plus amine precursors. The result is potentially increased intermolecular packing space for growing crystallites in a still stably cross-linked collagen fibril lattice (Eyre and Weis, 2013).

Future challenges

After more than half a century of study, we still do not understand at the molecular level the mechanism that drives the orderly mineralization of bone collagen. To what degree mineralization is driven by bone-specific features of the fibrils themselves, particularly their unique cross-linking chemistry, or is a process driven by extrafibrillar factors is still unclear. Understanding more broadly how differences in cross-linking chemistry between tissues and during development confer functional advantages will also help in understanding how defects in bone collagen cross-linking cause a compromised bone structure. Whether pyrrole cross-links contribute to the unique material properties of normal bone and how their loss might increase bone fragility in OI are also important questions. It should also not escape attention that the mechanisms causing bone collagen cross-linking abnormalities revealed by the study of rare genetic disorders may well be operative in more common brittle bone disorders, including osteoporosis and diabetes.

Chapter 15

Secreted noncollagenous proteins of bone

Jeffrey P. Gorski[1] **and Kurt D. Hankenson**[2]

[1]Department of Oral and Craniofacial Sciences, School of Dentistry, and Center for Excellence in Mineralized and Dental Tissues, University of Missouri–Kansas City, Kansas City, MO, United States; [2]Department of Orthopaedic Surgery, University of Michigan Medical School, Ann Arbor, MI, United States

Chapter outline

Introduction

Bone differs from soft connective tissues in that it is composed of a mineralized hydroxyapatite phase and an organic phase. Although the organic matrix of bone consists primarily of collagen(s) (as reviewed early in this volume), the existence of other secreted noncollagenous components was first proposed by Herring and coworkers in the 1960s (Herring and Ashton, 1974). Historically, using degradative techniques, a variety of carbohydrate-containing moieties were extracted and partially characterized. A major breakthrough in the isolation and characterization of noncollagenous proteins of bone came with the development of "dissociative" techniques whereby proteins could be extracted in an intact, nonaggregated form (Termine et al., 1980, 1981a,b). Although they are not as abundant as so-called structural components such as collagen, their importance in bone physiology cannot be underestimated. This is emphasized by the identification of mutations in a number of these proteins that result in abnormal bone (Gorski, 2011). This chapter discusses secreted noncollagenous proteins found in bone matrix. Since the publication of the previous edition of this work in 2008, substantial additions have been made to include recently reported functional studies, inclusion of noncollagenous proteins that were not previously considered, and new information regarding the developing area of bone–muscle/fat/pancreas/testis cross-talk signaling and the role that these proteins play in these interactions.

Proteoglycans

This class of molecules is characterized by the covalent attachment of long-chain polysaccharides (glycosaminoglycans, GAGs) to core protein molecules. GAGs are composed of repeating disaccharide units that are sulfated to varying degrees and include chondroitin sulfate, dermatan sulfate, keratan sulfate, and heparan sulfate (HS). Hyaluronic acid is also a GAG found in bone, but itself is not attached to a core protein. Different subclasses of proteoglycans are generally characterized by the structure of the core protein and by the nature of the GAG (Table 15.1). Although other types of molecules can be sulfated, proteoglycans bear greater than 95% of the sulfate groups within any organic matrix (Lamoureux et al., 2007).

Aggrecan and versican (PG-100)

There are two large chondroitin sulfate proteoglycans associated with skeletal tissue that are characterized by core proteins with globular domains at the amino and carboxy termini and by binding to hyaluronan to form large aggregates. Aggrecan was assumed to be virtually cartilage specific, but its mRNA is detected in developing bone (Wong et al., 1992) and is present in high-throughput gene expression studies of osteoblasts. It should also be noted that aggrecan is an important component of the primary spongiosa that forms during endochondral ossification. In the nanomelic chick, there is a mutation in the aggrecan core protein such that it is not expressed in cartilage (Primorac et al., 1999). However, there is an impact on bones that form via the intramembranous pathway, an unanticipated finding because these bones would not be expected to be affected by abnormal cartilage development. This suggests a role for aggrecan in bone matrix separate from its role in cartilage. Mutation of the aggregan gene results in a form of spondyloepiphyseal dysplasia in humans leading to premature osteoarthritis (Gleghorn et al., 2005), and in mice, a mutation leading to a null allele results in cartilage matrix deficiency with severe skeletogenesis defects and perinatal death (*cdm* mice) (Watanabe et al., 1994). While not specifically examined, there also appear to be defects in bones that form via intramembranous ossification. However, conditional mouse models that disrupt the aggrecan gene in an osteoblast-specific manner have not been described.

Closely related, but not identical, is a soft connective tissue—enriched proteoglycan termed versican, which is mostly localized to loose, interstitial mesenchyme in developing bone. It has been hypothesized that it captures space that will ultimately become bone. It is this proteoglycan that is destroyed as osteogenesis progresses. It is noteworthy that the core protein of versican contains epidermal growth factor (EGF)-like sequences (Wight, 2002), and release of these sequences may influence the metabolism of cells in the osteoblastic lineage. As osteogenesis progresses, versican is replaced by two members of another class of proteoglycans that contain core proteins of a different chemical nature (decorin and biglycan; Fisher et al., 1989). In the *hdf* (heart defect) mouse, the versican gene is disrupted and the protein is not expressed. The mutation is embryonic lethal, and in vitro studies have shown defective chondrogenesis by limb mesenchyme (Williams et al., 2005). A conditional versican allele has been generated and mice with limb bud mesenchymal disruption show altered digit formation and alterations in transforming growth factor β (TGFβ) localization, but an effect on bone has not been described (Choocheep et al., 2010).

Decorin (PG-II) and biglycan (PG-I)

The two small proteoglycans that are heavily enriched in bone matrix are decorin and biglycan, both of which contain chondroitin sulfate chains in bone, but bear dermatan sulfate in soft connective tissues. They are characterized by core proteins that contain a leucine-rich repeat (LRR) sequence, a property shared with proteins that are associated with morphogenesis such as *Drosophila* toll protein and chaoptin, the leucine-rich protein of serum, and adenylyl cyclase (Fisher et al., 1989). As leucine-rich proteoglycans, they are included in a family referred to as small leucine-rich proteoglycans (SLRPs). The crystal structures of decorin (McEwan et al., 2006) and biglycan (Scott et al., 2006) have been determined, and based on this analysis, it appears that the SLRPs are not as curved as ribonuclease and that they may dimerize.

Although decorin and biglycan share many properties owing to the high degree of homology of their core proteins, they are also quite distinct, as best demonstrated by their patterns of expression (Bianco et al., 1990). In cartilage, decorin is found in the interterritorial matrix away from the chondrocytes, whereas biglycan is in the intraterritorial matrix. In keeping with this pattern, during endochondral bone formation, decorin is widely distributed in a pattern that is virtually indistinguishable from that of type I collagen. It first appears in preosteoblasts, is maintained in fully mature osteoblasts, and is subsequently downregulated as cells become buried in the extracellular matrix to become osteocytes. However, biglycan exhibits a much more distinctive pattern of distribution. It is found in a pericellular location in unique areas undergoing morphological delineation. It is upregulated in osteoblasts and, interestingly, its expression is maintained in osteocytes and

TABLE 15.1 Proteoglycans in bone matrix.

Molecule	Structural characteristics	Gene ontology biological processes
Aggrecan	1×10^6 to 3×10^6 MW; 210- to 250-kDa core protein; 100–150 kDa GAG chains (CS and KS); two globular domains (G1 and G2) and a third globular domain (G3)	Skeletal system development; chondrocyte development; proteolysis; cell adhesion; central nervous system development; heart development; keratan sulfate biosynthetic process; extracellular matrix disassembly; proteoglycan biosynthetic process; extracellular matrix organization; collagen fibril organization; keratan sulfate catabolic process
Versican (PG-100)	1×10^6 MW intact protein ; 360-kDa core; 12 CS chains of 45 kDa, G1 and G3 globular domains with hyaluronan-binding sites; EGF- and CRP-like sequences	Skeletal system development; osteoblast differentiation; cell adhesion; multicellular organism development; central nervous system development; cell recognition; extracellular matrix organization; GAG metabolic process; CS metabolic, biosynthetic, and catabolic processes; dermatan sulfate biosynthetic process; posttranslational protein modification; cellular protein metabolic process
Decorin	130-kDa intact protein; 38- to 45-kDa core with 10 leucine-rich repeat sequences, 1 CS chain of 40 kDa	RNA binding; protein kinase inhibitor activity; protein binding; collagen binding; GAG binding; protein N-terminus binding; extracellular matrix binding
Biglycan	270-kDa intact protein, 38- to 45-kDa core protein with 12 leucine-rich repeat sequences, two CS chains of 40 kDa	May bind to collagen; may bind to TGFβ; pericellular environment; a genetic determinant of peak bone mass
Fibromodulin	59-kDa intact protein, 42-kDa core protein with leucine-rich repeat sequences, one N-linked KS chain	TGFβ receptor complex assembly; NOT axonogenesis; KS biosynthetic process; collagen fibril organization; KS catabolic process
Osteoglycin (mimecan)	299-aa precursor, 105-aa mature protein, leucine-rich repeat sequences	Axonogenesis; regulation of receptor activity; KS biosynthetic process; KS catabolic process; negative regulation of smooth muscle cells
Asporin	43-kDa core protein	Negative regulation of protein kinase activity; cytokine-mediated signaling pathway; bone mineralization; negative regulation of TGFβ receptor signaling pathway; biomineral tissue development; negative regulation of JAK–STAT cascade; negative regulation of tooth mineralization
Osteoadherin (osteomodulin)	85-kDa intact protein, 47-kDa core protein, 11 leucine-rich repeat sequences, RGD sequence	Cell adhesion; NOT axonogenesis; KS biosynthetic process; regulation of bone mineralization; KS catabolic process
Syndecan	32-kDa intact protein	Retinoid metabolic process; ureteric bud development; GAG biosynthetic process; GAG catabolic process; inflammatory response; response to toxic substance; response to organic substance; cell migration; GAG metabolic process; wound healing; odontogenesis; response to hydrogen peroxide; myoblast development; leukocyte migration; response to glucocorticoid; response to cAMP; response to calcium ion; striated muscle cell development; Sertoli cell development; canonical Wnt signaling; positive regulation of exosomal secretion; positive regulation of extracellular exosome assembly
Perlecan	660-kDa intact protein, 450-kDa core protein, three 70- to 100-kDa HS GAGs	Interacts with matrix components, regulates cell signaling
Glypican	Lipid-linked HSPG, 66-kDa core, two HS GAGs	Copper ion binding; fibroblast growth factor binding; laminin binding; HS proteoglycan binding
Hyaluronan	Multiple proteins associated outside of the cell, structure unknown	May work with versican-like molecule to capture space destined to become bone

CRP, C-reactive protein; *CS*, chondroitin sulfate; *EGF*, epidermal growth factor; *GAG*, glycosaminoglycan; *HS*, heparan sulfate; *HSPG*, heparan sulfate proteoglycan; *KS*, keratan sulfate; *MW*, molecular weight; *TGFβ*, transforming growth factor β.
Gene ontologies listed are derived in large part from one of two on-line sources: www.informatics.jax.org/vocab/gene_ontology or www.genecards.org/search/keyword.

is localized to lacunae and canaliculi. Osteocytes act as mechanoreceptors within the bone matrix (Bonewald, 2006), and proteoglycans, possibly biglycan or cell surface–associated molecules (such as HS proteoglycans), may play a role as force transducers.

Transgenic mice that are deficient in decorin have primarily thin skin (Danielson et al., 1997), whereas mice deficient in biglycan fail to achieve peak bone mass and develop osteopenia (Xu et al., 1998). Animals that are double deficient for decorin and biglycan exhibit a phenotype reminiscent of the progeroid form of Ehlers–Danlos syndrome, whereby collagen fibrils are highly disrupted in both the dermis and the bone (Corsi et al., 2002). Disruption of biglycan in mice also impairs fracture healing, possibly through regulation of endostatin (Myren et al., 2016).

Both decorin and biglycan have been found to bind to TGFβ and to regulate its availability and activity (Markmann et al., 2000). In view of current interest in bone muscle cross talk, it is interesting that decorin also binds specifically to myostatin, another activin superfamily member, and is able to block its inhibitory actions on myoblasts by sequestration (Miura et al., 2006). Subsequent work has shown that decorin's anti-myostatin action can be largely mimicked by an N-terminal Nos. 48–71 peptide, which is capable of blocking myostatin's binding to the activin type II receptor (El Shafey et al., 2016). Interestingly, anti-myostatin peptides derived from decorin are associated with human atrial fibrillation (Barallobre-Barreiro et al., 2016). Further work is needed to determine if decorin and decorin N-terminal peptides can modulate the receptor-mediated actions of TGFβ on osteoblastic cells in a similar manner.

A novel role for biglycan, and another SLRP, fibromodulin, has also been demonstrated in regulating osteoclastogenesis (Kram et al., 2017). Double-knockout mice for both genes show significant osteopenia because of enhanced osteoclastogenesis. Biglycan and fibromodulin bind to both tumor necrosis factor α and receptor activator of NF-κB ligand (RANKL) and thereby regulate osteoclastogenesis. In the absence of the proteins, osteoblasts are unable to sequester these proosteoclastic factors, and osteoclastogenesis is unregulated.

Decorin also binds to collagen (decorating collagen fibrils), as does biglycan. This interaction has dramatic effects on collagen fibril assembly and on the mechanical properties, including tensile strength, of the resultant matrix (Reese et al., 2013). Another activity has been demonstrated by in vitro cell attachment assays in which decorin and biglycan were both found to inhibit bone cell attachment, presumably by binding to fibronectin and inhibiting its cell–matrix binding capabilities (Grzesik and Robey, 1994).

Other leucine-rich repeat sequence proteins and proteoglycans

Interestingly, there are at least 60 proteins that have been found to contain LRRs, and many of them are also SLRPs (Matsushima et al., 2000). Another SLRP found in bone is osteoglycin, previously termed "osteoinductive factor" and later found to be a protein bound to TGFβ (Ujita et al., 1995). This molecule is similar but not identical to the proteoglycan PG-Lb, which has now been found to be epiphycan, localized primarily in epiphyseal cartilage. More recently, another LRR, asporin, has been localized to developing bone. Unlike other LRRs, it has an aspartic acid–rich amino sequence (Henry et al., 2001). Asporin-knockout mice have been generated and a defect in bone was not reported (Maccarana et al., 2017).

Other members of the SLRP family found in bone include fibromodulin, as previously mentioned, which contains keratan sulfate and binds to collagen fibrils in regions distinctly different from those of decorin (Hedbom and Heinegard, 1993); osteoadherin, also known as osteomodulin, which contains the cell attachment sequence Arg-Gly-Asp (RGD) (Sommarin et al., 1998); and lumican, which may regulate collagen fibril formation. Osteomodulin is highly upregulated during bone morphogenetic protein (BMP)-induced osteoblast differentiation, but it's impacts on bone in knockout mice are minimal.

Although SLRPs appear to be "born to bind," definitive functions are not known. The mouse deficient for both biglycan and fibromodulin exhibits initial joint laxity, followed by development of extra sesamoid bones in many tendons and development of an osteoarthritis-like condition (Ameye and Young, 2002). The lumican/fibromodulin-knockout mouse resembles a variant of Ehlers–Danlos syndrome (OMIM: 130000) and has ectopic calcification (Chakravarti et al., 2003). Other proteoglycans have been isolated from a variety of animal species by using varying techniques, for example, HAPGIII (so named for its ability to bind to hydroxyapatite) and PG-100, which has been shown subsequently to be homologous to versican, as reviewed previously (Zu et al., 2007).

Although not generally found in the extracellular matrix, HS proteoglycans found associated with, or intercalated into, cell membranes may be very influential in regulating bone cell metabolism. Receptors for several growth factors (TGFβ and fibroblast growth factor 2 [FGF2], to name two) have been found to associate with HS (either bound covalently to core proteins or as free GAGs). Deficiency in the *EXT1* or *EXT2* genes in humans, which encode Golgi glycosyltransferases that are responsible for HS synthesis, results in hereditary multiple exostoses (HME) (OMIM: 133700). In HME, patients develop osteochondromas because of dysregulated BMP signaling (Pacifici, 2017).

Intercalated HS proteoglycans (the syndecan family) have been postulated to regulate cell growth, perhaps through modulation of growth factor and receptor activity (Markmann et al., 2000). Work shows that over-expression of syndecan-2 in mouse osteoblasts results in alterations in Wnt signaling and a reduction in the osteoclast regulatory protein RANKL (Mansouri et al., 2017). Perlecan is highly expressed in cartilage and has been found to interact with matrix components and to regulate cell signaling proteins, including FGF. Knockout mice have a phenotype that resembles thanatophoric dysplasia type I (OMIM: 187600) (Arikawa-Hirasawa et al., 1999), and mutations in humans are associated with Schwartz–Jampel syndrome (OMIM: 142461). Glypicans are another class of HS proteoglycans linked to cell membranes by phosphoinositol linkages that are cleavable by phospholipase C. Consequently, their activity may be in the pericellular environment or in the extracellular matrix. Mutations in glypican 3 give rise to Simpson–Golabi–Behmel syndrome (OMIM: 300037), and the knockout mouse has delayed endochondral bone formation and impaired osteoclastic development (Viviano et al., 2005). The complete cast of HS proteoglycans present in the cellular and pericellular environment in bone is not yet complete (see Zu et al., 2007, for a review).

Hyaluronan

This unsulfated GAG is not attached to a protein core and is synthesized by a completely different pathway. Hyaluronan is synthesized in the extracellular environment by a group of three plasma membrane hyaluronic acid synthases, which use cytoplasmic UDP-glucuronic acid and UDP-*N*-acetylglucosamine as substrates (Vigetti et al., 2014). Large amounts of hyaluronan are synthesized during the early stages of bone formation and may associate with versican to form high molecular weight aggregates (Fedarko et al., 1992; Falconi and Aubin, 2007). Interestingly, the long bones of hyaluronic acid synthase 2 (Has2)-deficient mice are severely shortened, implying that hyaluronic acid synthesis is required for normal longitudinal growth of all limbs (Matsumoto et al., 2009). A series of changes in the cartilage of *Has2*-null mice, e.g., reduced number of hypertrophic chondrocytes, disorganized growth plates, and lower expression of hypertrophic differentiation markers, indicate that hyaluronic acid is also needed for normal chondrocyte maturation. In other tissues, hyaluronic acid is believed to participate in cell migration and differentiation (Fedarko et al., 1992).

Glycoproteins

Virtually all noncollagenous bone matrix proteins are modified post-translationally to contain either N- or O-linked oligosaccharides, many of which can be modified further by the addition of phosphate and/or sulfate (Table 15.2). In general, compared with their soft connective tissue counterparts, bone matrix proteins are modified more extensively and in a different pattern. In some cases, differences in posttranslational modifications result from differential splicing of heterogeneous nuclear RNA, but, in general, they result from differences in the activities of enzymes located along the intracellular pathway of secretion. The pattern of post-translational modifications may be cell type specific and consequently may be of use in distinguishing protein metabolism from one tissue type versus another.

The number of secreted glycoproteins that have been identified in bone matrix grows every year. This, in part, is because of the explosion of information from high-throughput expression techniques, including RNA sequencing. What follows next is a brief description of secreted bone proteins that most likely play structural as well as metabolic roles. Other glycoprotein species have been identified primarily as growth factors and will be covered in more detail elsewhere in this volume.

Alkaline phosphatase

Tissue nonspecific alkaline phosphatase (TNAP) is a product of the *ALPL* gene. TNAP is localized to the cell membrane of osteoblasts and plays an essential role in bone mineralization. Human mutations in *ALPL* are responsible for hypophosphatasia (OMIM: 146300, 241510, and 241500), a disease condition characterized by hypomineralized bones, abnormal bone formation and skeleton growth, and dental abnormalities. TNAP is present in abundance on matrix vesicles and thus in developing bone matrix, where it degrades extracellular pyrophosphate, a potent inhibitor of bone mineralization. Mice with deficiency in TNAP have severe bone abnormalities (Millan and Whyte, 2016).

Sclerostin

Sclerostin is a product of the *SOST* gene and is secreted by kidney, vascular cells, and bone osteocytes. Early work suggested that sclerostin may work in combination with noggin to form complexes that antagonize BMP mitogenic activity

TABLE 15.2 Characteristics of glycoproteins in bone matrix.

Molecule	Structural characteristics	Gene ontology biological processes
Alkaline phosphatase	Two identical subunits of 80 kDa, disulfide-bonded, tissue-specific posttranslational modifications	Skeletal system development; osteoblast differentiation; endochondral ossification; developmental process involved in reproduction; C-terminal protein lipidation; metabolic process; dephosphorylation; biomineral tissue development; response to lipopolysaccharide; response to vitamin D; response to antibiotic; response to glucocorticoid; cellular response to organic cyclic compound; cementum mineralization
Sclerostin	24 kDa, C-terminal cysteine knot-like domain similar to BMP antagonists	Ossification; response to mechanical stimulus; Wnt signaling; negative regulation of ossification; negative regulation of BMP signaling pathway; negative regulation of protein complex assembly; positive regulation of transcription, DNA-templated; cellular response to parathyroid hormone stimulus; negative regulation of canonical Wnt signaling pathway; negative regulation of Wnt signaling pathway involved in dorsal/ventral axis specification
Periostin	93 kDa	Skeletal system development; response to hypoxia; negative regulation of cell–matrix adhesion; regulation of systemic arterial blood pressure; cell adhesion; regulation of notch signaling pathway; response to mechanical stimulus; tissue development; response to muscle activity; positive regulation of smooth muscle cell migration; extracellular matrix organization; response to estradiol; wound healing; cellular response to fibroblast growth factor stimulus; cellular response to vitamin K; cellular response to tumor necrosis factor; cellular response to transforming growth factor β stimulus; negative regulation of substrate adhesion-dependent cell spreading; positive regulation of chemokine (C–C motif) ligand 2 secretion; neuron projection extension; bone regeneration
Osteonectin/ SPARC	35–45 kDa, intramolecular disulfide bonds; α-helical amino terminus with multiple low-affinity, Ca^{2+} binding sites; two EF-hand high-affinity, Ca^{2+} sites; ovomucoid homology; glycosylated, phosphorylated, tissue-specific modifications	Ossification; negative regulation of endothelial cell proliferation; platelet degranulation; receptor-mediated endocytosis; signal transduction; heart development; response to gravity; response to lead ion; positive regulation of endothelial cell migration; negative regulation of angiogenesis; regulation of cell morphogenesis; extracellular matrix organization; lung development; response to lipopolysaccharide; response to L-ascorbic acid; response to cytokine; wound healing; regulation of cell proliferation; response to peptide hormone; pigmentation; response to ethanol; response to cadmium ion; inner ear development; response to glucocorticoid; response to cAMP; response to calcium ion; bone development; cellular response to growth factor stimulus
Tetranectin	21-kDa protein composed of four identical subunits of 5.8 kDa, sequence homologies with asialoprotein receptor and G3 domain of aggrecan	Ossification; platelet degranulation; positive regulation of plasminogen activation; bone mineralization; cellular response to organic substance; cellular response to transforming growth factor β stimulus

BMP, bone morphogenetic protein.
Gene ontologies listed are derived in large part from one of two on-line sources: www.informatics.jax.org/vocab/gene_ontology or www.genecards.org/search/keyword.

by physically sequestering the latter (Winkler et al., 2004). However, more recently, sclerostin is most recognized as an inhibitor of Wnt signaling. Sclerostin expression has been shown to be important for skeletal function because deficient individuals homozygous for a nonsense mutation in the N-terminal coding region exhibit characteristics of sclerosteosis (severe bone overgrowth often including syndactyly; Brunkow et al., 2001). Van Buchem's disease represents a milder form of sclerosteosis caused by a regulatory mutation that reduces the expression of sclerostin and results in abnormal bone growth (Vanhoenacker et al., 2003). These sclerosteosis conditions are similar to a high-bone-mass disorder caused by an activating mutation in the Wnt co-receptor, *LRP5* (Gong et al., 2001). Sclerostin is recognized as a key osteocyte-produced feedback mechanism that serves to modulate the development and activity of osteoblasts.

The functional importance of sclerostin as an inhibitor of bone formation has been reinforced through many mouse knockout and transgenic studies, as well through clinical and translational studies (Ominsky et al., 2010; Padhi et al., 2011). For example, multiple myeloma is associated with increased fracture risk and low bone density, due to the production of paracrine factors that stimulate osteoclastic bone resorption (Roodman, 2011). Blocking osteoclast action with bisphosphonates has been shown to reduce bone loss; however, it does not stimulate replacement of bone and treated

patients still experience low bone mass and increased fracture risk. It has now been shown that anti-sclerostin antibodies are able to induce new bone formation in a mouse model of multiple myeloma (McDonald et al., 2017) and, importantly, tumor-bearing mice treated with both bisphosphonate and anti-sclerostin antibodies gained more bone mass and displayed better vertebral fracture resistance than bisphosphonate-treated tumor control mice. These results suggest that antibody therapy against sclerostin may ultimately be beneficial in stimulating new bone formation. However, a number of issues remain to be resolved before therapeutic anti-sclerostin antibodies can be prescribed safely for building bone mass in multiple myeloma or osteoporosis patients (Bhattacharya et al., 2018).

Periostin

The *POSTN* gene encodes a secreted $M_r = 90$ kDa extracellular protein involved in integrin-mediated adhesion of epithelial cells in heart, bone, and teeth. Deletion of *POSTN* leads to cardiac valve disease, as well as skeletal and dental abnormalities including low bone mineral density (BMD) and reduced cortical bone strength (Rios et al., 2005). As it is highly expressed in periosteal bone cells, work by Bonnet et al., 2017) suggests that periostin plays a positive role in the formation of cortical bone. They showed that periostin is a substrate and direct target of cathepsin K both in vivo and in vitro. Importantly, when cathepsin K was inhibited either pharmacologically or through genetic ablation, expression of periostin was increased in vivo, especially in the periosteum. Interestingly, the bone formation response to mechano-transduction signals was increased in cortical bone in mice treated with cathepsin K functional inhibitors or in cathepsin K−deficient mice (Bonnet et al., 2017). In a commensurate way, the mechanotransduction response was blocked in periostin-deficient mice. These results indicate that periostin may play a positive role in regulating growth and remodeling of cortical bone during development, e.g., growth in the width of long bones. It is highly likely that the ability of periostin to bind to multiple extracellular matrix proteins (fibronectin, laminin, collagens I and V, tenascin, and lysyl oxidase) contributes to its capacity to influence the transmission of mechanotransduction signals in bone. Further work is necessary to assess whether the actions of periostin on skeletal stem cells within the periosteum also contribute to this growth (Duchamp de Lageneste et al., 2018).

Osteonectin (SPARC, culture shock protein, and BM40)

With the development of procedures to demineralize and extract bone matrix proteins without the use of degradative enzymes, osteonectin was one of the first proteins isolated in intact form. This molecule was so named owing to its ability to bind to Ca^{2+}, hydroxyapatite, and collagen and to nucleate hydroxyapatite deposition (Termine et al., 1981a,b). Osteonectin is commonly referred to as SPARC (secreted protein acidic and rich in cysteine). It was one of the first extracellular proteins to be characterized as a "matricellular" protein by Sage and Bornstein (Sage and Bornstein, 1991). The osteonectin molecule contains several different structural features, the most notable of which is the presence of two EF-hand high-affinity calcium-binding sites. These structures are usually found in intracellular proteins, such as calmodulin, that function in calcium metabolism (Bhattacharya et al., 2004).

Although osteonectin is highly enriched in bone, it is also expressed in a variety of other connective tissues at specific points during development, maturation, or repair processes in vivo. It was identified after induction by cAMP in terato-carcinoma cells and was found to be produced at very early stages of embryogenesis. Interestingly, if osteonectin is inactivated by the use of blocking antibodies during tadpole development, there is a disruption of somite formation and subsequent malformations in the head and trunk (Purcell et al., 1993). Mice that are deficient in osteonectin present with severe cataracts (Bassuk et al., 1999) and develop severe osteopenia characterized by decreased trabecular connectivity, decreased mineral content, but increased apatite crystal size (Mansergh et al., 2007).

Tetranectin

This tetrameric protein has been identified in woven bone and in tumors undergoing mineralization (Wewer et al., 1994). This protein shares sequence homologies with globular domains of aggrecan and asialoprotein receptor. Mice deficient in tetranectin develop spinal deformities (Iba et al., 2001), but the specific functional role that tetranectin plays in osteogenesis is unknown.

RGD-containing glycoproteins

Some of the major glycoproteins in bone matrix (collagens, thrombospondin (TSP), fibronectin, vitronectin, fibrillins, osteoadherin, osteopontin (OPN), bone sialoprotein (BSP), dentin matrix protein 1 (DMP1), and proteins derived from the

dentin sialophosphoprotein gene) contain the amino acid sequence RGD, which conveys the ability of the extracellular matrix protein to bind to the integrin class of cell surface receptors (Table 15.3). This binding is the basis of many cell attachment activities that have been identified by in vitro analysis; however, it should be noted that in many cases it is not clear how this in vitro activity translates into in vivo physiology.

TABLE 15.3 Glycoproteins in bone matrix, continued: RGD-containing glycoproteins.

Molecule	Structural characteristics	Gene ontology biological processes
Thrombospondins	450-kDa molecule; three identical disulfide-linked subunits of 150–180 kDa; homologies to fibrinogen, properdin, EGF, collagen, von Willebrand Factor , *Plasmodium falciparum*, and calmodulin; RGD at the C-terminal globular domain	Apoptosis-related network due to altered Notch3 in ovarian cancer; bladder cancer; focal adhesion; inflammatory response pathway; microRNA targets in ECM and membrane receptors; senescence and autophagy in cancer; syndecan-4-mediated signaling events; TGFβ receptor signaling; TGFβ signaling pathway
Fibronectin	400 kDa with two nonidentical subunits of 200 kDa, composed of type I, II, and III repeats; RGD in the 11th type III repeat 2/3 from the N terminus	MicroRNA targets in ECM and membrane receptors; nanoparticle-mediated activation of receptor signaling overview of nanoparticle effects; Rac1/Pak1/p38/MMP-2 pathway; regulation of actin cytoskeleton; senescence and autophagy in cancer; simplified interaction map between LOXL4 and oxidative stress pathway; syndecan-2-mediated signaling events; syndecan-4-mediated signaling events; TGFβ signaling in thyroid cells for epithelial–mesenchymal transition; TGFβ signaling pathway; VEGFR3 signaling in lymphatic endothelium
Irisin	24-kDa protein with fibronectin III domain, N-glycosylated, extracellular domain is membrane cleaved	Biological process; regulation of receptor activity; response to muscle activity; positive regulation of brown fat cell differentiation
Vitronectin	Cell attachment protein, terminus, homology to somatomedin B, rich in cysteines, sulfated, phosphorylated	αMβ2 integrin signaling; focal adhesion; FOXA1 transcription factor network inflammatory response pathway; integrins in angiogenesis; primary focal segmental glomerulosclerosis; senescence and autophagy in cancer
Fibrillin1	350 kDa, EGF-like domains, RGD, cysteine motifs	Integrin binding; hormone activity; ECM structural constituent; calcium ion binding; protein binding; heparin binding; ECM constituent conferring elasticity; protein complex binding; identical protein binding
Osteopontin	44–75 kDa, polyaspartyl stretches, no disulfide bonds, glycosylated, phosphorylated, RGD located 2/3 from the N terminus	Brain-derived neurotrophic factor signaling pathway; direct *p*53 effectors; endochondral ossification; FGF signaling pathway; focal adhesion; integrins in angiogenesis; lung fibrosis; osteoclast signaling; osteopontin signaling; osteopontin-mediated events; TGFβ receptor signaling; Toll-like receptor signaling pathway
Bone sialoprotein	46–75 kDa, polyglutamyl stretches, no disulfide bonds, 50% carbohydrate, tyrosine-sulfated, RGD near the C terminus	Focal adhesion; interleukin-11 signaling pathway; osteoblast signaling
Matrix extracellular phosphoglycoprotein	58 kDa	Skeletal system development; biomineral tissue development; posttranslational protein modification; cellular protein metabolic process
BAG-75	75 kDa; sequence homologies to dentin matrix protein-1, osteopontin, and bone sialoprotein; 7% sialic acid, 8% phosphate, 29% acidic amino acid content	Binds large number of calcium ions/mole, may act as a cell attachment protein (RGD sequence not yet confirmed), may regulate bone resorption

ECM, extracellular matrix; *EGF*, epidermal growth factor; *FGF*, fibroblast growth factor; *FOXA1*, forkhead box A1; *LOXL4*, lysyl oxidase-like 4; *MMP-2*, matrix metalloproteinase 2; *TGFβ*, transforming growth factor β; *VEGFR3*, vascular endothelial growth factor receptor 3.
Gene ontologies listed are derived in large part from one of two on-line sources: www.informatics.jax.org/vocab/gene_ontology or www.genecards.org/search/keyword.

Thrombospondins

TSPs are a family of five multidomain, matricellular proteins. TSP-1 was first identified as the most abundant protein in platelet alpha granules, but is found in many tissues during development, including bone, where it is highly expressed (Robey et al., 1989). Subsequently, four other members have been described, including COMP (cartilage oligomeric matrix protein) as TSP-5 (reviewed in Adams, 2004). In bone, all five proteins are present, synthesized by different cell types at different stages of maturation and development (Carron et al., 1999), but TSP-1 and TSP-2 are the most highly expressed by osteoblast lineage cells and the best characterized TSP proteins in bone. TSP-1 and TSP-2 are trimeric proteins, whereas TSP-3 to 5 are pentameric. TSP-1 and 2 are able to bind to a variety of cell surface receptors, including CD36, CD47, LRP1, and integrins, but in addition can bind to other matrix proteins, matrix metalloproteinases (MMPs), and growth factors, particularly TGFβ. The bone phenotype of TSP-2-deficient mice has been extensively characterized. These mice exhibit an increase in osteoblast progenitors, but have defective mineralization. Cortical bone is thicker, but the bones are reduced in periosteal diameter. Manley et al. have shown that cells deficient in TSP-2 are unable to effectively process collagen and the mice have a brittle bone phenotype (Manley et al., 2015). Mice deficient in TSP-2 also show accelerated bone regeneration characterized by reduced chondrogenesis and accelerated intramembranous bone formation. This phenotype is linked to the well-described role of TSPs in regulating vascularization.

Fibronectin

Fibronectin is synthesized by virtually all connective tissue cells and is a major component of serum. There are a large number of different mRNA splice variants such that the number of potential forms is quite high. Consequently, bone matrix could contain fibronectin that originates from exogenous as well as endogenous sources (Pankov and Yamada, 2002). The precise form that is present in cells of the osteoblastic lineage is unknown. Fibronectin is produced during early stages of bone formation and has been found to be highly upregulated in the osteoblastic cell layer. Interestingly, bone cell attachment to fibronectin in vitro takes place in an RGD-independent fashion (Grzesik and Robey, 1994). However, this correlates well with the expression of the fibronectin receptor α4β1, which binds to a sequence other than RGD in the fibronectin molecule and is also expressed by some osteoblastic cells. Cell−matrix interactions mediated by fibronectin receptor−α4β1 binding may play a role in the maturation sequence of cells in the osteoblastic lineage.

In 2017, Lee et al. showed that mutations in fibronectin cause a subtype of spondylometaphyseal dysplasia (SMD) with "corner fractures" at metaphyses. SMDs are often characterized by growth plate abnormalities, short stature, and vertebral problems. Comparisons of the exomes of three individuals with SMD with corner fractures yielded fibronectin mutations in highly conserved residues. The functional consequences of these mutations were examined by expressing the three missense variants into a recombinant secreted N-terminal 70-kDa fragment and into full-length fibronectin. While wild-type forms were secreted into the culture medium as expected, all mutant proteins were either not secreted or secreted only at dramatically lower amounts (Lee et al., 2017). Thus, SMD with corner fractures is caused by defective fibronectin secretion and reinforces the importance of fibronectin in cartilage and bone, two tissues whose structure is altered with functional consequences.

Irisin (FRCP2, fibronectin type III domain−containing protein 5)

Irisin is encoded by a distinct gene that generates several different transcripts produced by alternative splicing. Fibronectin type III domain−containing protein 5 (FNDC5)/irisin, a novel secreted energy-regulating hormone, has been associated with bone lipid and carbohydrate metabolism. Expressed at high levels by muscle, particularly when exercised, irisin has been implicated in muscle−bone cross-talk signalling reactions. Several specific examples illustrate this point.

For one, the use of models of mechanical unloading (hindlimb unloading and sciatic neurectomy) reduce both tibial trabecular bone mineral and surrounding muscle volume. Interestingly, *irisin* mRNA in soleus muscle correlated positively with bone BMD in respective controls and in unloaded mice (Kawao et al., 2018). Since irisin also negatively correlated with RANKL mRNA levels in bone of control and hindlimb-unloaded mice, these authors suggested that irisin is directly implicated in the suppression of osteoclasts and osteoclastic bone resorption, particularly in situations where mechanical stress regulates muscle and bone structure. Using similar mechanical-unloading models in mice, Colaianni et al. showed also that irisin was able not only to prevent but also to restore bone and muscle loss (Colaianni et al., 2017). Treatment maintained muscle volume as well as fiber cross-sectional area and myosin type II composition. These data followed up on earlier pioneering work showing that irisin had positive effects on anabolic bone formation in vivo in mice (Colaianni et al., 2015). Finally, intraperitoneal injection of irisin has also been shown to increase trabecular and cortical bone volume in mice, a result mimicked by intraperitoneal FNDC5.

Vitronectin

This serum protein, first identified as S-protein because of its cell-spreading activity, is found at low levels in mineralized matrix (Grzesik and Robey, 1994). Its cell surface receptor, αVβ3, is distributed broadly throughout bone tissue. In addition to cell attachment activity, it also binds to and affects the activity of plasminogen activator inhibitor (Schvartz et al., 1999). Osteoclasts utilize vitronectin as a cell adhesion substrate when bound to bone.

Fibrillins

In addition to their RGD sequences, fibrillin-1 and fibrillin-2 are glycoproteins that also contain multiple EGF-like repeats. Although generally minor constituents of skeletal tissues in terms of mass, fibrillins are major components of microfibrils, and mutations in these genes lead to Marfan's syndrome and congenital contractural arachnodactyly, which exhibit abnormalities in bone growth (reviewed in Ramirez and Dietz, 2007). Fibrillin-1 and fibrillin-2 associate with LTBP (latent TGFβ-binding protein) in microfibrils and regulate TGFβ bioactivity (Chaudhry et al., 2007). Deletion of fibrillin-1 with Prx1 Cre leads to abnormal mesenchymal stem cell differentiation with resultant bone loss (Smaldone et al., 2016). Work also demonstrates that fibrillin-2 exhibits a special capacity to regulate BMP-7 activity during limb patterning (Nistala et al., 2010). In addition, both fibrillin-1 and fibrillin-2 regulate commitment and differentiation of bone marrow skeletal stem cells (Smaldone et al., 2016). Taken together, the data show that fibrillins function as critical components of the extracellular matrix where, in combination with activin growth and differentiation factors, they regulate the differentiation of skeletal stem cells directly and hemopoietic stem cells indirectly.

Bone acidic glycoprotein-75

The identity of bone acidic glyprotein-75 (BAG-75) relies upon its detection and recognition with three different antibodies, e.g., a monoclonal antibody (HTP IV-#1), a rabbit polyclonal antibody (#704), and an anti-peptide #3−13 antibody against its N-terminal sequence, and its unique N-terminal sequence as well as accumulated internal peptide sequences totaling about 100 residues (Gorski and Shimizu, 1988; Gorski et al., 1990; Wang et al., 2009) (J.P. Gorski, personal communication). Functionally, direct comparisons with OPN and BSP revealed that BAG-75 bound more calcium ions per mole (139 atoms/molecule) than either of the other bone glycoproteins (Chen et al., 1992). When added to osteoclast cultures, BAG-75 was also able to block resorption, presumably by blocking or interfering with the adhesion of osteoclasts with mineralized bone matrix (Sato et al., 1992). Finally, an intriguing property of BAG-75 remains its capacity to identify matrix sites within developing primary bone or in osteoblastic cultures that will be subsequently mineralized (Gorski et al., 2004; Midura et al., 2004). In this sense, it remains an unusual biomarker of sites that are about to become calcified.

Small integrin-binding ligands with N-linked glycosylation

Several bone matrix proteins are characterized not only by the inclusion of RGD within their sequences, but also by the presence of relatively large amounts of sialic acid. Interestingly, they are clustered at a distinct gene locus, 4q21−q23 and appear to have arisen by gene duplication. For this reason, the family has been termed SIBLINGs (small integrin-binding ligands with N-linked glycosylation) (Fisher and Fedarko, 2003) (Table 15.3). The family includes OPN and BSP, the two best characterized proteins of the family; along with DMP1, dentin sialoprotein, and dentin phosphoprotein, which are coded for by the same gene, now termed dentin sialophosphoprotein; matrix extracellular phosphoglycoprotein (MEPE); and the more distantly related protein, enamelin. Although the SIBLINGs were initially thought to be specific for mineralized tissues, it is now apparent that many of them are expressed in metabolically active epithelial cells (Ogbureke and Fisher, 2005). Interestingly, three of the family members bind to and activate specific MMPs (BSP−MMP-2, OPN−MMP-3, and DMP1−MMP-9) (Fedarko et al., 2004).

Osteopontin (spp, BSP-I)

This sialoprotein was first identified in bone matrix extracts, but it was also identified as the primary protein induced by cellular transformation. In bone, it is produced at late stages of osteoblastic maturation corresponding to stages of matrix formation just prior to mineralization. In vitro, it mediates the attachment of many cell types, including osteoclasts. In osteoclasts, it has also been reported to induce intracellular signaling pathways as well. In addition to the RGD sequence, it also contains stretches of polyaspartic acid and it has a fairly high capacity for binding Ca^{2+}ions; however, it does not appear to nucleate hydroxyapatite formation in several different assays. The OPN-deficient mouse develops normally, but

has increased mineral content, although the crystals are smaller than normal. The role of OPN in skeletal homeostasis is covered elsewhere in this volume, and there are numerous reviews available for its role in cancer and immune function (for example, Scatena et al., 2007).

Bone sialoprotein (BSP-II)

The other major sialoprotein is BSP, composed of 50% carbohydrate (12% is sialic acid) and stretches of polyglutamic acid (as opposed to polyaspartic acid in OPN). The RGD sequence is located at the carboxy terminus of the molecule, whereas it is located centrally in OPN. The sequence is also characterized by multiple tyrosine sulfation consensus sequences found throughout the molecule, in particular, in regions flanking the RGD (Fisher et al., 1990). Sulfated BSP has been isolated in a number of animal species, but the levels appear to be variable.

BSP exhibits a more limited pattern of expression than OPN. In general, its expression is tightly associated with mineralization phenomena (although there are exceptions). In the skeleton, it is found at low levels in chondrocytes, in hypertrophic cartilage, in a subset of osteoblasts at the onset of matrix mineralization, and in osteoclasts (Bianco et al., 1991). Consequently, BSP expression marks a late stage of osteoblastic differentiation and an early stage of matrix mineralization. Outside of the skeleton, BSP is found in trophoblasts in placental membranes, which in late stages of gestation fuse and form mineralized foci.

BSP may be multifunctional in osteoblastic metabolism. It is very clear that it plays a role in matrix mineralization as supported by the timing of its appearance in relationship to the appearance of mineral and its Ca^{2+}-binding properties. BSP has a high capacity for binding calcium ions. The polyglutamyl stretches were thought to be solely responsible for this property; however, studies using recombinant peptides suggest that although the polyglutamyl stretches are required, they are not the sole determinants (Stubbs et al., 1997). Unlike OPN, BSP does nucleate hydroxyapatite deposition in a variety of in vitro assays.

It is also clear from in vitro assays that BSP is capable of mediating cell attachment, most likely through interaction with the somewhat ubiquitous $\alpha V\beta 3$ (vitronectin) receptor. Bone cells attach to the intact molecule in an RGD-dependent fashion. However, when BSP is fragmented, either endogenously by cells or using commercially available enzymes, the fragment most active in cell attachment does not contain the RGD sequence (Mintz et al., 1993). Studies indicate that the sequence upstream from the RGD mediates attachment (in an RGD-independent fashion) and suggest that the integrin-binding site is more extended than had been envisioned previously. Sequences flanking the RGD site are often tyrosine sulfated. However, it is not known how sulfation influences BSP activity, as in vitro, unsulfated BSP appears to be equivalent in its activity. Once again, it is not clear if currently available in vitro assays are sufficiently sophisticated to determine what influence post-translational modifications, such as sulfation, have on the biological activity. In addition to sulfation, conformation of the RGD site may also influence the activity of the protein. Although the RGD region in fibronectin is found in a looped-out region that is stabilized by disulfide bonding, there are no disulfide bonds in BSP. However, the flanking sequences most likely influence the conformation of the region. The cyclic conformations also appear to have a higher affinity for cell surface receptors than linear sequences (van der Pluijm et al., 1996).

BSP-knockout mice have been extensively studied by the Malaval laboratory (Bouleftour et al., 2016). Initial studies of the knockout mouse clearly implicate BSP in playing an important role in mineralization and cortical or primary bone formation, but not endochondral bone formation (Bouleftour et al., 2014). More recent studies have demonstrated that BSP can also influence hematopoiesis and vascularization (Granito et al., 2015). Interestingly, in the absence of BSP, OPN is upregulated and it is speculated that some aspects of the BSP-deficient phenotype may be secondary to upregulation of OPN (Granito et al., 2015; Bouleftour et al., 2016)

Dentin matrix protein 1

Although DMP1 was originally thought to be specific to dentin, it was subsequently found to be synthesized by osteoblasts as well (D'Souza et al., 1997). However, its function in bone metabolism is not known as of this writing. The DMP1-deficient mouse has craniofacial and growth plate abnormalities, along with rickets and osteomalacia owing to increased secretion of the phosphate-regulating hormone FGF23. The overproduction of FGF23 is hypothesized to be caused by abnormal osteocyte function (Feng et al., 2006). Mutations in *DMP1* have been identified in patients with dentinogenesis imperfecta (OMIM: 600980) and in forms of autosomal recessive hypophosphatemic rickets (OMIM: 241520). *DMP1* is well recognized as a gene highly expressed by early osteocytes.

Matrix extracellular phosphoglycoprotein

MEPE is expressed in bone and bone marrow, but also at high levels in the brain and low levels in the lung, kidney, and placenta. This protein is also highly expressed by tumors that induce osteomalacia, and it has been regarded as a potential phosphate-regulating hormone (Rowe et al., 2000). It is thought that the C-terminal portion of MEPE (ASARM), together

with PHEX, regulates mineralization and renal phosphate metabolism (Rowe, 2004). Conversely, animals deficient in MEPE have significantly increased bone mass owing to increased numbers of trabeculae and increased cortical thickness (Gowen et al., 2003).

γ-Carboxyglutamic acid-containing proteins

In bone matrix, there are three proteins that undergo γ-carboxylation via vitamin K-dependent enzymes: matrix γ-carboxyglutamic acid (Gla) protein (MGP) (Price et al., 1983) and osteocalcin (Gla protein) (Price et al., 1976), both of which are made by bone cells, and protein S (made primarily in the liver but also made by osteogenic cells) (Maillard et al., 1992) (Table 15.4). The presence of dicarboxylic glutamyl residues confers low-affinity calcium-binding properties to these proteins.

Matrix Gla protein

MGP is found in many connective tissues and is highly expressed in cartilage. It appears that the physiological role of MGP is to act as an inhibitor of mineral deposition. Similar to secreted proteins in other calcium-rich environments, e.g., casein, MGP possesses three highly conserved phosphorylation sequence motifs (Ser-X-Glu/Ser(P)) within its N-terminal region (Price et al., 1994). MGP-deficient mice develop calcification in extraskeletal sites such as in the aorta (Luo et al., 1997). Interestingly, the vascular calcification proceeds via transition of vascular smooth muscle cells into chondrocytes, which subsequently hypertrophy (El-Maadawy et al., 2003). In humans, mutations in *MGP* have also been associated with excessive cartilage calcification (Keutel syndrome, OMIM: 245150). And it has been reported that deficiency of MGP in mice closely mimics the phenotype of patients with Keutel syndrome (Marulanda et al., 2017). A 2017 meta-analysis of 23 different case−control studies now shows that there is a significant association between the *MGP* gene rs1800801 polymorphism and vascular calcification and atherosclerotic disease, particularly in the Caucasian subgroup (Sheng et al., 2017).

Functionally, MGP is an antagonist of BMPs and is highly expressed by vascular endothelial cells. However, another consequence of deletion of *MGP* in mice is the dysregulation of endothelial cell differentiation from mouse embryonic stem cells (Yao et al., 2016). These authors have subsequently shown that this effect may have broader downstream effects,

TABLE 15.4 Characteristics of γ-carboxyglutamic acid−containing proteins in bone matrix.

Molecule	Structural characteristics	Gene ontology biological processes
Matrix Gla protein	15 kDa, five Gla residues, one disulfide bridge, phosphoserine residues	Cartilage condensation; ossification; multicellular organism development; cell differentiation; regulation of bone mineralization; cartilage development
Osteocalcin	5 kDa, one disulfide bridge, Gla residues located in α-helical region	Skeletal system development; ossification; osteoblast differentiation; osteoblast development; signal peptide processing; ER-to-Golgi vesicle-mediated transport; cell adhesion; aging; cell aging; response to mechanical stimulus; response to gravity; response to inorganic substance; response to zinc ion; response to organic cyclic compound; response to activity; peptidylglutamic acid carboxylation; bone mineralization; regulation of bone mineralization; biomineral tissue development; response to nutrient levels; response to vitamin K; response to vitamin D; response to testosterone; response to hydroxyisoflavone; odontogenesis; response to drug; response to estrogen; regulation of bone resorption; response to ethanol; regulation of osteoclast differentiation; response to glucocorticoid; bone development; cellular response to vitamin D; cellular response to growth factor stimulus
Protein S	75 kDa	Platelet degranulation; signal peptide processing; ER-to-Golgi vesicle-mediated transport; blood coagulation; hemostasis; negative regulation of endopeptidase activity; peptidylglutamic acid carboxylation; negative regulation of blood coagulation; regulation of complement activation; fibrinolysis; leukocyte migration

ER, endoplasmic reticulum.
Gene ontologies listed are derived in large part from one of two on-line sources: www.informatics.jax.org/vocab/gene_ontology or www.genecards.org/search/keyword.

since dysregulated *MGP*-deficient endothelial cells were subsequently shown to stimulate epithelial cell precursors in the lung toward a hepatic rather than pulmonary phenotype via altered cross-talk signaling (Yao et al., 2016). Finally, MGP has been suggested to act as an inhibitor of BMPs. While not providing mechanistic details, the work of Malhotra et al. (2015) demonstrates that BMPs play a key role in the signal transduction pathway regulating medial vascular aortic calcification in MGP-deficient mice. Specifically, two separate BMP inhibitors lowered calcification by 80% and prolonged life span compared with vehicle controls (Malhotra et al., 2015).

Osteocalcin

Whereas MGP is broadly expressed, osteocalcin is somewhat bone specific, although mRNA has been found in platelets and megakaryocytes (Thiede et al., 1994). Osteocalcin-deficient mice were first reported to have increased BMD compared with normal controls (Ducy et al., 1996). In human bone, it is concentrated in osteocytes, and its release may be a signal in the bone-turnover cascade (Kasai et al., 1994). Osteocalcin measurements in serum have proved valuable as a marker of bone turnover in metabolic disease states.

Importantly, it has been demonstrated that osteocalcin also acts as a bone-derived hormone that influences energy metabolism by muscle and fat cells, and, that regulates male reproductive function (Lee et al., 2007; Karsenty and Mera, 2017). This topic is considered in detail in Chapter 86. By specifically binding to the G-coupled receptor Gprc6a (Pi and Quarles, 2012), decarboxylated osteocalcin increases insulin secretion by pancreatic cells, promotes glucose homeostasis by muscle and fat tissues, and stimulates testosterone synthesis by Leydig cells of the testis (Ferron et al., 2012; Karsenty and Oury, 2014; Oury et al., 2015). These data provide clear evidence that bone can act as an endocrine organ, regulating systemic functions via receptor-mediated signaling pathways in metabolically active tissues such as bone, muscle, pancreas, fat, and testis. It is expected that new discoveries will help further define the detailed regulatory loops and feedback networks that are likely to exist among and between these skeletal tissues.

Serum proteins

The presence of hydroxyapatite in the bone matrix accounts for the adsorption of a large number of proteins that are synthesized elsewhere and brought in contact with bone via the circulation (Delmas et al., 1984). Most of these proteins are synthesized in the liver and hematopoietic tissue and represent classes of immunoglobulins, carrier proteins, cytokines, chemokines, and growth factors. Interestingly, some of these proteins are also synthesized endogenously by cells of the osteoblastic lineage. It is not known if the origin of a particular factor (and hence proteins with potentially different post-translational modifications) affects its function.

Although serum proteins are not synthesized locally, they may have a significant impact on bone metabolism (Table 15.5). Albumin, which is synthesized by the liver, is concentrated in bone severalfold above levels found in the

TABLE 15.5 Characteristics of serum proteins found in bone matrix.

Molecule	Structural characteristics	Gene ontology biological processes
Albumin	69 kDa, nonglycosylated, one sulfhydryl, 17 disulfide bonds, high-affinity hydrophobic binding pocket	Retina homeostasis; platelet degranulation; receptor-mediated endocytosis; cellular response to starvation; bile acid and bile salt transport; hemolysis by symbiont of host erythrocytes; high-density lipoprotein particle remodeling; negative regulation of apoptotic process; negative regulation of programmed cell death; sodium-independent organic anion transport; posttranslational protein modification; cellular protein metabolic process; maintenance of mitochondrion location; cellular oxidant detoxification
α_2-HS-glycoprotein	Precursor protein of fetuin, cleaved to form A and B chains that are disulfide linked, Ala-Ala and Pro-Pro repeat sequences, N-linked oligosaccharides, cystatin-like domains	Skeletal system development; ossification; platelet degranulation; pinocytosis; acute-phase response; negative regulation of endopeptidase activity; regulation of bone mineralization; negative regulation of bone mineralization; negative regulation of phosphorylation; neutrophil degranulation; post-translational protein modification; cellular protein metabolic process; negative regulation of insulin receptor signaling pathway; regulation of inflammatory response; positive regulation of phagocytosis; negative regulation of biomineral tissue development

Gene ontologies listed are derived in large part from one of two on-line sources: www.informatics.jax.org/vocab/gene_ontology or www.genecards.org/search/keyword.

circulation. It is not known whether it plays a structural role in bone matrix formation but it does have an influence on hydroxyapatite formation. In in vitro assays, albumin inhibits hydroxyapatite growth by binding to several faces of the seed crystal (Garnett and Dieppe, 1990). In addition to this inhibitory activity, it also inhibits crystal aggregation.

Another serum protein, α_2-HS-glycoprotein, is even more highly concentrated in bone than albumin (up to 100 times more concentrated). It is known that α_2-HS-glycoprotein is the human analog of bovine fetuin (Ohnishi et al., 1993). This protein is synthesized as a precursor that contains a disulfide bond linking the amino- and carboxy-terminal regions. Subsequently, the midregion is cleaved and removed from the molecule, yielding the A and B peptides (much in the same way that insulin is processed). In rat, the midregion is not removed and the molecule consists of a single polypeptide. This protein also contains cystatin-like domains (disulfide-linked loop regions) and another member of this family has been identified in bone matrix extracts.

α_2-HS-glycoprotein has many proposed functions that may also be operative in bone cell metabolism. It is a chemoattractant for monocytic cells, and consequently, it may influence the influx of osteoclastic precursor cells into a particular area (Nakamura et al., 1999). Furthermore, it is a TGFβ type II receptor mimic and cytokine antagonist (Demetriou et al., 1996). Fetuin, the bovine homolog, has been found to be a major growth-promoting factor in serum, and results in vitro suggest that fetuin, along with TGFβ, inhibits osteogenesis (Binkert et al., 1999). Interestingly, deletion of the fetuin gene in mice leads to widespread ectopic calcification throughout the body (Jahnen-Dechent et al., 1997). Consequently, this protein may play a very important role in bone cell metabolism irrespective of whether or not it is synthesized locally.

Other proteins

In addition to the proteins already described, there are representatives of many other classes of proteins in the bone matrix, including proteolipids, enzymes and their inhibitors (including metalloproteinases and tissue inhibitors of metalloproteinase, plasminogen activator and plasminogen activator inhibitor, matrix phosphoprotein kinases, and lysosomal enzymes), morphogenetic proteins, and growth factors (Zu et al., 2007). Although their influence on bone cell metabolism is highly significant and they may cause important alterations of the major structural elements of bone matrix, they are not necessarily part of the bone matrix (with the possible exception of proteolipids). Important aspects of many of these classes of proteins are reviewed elsewhere.

Control of gene expression

Even a cursory analysis of noncollagenous protein expression reveals a complex regulatory pathway of interacting environmental, hormonal, and nuclear factors by which cells of the osteoblastic lineage secrete these factors in a temporal and distribution-sensitive manner to produce biomechanically functional mineralized bone (Stein et al., 1996; Wu et al., 2014).

Bone matrix glycoproteins and ectopic calcifications

The development of sensitive radiographic techniques, in addition to histological observations, has led to the description of ectopic calcifications in many different pathological disorders. Although dystrophic mineralization has long been noted, it was not thought that bone matrix proteins played a role in generating this type of mineralization. Dystrophic mineralization (such as in traumatic muscle injury) is brought about by cell death (perhaps in the form of apoptosis) and not by the physiological pathways mediated by collagen or matrix vesicles. However, bone matrix proteins have been identified in mineralized foci in several different pathological states. Osteonectin, OPN, and BSP have been found in mineralized foci in primary breast cancer (Bellahcene and Castronovo, 1997). BSP has also been found in other cancers, such as prostate, thyroid, and lung (Bellahcene et al., 1997; Bellahcene et al., 1998; Waltregny et al., 1998). Although it is possible that, in some cases, the area mineralizes dystrophically and bone matrix proteins are adsorbed from the circulation because of their affinity to hydroxyapatite, mRNAs for the bone matrix proteins are expressed and it appears that the proteins are actually synthesized by resident cells that have been triggered by factors that have yet to be identified.

Given the fact that bone matrix proteins are expressed by a number of different cancers, the obvious question is why. The processes by which cancer cells invade the surrounding normal tissue, gain entry into the circulation, and metastasize to other tissues are complex, but members of the SIBLING family have emerged as active players in tumorigenesis and metastasis. SIBLINGs and their proteolytic fragments, along with their partner MMPs (for BSP, OPN, and DMP1, at least), may modulate a tumor cell's adhesion via specific integrins, matrix degradation, and migration (reviewed in Bellahcene et al., 2008).

Another example of ectopic calcification is seen in atherosclerosis, again, associated with the production of bone matrix proteins (Bini et al., 1999). Unlike dystrophic calcification, vascular calcification appears to form in a regulated fashion similar to what is seen in bone formation in the skeleton. As mentioned earlier in relationship to the *MGP*-deficient mouse, it appears that vascular smooth muscle cells are emerging as the culprit. Factors that stimulate the expression of bone matrix proteins are not yet known but may include changes in cell−cell interactions, serum lipid composition, and phosphate concentrations, and apoptosis of vascular smooth muscle cells may initiate the process (Johnson et al., 2007). It may also be that there exists a population of stem cells that are normally quiescent, but then are induced to become osteogenic again, by factors that are not known. The aorta has its own vasculature, which may harbor these stem cells. Supporting this hypothesis, pericytes from the retinal vasculature have been shown to undergo bone formation in vitro and in vivo (Canfield et al., 2000).

Summary

Bone matrix proteoglycans and glycoproteins are proportionally the most abundant constituents of the noncollagenous proteins in bone matrix. Proteoglycans with protein cores composed of the LRR sequences (decorin, biglycan, fibromodulin, and osteoadherin) are the predominant form found in mineralized matrix, although hyaluronan-binding forms (in particular, versican) are present during early stages of osteogenesis. They participate in matrix organization and in regulating growth factor activity. Glycoproteins such as alkaline phosphatase, osteonectin, RGD-containing proteins (osteoadherin, TSP, fibronectin, vitronectin, OPN, and BSP), irisin, fibrillin, and tetranectin are produced at different stages of osteoblastic maturation. They exhibit a broad array of functions ranging from control of cell proliferation to cell−matrix interactions, mediation of hydroxyapatite deposition, and bone−muscle/adipocyte cross-talk signaling. Finally, sclerostin and DMP1 are preferentially expressed by osteocytic cells in bone where they regulate osteogenesis by feeding back to osteoblastic cells and (together with PHEX) regulate phosphate metabolism via FGF23 production by osteocytes, respectively. The ectopic expression of bone cell secreted noncollagenous proteins may also play a significant role in, normal systemic regulation of glucose and energy metabolism, and of male reproductive function, as well as in pathological processes such as bone metastasis and in atherosclerosis.

Chapter outline

Introduction

This chapter surveys our knowledge of the proteinases expressed in bone. Although for a long time the osteoclast had been considered the main producer of proteinases in bone, it became increasingly clear that the osteoblast lineage plays a significant role in the production of many of these proteinases. For example, it is true that the osteoclast secretes abundant lysosomal cysteine proteinases, especially cathepsin K (Vaes, 1988; Xia et al., 1999; Sahara et al., 2003), and produces some of the neutral proteinases, e.g., matrix metalloproteinase-9 (MMP-9; Wucherpfennig et al., 1994; Delaissé et al., 2000). However, osteoblasts and osteocytes, like their related cells, fibroblasts, are able to secrete a host of proteinases, including neutral proteinases such as serine proteinases, plasminogen activators (PAs), and metalloproteinases such as MMP-13, as well as lysosomal proteinases, e.g., cathepsins. Thus, osteoblasts and osteocytes, like fibroblasts, have the capacity not only to synthesize a range of matrix proteins, including type I collagen, but also to remodel their own extracellular matrix via the secretion of a range of proteinases.

Proteinases can be classified into four groups: metalloproteinases, e.g., MMP-13 (also known as collagenase-3); serine proteinases, e.g., PA; cysteine proteinases, e.g., cathepsin K; and aspartic proteinases, e.g., cathepsin D. This subdivision is based on the structure and the catalytic mechanism of the active site involving particular amino acid residues and/or zinc. In the following review of the proteinases synthesized in bone, we deal with each group according to this subdivision in the order just given. For some, much more is known than for others and they have warranted their own section.

Metalloproteinases

MMPs are a family of zinc- and calcium-dependent neutral endoproteinases. MMPs are responsible for remodeling the extracellular matrix (ECM), which is necessary for physiological events such as angiogenesis, wound healing, and bone development (Page-McCaw et al., 2007). Abnormal expression and activation of MMPs lead to the development of diseases such as cirrhosis, cancer, and arthritis (Gong et al., 2014). To maintain homeostasis, MMPs are tightly regulated at the levels of transcription, posttranslational modification, production of the enzymes as inactive zymogens requiring activation, coexpression of tissue inhibitors of metalloproteinases (TIMPs), and receptors to regulate their extracellular abundance (Varghese, 2006; Cerda-Costà and Gomis-Rüth, 2014). At this writing, the MMP family comprises ~24

Principles of Bone Biology. https://doi.org/10.1016/B978-0-12-814841-9.00016-6

structurally and functionally related members in mammals (23 in humans, 22 in mice). According to their structural and functional characteristics, human MMPs can be classified into at least six different subfamilies of closely related members: collagenases (MMP-1, -8, and -13), type IV collagenases (gelatinases, MMP-2, and MMP-9), stromelysins (MMP-3, -10, and -11), matrilysins (MMP-7 and -26), membrane-type MMPs (MT-MMPs; MMP-14, -15, -16, -17, -24, and -25), and other MMPs (MMP-12, -19, -20, -21, -23, -27, and -28) (Matrisian, 1992; Vu and Werb, 2000; Visse and Nagase, 2003). All MMPs are active at neutral pH, require Ca^{2+} for activity, and contain Zn^{2+} in their active site. Mammalian MMPs share a conserved domain structure that consists of a catalytic domain and an autoinhibitory prodomain. The prodomain contains a conserved Cys residue that coordinates the active-site zinc to inhibit catalysis. The catalytic domain of MMPs contains the conserved sequence HEXGH, which is believed to be the zinc-binding site. Metalloproteinases are secreted or inserted into the cell membrane in a latent form caused by the presence of a conserved cysteine residue in the prosegment, which completes the tetrad of zinc bound to three other residues in the active site. Cleavage of this propiece by other proteolytic enzymes (e.g., trypsin, plasmin, cathepsins, or other unknown activators) causes a loss of ~10 kDa of the propiece; this disrupts the cysteine's association with the zinc and results in a conformational change in the enzyme yielding activation. Metalloproteinases all have homology to human fibroblast collagenase (collagenase-1, MMP-1) (Varghese, 2006). It should be noted that MMPs, named "gelatinases" when originally characterized, clearly function as collagenases in vitro, and could potentially function as collagenases in vivo. MMP-2, for example, when free of TIMPs, cleaves native collagens to yield the typical 3/4−1/4 fragments (Ames and Quigley, 1995; Seandel et al., 2001). There are four members of the TIMP family, TIMP-1, -2, -3, and -4, each inhibiting the activities of MMPs with varying efficiency (Gong et al., 2014; Brew et al., 2010).

MMPs play an important role in tissue remodeling associated with various physiological processes; however, abnormal expression and activation of MMPs is implicated in the pathogenesis and pathological progression of multiple diseases, including cirrhosis, arthritis, and cancer (Gong et al., 2014; Fingleton, 2007). The MMPs are promising drug targets in diverse pathologies (Nam et al., 2016). Although many synthetic inhibitors of MMPs (MMPIs) were designed and tested in animal models and in human clinical trials, all of these trials failed (to date, the only approved MMPI is Periostat, for the treatment of chronic periodontal disease). Broad-spectrum MMPIs have failed in clinical trials due to their very strong targeting of the catalytic zinc ion but low specificity (Zucker et al., 2000). In 2017, a novel strategy was used to develop JNJ0966, which binds zymogen and prevents generation of active MMP-9. The agent did not inhibit the production of the mature, active forms of MMP-1, MMP-2, MMP-3, and MMP-14. There is a hope that there will be the development of a next generation of MMP drugs: specific and without off-target effects (Scannevin et al., 2017).

Activation of MMPs can occur via the PA/plasmin pathway. PAs convert plasminogen to plasmin, which subsequently can activate prostromelysin to stromelysin and procollagenase to collagenase. The activated MMPs can then degrade collagens and other ECM proteins. MT-MMP is necessary for MMP-2 activation in fibroblasts (Ruangpanit et al., 2001), and MT-1 MMP (MMP-14)−mediated MMP-2 activation is important for invasion and metastasis of tumors (Mitra et al., 2006).

Apart from the regulation of secretion, activation, and/or inhibition, MMPs are substantially regulated at the transcriptional level (Matrisian, 1992; Crawford and Matrisian, 1996). Several *MMPs* contain specific regulatory elements in their promoter sequences. Human and rat stromelysin-1 and -2 contain activator protein-1 (AP-1)- and polyoma enhancer activator-3 (PEA-3)-binding sites that may be important for basal levels and inducibility. AP-1 and PEA-3 consensus sequences have also been found in human, rabbit, and rat collagenase genes (Brinckerhoff, 1992; Selvamurugan et al., 1998; Tardif et al., 2004). The transcription factors Fos and Jun form heterodimers and act through the AP-1 sequence (Lee et al., 1987; Chiu et al., 1988), whereas c-*ets* family members bind at the PEA-3 sequence (Wasylyk et al., 1993). The urokinase PA gene also contains AP-1- and PEA-3-binding sites and, as a result, agents acting through these sites could lead to coordinate expression of many of these genes (Matrisian, 1992; Hsieh et al., 2007). Moreover, TIMP-1 is controlled by AP-1 transcription factor in brain, and there is a role for AP-1 in regulation of the neuronal *Mmp9* gene (Kaczmarek et al., 2002). Glucocorticoids and retinoids can suppress metalloproteinase synthesis at the transcriptional level (Brinckerhoff, 1992) by forming a complex with AP-1 transcription factors and inhibiting their action (Schroen et al., 1996).

A second transcription factor-binding site was identified in the *Mmp13* (collagenase-3) promoter as well as in bone-specific genes such as osteocalcin (Shah et al., 2004; Selvamurugan et al., 2006). This site is referred to as the runt domain (RD)-binding site or polyomavirus enhancer-binding protein-2A/osteoblast-specific element-2/nuclear matrix protein-2-binding site (Geoffroy et al., 1995; Merriman et al., 1995). Members of the core-binding factor (CBF) protein family (renamed Runx by the Human Genome Organization), such as the osteoblastic transcription factor Runx2 (Cbfa1), bind to these RD sites (Kagoshima et al., 1993). Runx proteins are capable of binding to DNA as monomers, but can also heterodimerize with CBF subunit B, a ubiquitously expressed nuclear factor (Kanno et al., 1998). Runx2 is essential for the maturation of osteoblasts, and targeted disruption of the *Runx2* gene in mice produces skeletal defects

that are essentially identical to those found in human cleidocranial dysplasia (Banerjee et al., 1997; Ducy et al., 1997; Mundlos et al., 1997; Otto et al., 1997).

Stromelysin

Stromelysin-1 (MMP-3) degrades fibronectin, gelatin, proteoglycans, denatured type I collagen, laminin, and other ECM components (Chin et al., 1985). Mesenchymal cells, such as chondrocytes and fibroblasts, are commonly found to secrete stromelysin-1 (Matrisian, 1992). Transin, the rat homolog of human stromelysin, was originally discovered in fibroblasts transformed with the polyomavirus (Matrisian et al., 1985). One importance of stromelysin comes from its implication in the direct activation of procollagenases, including MMP-1, -8, -9, and -13 (Murphy et al., 1987; Knauper et al., 1993), and the enzyme is thought to play a role, together with collagenases, in the destruction of connective tissues during disease states (Brinckerhoff, 1992; Posthumus et al., 2000). It has also been identified to have a crucial role in MMP-mediated cartilage damage in osteoarthritis, as *Mmp3*-knockout mice were shown to have reduced MMP-mediated cartilage breakdown after induction of osteoarthritis (Blom et al., 2007).

Stromelysin-1 is regulated by growth factors, oncogenes, cytokines, and tumor promoters. Epidermal growth factor (EGF) has been shown to increase stromelysin transcription through the induction of Fos and Jun, which interact at the AP-1 site in the promoter (McDonnell et al., 1990). Platelet-derived growth factor is also important in the induction of stromelysin (Kerr et al., 1988a). The protein kinase C (PKC) activator, phorbol myristate acetate (PMA), is a notable stimulator of stromelysin transcription (Brinckerhoff, 1992; Prontera et al., 1996). Transforming growth factor β (TGFβ), however, causes an inhibition of transin (rat stromelysin) expression (Matrisian et al., 1986; Kerr et al., 1988b) through a TGFβ inhibitory element (Kerr et al., 1990). Other studies have shown that bone morphogenetic protein (BMP-4) represses *Mmp3* and *Mmp13* gene expression, but does not induce adipocyte differentiation in C3H10T1/2 cells (Otto et al., 2007). Interleukin-4 (IL-4) and IL-13 were shown to inhibit MMP-3 synthesis in human conjunctival fibroblasts (Fukuda et al., 2006; Stewart et al., 2007).

In bone, stromelysin-1 has been shown to be produced by normal human osteoblasts (Meikle et al., 1992) after stimulation with parathyroid hormone (PTH) or monocyte-conditioned medium (cytokine-rich). Similarly, Rifas et al. (1994) have shown that two human osteosarcoma cell lines (MG-63 and U2OS) secrete stromelysin and this may be increased by treatment with PMA, IL-1β, and tumor necrosis factor-α (TNFα), but these authors were not able to find the enzyme in medium conditioned by cultured normal human osteoblasts. Mouse osteoblasts and osteoblastic cell lines also produce stromelysin-1 and demonstrate enhanced expression with $1,25(OH)_2D_3$, IL-1, or IL-6 treatment (Thomson et al., 1989; Breckon et al., 1999; Kusano et al., 1998; Le Maitre et al., 2005). There have also been reports that this stromelysin is expressed by osteoclasts (Witty et al., 1992). Despite the many papers on stromelysin-1 it is not clear what its physiological substrate is, nor is its role in physiological and pathophysiological skeletal resorption established.

Type IV collagenases (gelatinases)

Type IV collagenases or gelatinases are neutral metalloproteinases requiring Ca^{2+} for activity and are involved in the proteolysis and disruption of basement membranes by degradation of type IV, type V, and denatured collagens. There are two types of gelatinases, 72-kDa gelatinase (gelatinase A), or MMP-2 (Collier et al., 1988), and 92-kDa gelatinase (gelatinase B), or MMP-9 (Wilhelm et al., 1989). There are very distinct differences between the two gelatinases. The 72-kDa gelatinase has been found complexed to TIMP-2 (Stetler-Stevenson et al., 1989), whereas the 92-kDa gelatinase has been found complexed to TIMP-1 (Wilhelm et al., 1989). Regulation of the two gelatinases is also very distinct. Analysis of the genomic structure and promoter of the 72-kDa gelatinase has revealed that this gene does not have an AP-1 site or a TATA box in the 5′ promoter region as all the other *MMPs* have been shown to have (Huhtala et al., 1990). This enzyme is also not regulated by PMA and, in many cases, seems to be expressed constitutively rather than in a regulated fashion. In contrast, the 92-kDa gelatinase has a promoter very similar to that of the other *MMPs* and is regulated similarly (Huhtala et al., 1991). Nevertheless, expression and activity of both types of gelatinase are markedly stimulated by IL-1 (Kusano et al., 1998).

In bone, as is to be expected, MMP-2 is expressed constitutively by many osteoblastic preparations (Overall et al., 1989; Rifas et al., 1989, 1994; Meikle et al., 1992) and is unchanged by treatment with any of the agents tested. The zymogen form of MMP-2 is also resistant to activation by serine proteases, but MT1-MMP (MMP-14) can initiate the activation of MMP-2 by cleavage of the Asn66−Leu peptide bond (Sato et al., 1994). In 2001, Martignetti et al. (2001) described a form of multicentric osteolysis (Winchester/Torg syndrome) with striking tarsal and carpal bone resorption, accompanied by arthropathy, osteoporosis, subcutaneous nodules, and a distinctive facies in large, consanguineous Saudi

Arabian families. They localized the gene to 16q12−q21 and demonstrated two homoallelic, family-specific, mutations in the region that encodes *MMP2*. Nonsense and missense mutations have been documented that are consistent with decreased levels of MMP-2 (Al-Aqeel, 2005). *Mmp2*-null mice were first reported by Itoh et al. (1997) to have no phenotype except for some shortening of limb bones. Subsequent work by this group documented osteoporosis in older mice as well as altered remodeling of the canalicular system with osteocyte apoptosis, fewer canaliculi, and decreased canalicular connectivity (Inoue et al., 2006). They also described striking defects in formation/maintenance of osteocyte networks and connectivity in collagenase-resistant (r/r) mice; the r/r mice had previously been shown to have osteocyte and osteoblast apoptosis and prominent emptying of osteocyte lacunae (Zhao et al., 2000). We emphasize, however, that although the *Mmp2*-null mice had osteoporosis, the characteristic nodulosis and severe focal osteolysis of the human NAO (nodulosis, arthropathy and osteolysis) syndrome with mutations in *MMP2* were not found in the $Mmp2^{-/-}$ mice. Later, Mosig et al. (2007) reported that *Mmp2*- null mice obtained from Itoh et al. (1997), and described above, display progressive loss of bone mineral density, articular cartilage destruction, and abnormal long bone and craniofacial development. These mice had 50% fewer osteoblasts and osteoclasts compared with control littermates at 4 days, while there was almost no difference after 4 weeks of age. In addition, inhibition of MMP-2 via small interfering RNA in human SaOS2 and murine MC3T3 osteoblast cell lines caused a decrease in cell proliferation rates. These findings imply that MMP-2 is critical for normal skeletal and craniofacial development, as well as bone cell growth and proliferation. Mosig et al. (2007) did not comment on focal osteolysis of the NAO human syndrome in the *Mmp2*-null mice they studied, nor did they examine the canalicular networks using approaches similar to those of Inoue et al. (2006).

$Mmp7^{-/-}$ mice were reported to have several abnormalities, such as decreased intestinal tumorigenesis, but no obvious skeletal defects (Wilson et al., 1997). Later work from this group demonstrated in a prostate cancer model that MMP-7 produced by osteoclasts at the tumor−bone interface has the capacity to process cell-bound receptor activator of NF-κB ligand (RANKL) to a soluble form that further promotes osteoclast activation (Lynch et al., 2005). In *Mmp7*-deficient mice, there was reduced RANKL processing and reduced tumor-induced osteolysis. It appears, however, that $Mmp7^{-/-}$ mice have no physiological abnormality in physiological skeletal remodeling (i.e., no abnormality in the absence of bone metastasis).

The 92-kDa gelatinase (MMP-9) is secreted by three osteosarcoma cell lines (TE-85, U2OS, and MG-63) (Rifas et al., 1994) and, in some of the cell lines, can be stimulated by PMA, IL-1β, and TNFα, analogous to these authors' observations regarding stromelysin. Similarly, they were unable to identify secreted MMP-9 in the media of normal human osteoblasts or the human osteosarcoma cell line SaOS-2, which has been shown to have retained many characteristics of highly differentiated osteoblasts. Likewise, Meikle et al. (1992) found very little immunohistochemical staining for MMP-9 in normal human osteoblasts. In fact, this enzyme has been found to be highly expressed by rabbit and human osteoclasts (Tezuka et al., 1994a; Wucherpfennig et al., 1994; Vu et al., 1998). Indeed, a lack of expression of MMP-9 in mature osteoclasts of c-*fos*-null mice may be one of the reasons the animals exhibit an osteopetrotic phenotype (Grigoriadis et al., 1994). Furthermore, studies of mice with a targeted inactivation of the gene indicate that MMP-9 plays a role in regulating endochondral bone formation, particularly of the primary spongiosa, possibly by mediating capillary invasion. Mice containing a null mutation in the *Mmp9* gene exhibit delays in vascularization, ossification, and apoptosis of the hypertrophic chondrocytes at the skeletal growth plates (Vu et al., 1998). These defects result in an accumulation of hypertrophic cartilage in the growth plate and lengthening of the growth plate. The defects are reversible, and by several months of age the affected mice have an axial skeleton of normal appearance. It was postulated that MMP-9 is somehow involved in releasing angiogenic factors such as vascular endothelial growth factor, which is normally sequestered in the ECM (Gerber et al., 1999). Extracellular galectin-3 could be an endogenous substrate of MMP-9 that acts downstream to regulate hypertrophic chondrocyte death and osteoclast recruitment during endochondral bone formation. Thus, the disruption of growth plate homeostasis in *Mmp9*-null mice links galectin-3 and MMP-9 in the regulation of the clearance of late chondrocytes through regulation of their terminal differentiation (Ortega et al., 2005).

Membrane-type matrix metalloproteinases

While most MMPs are secreted, a subtype called MT-MMPs are inserted into the cell membrane (Sato et al., 1997; Pei, 1999). These proteases contain a single transmembrane domain and an extracellular catalytic domain. Characteristically, MT-MMPs have the potential to be activated intracellularly by furin or furin-like proteases through recognition of a unique amino acid sequence: Arg−Arg−Lys−Arg111 (Sato et al., 1996). To date, six MT-MMPs have been described, four transmembrane proteins (MMP-14, -15, -16, and -24) and two glycosylphosphatidylinositol-anchored ones (MMP-17 and -25). MT1-MMP (MMP-14), MT2-MMP (MMP-15), and MT3-MMP (MMP-16) have been shown to have a wide range of activities against ECM proteins (Pei and Weiss, 1996; Velasco et al., 2000). MT1-MMP is involved in endothelial cell

migration and invasion (Galvez et al., 2000; Collen et al., 2003), and MT2-MMP and MT3-MMP are also involved in cell migration and invasion, depending on the cell type (Hotary et al., 2000; Shofuda et al., 2001). In a collagen-invasion model, MT1-MMP appears to be the critical MMP (Sabeh et al., 2004).

MT4-MMP (MMP-17) has the smallest degree of sequence identity to the other family members and has TNFα convertase activity, but does not activate pro-MMP-2 (Puente et al., 1996; English et al., 2000). Conversely, MT5-MMP (MMP-24) and MT6-MMP (MMP-25) may facilitate tumor progression through their ability to activate pro-MMP-2 at the membrane of cells from tumor tissue (Llano et al., 1999; Velasco et al., 2000). As mentioned earlier, MT1-MMP (MMP-14) serves as a membrane receptor or activator of MMP-2 and possibly other secreted MMPs (Sato et al., 1994). Further, studies indicate that MT1-MMP may also function as a fibrinolytic enzyme in the absence of plasmin and facilitate the angiogenesis of endothelial cells (Hiraoka et al., 1998). MT1-MMP is highly expressed in embryonic skeletal and periskeletal tissues and has been identified in osteoblasts by in situ hybridization and immunohistochemistry (Apte et al., 1997; Kinoh et al., 1996). Targeted inactivation of the *Mmp14* gene in mice produces several skeletal defects that result in osteopenia, craniofacial dysmorphisms, arthritis, and dwarfism (Holmbeck et al., 1999; Zhou et al., 2000). Several of the notable defects in bone formation include delayed ossification of the membranous calvarial bones, persistence of the parietal cartilage vestige, incomplete closure of the sutures, and marked delay in the postnatal development of the epiphyseal ossification centers characterized by impaired vascular invasion. Histological observation suggested that the progressive osteopenia noted in these animals may be attributed to excessive osteoclastic resorption and diminished bone formation. This finding was supported by evidence that osteoprogenitor cells isolated from the bone marrow of these mutant mice demonstrate defective osteogenic activity. A similar human disease of "vanishing bone" was observed in two sisters with mutations in MT1-MMP preventing its membrane localization (Evans et al., 2012). This raises the question of a protective effect in bone exerted by MT1-MMP and/or activation of MMP-2. In contrast, a 2018 paper (Delgado-Calle et al., 2018) has shown that MT1-MMP is stimulated by constitutively active PTH receptor 1 signaling in bone and appears to be partly responsible for the high bone turnover phenotype of these mice. The authors showed that MT1-MMP is, in some way, associated with increases in soluble RANKL production. MT1-MMP is also associated with osteoclast-mediated bone resorption in rheumatoid arthritis (Pap et al., 2000).

Collagenases

Collagenases generally cleave fibrillar native collagens I–III at a single helical site at neutral pH (Matrisian, 1992). The resultant cleavage products denature spontaneously at 37°C and become substrates for many enzymes, particularly gelatinases. The collagenase subfamily of human MMPs consists of three distinct members: fibroblast collagenase-1 (MMP-1), neutrophil collagenase-2 (MMP-8), and collagenase-3 (MMP-13) (Goldberg et al., 1986; Freije et al., 1994). An additional collagenase, called collagenase-4 (initially called MMP-18), was identified in *Xenopus laevis* (Stolow et al., 1996), and a human homolog of this enzyme was identified and was given other names, such as MMP RASI-1, and has now been designated MMP-19. As of this writing, only one rat/mouse interstitial collagenase has been studied thoroughly and shown to be expressed by a range of cells, including osteoblasts and osteocytes. This collagenase has a high degree of homology (86%) to human collagenase-3 and is aptly given the same name (Quinn et al., 1990), and both are now called MMP-13. MMP-13 is secreted by osteoblasts and osteocytes, hypertrophic chondrocytes, smooth muscle cells, and fibroblasts, in proenzyme form at 58 kDa, and is subsequently cleaved to its active form of 48 kDa (Roswit et al., 1983). Two murine orthologs of human collagenase-1 (MMP-1), called murine collagenase-like A (Mcol-A) and murine collagenase-like B (Mcol-B), were first identified by nucleotide sequence similarity to human MMP-1, but only Mcol-A was able to degrade native type I and II collagens, casein, and gelatins (Balbin et al., 2001). In this report, the expression of Mcol-A was limited to early embryos. It should be noted here that studies of mouse and rat tissues that report expression of MMP-1 by immunohistochemistry or in situ hybridization are probably not detecting MMP-1. We also made the mistake of calling rat collagenase-3 (i.e., MMP-13) MMP-1 when the nomenclature of the MMPs was being thrashed out (Omura et al., 1994). A murine ortholog of collagenase-2 (MMP-8) has been identified by two groups (Lawson et al., 1998; Balbin et al., 1998). A role for Mcol-A, Mcol-B, or murine collagenase-2 (MMP-8) in bone cell function has not been demonstrated, although human MMP-8 is expressed in chondrocytes and other skeletal cells. *Mmp8*$^{-/-}$ mice (Balbin et al., 2003) have no skeletal abnormalities during development; skeletal changes in adults have not yet been reported.

As noted previously, it has also been shown that other MMPs (MMP-2 [gelatinase A (GelA or 72-kDa gelatinase)] and MMP-14 [MT1-MMP]) can function as collagenases in vitro (Aimes and Quigley, 1995; Ohuchi et al., 1997). These MMPs (-1, -2, -8, -13, and -14) all cleave each of the triple-helical interstitial collagens at the same locus and therefore must also be considered collagenases.

Collagenase-3/MMP-13

In developing rat calvariae, we have found ample amounts of MMP-13 by immunohistochemistry 14 days after birth (Davis et al., 1998). These are always in select areas, mostly associated with sites of active modeling. At the cellular level, staining is associated with osteocytes and bone-lining cells that have the appearance of osteoblasts. Originally, there was controversy regarding the cellular origin of bone collagenase. The osteoclast was reported to show immunohistochemical staining for collagenase (Delaissé et al., 1993), but it was not determined whether this was a gene product of the osteoclast or was, perhaps, produced by osteoblasts/osteocytes and bound by the osteoclast through a receptor (see later). However, in situ hybridization of 17- to 19-gestational-day rat fetal long bones showed *Mmp13* expression only in chondrocytes, bone surface mononuclear cells, and osteocytes adjacent to osteoclasts; there was no evidence of expression in osteoclasts (Fuller and Chambers, 1995). Similarly, Mattot et al. (1995) showed expression of mouse *Mmp13* in hypertrophic chondrocytes and in cells of forming bone from humeri of mice at the 18th gestational day. In human fetal cartilage and calvaria, *MMP13* transcripts were detected in hypertrophic chondrocytes, osteoblasts, and periosteal cells by in situ hybridization, whereas no expression of *MMP13* was detected in osteoclasts (Johansson et al., 1997). In addition, it has been known for some time that bone explants from osteopetrotic mice (lacking active osteoclasts) continue to produce abundant collagenolytic activity, either unstimulated or stimulated by bone-resorbing hormones (Jilka and Cohn, 1983; Heath et al., 1990). These studies demonstrate that osteoblasts/osteocytes and hypertrophic chondrocytes are the sources of collagenases in skeletal tissue, whereas the osteoclast does not appear to express these genes. It should also be noted that the expression of *Mmp13* assayed by in situ hybridization was strikingly reduced (Lanske et al., 1996) in the distal growth plate and midshafts of bones from *Pthr1*$^{-/-}$ mouse embryos (Lanske et al., 1998).

The remodeling of the fracture callus mimics the developmental process of endochondral bone formation. Excess tissue accumulates as callus prior to endochondral ossification followed by osteoclast repopulation. In collaboration with Dr. Mark Bolander, we demonstrated profuse concentrations of metalloproteinases in the fracture callus of adult rat long bones (Partridge et al., 1993). The predominant cells observed to stain for MMP-13 are hypertrophic chondrocytes during the phase of endochondral ossification, marrow stromal cells (putative osteoblasts) when the primary spongiosa is remodeled, and osteoblasts/osteocytes at a time when newly formed woven bone is being remodeled to lamellar bone. This indicates that the adult long bone has the ability to produce profuse levels of MMP-13, but only when challenged, e.g., by a wound-healing situation or an osteotropic hormone. As well, it was shown that *Mmp13*-null mice have delayed bone fracture healing, characterized by a retarded cartilage response in the fracture callus (Kosaki et al., 2007). The consistent observation here is a role for this enzyme when a collagenous matrix must undergo substantial, rapid remodeling.

Liu et al. (1995) have demonstrated that targeted mutation around the collagenase cleavage site in both alleles of the endogenous mouse type I collagen gene Colla1, which results in resistance to collagenase cleavage, leads to dermal fibrosis and uterine collagenous nodules. These animals are able to develop normally to adulthood, and some of the major abnormalities become apparent only with increasing age. Studies of these mice revealed that homozygous mutant (r/r) mice have diminished PTH-induced bone resorption, diminished PTH-induced calcemic responses, and thicker bones (Zhao et al., 1999). These observations imply that collagenase activity is necessary not only in older animals for rapid collagen turnover, but also for PTH-stimulated bone resorption. In the r/r mice, as early as 2 weeks of age, empty osteocyte lacunae were evident in the calvariae and long bones, with the number of empty lacunae increasing with age, and an increase in apoptosis was observed in osteocytes, as well as periosteal cells (Zhao et al., 2000). Thus, normal osteocytes (and osteoblasts) and osteoclasts might bind to cryptic epitopes that are revealed by the collagenase cleavage of type I collagen by liganding the αVβ3 integrin and, if such signals are not induced (as postulated for the osteoclastic defect in r/r mice), they would undergo apoptosis and their lacunae would empty. Young r/r mice are also observed to develop thickening of the calvariae through the deposition of new bone predominantly at the inner periosteal surface; an increased deposition of endosteal trabecular bone was found in long bones in older r/r mice. Thus, the failure of collagenase to cleave type I collagen in r/r mice was associated with increased osteoblast and osteocyte apoptosis and, paradoxically, increased bone deposition as well.

To elucidate the functional roles of MMP-13 during skeletal development in vivo, Inada et al. (2004) generated *Mmp13*-null mice. These mice were found to have lengthened growth plates, due to an increase in the hypertrophic chondrocyte zone, as well as delayed ossification at the primary centers. Abnormalities of growth plates were apparent in the early stages of embryonic development and persisted throughout adulthood. This abnormality is most likely due to a decrease in degradation of ECM cartilage, as was shown by the significant increase in the area of type X collagen deposition, although an increase in the synthesis of type X collagen also remains a possible cause. These observations suggest that MMP-13 plays a critical role in collagen degradation during growth plate development and endochondral ossification. Similar to these findings, Stickens et al. (2004) found that deletion of MMP-13 caused abnormal endochondral

bone development as a result of impaired ECM remodeling. These *Mmp13*-deficient mice were viable, were fertile, and had a normal life span, with no gross phenotypic abnormalities. However, an increase in the hypertrophic chondrocyte zone of the skeletal growth plate was observed, as a result of the delayed exit of chondrocytes from the growth plate. In addition, unlike the late phenotype of the collagenase-resistant mice, these mice showed an early increase in trabecular bone that persisted for months. This was due to the absence of collagenase expression in osteoblasts, not chondrocytes, as was shown by tissue-specific knockouts. The crucial role of MMP-13 in bone formation and remodeling is further demonstrated by a missense mutation, F56S, in the proregion domain of MMP-13 in a form of chondrodysplasia in humans. This mutation, the substitution of an evolutionarily conserved phenylalanine residue for a serine, causes the Missouri type of spondyloepimetaphyseal dysplasia, an autosomal dominant disorder characterized by defective growth and modeling of vertebrae and long bones (Kennedy et al., 2005). This is thought to be due to intracellular autoactivation and degradation of the mutant enzyme.

Related to work in whole animals, we have shown, together with Drs. Jane Lian and Gary Stein, that *Mmp13* is expressed late in differentiation in in vitro mineralizing rat osteoblast cultures (Shalhoub et al., 1992; Winchester et al., 1999, 2000). The appearance of the enzyme in late differentiated osteoblasts may correlate with a period of remodeling of the collagenous ECM. These observations regarding the differentiation of rat osteoblasts may explain the very low levels of MMP-1 observed in cultures of normal human osteoblasts (Rifas et al., 1989), where mRNAs and proteins were isolated from cells at confluence, but apparently not from mineralized cultures. Alternatively, the cultures may predominantly express MMP-13 (rather than MMP-1), which has been shown to be expressed by osteoblasts, by chondrocytes, and in synovial tissue, particularly in pathological conditions such as osteoarthritis (Johansson et al., 1997; Mitchel et al., 1996; Reboul et al., 1996; Wernicke et al., 1996). At the time that Rifas and colleagues conducted the work on human osteoblasts, human MMP-13 had not been identified.

Canalis's group has conducted considerable research on the hormonal regulation of MMP-13 in rat calvarial osteoblasts, including demonstrating stimulation by retinoic acid (Varghese et al., 1994). They have also demonstrated that triiodothyronine, platelet-derived growth factor, and basic fibroblast growth factor (bFGF) all stimulate *Mmp13* transcription (Pereira et al., 1999; Rydziel et al., 2000; Varghese et al., 2000). Interestingly, they have also shown that insulin-like growth factors (IGFs) inhibit both basal and retinoic-stimulated collagenase expression (Canalis et al., 1995) by these cells. We have shown that TGFβ1 stimulates *Mmp13* expression in the rat osteosarcoma cell line UMR 106-01 (Selvamurugan et al., 2004).

We have conducted many studies with the clonal rat osteosarcoma line UMR 106-01, which has been described as osteoblastic in phenotype (Partridge et al., 1980, 1983). This cell line responds to all of the bone-resorbing hormones by synthesizing MMP-13 (Partridge et al., 1987; Civitelli et al., 1989). In contrast to the physiological regulation of collagenase in fibroblasts (Woessner, 1991), synoviocytes (Brinckerhoff and Harris, 1981), and uterine smooth muscle cells (Wilcox et al., 1994), the control of expression of MMP-13 in bone and osteoblastic cells appears to have some distinct differences. First, it is stimulated by all the bone-resorbing hormones (Partridge et al., 1987; Delaissé et al., 1988), which act through different pathways, including protein kinase A (PKA; PTH and prostaglandins [PGs]), PKC (PTH and PGs), tyrosine phosphorylation (EGF), and direct nuclear action ($1,25(OH)_2D_3$, retinoic acid). Second, glucocorticoids do not inhibit stimulation by PTH (Delaissé et al., 1988; T.J. Connolly, N.C. Partridge, and C.O. Quinn, unpublished observations), whereas retinoic acid stimulates MMP-13 expression rather than inhibiting it (Delaissé et al., 1988; Connolly et al., 1994; Varghese et al., 1994). Last, in rat osteosarcoma cells, PMA is unable to elicit a pronounced stimulatory effect on *Mmp13* gene expression.

Among the bone-resorbing agents tested, PTH is the most effective in stimulating MMP-13 production by UMR cells. A single 10^{-7} M PTH dose significantly stimulates transient MMP-13 secretion, with maximal extracellular enzyme concentrations achieved between 12 and 24 h (Partridge et al., 1987; Civitelli et al., 1989). This level is maintained at 48 h, decreases to 20% of the maximum by 72 h, and is ultimately undetectable by 96 h. We hypothesized that MMP-13 was removed from the medium through a cell-mediated binding process because the enzyme is stable in conditioned medium, and experiments showed that this disappearance was not due to extracellular enzymatic degradation. Binding studies conducted with ^{125}I-MMP-13 revealed a specific receptor with high affinity ($K_d = 5$ nM) for rat MMP-13 (Omura et al., 1994). Further studies showed that binding of MMP-13 in this fashion is responsible for its rapid internalization and degradation. The processing of MMP-13 in this system requires receptor-mediated endocytosis and involves sequential processing by endosomes and lysosomes (Walling et al., 1998). In addition to UMR cells, we identified a very similar MMP-13 receptor on normal, differentiated rat osteoblasts, rat and mouse embryonic fibroblasts, and human and rabbit chondrocytes (Walling et al., 1998; Barmina et al., 1999; Raggatt et al., 2006). These results indicate that the function of these receptors is to limit the extracellular abundance of MMP-13 and, consequently, breakdown of the ECM.

Further investigation of the MMP-13 receptor system led us to conclude that MMP-13 binding and internalization required a two-step mechanism involving both a specific MMP-13 receptor and a member of the low-density lipoprotein (LDL) receptor—related superfamily. Ligand blot analyses demonstrated that ^{125}I-labeled MMP-13 specifically bound two proteins (approximately 170 and 600 kDa) in UMR 106-01 cells (Barmina et al., 1999). Of these two binding proteins, the 170-kDa protein appeared to be a high-affinity primary binding site, and the 600-kDa protein appeared to be the LDL receptor—related protein-1 (LRP-1) responsible for mediating internalization. The LDL receptor superfamily represents a diverse group of receptors, including the LDL receptor; the VLDL receptor; LRP-1; megalin (LRP-2); and LRP-4, -5, and -6 (Herz and Bock, 2002; Pohlkamp et al., 2017). All of these plasma membrane receptors have a single membrane-spanning domain and several stereotyped repeats, ligand-binding type and EGF-precursor-like. Most receptors in this family participate in receptor-mediated endocytosis, whereby the receptor—ligand complex is directed (via an NPXY signal in the receptor) to clathrin-coated pits and then internalized. Ligands of these receptors include LDL, VLDL, urokinase-type PA (uPA)— or tissue-type PA (tPA)—PA inhibitor-1 (PAI-1) complexes, tPA, lactoferrin, activated α_2-macroglobulin/proteinase complexes, apolipoprotein E—enriched β-VLDL, lipoprotein lipase, *Pseudomonas* exotoxin A, Wnts, Wnt inhibitors, BMP-4, vitamin D—binding protein, and vitellogenin (Herz and Bock, 2002; Pohlkamp et al., 2017; Yang and Williams, 2017).

The striking stimulation of MMP-13 secretion by bone-resorbing agents in UMR cells was shown to be paralleled by an even more striking induction of *Mmp13* mRNA. Northern blots showed an ∼180-fold induction of *Mmp13* mRNA 4 h after PTH treatment (Scott et al., 1992), with an initial lag period between 0.5 and 2 h before *Mmp13* mRNA levels rose above basal. Nuclear run-on studies showed a comparable increase in transcription of the gene 2 h after treatment with PTH. The PTH-induced increase in *Mmp13* transcription was completely inhibited by cycloheximide, whereas the transcriptional rate of β-actin was unaffected by inclusion of the protein synthesis inhibitor (Scott et al., 1992). These results demonstrate that the PTH-mediated stimulation of MMP-13 involves transcription and requires de novo synthesis of a protein factor(s), i.e., it is a secondary response gene.

PTH treatment was found to increase the transcription of *Mmp13* in rat osteoblastic osteosarcoma cells primarily by stimulation of the cAMP signal transduction pathway (Scott et al., 1992). Second-messenger analogs were used to test which signal transduction pathway is of primary importance in the PTH-mediated transcriptional induction of the *Mmp13* gene. The cAMP analog 8BrcAMP was capable of inducing *Mmp13* transcription to levels close to those of PTH. In contrast, neither the PKC activator, PMA, nor the calcium ionophore, ionomycin, when used alone, resulted in any increase in *Mmp13* gene transcription similar to that elicited by PTH after 2 h of treatment. Furthermore, this effect requires protein synthesis and a 1- to 1.5-h lag period, suggesting that the transcriptional activation of the *Mmp13* gene may be the result of interactions with immediate early gene products. PTH treatment was also found to transiently increase the mRNA expression of the AP-1 protein subunits c-Fos and c-Jun (Clohisy et al., 1992). Both mRNA species were maximally induced within 30 min, well before the maximal transcription rate at 90 min for *Mmp13*. Later, it was determined that PTH is responsible for phosphorylation of the cAMP response element—binding (CREB) protein at serine 133 (Tyson et al., 1999). Once phosphorylated, the CREB protein binds a cAMP response element in the c-Fos promoter and activates transcription (Pearman et al., 1996).

The *Mmp13* gene has 10 exons (Rajakumar et al., 1993), encoding an mRNA of ∼2.9 kb, which in turn encodes the proenzyme, with a predicted core protein molecular weight of 52 kDa (Quinn et al., 1990). A series of deletion and point mutants of the promoter region was generated to identify the PTH-responsive region and subsequently the primary response factors, which convey the hormonal signal and bind to this region(s) of the *Mmp13* gene. The minimum PTH regulatory region was found to be within 148 bp upstream of the transcriptional start site (Selvamurugan et al., 1998). This region contains several consensus transcription factor recognition sequences, including SBE (Smad binding element), C/EBP (CCAAT enhancer-binding protein site), the RD binding sequence, p53, PEA-3, and AP-1 and -2. The AP-1 site is a major target for the Fos and Jun families of oncogenic transcription factors (Chiu et al., 1988; Lee et al., 1987; Angel and Karin, 1991). The RD site is a target for CBF proteins, specifically Runx2. Mice containing a targeted disruption of the Runx2 gene die at birth and lack both skeletal ossification and mature osteoblasts (Ducy et al., 1997; Komori et al., 1997; Otto et al., 1997). These mutant mice also do not express *Mmp13* during fetal development, indicating that *Mmp13* is one of the target genes regulated by Runx2 (Jimenez et al., 1999).

Additional experiments on the *Mmp13* promoter determined that both native AP-1 and RD sites and their corresponding binding proteins, AP-1 and Runx2-related proteins, are involved in PTH regulation of *Mmp13* transcription. Using gel-shift analysis, we further showed enhanced binding of c-Fos and c-Jun proteins at the AP-1 site upon treatment with PTH (Selvamurugan et al., 1998), although there was no significant change in the level of Runx2 binding to the RD site. We determined that PTH induces PKA-mediated posttranslational modification of Runx2 and leads to enhanced *Mmp13* promoter activity in UMR cells (Selvamurugan et al., 2000b). The binding of members of the AP-1 and Runx
